TIME AND SPACE.

A Theory of Time and Space. By A. A. Robb. Pp. vi + 373. (Cambridge University Press, 1914.) Price 10*s.* 6*d.* net.

THE appearance of Dr. Robb's treatise, if such a word can be applied to a volume which opens out a new field of philosophical inquiry on the basis of modern physical science, is a very welcome event, and more especially to students of the fundamental nature of the conceptions which we employ in our attempts to describe physical experiences. There is a general feeling, at least in this country, that in spite of the remarkable success of the principle of relativity in simplifying our descriptions of physical science, the more logical aspect of the principle is seriously at fault, and herein lies the reason for the noticeable decline in favour which the principle has experienced recently. The present work, as its title implies, is a definite *theory* of space and time, and although its aim is strictly logical throughout, it deals with its subject in a simple geometrical manner, readily followed by anyone who has made a study of Euclid. The author's selection of a model is very judicious, and makes the argument flow so smoothly that the reader will probably realise with a shock, at some point, the far-reaching nature of the conclusions to which he has been led.

The author had already published the introduction to the work as a tract, but it is reproduced in the present volume. It gives a brief statement of the history and essential meaning of the principle of relativity, pointing out the more important difficulties which are felt, and which the more formal treatises on the principle, by tending to emphasise unduly the purely mathematical aspect, do not attempt to meet. As is well known, relativity demands that events which are simultaneous events for one observer are not necessarily so for another. This is at variance with the fundamental principles of logic, which demand that "a thing cannot both be and not be *at the same time*." But the simplicity brought about by the introduction of such postulates is such that physicists have allowed them to pass for a time, always, however, realising that our ideas of space, and more especially of time, must be so modified as to make them intelligible and part of a logical system. This simple example will illustrate the scope of Dr. Robb's work, and the exact manner in which it differs fundamentally from the more usual treatises. He has shown that, as a corollary from his treatment of space and time relations, such a logical scheme of geometry and of time can be built up, in which our ordinary geometries find a place.

The foundation of the work involves a new idea —that of *conical order.* The spacial relations are to be regarded as the manifestation of the fact that elements of time, or instants, form a system in conical order. This conception may be analysed in terms of the relations of *after* and *before.* From some twenty-one postulates involving these relations it is possible to set up a system of geometry in which any element can be represented by four co-ordinates, x, y, z, t. The first three correspond to space co-ordinates, and the fourth to time as generally understood. But since an element in this geometry corresponds to an instant, and bears the relations of after and before to other instants, the theory of space appears as a part of the theory of time. Simple geometrical interpretations of the initial postulates in three dimensions are given in the volume. One remarkable feature is that it seems necessary for a really consistent theory to limit the number of dimensions to four. The geometrical system is developed to a considerable extent, and is left at a point from which it may be easily carried in its correspondence with the whole range of ordinary geometrical detail.

The investigation is made in connection with the phenomena of optics. This is, of course, necessary in any attempt to analyse the foundations of any space and time theory. The view taken is that the axioms of geometry are mainly the formal expression of certain optical facts, and the author rightly points out the defects in systems some of the axioms of which have this significance, while others depend on such things as the properties of purely ideal rigid bodies. The significance of all axioms in a logical scheme must be of the same character, and the optical character is the only legitimate one we have at our disposal.

It is not possible in a review to give any account of the detailed working out of these ideas. It can only be said that their development is extremely elegant, and is worthy of being taken as a model for any type of geometrical work. The book is in the standard form of the Cambridge University Press, and bearing in mind the traditional excellence of this series, it is perhaps superfluous to say that the tradition is well maintained in the present case.

APPLIED MECHANICS AND AMERICAN TIMBERS.

The Mechanical Properties of Wood. By Prof. S. J. Record. Pp. vi+165. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 7*s.* 6*d.* net.

TO those unfamiliar with the composition and construction of wood it comes as a matter of surprise that the "hardness," calorific value, also, to some extent, the strength and certain other mechanical qualities, are proportional to the apparent specific gravity. Yet the unexpectedness of these relations vanishes when it is realised that a piece of completely dried wood contains, in addition to air and insignificant amounts of various substances, wood-substance the specific gravity of which is approximately (or truly?) the same in all kinds of woods. Two pieces of dry wood of the same volume thus differ in weight nearly solely because one contains more wood-substance than the other. Wood is not a material, but is a heterogeneous and varied structure, and its particular mechanical properties are dependent not merely on the amount of wood-substance contained in its unit of volume, but also on the manner in which that substance is excavated in the form of strong fibres, weak vessels, and so forth. The arrangement, form, and numbers of these constituents vary widely in different kinds of timbers, with the result that these display corresponding differences in their mechanical properties.

In view of Prof. Record's botanical work on the structure of the woods of the United States, it might have been anticipated that the book under review would deal considerably with the interesting, and incompletely investigated, problems concerning the correlation between the structure and properties of timbers. Very different, however, are the scope and contents of the book, the subject matter of which includes, in order, a brief account of the elementary mechanics of materials, a special consideration of the mechanical properties of wood and of the factors influencing them, and a description of the methods of wood-testing officially adopted in the United States. It gives concise information as to facts gleaned particularly in that country from experiments conducted along the lines laid down by workers in Austria, Germany, and Switzerland; and the information is illustrated by well-chosen figures, including photographs.

The book, however, is akin to a collection of lecture notes dealing with actual experimental results obtained, rather than to a reasoned exposition of the subject. The resultant curtailment is consequently apt at times to lead the student into lack of comprehension or to misconception. The latter is the case when two definitions of hardness are given, the second being "resistance to abrasion or scratching." The truth is that when measured by abrasion the resultant estimates of hardness agree with those obtained by indentation tests and everyday experience with a saw; whereas when tested by scratching all woods are approximately of the same degree of hardness, and that degree is a low one (about equal to muscovite). One feature that takes from the value of the book to English students is that in it, as unfortunately in an increasing number of American scientific books, the language, terminology, and nomenclature are partly foreign to England. Not only are the timbers mentioned exclusively under American names, but popular technical terms unknown in this country are employed, and scientific definitions do not at times accord with those in use here. For instance, a unit stress is defined as "the stress on a unit of sectional area." (Not thus explicable is the erroneous statement on the same page that a "stress-strain diagram" is "a diagram or curve plotted with the increments of load or stress as ordinates, and the increments of strain as abscissæ"; the curve in question supplied shows that the words "increments of" should be omitted.)

In addition to the well-illustrated account of the methods of wood-testing adopted by the U.S. Forest Service, a useful bibliography of the subject, and particularly a list of less-known American papers, gives value to the book. P. G.

WATER REPTILES.

Water Reptiles of the Past and Present. By Prof. S. W. Williston. Pp. vii+251. (Chicago: University of Chicago Press; London: Cambridge University Press, n.d.) Price 12*s.* net.

JUST as it is clear that the existing whales and porpoises are descended from quadrupeds which formerly lived on land, it is gradually being recognised that the marine reptiles which occupied their place during the Secondary Period of geological time also had land-ancestors. Many of the connecting links can now be traced among the fossils discovered during recent years, and so much progress has been made in interpreting them that it is interesting to pause and survey the result. The original papers are scattered through special journals, some of them not easily accessible, and it is necessary to collect the essential facts from numerous sources. We therefore welcome the small book by Prof. Samuel W. Williston, who has devoted many years to the successful study of these reptiles and now reviews the subject exhaustively with first-hand knowledge.

Though the work is mainly suited for students who have some preliminary acquaintance with vertebrate palæontology, Prof. Williston hopes to attract more general readers by a series of introductory chapters dealing with a few elementary geological considerations, and with the structure of the reptilian skeleton and its various modifications in those animals which are adapted for life in water. He then treats the groups of water reptiles in systematic order, referring to the few that survive as well as the great tribes of extinct forms. The descriptions are illustrated both by drawings of the skeletal remains themselves and by many spirited restorations, some original and others by well-known authorities. The technical accounts of structure, indeed, are followed in all cases by a discussion of the inferences they suggest as to the habits and mode of life of the animals in question. All the chapters are well up-to-date, and that on the Cretaceous Mosasauria is especially interesting from its intimate connection with the author's own researches.

As we turn over the pages of this book we are led to speculate as to why nearly all these groups of water reptiles, so widely distributed in every sea, suddenly became extinct at the end of the Secondary Period, without coming in contact with the whales and porpoises which in later times took their place. Prof. Williston can only suggest that the races may have become effete and died of old age. It is evident that the mystery still awaits solution. A. S. W.

MIND AND MATTER.

(1) *The Master-Key: a New Philosophy.* By D. Blair. Pp. 118. (Wimbledon: Ashrama Agency, 1914.) Price 3*s.* 6*d.* net.

(2) *Essays on the Life and Work of Newton.* By A. de Morgan, edited by P. E. B. Jourdain. Pp. xiii+198. (Chicago and London: The Open Court Publishing Co., 1914.) Price 5*s.* net.

(3) *The Analysis of Sensations and the Relation of the Physical to the Psychical.* By Dr. E. Mach. Translated by C. M. Williams. Pp. xv+380. (Chicago and London: The Open Court Publishing Co., 1914.) Price 6*s.* 6*d.* net.

(4) *Proceedings of the Aristotelian Society.* New series, vol. xiv. Pp. 438. (London: Williams and Norgate, 1914.) Price 10*s.* 6*d.* net.

(5) *The Philosophy of Change: a Study of the Fundamental Principle of the Philosophy of Bergson.* By Dr. H. W. Carr. Pp. xii+216. (London: Macmillan and Co., Ltd., 1914.) Price 6*s.* net.

(1) THE writer condemns himself by his own pretensions. He calls his system a "new philosophy," and is writing another book—"The Truth about the Other World"—which "will be the first genuine Revelation ever published." In the volume under notice he discusses all things in heaven and earth, from the solar spectrum, heredity, and space, to Platonism, hallucinations, and Vedanta. There is evidence of a great deal of heterogeneous and elementary knowledge, but all is confused and superficial. Apparently the author finds salvation in the word Monad—though he does not expound Leibniz—but his explanations do not explain much. He posits a "nerve-ether" which is quite different from the luminiferous æther, which latter is "no use" to him; and he seems to have a very poor opinion of the Royal Society. No doubt the society will survive.

(2) These reprinted essays, written more than half-a-century ago, are still worth reading, both for their matter and their style. De Morgan was an able mathematician, he made careful researches into the details of Newton's life and controversies, and he had a very characteristic wit. His treatment of Newton is respectful yet critical. Sir

Isaac was not the almost superhuman moral paragon which for long it was the fashion to suppose him; he had a petulant dislike of opposition, a tendency to keep his discoveries to himself instead of letting the world have the benefit of them —in which he compares badly with the frankness of Leibniz—and a rather mean revengefulness, as in his treatment of Flamsteed, whose observations had been pre-eminently useful to him. On the other hand, De Morgan readily acclaims him as the greatest scientific genius of all time, and indeed above the average level of his time as to character also. His protest is merely against excessive veneration. Section viii. of the last essay is on Newton's religion, which has been the subject of much debate. The Unitarians claim him, and, in spite of Brewster, they are probably right.

There is a small mistake in the footnote on p. 21—"Uranus" should be "Neptune"—but we mention it only in order that it may be put right in the next edition. We see no other slips, and the editor is to be congratulated on a piece of good work.

(3) This book is not so much a new edition of the English translation of Prof. Mach's "Contributions to the Analysis of the Sensations," published in 1897, as an entirely new work; for it is considerably enlarged. Its contentions, however, are the same, and the expansion is in the details. Mach disclaims the title of philosopher, considering himself a physicist; but inasmuch as he seeks a unifying principle applicable to all sciences, he philosophises. According to his view, all experience is made up of elements which are best regarded as of one kind. The distinction of material and psychical, of subject and object, is mischievous. All experience is of one stuff, and the task of science is to investigate relations. A psychical fact is as real as a material fact; indeed, each element exists in both the worlds, according to our purposes of the moment. And as this web of experience—and its threads of relations—is all that we need concern ourselves with, we can throw overboard the *Dinge an sich* which modern philosophy inherits from Kant, and with these useless *noumena* lying behind material phenomena we can throw overboard the *noumenon* which lies or was supposed to lie behind our own mental phenomena.

This radical abolishment of the ego is the main difficulty. Mach counters the inevitable question "*Who* experiences?" by saying that the question itself shows the questioner to be still in the bonds of the fatal habit of subsuming every element (sensation) under an unanalysed complex (p. 26), and this is admittedly a neat and suggestive answer. It does not prove that there is nothing in that complex but its elements and their relations, but, on the other hand, the ego-advocates cannot prove that there is something. J. S. Mill reached this same stalemate, being unable to see how a chain of memories can be conscious of itself. ("Examination of Sir William Hamilton's Philosophy," particularly the chapter on the "Psychological Theory of an External World.") The fact is that we can no more circumnavigate and exhaustively comprehend the totality of our own self, than we can lift ourselves off the ground by pulling at our own bootstraps. It follows from this, and quite harmoniously with Prof, Mach's principles, that our attitude towards possible survival of death should be entirely non-committal, so far as *a priorism* is concerned. He himself decides against it, somewhat vehemently—which perhaps indicates human prejudice overcoming philosophic calm. But he writes for the most part with a saving humour and modesty, and in moments of quiet reflection he would probably admit that his "Weltanschauung" does not necessitate the annihilation of the large complex which is himself, when the portion of that complex which he calls his body is detached.

(4) The Proceedings of the Aristotelian Society are for exceedingly athletic thinkers, and are probably the cause of many headaches even to them. The papers are highly technical, and in so far as they are philosophic rather than scientific, they do not call for detailed review in NATURE. The present volume contains, among other things, the following: "Appearance and Real Existence," by G. Dawes Hicks; "William of Ockham on Universals," by C. Delisle Burns; "Philosophy as the Co-ordination of Science," by H. S. Shelton; "Intuitionalism," by N. O. Lossky; "Discussion —The Value of Logic," by A. Wolf and F. C. S. Schiller; "The Psychology of Dissociated Personality," by W. Leslie MacKenzie (who inclines too much to Münsterberg and Freud, and does not mention F. W. H. Myers); "Freedom," by S. Alexander; "The Status of Sense-Data," by G. E. Moore and G. F. Stout; and "The Principle of Relativity," by H. Wildon Carr, who discusses difficulties about the objectivity of the æther, etc., and finds absolute reality in life or consciousness itself only.

(5) Probably no one can read M. Bergson without feeling the fascination of his style and the persuasiveness of his apt imagery; and the same is true of his chief disciple and expounder in this country. Mr. Carr gives us a sincere and careful account of the new philosophy as he sees it, emphasising its fundamental stress on change, and pointing out that with regard to science it is

neither contemptuous like Hegelianism nor degraded to a servile co-ordinator as in the positivism of Comte and Spencer, but is equal and friendly, bringing a new method of its own for the attainment of further truth. This intuitional method requires a great effort at the outset, he admits; for it involves a turning away from the intellectual methods of the last 2500 years. After reading this book of Mr. Carr's and the whole of M. Bergson's published writings, one reviewer at least feels that while M. Bergson is undoubtedly trying to express what is very real and true to him—and doing it in beautiful language—the thing is difficult and almost impossible, because the philosophy consists of an attitude, so to speak —or of a vividness of personal experience, which is incommunicable. Mr. Carr denies that it is mystical, and, taking some senses of that much-abused word, he is no doubt right; but it is mystical in its anti-conceptualism, and is essentially allied to various Oriental systems. It is a grafting of East on West, including the excellences of both. Perhaps at bottom it is a release from old fetters rather than a new doctrine. A heterodoxy does its chief good not by bringing new truth, but by cancelling out old error, and allowing the mind to go forward unencumbered. J. A. H.

OUR BOOKSHELF.

Panama, the Canal, the Country, and the People. By Arthur Bullard (Albert Edwards). Revised edition. Pp. xiv+601. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 8s. 6d. net.

MR. BULLARD (Mr. Edwards of the first edition) has brought his sketch of Panama up-to-date by the addition of chapters describing the progress of the canal since 1911. The book consists chiefly of two parts, first a history of the State of Panama, and secondly a very pleasant description of the life of the Americans during the last ten years in the huge construction camp on the canal line. This life was well worth description, being truly a remarkable phenomenon. In the midst of a tropical wilderness, far from their own country, and in a pestilential climate, a labour-camp of fifty thousand hands settled at once to an orderly and civilised life, and, under the protection of a medical despotism, enjoyed on the whole excellent health.

Mr. Bullard provides character sketches of the principal constructors—Colonel Goethals, Colonel Sibert, Doctor Gorgas, and the rest, including Mr. Comber, the dredging expert, who is responsible, under Colonel Goethals, for most of the work now going on. This consists in the removal of the material which comes into the Culebra cut from the breaking ground along a length of about two miles near the deepest part of the excavation. Part of it slides in from above, part of it squeezes up from below under pressure from the sides. It is this latter movement which is so disquieting. In one or two cases ships have gone aground before it was known that there had been an upheaval beneath the opaque and muddy waters of the canal. Some years may elapse before the Culebra cut is stable; meanwhile, the canal is used, though not without interruption, and the whole of the complicated lock machinery works without a hitch.

V. C.

Catalogue of Scientific Papers. Fourth Series. (1884–1900.) Compiled by the Royal Society of London. Vol. xiv. C—Fittig. Pp. 1024. (Cambridge University Press, 1915.) Price 2l. 10s. net.

THE first volume of the fourth series of the Royal Society's Catalogue of Scientific Papers was noticed in the issue of NATURE for August 20 last. It was pointed out on that occasion that this series comprises the titles of papers published or read during the period 1884–1900, and concludes the work undertaken by the Royal Society. The catalogue thus completed will contain titles of papers for the whole of the nineteenth century. It will be remembered that the continuation of the work is now undertaken by the authorities of the International Catalogue of Scientific Literature.

The present volume contains 24,994 entries of titles of papers by 4351 authors with the initial C, 17,665 entries by 3072 authors with the initial D, 7750 entries by 1368 authors with the initial E, and 6646 entries by 1230 authors under F, as far as Fittig. The total for the first two volumes of the series is 108,775 entries by 18,950 authors.

It is to be hoped that the series of volumes will be added to every reference library of importance throughout the world, so that the public-spirited conduct of the publishers, who have undertaken the complete risk of printing and publishing, may not result in financial loss.

What do We Mean by Education? By Prof. J. Welton. Pp. xii+257. (London: Macmillan and Co., Ltd., 1915.) Price 5s. net.

PROF. WELTON'S question has been heard in every direction since the war began; and perhaps the outstanding characteristic of the answers which have been offered is the almost complete disagreement among them. Most competent persons will agree with Prof. Welton that "an investigation into fundamental principles" is necessary before a satisfactory reply to the question can be given. This book undertakes such an inquiry, and certainly the reader who follows the argument to the end will leave the volume with much clearer ideas on the subject. The titles of the chapters indicate the trend of the discussion: "The end rules the means"; "What should be the end?"; "Synthesis of liberty and authority"; "What are the means?"; "Who are the agents?" Though difficult reading in parts, the volume deserves the careful attention of teachers and educational administrators.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Spectra of Hydrogen and Helium.

IN a letter to NATURE of February 11, Prof. J. W. Nicholson discusses the recent interesting experiments of Mr. Evans on the spectrum emitted from a vacuum tube containing highly purified helium and subject to a heavy discharge. Evans found that the 4686 series and the Pickering series can be obtained in a helium spectrum showing no trace of the ordinary hydrogen lines. These series were observed a few years ago by Prof. Fowler by sending a heavy discharge through a mixture of hydrogen and helium; previously they had been observed only in star spectra. In addition, Evans observed that under the same conditions as the 4686 series and the Pickering series a new series of lines appeared, which, with regard to position and intensity, could be united with the Pickering series into a single series of the same type as the 4686 series. The lines of the new series have wave-lengths very close to the hydrogen lines of the Balmer series. In his letter Prof. Nicholson expresses the opinion that Evans's results cannot be used to discriminate between the different theoretical interpretations of the spectra in question, since the new series as well as the Pickering series can be deduced from the 4686 series on the general principle of combination of spectral lines. I cannot agree with this view, and should like here to state my reasons.

According to the theory proposed by Rydberg, and generally accepted for a long time, all the lines in question are ascribed to hydrogen. This theory is based on a supposed analogy between the hydrogen spectrum and the spectra of the alkalies. The Balmer series, the Pickering series, and every second member of the 4686 series are considered as diffuse series, sharp series, and principal series.

According to the theory proposed by the writer, the series spectrum of hydrogen is simply represented by the formula

$$\nu = K\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right), \quad . \quad . \quad . \quad . \quad . \quad (1)$$

including only the Balmer series, the Ritz series in the ultra-red, and the series in the ultra-violet recently observed by Lyman. The other series are all ascribed to helium and represented by the formula:

$$\nu = 4K'\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right), \quad . \quad . \quad . \quad . \quad . \quad (2)$$

including the 4686 series, the Pickering series, and Evans's new series. K′ is not exactly equal to K, though very nearly so, the theoretical value for the ratio K′/K being 1·00041. The theory rests upon a certain application of the quantum theory to the theory of the nucleus atom, and essentially involves the combination principle. While the ordinary helium spectrum is supposed to be emitted from a helium atom which has lost a single electron, spectrum (2) is emitted, according to the theory, from a helium atom which has lost both its electrons. If spark spectra result from the removal of two electrons from the atom, formula (2) should correspond to the spark spectrum of helium, while hydrogen, which is supposed to have only one electron in the atom, cannot give a spark spectrum.

Since the numerical relations between the different series claimed by the two theories are not exactly the same, it would be possible at once, as mentioned by Prof. Nicholson, to discriminate between the theories if the wave-lengths of the lines were exactly known. It seems that both the measurements of Fowler and Evans are in close agreement with formula (2), but that it would be difficult to reconcile Evans's redetermination of the wave-length of the Pickering lines with Rydberg's assumption that the Balmer series and the Pickering series have the same limit. Quite apart, however, from the question of the exact numerical relationship between the series, it seems that fundamental difficulties in Rydberg's view are brought to light by the experiments of Fowler and Evans. Fowler's observation that the 4686 series contains twice as many members as the series predicted by Rydberg, and Evans's observation of the new series accompanying the Pickering series, destroy completely the simple analogy with the alkali spectra which forms the basis of Rydberg's theory. If, as Prof. Nicholson proposes, we look upon the Pickering series and the Evans series as a simple combination series deduced from the 4686 series, the contrast with the alkali spectra seems even more striking, since then apparently no sharp series is observed. On the other hand, it will be noticed that this simple relation between the series is an immediate consequence of formula (2), and that Evans's observation makes the representation of this formula more complete than before since only every second member of the series corresponding to $n_1 = 4$ was previously observed.

I must confess, however, that perhaps the strongest objection to Rydberg's view seems to be the entirely different chemical conditions for the appearance of the Balmer series and the other series, so clearly shown by Evans's experiments. This difference has no analogy in the appearance of the diffuse series in the alkali spectra. I am afraid that it may not seem reasonable to emphasise this objection so strongly, since it, of course, has been contemplated by spectroscopists ever since the theory was proposed, but it appears that the basis for the consideration of this question recently has entirely changed. Rydberg's theory of the hydrogen spectrum offered not only an adequate representation of the evidence at hand at that time, but it was apparently the only way to bring the Pickering series into line with Rydberg's own fundamental investigations on the general relations between spectral series. However, Fowler's recent important work on series in spark spectra has shown that these spectra obey laws of exactly the same character as the ordinary arc spectra, with the only exception that the Rydberg constant is replaced by a constant four times as large. Consequently formula (2) corresponds to the general formula for series in spark spectra exactly as formula (1) corresponds to the general formula for series in arc spectra. It would therefore appear that at present there is scarcely sufficient theoretical evidence to justify us in disregarding the direct evidence as to the chemical origin of the lines given by Evans's experiments.

It may be of interest in this connection to mention that the above conclusions seem to be supported by spectroscopic evidence of an entirely different character. Recently Dr. Rau (*Sitz. Ber. d. Phys. med. Ges. Würzburg*, 1914) has made some interesting experiments on the minimum voltage necessary to produce spectral lines. He finds that about 30 volts are necessary to produce the lines of the ordinary helium spectrum, and that the voltage necessary to produce the different lines and series in this spectrum differ only by a few volts. On the other hand, he finds that the lines of the Balmer series appear with a voltage of only about 13 volts, while about 80 volts are necessary to produce the lines of the 4686 series and the Pickering series. According to the theory of the writer, the energy necessary to remove the electron from the hydrogen atom corresponds to a fall of an electron through a potential difference of 13·6 volts, while the energy to be used in removing one electron from the helium atom corresponds to a fall of 29·0 volts, and in removing both electrons to a fall of 83·4 volts. N. BOHR.

Physical Laboratory, University of Manchester, February 21.

X-Ray Fluorescence and the Quantum Theory.

THE experimental conclusions which I briefly outlined in a letter to NATURE of February 18 point directly to a theory of X-ray fluorescence and of the emission of radiation in quanta, which certainly bears a resemblance to Bohr's theory of line spectra. The experimental evidence obtained is, however, so direct that there seems little possibility of escape from the conclusions given below. Indeed, the theory was forced upon the writer directly by the experimental results, and it was only afterwards that he was reminded of some similarity with the theory of Bohr based on the Rutherford atom.

It is an experimental fact that in the case carefully investigated (and obviously in many, if not in all, other cases), the ejection from an atom of an electron associated with a fluorescent X-radiation of frequency n necessitates an absorption of energy greater than the kinetic energy carried away by the electron by approximately the energy (hn) of one quantum of radiation of frequency n. Thus :—

(1) Total absorption per electron emitted $=\frac{1}{2}mv^2+hn$ (approximately)—that is, the energy required to separate the electron (a K electron, say) from the parent atom, is approximately equal to the energy of a quantum of the fluorescent radiation of series K associated with that electron.

The energy of a quantum of radiation may therefore be regarded as the mutual potential energy of the separated atom and electron, measured from the zero given by the electron in its normal position and state. When the displaced or any other electron falls back into the position of the displaced electron, the energy is re-emitted as a radiation characteristic of the atom, and this, of course, in definite quantity. So much may be claimed as at any rate giving a first approximation to the truth. The results of experiments, however, suggest the possibility of the necessity for some modification of this theory in detail, though not in principle. For in the one case thoroughly investigated we get a nearer approximation to the experimental results by writing

(2) Total absorption per electron emitted $=\frac{1}{2}mv^2+hn_K+hn_L$, where n_K and n_L are the frequencies of the K and L fluorescent radiations respectively. As the third term (hn_L) is at its maximum value only about 7 per cent. of the whole, it is impossible at this stage to say definitely whether or not it expresses a physical fact. This term was, however, suggested by a consideration of the probable process following the ejection of a K electron. The relation indicates that *possibly* the energy required to free a K electron is equal to the sum of the energies of quanta of K, L, and any other fluorescent radiation of lower series M, N, etc.—presumably originating in vibrations in the outer rings of the atom.

If we accept this provisionally it means that the energy of a quantum of K radiation is that required to displace a K electron into the position of an L electron, while the energy of a quantum of L radiation is that required to displace an L electron into the position of an M electron, and so on. Such a process may never occur; it is, however, a convenient way of expressing the energy required completely to eject the electron in terms of steps which can only be regarded as extremely probable in the inverse process involving radiation.

Thus the energy of a quantum of K radiation is left in the atom from which a K electron is hurled; or *possibly* the energies of one quantum of each of the fluorescent radiations, K, L, M, etc., are left in the atom. This energy must, of course, be radiated while the atom is regaining its original configuration by the absorption of an electron into the K position. It seems probable, however, that the readjustment of the atom and the principal radiation take place even before the atom as a whole regains an electron, by an L electron falling into the position of a displaced K electron, an M electron replacing an L electron, and so on; only the final stage of the readjustment being completed by the absorption of an electron into an outer depleted ring.

It is obvious in this case—unlike that studied by Bohr—when and why an electron falls into an inner ring; it is simply subsequent to and due to the removal of an inner ring electron. No new principle of radiation is involved, yet it accounts for radiation taking place in quanta. We should thus expect L radiation to be associated with the emission of K electrons as well as with L electrons. Search for such a radiation is at present being made. Pointing to the probability of such an associated radiation is the fact that when hn_L becomes a smaller fraction of the whole absorption, the discrepancy found when it is omitted, as in equation (1), diminishes. Not only is this so, but the energy of the corpuscular radiation and of the K fluorescent radiation actually emitted, do not quite fully account for the whole energy absorbed. The discovery of the L radiation in calculated intensity would give almost perfect agreement.

In spite of these indications the writer hesitates to make a definite statement about the physical reality of the third term concerned with L radiation; experiments will very soon decide the point.

In either case we have the direct evidence that the energy of a quantum is simply energy absorbed in removing the corresponding electron from its normal orbit; it is the energy afterwards set free, presumably when the electron returns.

It is hoped that experiments now being undertaken will determine also if X-ray fluorescence—that arising from the vibration of inner ring electrons—can be appreciably delayed by retarding the return of the ejected or other electrons from outside the atom. It is more probable that X-ray *phosphorescence* will not be detected, the readjustment of the interior of the atom taking place immediately after the ejection of an inner electron, and the final absorption of an electron into a surface ring being the only part of the process susceptible to external conditions. The subject can, however, only receive adequate treatment in communications to other journals. C. G. BARKLA.

University of Edinburgh, February 27.

The Physical Properties of Isotopes.

PROF. SODDY's letter in NATURE of February 4 would seem to lead to certain interesting conclusions about the structure of the atom. It is easy to show that two elements of different atomic weight must differ either in their chemical or in their physical properties. If elements are inseparable chemically their affinity A must be equal. Now $A=-T\int_0^T \frac{U}{T^2}dT$ if T is the temperature and $U=\int_0^T C_p dT$, where C_p is the atomic heat.

The fact that emerges most clearly from all the work done on this subject is that the atomic heats of similar substances may all be represented by the same function $f(\nu)$ of the atomic frequency ν. Therefore, if A is the same for isotopes, and this would seem to be the definition of the word, their atomic frequencies must be identical. But as ν is a function of the atomic weight and of the forces acting between the atoms, the latter must vary when the atomic weights are different. If the force of attraction between two atoms is $a\phi(r)$ and the repulsive force $b\psi(r)$, r being the distance, then at a sufficiently low temperature the quasi-elastic force holding an atom in position is $a=2k(a\phi'(r)-b\psi'(r))$. The constant k represents the action of the surrounding atoms and depends only upon the type of space-lattice formed by the atoms. As the atomic frequency $\nu=\frac{1}{2\pi}\sqrt{\frac{a}{M}}$ is the same for all isotopes, $\frac{a\phi'(r)-b\psi'(r)}{M}$ must be identical, whatever the atomic weight M may be. As Prof. Soddy has shown that the atomic volume and consequently r is also constant, it follows that both a and b must be proportional to the atomic weight.

This conclusion might, perhaps, be tested by a measurement of the vapour pressure of the different sorts of lead. The latent heat of sublimation λ is proproportional to $a\int_r^\infty \phi(r)dr - b\int_r^\infty \psi(r)dr$, that is to M, as r is the same in both cases. The well-known equation $\lambda=RT^2\frac{d\ln p}{dT}$, where p is the vapour pressure, leads to $e^{\frac{\lambda_1-\lambda_2}{RT}}$ as the ratio of the vapour pressures, if the chemical constant is equal. This is of the order $e^{\frac{68}{T}}$ if M varies by 0·26 per cent, *i.e.* about 20 per cent. at 100° C. The vapour pressure of radium D the atomic weight of which is 210 should be about $e^{\frac{360}{T}}$ times less than that of ordinary lead, that is, 2·6 times less at 100° C.

Another posible test would be to measure the melting point. In a great many cases $\nu=\text{const.}\sqrt{\frac{T_m}{Mr^2}}$. As ν cannot vary, and as Prof. Soddy has shown that r is constant, the melting point T_m should be proportional to M. Thus, for instance, the melting point of Prof. Soddy's lead should be 1·54° higher than that of ordinary lead. In all probability the atomic weight of the final product of thorium is 208·4, in which case the difference in the melting point should be as much as 3·75°. These consequences are not necessary but, admitting the absolute chemical identity, highly probable. They include the assumption that the radii of the atoms are equal as well as their mean distance apart in the solid state. In any case, a measurement would seem well worth while, as a negative result would be of almost as great interest as if a difference were observed. Unfortunately, the elastic constants which should vary by a corresponding amount can scarcely be measured with sufficient accuracy.

The following conclusions about the structure of the atom would seem to result. The purely chemical properties are determined by the external electrons which probably also account for the apparent radius of the atom. The forces of attraction and repulsion between the atoms, the interaction of which results in the solid state, have their origin in the nucleus. In isotopes they are proportional to the atomic weight, *i.e.* probably to the number of positive particles. They cannot, however, be considered simply as the sum of the forces between the positive particles, as they are additive only in isotopes, that is, when the charge on the nucleus is equal. The simplest assumption, therefore, would appear to be that the nuclei of isotopes differ in their linear dimensions, but not at all, or only very little, in the arrangement of the particles.

F. A. LINDEMANN.

Sidholme, Sidmouth, February 10.

The Green Flash.

PROF. PORTER'S explanation of the green flash (NATURE, February 18) is unable to account for its appearance at sunrise, when it can be observed with great brilliance. When I was passing through the Indian Ocean on my way to observe the total eclipse of 1875 I happened to be on deck before sunrise one morning, and, watching for the first ray of the sun, was surprised to see the first flash of light appear as a vivid green. I had never heard of the phenomenon before, but atmospheric dispersion seemed to me sufficient to account for it, and I took it for granted that it was a well-known occurrence. I continued to observe the same effect several mornings in succession.

Since then I have undertaken many sea journeys, and though I do not recollect having ever again observed the flash or tried to observe it at sunrise, I have never lost an opportunity of watching for it at sunset. My experience does not support Prof. Porter's explanation, because the redder the sun at sunset, the less likely is the green flash to appear. The atmospheric conditions must be such that there is as little absorption as possible of the more refrangible part of the spectrum.

Those who want to see the appearance at its best should keep one eye closed as long as possible, and when the sun is just about to disappear, shut the eye which has been watching the setting sun, and open the other, which is then unaffected by the troublesome after-images which are otherwise seen. It is, of course, impossible to open the eye just at the critical moment, so that this alone is not sufficient to disprove Prof. Porter's explanation.

ARTHUR SCHUSTER.

Yeldall, Twyford, Berks., February 21.

Hormones and Heredity.

THE reviewer of Mr. H. Elliot's translation of Lamarck's "Philosophie Zoologique" in NATURE of February 11 remarks: "Unless we have misunderstood, a similar suggestion was made by Mr. J. T. Cunningham in 1908." The word "similar" refers to an alleged suggestion by Prof. MacBride that hormones may afford a clue to a possible *modus operandi* of the transmission of modifications. I should be glad to know when and where Prof. MacBride's suggestion was published, as I have not heard of it before. It would seem from the terms of this review that neither Mr. H. Elliot nor J. A. T. are fully acquainted with my paper on the heredity of secondary sexual characters in relation to hormones, published in the *Archiv für Entwicklungsmechanik* in 1908. The hormone theory of heredity is elaborated in considerable detail in my paper. I do not think it is possible to misunderstand it, and it is much more than a "suggestion."

J. T. CUNNINGHAM.

S.W. Polytechnic, Chelsea, February 15.

IT seemed to me that there was some historical interest in recalling Mr. Cunningham's paper of 1908.

As I was unable at the time to refresh my memory on the subject, I wrote guardedly, "Unless we have misunderstood." A fitter expression would have been, "If we remember aright." It is satisfactory to know that my recollection was substantially correct. To object to the theory being called a "suggestion" seems fastidious. As to Prof. MacBride's suggestion, Mr. Elliot's reference was to a proof of vol. i. of "A Treatise on Embryology."

J. A. T.

THE NATURAL HISTORY BUILDING OF THE UNITED STATES NATIONAL MUSEUM.[1]

MR. RATHBUN has done well to publish a full technical account of this building, which claims "to be greatly in advance of all other museum buildings intended for a similar purpose." The three objects aimed at have been storage, usable exhibition space, and laboratory accommodation. The epithet "usable" is important, for in exhibition galleries dark corners and obtrusive architectural details are worse than useless. "Usable" also implies facility of accommodation to growing and changing needs. With this in view, the building has been planned as a great shell, with few permanent division walls; and, by giving exceptional width to the main mass, the floor area is large in proportion to the extent of outer wall. The plan, which covers nearly four acres, shows a large pavilion surmounted by a rotunda facing south, and from it three wings extending towards the east, west, and north; the latter are connected near their outer ends by two L-shaped ranges, completing the enclosure of two large uncovered courts.

The length of the southern façade, shown in perspective in our Fig. 1, is 561 ft.; the greatest north and south measurement, which is along the middle block, is about 364 ft.; each court is 128 ft. square. The wings have a width of 116 ft.; and the L-shaped ranges a width of 61 ft. This great width and the fact that the building is four storeys high might lead one to expect a deficiency of light. The modern classic style, however, has permitted exceptionally large windows (Fig. 1) in all but the upper storey, where, of course, skylights are available. Moreover, in these windows a maximum of glass surface has been secured by the use of light metal framing. Light is also furnished to the wings by light-wells 50 ft. wide, which break through the upper storeys and light all except the basement or ground storey. The floor of the first storey is thus all available, but the top-lit area is usually separated by glazed

FIG. 1.—United States National Museum, Natural History Building, viewed from S.E., showing the South front, the outer end of the East wing, and the beginning of the East range.

[1] "A Descriptive Account of the Building recently Erected for the Departments of Natural History of the United States National Museum." By Richard Rathbun. U.S. National Museum, Bull. 80. Pp. 132+xxxiv plates. (Washington, 1913.)

screens from the surrounding aisles. Our second figure shows part of an L-shaped range on this floor, with the outer windows on the right, and on the left windows to the open court. The actual interior width is 54 ft. 2 in., and the ceiling height is 20 ft. The severity of the interior is not unpleasing, and for exhibition galleries is better than any ornament.

The general absence of interior structural walls has necessitated the introduction of piers and columns arranged in one or more rows, as shown on the right of our Fig. 2. These, as well as the wall piers, are at a distance of 18 ft. 6 in. from centre to centre. Rooms can be formed in multiples of this unit by the building of partitions between the columns, or to meet varying needs the exhibition galleries can likewise be broken up by slighter screens of material appropriate to each case. As the museum grows and changes there will be no difficulty in making such alterations, for all the mains from the heating and lighting plant run in tunnels under the basement, and are connected with each floor by two vertical chases cut in each wall pier. These chases also serve for electrical communications, ventilating flues, vacuum-cleaning pipes, hot and cold water supply, and the like. Thus for the future we can almost imagine that in this building "neither hammer, nor axe, nor any tool of iron" will be heard in the hands of the workmen, but that the staff will be left to work in peace.

The vacuum-cleaning pipes lead from a single pump in the basement, driven by a 25-h.p. motor, and are connected with seventy-three inlets to which can be attached rubber dust-hose provided with a complete equipment of dusting tools. These will be of particular value in the cleaning of exhibition cases.

The rounds of the night-watch are controlled by a system of recording clocks with paper dials, which mark the signals and transmit them to a central station. Time is indicated by sixteen dials electrically controlled by a master clock and corrected each noon from the Naval Observatory.

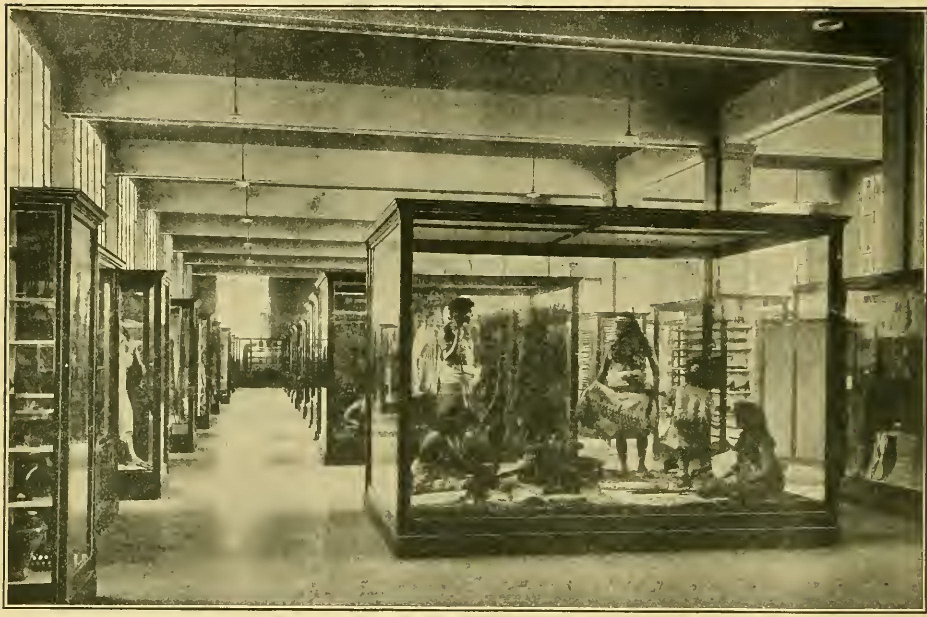

Fig. 2.—United States National Museum, Natural History Building. The Gallery of Ethnology, on the first storey of the East range.

There are six electric Otis elevators, four for passengers and two for freight. The latter are near the large wagon entrances, and run from ground to attic; their cars measure 7 ft. 3 in. by 11 ft. 4 in., by 12 ft. high, and can take a load of 12,000 lb.

Nearly all the ground storey of the east wing is occupied by the machinery plant, which serves the older buildings also. Except for the generator engines, the two stoker engines, and six pumps in the engine-room, which are worked by steam, all motive power is supplied by electricity and is conveyed to the various laboratories and workshops.

The latter consist of painters', cabinet-makers', joiners', and metal-workers' shops, all on the south of this wing. This concentration warrants the use of machinery, and almost every kind of wood-working tool, down to the oil-stone, has its individual electric motor. The "sweat of man's brow" sounds archaic here, but none the less the artisans have a shower-bath and dressing-room. Each department has also its own laboratories, work-rooms, and "comfort-rooms."

The abundant storage space is fitted with standardised shelves, drawers, and cases, permitting ready rearrangement and interchange.

The auditorium is well designed, accessible, and isolated. There are also two rooms for committees and small scientific meetings.

This book does not profess to describe the installation of the exhibits, though a few plates (see Fig. 2) show the general effect. Its value lies in its account of structural detail and practical fitments; it should be read by every museum governor, and digested by every architect of future museum buildings. The claim advanced may not be substantiated at every point, but as regards those here mentioned it is enough to say that the United States Museum possesses what our own Natural History Museum notoriously lacks.

DUTY-FREE ALCOHOL FOR SCIENTIFIC PURPOSES.

In the recent discussions on the best means of developing the colour industry in this country, reference has frequently been made to the duty charged upon pure methyl and ethyl alcohol, which are essential for certain products. Although the past and present stagnation is mainly due to other and much more deep-seated causes, the fact that the trade is still handicapped by a form of taxation which does not exist in Continental countries is one of the signs of the steady indifference of the Government to scientific industrial development of which Thomas Thomson so bitterly complained in his history of chemistry written nearly a century ago.

As the result of a very widespread feeling of dissatisfaction with the high cost of these alcohols (a feeling which had long existed in all the important centres of chemical research in this country) the subject was brought before the chemical section of the British Association at the Glasgow meeting in 1901, and an influential committee was formed, which was successful in persuading the Board of Inland Revenue to forgo the duty on methyl and ethyl alcohol used for scientific purposes in approved institutions. Their recommendations were embodied in the Finance Act of 1902, the working of which has, we believe, given general satisfaction. Whether or not the laboratories of manufacturing firms are permitted to share these advantages we cannot state. Yet in spite of the virtual, if tardy, concession of the principle that research can be usefully promoted in this way, one is constantly confronted with the sort of trivial annoyance such as Sir William Ramsay and Prof. Hickson have recently suffered at the hands of the excise authorities (see NATURE, February 11 and 18), who imposed a duty on the spirit in which specimens coming from abroad were preserved. "Red tape" seems almost too soft a material for binding the cast iron regulations which govern the Excise Department. If, however, the above principle is recognised and conceded, surely it might be adopted in a broad and, if possible, scientific spirit on the part of the authorities. It is not only carried out in the narrowest spirit of officialdom, but also is applied with an extraordinary absence of logic, such as is only conceivable where ignorance of the elements of organic chemistry exists.

For example, chloroform and ether made from ethyl alcohol pay duty, whereas that from methylated spirit (methylated ether) in one case and acetone in the other do not, although the products are practically identical. Again, methyl and ethyl alcohol used for research are exempt from duty, whereas ethyl acetate and butyrate, ethyl chloride, bromide, iodide, and chloral hydrate, in all of which ethyl alcohol is used, are not exempt. The corresponding methyl derivatives which are obtained in precisely the same way from methyl alcohol are not scheduled and, we presume, are free to all consumers. It may be seen from the table of excise regulations that chemists keeping or using stills are subject to a tax of ten shillings on each still, although it should be stated to the credit of the excise department that the payment is rarely if ever enforced in laboratories so far as we know. Perhaps at some future date the regulation may be modified. We see in all this a tardy and grudging response to those pressing demands for liberty of research, which foreign Governments have so successfully encouraged.

But it is not the duty on alcohol which has been the main factor in crippling the colour industry during the last thirty years. Nor is it defective training, equipment, or ability of the young chemists turned out from our universities, whose scientific work stands second to none. It is that the manufacturing world is only beginning to realise at this time of crisis in the chemical industry the true value of the research chemist. We say "beginning to realise," for it was only a few days ago that a professor of chemistry in one of our provincial universities received a request from a large and wealthy corporation to recommend a first-rate chemist, to whom the handsome salary of thirty shillings a week was offered, or about a third of the earnings of a coal-miner working full time!

It would take up too much space to attempt to trace the cause of that attitude of indifference among nearly all classes to the application of scientific research to industry which is such a striking feature of German commercial development. There can be no question that the key to the problem is to be found in our educational system. The very terms "humanities" and "stinks" are fraught with deep significance. They would appear to contrast what is real and living with what is dead and corrupt; what is ennobling with what is contemptible. Yet if a comparison were possible it is the humanities which include the dead languages and literature and the history of dead institutions, whilst the sciences bring us directly into contact with present realities. Nevertheless, it is the former which take precedence in our public schools and our older seats of learning and command the highest marks in Civil Service examinations, whilst chemistry and the other sciences are tolerated though not encouraged, and are valued by the Civil Service commissioners at less than one-third that of the classics and one-quarter that of pure and applied mathematics.

The conclusions are obvious. Our highly-educated Government officials and princes of industry are more or less ignorant of science. It is for many of them an unknown and mysterious region into which they would prefer not to penetrate. That Nemesis now confronts our industries may be a blessing in disguise. It is only in a struggle that the weak points in one's armour are disclosed. We are learning a lesson, which might have been learnt years ago had we not been so inexorably bound by tradition, and the sooner we profit by it the better.

METEOROLOGY AND THE WAR.

In an article which occupies a prominent position in *Le Petit Journal* of February 9, l'Abbé Moreux, the director of Bourges Observatory, emphasises the importance which Germany attaches to meteorological observations and forecasts in connection with the war on land, on sea, and in the air. The fact is scarcely surprising when it is remembered that the great damage done sixty years ago on November 14, 1854, to the allied fleets in the Black Sea by a storm, the course of which could be followed across Europe, was the factor which led Leverrier to conceive and inaugurate the service of international meteorological telegrams. Meteorology is essentially so co-operative and peaceful a science that its stormy birth is apt to be forgotten.

According to M. Moreux, Germany transferred meteorologists from Aix-la-Chapelle to Liège and then to Brussels almost simultaneously with the entry of her army into these cities; and when she found the Aix-la-Chapelle staff not sufficiently expert for her needs she brought up more competent authorities from Berlin and reinforced them with astronomers whose special duty was to watch sounding balloons. The evidence on this point does not appear, however, to be very conclusive, and from the marvellous successes in the prophetic sphere which have been attributed to the German representatives in Belgium it would appear probable that the race of Galeotti, and not that of Galileo, has been invited to render assistance.

Meteorology, along with other departments of science, is bound to have important bearings on the present war. It is, perhaps, more closely associated with the actual active operations than many other departments of science; but its application is not likely to be rendered more successful by substituting for men who are intimately acquainted with the subject men who have achieved distinction in quite a different field; nor by moving the experts from the central institution to the local field of operations. Progress in forecasting in recent years has been achieved by extending the area from which observations are received by telegraph rather than by special observations at a single place; and the meteorological expert's work is to co-ordinate the results of other people's observations, mainly by charting them, rather than to make the observations or to apply the deductions based upon them.

It may be added that in normal times Hamburg is the official centre of the German system of weather-telegraphy and forecasting.

NOTES.

WE announce with much regret the death on Monday, March 1, at seventy-five years of age, of Prof. James Geikie, F.R.S., emeritus professor of geology and mineralogy in the University of Edinburgh.

THE King of the Belgians, and Admiral Lord Fisher of Kilverstone, First Sea Lord of the Admiralty, have been elected honorary members of the Institution of Civil Engineers.

A BRONZE statue of Captain R. F. Scott, erected at Portsmouth Dockyard by the subscriptions of naval officers and officials of the Dockyard, was unveiled on February 26 by Admiral Sir Hedworth Meux, the Commander-in-Chief at Portsmouth. The monument is the work of Lady Scott, and shows Captain Scott in his Antarctic dress.

THE following candidates have been selected by the Council of the Royal Society to be recommended for election into the Society:—Prof. F. W. Andrewes, Prof. A. W. Conway, Mr. L. Doncaster, Mr. J. Evershed, Dr. W. M. Fletcher, Prof. A. G. Green, Mr. H. H. Hayden, Dr. J. Mackenzie, Prof. J. C. McLennan, Dr. A. T. Masterman, Prof. G. T. Morgan, Dr. C. S. Myers, Mr. G. C. Simpson, Mr. A. A. Campbell Swinton, Mr. A. G. Tansley.

WE regret to see the announcement of the death, in his fifty-seventh year, of Mr. Frank T. Bullen, whose knowledge of the sea and its natural history made him distinguished among writers of sea stories. Mr. Bullen was a junior clerk in the Meteorological Office for several years previous to 1899, and while occupying that post he contributed to NATURE of June 4, 1896, a very interesting article on "The Sperm Whale and its Food." This was before he had attained fame by his book, "The Cruise of the Cachalot," but we were impressed at the time by the clear and attractive style of the article, and were glad to know that later Mr. Bullen's real literary gifts received general recognition.

SIR CHARLES A. PARSONS has made a gift of 5000*l.* to the Royal Institution. The following resolution passed by the managers was approved by the members on March 1:—"That the managers of the Royal Institution desire to express to the Hon. Sir Charles A. Parsons, K.C.B., F.R.S.,, who has unconditionally placed at their disposal, for the purposes of the institution, the sum of 5000*l.*, their most grateful appreciation of his munificence and discernment. They accept the gift as a timely and noble recognition of the good public work the institution has done in the past, and is still doing, in the acquisition and diffusion of scientific knowledge, and as an incitement to maintain and extend its usefulness in the unique position which it has for more than a century occupied."

NEWS received from the Russian Arctic voyager Vilkitski now definitely locates him in Taimyr Bay, to the west of Cape Chelyuskin. A wireless message from him has been picked up by Captain Sverdrup, who is laid up further to the south-west on the same inhospitable coast. Vilkitski, having set out in July from Vladivostok to make the passage to European Russia, has thus accomplished about three-fifths of the voyage along the Russian arctic coast. He proposes to send some of his men to Sverdrup, thus relieving the pressure upon his supplies, for he has encountered such heavy ice conditions hitherto that it does not seem certain that he will be able to get on with his ships next summer. The expedition has ample opportunity to add to geographical knowledge (as it has done already) on the coast where it is now imprisoned.

THE appeal for subscriptions to the Sir William White Memorial Fund has resulted in a sum of 3076*l.* 14*s.* 6*d.*, contributed by 455 subscribers. The committee of the fund has decided that the most suitable form which the memorial could take would be the establishment of a research scholarship in naval architecture to be named after Sir William White; and it has been arranged to hand over to the council of the Institution of Naval Architects the greater part of the funds subscribed so that a sum of at least 100*l.* a year shall be available for the scholarship, which will be administered by the council of that institution. In addition, a medallion portrait will be placed in the new building of the Institution of Civil Engineers; and, finally, at the suggestion of Lady White, a donation of one hundred guineas has been made to the Westminster Hospital, where Sir William White passed away.

A REVISED memorandum on cerebro-spinal meningitis, or "spotted fever," has been issued by the Local Government Board in view of cases of the disease which have occurred in various part of the country. It is issued as a purely precautionary measure, and is intended to indicate to medical practitioners, especially village doctors, that the department is watching the outbreak, and that should suspicious cases occur, free bacteriological examination and isolation accommodation will at once be provided. Suspicious cases should be isolated immediately, and any contact cases closely watched. A warning is issued against overcrowding, and as the germs are first located at the back of the throat any person even slightly suspected of having contracted the disease should refrain from kissing anyone else. So far as the general public is concerned, the outbreak may be regarded with indifference. In London it is stated that not more than twenty cases of the disease have been recognised during the last two months.

WE have recorded already the sudden death, on February 13, of Prof. Wesley Mills, emeritus professor of physiology, McGill University, Montreal. From an obituary notice in the issue of the *British Medical Journal* of February 27 we learn that Prof. Mills took the degree of M.D. in McGill University in 1878. He was for several years demonstrator of physiology with Sir William Osler, and studied at University College with Sir J. Burden-Sanderson and Sir E. A. Schäfer. In 1884 he became lecturer in physiology, and in 1886 professor of the subject at McGill University. He organised the teaching of physiology on modern lines, and was the first Canadian teacher of the subject to have a thoroughly up-to-date, well-equipped laboratory. Among his early contributions to physiology were the studies of cardiac innervation. He became much interested in comparative physiology, and the results of a long series of studies are embodied in a work on "The Nature and Development of Animal Intelligence." In 1889 appeared his "Text-book of Animal Physiology," which was modified in the new edition of 1890 to the "Text-book of Comparative Physiology." In 1906 appeared his "Voice Production in Singing and Speaking," a work which brought him much reputation outside of medical circles. After a serious illness in 1910 he retired, and lived in London, devoting himself with energy and enthusiasm to the study of music.

THE Royal Swedish Academy of Science, Stockholm, has recently erected a monument in the Swedish cemetery at Brookwood, Woking, to the memory of Daniel Solander, F.R.S. The memorial consists of an obelisk of unhewn Swedish stone, with the inscription of the name, and dates of birth and death, and that the memorial was erected by the Academy. Daniel Solander was the son of a clergyman in Pite Lappmark, was born in 1733, entered the University of Uppsala as a student in 1750, and left his native country ten years later for London. Here he became employed in the British Museum, in 1764 was elected a Fellow of the Royal Society, and in 1767 made the acquaintance of Banks, who induced Solander to travel with him in that eventful voyage in the *Endeavour* which was Cook's first expedition to the southern seas. On returning from this voyage in 1771, Solander was adopted by Banks as his secretary and librarian, until his death in 1782 from an apoplectic seizure, in the presence of Sir Charles Blagden and the younger Linnæus, dying ten days later. There exist several portraits of Solander; one, a full-length engraving depicting him as "a Simpling Salamander," another of head and bust to left; and, by far the best, a full-length portrait in oil, by John Zoffany, which belongs to the Linnean Society, and was copied for Sir Joseph Hooker's edition of Banks's *Journal*, published in 1896.

The death is announced, on February 20, of Dr. Ed. C. Seaton, consulting medical officer of health to the Surrey County Council. We are indebted to the *British Medical Journal* for the following particulars of his life and work. He studied medicine at St. Thomas's Hospital, and took the degree of M.D. at the University of London in 1871. From 1886 to 1908 he was lecturer on public health at St. Thomas's Hospital, and was at different times examiner in State medicine in the Universities of London, Oxford, and Cambridge, and at the Royal Colleges of Physicians and Surgeons of London. He was the author of the article on vaccination in Quain's "Dictionary of Medicine." He delivered the address in public medicine at the annual meeting of the British Medical Association in 1891, taking as his subject the evolution of sanitary administration in England. He read a communication on diphtheria before the International Congress of Medicine at Budapest in 1894, and delivered the Milroy Lectures at the Royal College of Physicians in 1896. His Chadwick Lectures at the University of London on "Infectious Diseases and their Preventive Treatment," published in 1910, may be taken as containing a summary of his matured views on subjects to the study of which he had given his professional life. Dr. Seaton took an active part in promoting legislation for the compulsory notification of infectious diseases, and was the author of numerous reports and papers on the subject. He was a Fellow of the Royal Sanitary Institute and a member of the Society of Public Analysts. For more than forty years he was a member of the British Medical Association.

Shortly after the commencement of the war, the British Science Guild referred to two of its committees the question of the supply of laboratory and optical glasses, most of which had been obtained from Germany and Austria. The reports of these committees have now been completed, and will be issued shortly. The Institute of Chemistry took up the subject about the same time, and appointed a Glass Research Committee, the main purpose of which was to determine, by experiment, the constitution of glasses suitable for various purposes and to communicate the formulæ to manufacturers. The research has been carried on at King's College, London, and formulæ have been arrived at for an alumina-soda glass suitable for the manufacture of chemical laboratory ware and for a glass which is a satisfactory substitute for Jena glass in respect of its resistance to water and reagents. Provided with these and other formulæ, the only question left for manufacturers contemplating the laying down of plant for the production of laboratory glass to consider was the prospect of the industry after the war. In order to obtain information upon this point, the British Science Guild, acting jointly with the Association of Public School Science Masters, sent a circular letter to local education committees throughout England, councils of universities and technical institutions, and governors of the chief secondary schools, including all the public schools represented on the Headmasters' Conference. The result of the inquiry has been most satisfactory. In general it may be said that about three-quarters of the bodies concerned have undertaken to use British-made laboratory glass during the war, and for a period of three years after, provided that the price is not prohibitive. Two scientific organisations, on their own initiative and without any assistance, financial or otherwise, from the Government, have thus been able to do most valuable work for British glass manufacture. It is to be hoped that official recognition will be given to the service they have rendered to national welfare.

The question of the origin of culture, through direct transmission by migration or trade from a single centre, or by independent evolution in more than one area, is in the air at present. A useful contribution to the controversy is provided by Mr. Eldson Best in the January issue of *Man*. One of the most beautiful of the several types of greenstone pendants made by the Neolithic Maori is that called the Tautau. The existence of this type has been, at various times, advanced as proof of American and Asiatic relationships in Maori art, and Mr. Hamilton, the best authority on the subject, states that this form is as yet unexplained. Mr. Best now brings forward evidence to show that this type is indigenous and not genetically related to objects of similar shape found in other parts of the world. He traces its origin to a form of fish-hook consisting of a bone barb, sometimes beautifully carved, fitted into a hole which passes through the lower end of a straight wooden shaft. A series of illustrations indicates the phases through which the ornament was gradually developed from this form of fish-hook.

Mr. A. S. F. Gow contributes to the *Journal of Hellenic Studies*, vol. xxxiv., part 2, a valuable paper on the evolution of the plough of Greek and Roman days. It starts with those ploughs in which the main timbers are of one piece. Then follows the plough which has stock and pole in one piece, but the tail inserted artificially. The next step in complexity is when all the three main members are separate timbers artificially joined. Fourthly, comes the variety in which pole and tail rise together from the hinder part of the stock, stock and pole have lost the exaggerated solidity seen in the earlier examples, and the pole, not the stock, is now the most important member in the implement. The accounts of the plough in Virgil and Hesiod are carefully discussed, with other classical references, and the paper is illustrated with a good series of photographs from the monuments and of modern Greek and Italian ploughs. The writer does not seem to be acquainted with the important article by Sir E. Tylor, "On the Origin of the Plough and Wheel-Carriage," in vol. x. of the Journal of the Anthropological Institute (1881).

We have received from Mr. E. J. Brill, of Leyden, a catalogue of books and pamphlets dealing with the geology, botany, zoology, etc., of the Dutch East Indies, together with others relating to tropical diseases and medicine and climatology.

At the monthly general meeting of the Zoological Society, held on February 17, it was stated in the report of the council that thirty additions had been made to the menagerie during January, of which twenty-two were acquired by presentation, one by purchase, and two by exchange, while three were received on deposit, and two were born in the gardens. Amongst these was a sing-sing waterbuck, a squirrel-monkey, a kinkajou, two Senegal genets, and a spotted fire-finch (*Lagonosticta niveiguttata*), the last a species new to the collection.

IN the reports on the Hunterian Collections in the University of Glasgow for 1913–14 it is stated that, in addition to a considerable number previously identified, many type-specimens of insects described by Fabricius have been recognised recently, as well as a number of the specimens figured in Drury's "Illustrations of Natural History," and Olivier's "Entomologie," 1789–1808. These the curator hopes may eventually be housed in a fireproof building. All the collections are reported to be in good condition; and in some instances have received considerable augmentation during the period under review.

NEXT time the editor of *My Children's Magazine* requires a picture of a whale he would be well advised to send his artist to the Natural History Museum instead of allowing him to evolve from his own mind the grotesque caricature of a sperm-whale (with upper teeth!) which forms the frontispiece to the March issue of that journal. The picture is intended to represent a whale stranded at Greenwich in the time of John Evelyn, by whom it was seen and measured. There is no proof that this was a sperm-whale, and it was much more probably a common rorqual (as is suggested by Evelyn's mention of a "picked snout"), a species of which, a female, was stranded some twenty years ago at Woolwich, where it gave birth to a couple of young. Another error in the same issue is the statement that the wool used in the manufacture of "cashmere" is the product of *wild* goats.

MR. C. F. JURITZ contributes a paper on plant poisons of South African plants in vol. xi., No. 4, of the *South African Journal of Science*, which is of value in pointing out the pharmacological possibilities of the rich native flora. Interesting particulars are given of the toxic properties of the fruits of the Cycad, Encephalartos, various Liliaceæ, and Amaryllidaceæ, which are so numerous at the Cape, and of many other plants under their respective natural orders.

THE pocket-book for 1915 issued by the Royal Botanic Society of London is a mine of miscellaneous and very useful information, giving not only the various horticultural fixtures for the year, but also such things as the different weights and measures and their conversion from one system to another, physical constants, chemical constituents of gems, the composition of soils, manures and their uses for different kinds of trees and plants, and so on. Several pages are devoted to lists of economic plants with their botanical names, natural orders, and uses, which form a very handy source of reference. At the end there is a plan of a tennis-court and croquet-lawn, but the Badminton court, which might have found a place, is not included.

JAPANESE primulas form the subject of an illustrated article by Mr. Takeda in No. xxxviii., vol. viii., of Notes from the Royal Botanic Garden, Edinburgh. Though China is the home *par excellence* of the genus, Japan, according to the present paper, possesses eleven native species. Of these *P. Sieboldii* and *P. japonica* are the best known. Hybridisation, which is uncommon, as a rule, in the genus, is common among the Japanese species, and *P. Sieboldii* is conspicuous as a parent of many hybrids. In the same number of the Notes fifty new Chinese plants are described, collected by G. Forrest or F. K. Ward in West China at altitudes of from 12,000 to 16,000 ft. *Draba alpina*, var. *involucrata*, from the Lichiang range at 15,000 to 16,000 ft., has been grown at the Edinburgh Botanic Garden. Other high-altitude plants are the gentians and saxifrages collected by F. K. Ward on the borders of Yunnan and Tibet up to 16,000 ft.

THE Hawaiian Volcano Research Association is a society founded in 1909 and supported by voluntary contributions. Its objects are to record volcanic outbursts and earthquakes in the Hawaiian Islands, and to offer opportunities to scientific men to pursue special studies in connection with volcanic action. The association possesses a volcano observatory near the edge of the crater of Kilauea, and a seismological station at a short distance which is furnished with two Bosch-Omori tromometers, an Omori tromometer, and an Omori seismograph. Weekly bulletins are issued in which the continual changes within the craters are described and lists are given of the numerous earthquakes recorded. An appeal for funds has recently been issued by the board of directors, partly for scientific objects, partly for the construction of stone refuge houses along the north-east rift line of Mauna Loa, as it is almost certain that an outflow of lava will shortly take place along that line.

ATTENTION has been directed on more than one occasion in these columns to the need of journals publishing summaries of current mathematical work in the form of lists of new books and of the contents of periodicals. This has been a feature of the Bulletin of the Calcutta Mathematical Society, which, however, has up till now reached us considerably out of date. The Tôhoku Mathematical Journal (vol. vi.), published in Sendai, Japan, now publishes these lists, and although some of the printed matter is scarcely likely to be intelligible to the majority of English readers, the titles of many papers are at any rate printed in the language of publication, and the references are to recent work.

IN his "Notes on Some Focometric Apparatus" in the December, 1914, number of the Journal of the Royal Microscopical Society, Mr. F. J. Cheshire states that he has found the following modification of Blakesley's arrangement for determining the focal length of a short-focus system by the method of magnification, most convenient for the ordinary requirements of the microscopist. An achromatic system of focal length 2·6 cm. is mounted in the middle of a tube having a millimetre scale at its lower and a slit a millimetre wide at its upper end, the slit and scale being at the foci of the system. The tube is fitted under the stage of a microscope with the slit in the plane of the stage. The eyepiece of the microscope is provided with a graduated scale, and on focussing the lower scale, the number of eyepiece divisions corresponding to a lower scale divisions is read. The system the focal length of which is to be determined is then introduced between the objective and the slit, the microscope again focussed, and the number of eyepiece divisions covered by a division of the lower scale again read. The quotient of the two readings gives the focal length of the system. By a proper choice of scales the focal length may obviously be read at one operation in any desired unit.

THE Bureau of Standards, Washington, U.S.A., has issued a circular (No. 51) describing the method adopted for testing watches and timepieces, and detailing the conditions under which the bureau is prepared to issue certificates showing the quality of the performance. The tests naturally do not differ greatly from those that experience has proved to be practical and satisfactory in other observatories and institutions, where regular tests are carried on. An omission of some importance, as it seems to us, is the failure to mention the connection between this testing department and any observatory of repute. No information is provided as to the manner in which the time determinations are made, or how the errors of the mean time clock are eliminated. The bureau may be in connection with the U.S. Naval Observatory at Washington, and the authorities in charge of that observatory may be responsible for the accuracy of the time record. More distinctness on this head would have been welcome, as in the last report from the Naval Observatory it was stated that an insufficient number of chronometers and watches were submitted for trial, and that every effort was being made to induce makers to submit instruments for test. Some useful information is provided concerning the care and treatment of accurate timekeepers, and a table is given showing the main centres on railways, etc., where the change of time is made in passing critical meridians. Where so many abrupt changes occur between the Atlantic and Pacific coasts, this table should prove valuable.

IN No. 1, vol. iv., of the Memoirs of the Department of Agriculture in India, Harrison and Subramania continue the account of their work on the gases of swamp rice soils. In the first paper on this subject it was suggested that the gases formed in the soil had an important connection with the aeration of the roots of the crop. This theory is now elaborated, and a detailed investigation is made of the mechanism by which the organised film, in contact with the surface of these swamp soils, utilises the soil gases for the production of oxygen. It is shown by experiment that the film can oxidise both methane and hydrogen, and, further, that the resulting carbon dioxide is decomposed, with evolution of oxygen, by the green algæ and diatoms which are always present in the film. Crude cultures of bacteria have been prepared capable of bringing about the first of these changes, but no specific organism was isolated having the power to oxidise either methane or hydrogen in pure culture. A mixed culture of two organisms, however, is stated to oxidise hydrogen to water in the presence of very small amounts of nitrogenous organic matter. The film may be looked upon as fulfilling the duty of an oxygen concentrator at a point which enables the maximum oxygen concentration to be produced in the water entering the soil. The practice of green manuring increases the production of soil gases, which is otherwise comparatively small, leading to an increased oxygen output by the surface film and better root aeration. Hence there is deeper root development resulting in sturdier and more productive plants. A further paper dealing mainly with the bacteriological side of the investigation is to be published shortly.

THE Isthmian Canal Commissioners decided some time ago that the requirements of the Panama Canal necessitated the provision of two large floating cranes capable of handling such heavy loads as the largest lock- and dock-gate leaves. Tenders were asked for two floating cranes, each of 250 tons capacity, and the contract was awarded to the Deutsche Maschinen Fabrik A.-G., of Duisburg, because "the proposal of the German firm was so much lower in price than any other, and the experience, facilities, and reputation of this firm so excellent, that it was unquestionably the best of those received." The quotation is from the official records, and *Engineering* for February 26 aptly puts the question as to whether this opinion is still held in view of what happened to the first of the cranes when undergoing its test loading. The load was not quite out to the specified distance when the jib collapsed. Our contemporary publishes photographs of the crane after the accident, from which it appears that the jib was insufficiently braced, and that the accident might have been avoided by the presence of a few additional members. The damage is estimated at about 120,000 dollars, and the work will take about six months to put right.

THE *Engineer* for February 26 gives an illustrated description of an enormous locomotive built for the Erie Railroad by the Baldwin Locomotive Works of Philadelphia. The engine is of the 2–8–8–8–2 type in wheel arrangement, and has six cylinders; two of the cylinders are high-pressure, and each of these exhausts into two low-pressure cylinders. All the cylinders are of the same size, viz., 36 in. diameter and 32 in. stroke. The wheel base is 90 ft. in length, and 89 per cent. of the weight of the engine and tender is carried on the driving wheels. The boiler is 8 ft. diameter at the smoke-box and 9 ft. diameter at the dome. A Schmidt superheater having 1584 sq. ft. of surface is fitted, and is said to be the largest yet made for a locomotive. The total weight of the engine and tender is 380 tons (long). The engine will do duty as a banking engine on a long gradient of 1 in 95, where at present the standard goods train, hauled by a 2–8–0 engine, requires two 2–8–0 engines and a Mallet engine as combined banking engines. The new engine will do the work of the three present engines on the bank. It will be coupled into the middle of the train, thus reducing the stresses on the couplings and drawbars and avoiding any tendency to buckle the train in the middle due to excessive pushing forces in the rear.

THE forthcoming books of Messrs. John Wiley and Sons, Inc. (New York), include: Elementary Chemical Microscopy, E. M. Chamot; The Examination of Hydrocarbon Oils and of Saponifiable Fats, D. Holde, translated by E. Mueller; Text-Book of Geology, L. V. Pirsson and C. Schuchert; A Meteorological Treatise on the Circulation and Radiation in the Atmospheres of the Earth and of the Sun, F. H. Bigelow; Manual for Health Officers, J. S. MacNutt; Constant-Voltage Transmission, H. B. Dwight; Field Book of Railroad Engineering, W. G. Raymond; Materials of Construction: their Manufacture, Properties and Uses, A. P. Mills; Steam Power, C. F. Hirshfeld and T. C. Ulbricht; The Railroad Taper: the Theory and Application of a Compound Transition Curve based upon 30-foot Chords, L. Perkins; Working Data for Irrigation Engineers, E. A. Moritz; A Shop Mathematics for Machinists, R. W. Burnham; Interpolated Six-Place Tables, H. W. Marsh; Masonry, M. A. Howe; Plain and Reinforced Concrete Arches, J. Melan, translated by D. B. Steinman.

OUR ASTRONOMICAL COLUMN.

THE RETURN OF METCALF'S COMET?—In NATURE of February 25 reference was made to a telegram received by Prof. Strömgren relative to the discovery of an object by Miss Leavitt believed to be Metcalf's comet. The *Morning Post* of February 23 published the following paragraph relative to this discovery: "A telegram from Prof. Pickering has just been received stating that the object reported as Comet Metcalf turns out to be a minor planet. This must be a disappointment to Miss Leavitt, but it accounts for the failure of astronomers to find the comet when better placed. The question of priority of discovery, as evidenced by the Southern comet of last year, which was discovered independently at Johannesburg, Arequipa, and Christchurch, New Zealand, on the very same day, has been already responsible for premature publication. Prof. Pickering is, however, generally prepared to take the risk and is sometimes fully justified."

THE CANADIAN 72-INCH REFLECTING TELESCOPE.—Dr. J. S. Plaskett communicates some very satisfactory information about the large Canadian mirror which is in process of being worked up. (Journal of the Royal Astronomical Society of Canada, Nov.–Dec., 1914.) The mirror is actually $73\frac{3}{8}$ inches in diameter and $13\frac{3}{8}$ inches thick, weighing 4962 pounds, or a little more than two tons. An excellent idea of the size of this vast piece of glass will be gathered from the illustration accompanying Dr. Plaskett's note, showing the disc with Dr. John Brashear sitting beside it. Already the edge has been ground, the labour occupying three weeks, and the more delicate and dangerous work of drilling the central hole has been satisfactorily completed. The latter involved first boring a hole of 9 inches diameter, then enlarging it to 10 inches, and finally smoothing and squaring it up and bevelling off the top edge. The next procedure is the figuring of the upper and lower surfaces to make each plane in order to choose which surface is the more suitable for shaping into parabolic form. It is satisfactory to read that "the more the disc is examined the better it seems to be, and hopes are high that it will prove a great success."

ANOMALOUS DISPERSION IN THE SUN.—No. 93 of the Contributions from the Mount Wilson Observatory contains a communication from Mr. Charles E. St. John, entitled "Anomalous Dispersion in the Sun in the Light of Observations." Mr. St. John first directs attention to recent publications by Prof. Julius, who has considered the displacements of the Fraunhofer lines at the centre and limb edges of eccentrically located sun-spots from the point of view of his theory of anomalous dispersion. In these Prof. Julius has set forth "a new deduction from the theory of anomalous dispersion—the "mutual influence" of the Fraunhofer lines upon each other; in particular, that a weak line on the violet side of, and near to, a stronger line is displaced less, but if on the red side more, than the average amount." The above deduction affords Mr. St. John, as he says, an opportunity of making a quantitative test of the rôle played by anomalous dispersion in the solar atmosphere, and this he does in the present paper. It may be remarked that Prof. Julius used the data published by Mr. St. John in his paper, "Radial Motion in Sun-spots." In the present discussion, which covers more than forty pages, it is impossible to refer even briefly to any of the details here stated. Mr. St. John sums up in eleven paragraphs the results of his investigation, and the reader must refer to the article itself for further information. The general result may, however, be expressed by reproducing the last paragraph of the summary. "The general conclusion from this review of solar observations is that the deductions from the anomalous dispersion theory which are susceptible of definite and quantitative tests are not supported by the observational data, and that observations are outstanding which have not yet been explained by the theory."

GREAT DETONATING FIREBALL IN SOUTH AFRICA.—Some of the South African newspapers just received give particulars of a fireball which appeared nearly over Cradock and Queenstown on January 9 last at 1.20 a.m. It vividly illuminated the heavens for several seconds, and was followed shortly after by a series of loud explosions.

The meteor evidently came from the N.N.W., passing between Cradock and Queenstown, and finally disappearing to the S.E. of the former place at a distance of about 24 miles, but the exact figures are doubtful. The estimated interval between the flash and the detonation was variously given by different persons at Cradock between 30 seconds and 3 minutes. The meteor may have fallen to the earth in the region S.E. of Cradock, and it is to be hoped that a thorough search has been instituted for the object. Its flight appears to have been directed from the position of the radiant of the January meteoric shower from Quadrans, the maximum display from which is usually developed on January 3. But the shower is certainly prolonged until January 9. The meteor, however, more probably owed its origin to a radiant in the constellation Draco.

The recent meteor startled a large number of persons by its loud detonation. Houses are said to have been shaken, and the visitation was ascribed by many people to an earthquake. The real path cannot be satisfactorily computed from the observations, which are not of a suitably exact character. The period from January 9 to 14 is notably rich in fireballs, and it merits further investigation. There are evidently a number of radiant points active at this epoch, and among those best pronounced will be found positions at $120°+0°$, $148°-12°$, $230°+52°$, and $332°+36°$.

PROFESSIONAL CHEMISTS AND THE WAR.[1]

It is a matter of importance to the representatives of the chemical profession that their aspect of the great coal-tar colour industry should be kept well to the fore in the Government scheme and in any other scheme that may hereafter be put forward. We desire to see the restoration of the industry to this country, and not only restored, but also permanently retained after the war. The discussions of the Government schemes in various parts of the country by dye-consuming organisations, chambers of commerce, and so forth, have all centred round political or economic questions; the vital principle, viz., adequate chemical control, has been subordinated or left out of consideration altogether. While there has been much wrangling over the question as to the method by which the industry may be established and maintained here, whether by free trade or protection, or subvention, or by any other device, the consideration of the questions whether a few years hence there will be anything in the way of dyestuffs worth protecting; whether there will be a sufficient basis of material products left for the politicians and economists and business people to wrangle over has been overlooked. It is not a purely business problem which the Government has undertaken to solve; it is primarily a chemical problem.

The conditions which have to be met if this country is to be once more the home of the colour industry are imperfectly understood by the public. Even those most concerned—those who are invited to subscribe to the capital—appear in most cases to have an idea that all that is necessary is to find the money, secure Government aid, appoint a board of business directors, and lo! the industry will forthwith spring into existence ready to cope with all emergencies. What are the facts of the case? About five hundred different dyestuffs of definite composition have been given to tinctorial industry as the products of chemical research. Of these a certain number only can be, and are being, made in this country. The total output of our factories is, at present, inadequate for the requirements of our textile industries. The first step to be taken, therefore, is to enlarge and develop existing factories so that the dyes which can be made here may be turned out in larger quantities. This necessity has been provided for in the Government scheme, and "so far so good." If the extension of the existing factories still produces insufficient supplies, new factories must be erected and equipped. That also is provided for in the scheme; but if we want to establish the industry here permanently we must look beyond all this. Where shall we be left after the war? We shall be in possession of processes for making a certain number of dyes, and the supply of their products may possibly be sufficient for the particular purposes for which they are required. But there will still be an outstanding number of other products which have never yet been made here, and for the working out of these processes no combination of "business" talent is of the slightest value. It is not a business question, but a chemical question, and it is by chemical research alone that our colour industry will be saved. The German colour industry has been built up by the utilisation of the results of research carried on in the factories and universities and technical schools for a period of more than forty years! To suppose that we can retrieve our position by starting a company the directorate of which was to consist solely of business people is ludicrous.

One feature of the new scheme which the chemical profession can view with favour is the distinct recognition of research as a necessity for the development of the industry. The Government "will, for ten years, grant not more than 100,000*l.* for experimental and laboratory work." That is certainly a concession which marks an advance in official opinion. It will be for the satirist of the future to point out that it required a European war of unparalleled magnitude to bring about this official recognition of the bearing of science upon industry. Who is to direct this research? A directorate of purely business people will certainly be incompetent; a board composed of dye users can do no more than indicate what dyestuffs were needed. True, it is proposed that the company should take powers to secure the assistance of a committee of experts, but this appears to be simply a reversion to the policy of "drift." The experts are, as usual in this country, to be subordinated and their assistance is to be invoked at the discretion of a board the members of which can have no real knowledge of the conditions necessary for producing the materials they require. Will they be competent to point out dangers ahead? The "staple products" upon which they are asked to stake their capital may a few years hence be superseded by the products of later discovery. The policy of attempting to run a highly specialised and rapidly developing branch of organic chemical industry by a company of business people with expert assistance when required is fatal if it is intended to establish the industry permanently here. The group of industries which has arisen from the products of the tar still is not going to remain stagnant after the war, and it is scientific guidance and not mere assistance that will keep them alive. It is the expert, and the expert only, who can foresee the course of development, who can keep in touch with the progress of research, and direct with intelligence the campaign against competitors. If such scientific direction is withheld, all schemes are sooner or later bound to end in failure.

To other branches of manufacture in which our dependence upon foreign products has been forcibly revealed by the war, professional chemists have been able to render considerable service. It has long been known that laboratory glass and porcelain apparatus and filter paper have been mainly supplied from abroad, and that large quantities of pure chemical reagents and of the special chemicals required for analytical or research work have borne non-British labels. This state of affairs called for prompt action, and the councils of the Institute of Chemistry and the Society of Public Analysts have acted conjointly as a committee for dealing with this matter of such vital importance to the profession. The inquiries instituted by this committee soon brought the fact that failure in the supply of laboratory glass apparatus would not only cripple the work of the chemists, but would also influence to a serious extent certain important industries the dependence of which upon supplies of suitable glass had not at first been foreseen. In connection with these inquiries, it was at a later period considered necessary, in view of the great national interests involved, that the institute should take part in giving practical aid to would-be manufacturers. For this purpose a Glass Research Committee was appointed, and is still carrying on its work. Formulas supplied by members of the committee have been made in the laboratory of the institute and submitted to the recognised tests. The experiments have perforce been carried out on a small scale, but the co-operation of a number of glass manufacturers has been secured, and the results will be tested on a fairly large scale under complete expert control. Not the least important of the glass problems is the production of a suitable glass for miners' safety-lamps, the necessary protecting

[1] From the presidential address delivered to the Institute of Chemistry on March 1, by Prof. Raphael Meldola, F.R.S.

shades for which have also been hitherto mainly imported from abroad. This particular kind of glass is of pressing importance in relation to coal-mining, and it is certainly humiliating to learn from the makers of these lamps that for glass of the required quality capable of complying with the Home Office tests, we have been so largely dependent upon foreign glass manufacturers.

With respect to the supplies of chemical reagents, the joint committee found it necessary to entrust to a special sub-committee the somewhat arduous task of compiling a list of all the commonly used reagents with indications of the standard of purity required and the tests necessary for ascertaining whether the required standard had been reached. The list has been published as a pamphlet, and has been sent to many firms and companies of manufacturing chemists with the view of ascertaining which reagents of their own manufacture they are prepared to supply. When the replies have been received the joint committee will know the requirements of the profession could be met by British manufacturers.

It is hoped that sooner or later laboratory supplies both of apparatus and materials will be entirely of British origin. The manufacturers are—in some cases at considerable cost—developing lines of industry which are of the nature of new departures for this country. It is the duty of consumers and users—in fact, of every branch of the profession—to do their utmost to encourage and support these new home industries. Patriotism and the credit of our country alike demand that, after the war, they should help those who are helping them by insisting upon having nothing but the products of British manufacture. They should not only assist in the development of these industries now, but insure their permanent retention after the declaration of peace. With the achievement of this result there would be removed the reproach that the nation which gave to chemical science Priestley, Black, Boyle, Cavendish, Davy, Dalton, Faraday, and Graham—the country which founded the coal-tar colour industry, and which had taken the lead in the manufacture of "heavy chemicals," allowed her laboratory work to be dependent upon foreign materials, and her great textile and metallurgical industries to be threatened through the stoppage of supplies from inimical countries.

LORD KELVIN'S WORK ON GYROSTATICS.[8]

V. *Gyrostatic Theory of Elasticity.*

[*Note.*—In the explanation of steady precession, near the foot of the first column of p. 715 of NATURE of February 25, the words, "the horizontal axis A of the couple," referred to a cut, which, owing to an accident, could not be given. But Fig. 6 there printed, and repeated here on page 21 will serve instead. In that, as indicated in the small diagram at the bottom of the figure, the axis of angular momentum—the spin-axis—is to be supposed drawn towards the right, from the centre of the gyrostat along the (horizontal) axis of rotation, and the axis of the couple horizontally from the centre towards the observer. The dotted arc, marked 90°, should be continued round to the axis marked $mk^2\omega$. The angle 90° is that between the spin-axis and the couple-axis.—A.G.]

ONE other experiment I shall make with the veteran gyrostat, which has been spun again. You see that the rim carries two trunnions in line with the centre of the wheel (Fig. 10). These are placed on bearings attached to this square wooden frame; and now you see that as I hold the tray in my hands in a horizontal position, the gyrostat rests with its axis vertical or nearly so. The direction in which the wheel is spinning is shown by the arrow on the upper side. I now carry the tray round in azimuth in the direction of spin: nothing happens; the gyrostat spins on placidly. If, however, I carry the tray slowly round the other way, the gyrostat immediately turns upside down on the trunnions; and now, as I go on carrying the tray round in the same direction as before, the gyrostat is quiescent as at first; but the spin, by the inversion of the gyrostat, has been brought into the same direction as the azimuthal motion.

The gyrostat behaves as if it possessed volition—a very decided will of its own. It cannot bear to be carried round in the direction opposed to the rotation, and, as it cannot help the carrying round, it accommodates itself to circumstances by inverting itself so that the two turning motions are made to agree in direction. Again I reverse the azimuthal motion, and the gyrostat inverts itself so that the wheel turns in the same direction in space as at first.

The inversion brings into play a wrench on the hands of the experimenter. A varying couple, lasting during the time of the inversion, is required to reverse the angular momentum of the wheel in space, and this is applied to the gyrostat by the frame at the trunnions, and to the frame, because that is kept steady, by the hands of the operator. The total change of angular momentum is 2 N, where N is the angular momentum of the flywheel, and this is the time-integral of the couple.

It will be noticed that in this experiment, in which the gyrostat displays this curious one-sided stability and instability, it is affected by a precession impressed upon it from without. The system was not

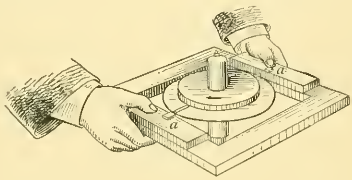

FIG. 10.

left to itself, I carried it round. The gyrostat had little or no gravitational stability—the centre of gravity was nearly on a level with the trunnions; but even if it were gravitationally unstable, sufficiently rapid azimuthal motion would keep it upright if that motion agreed with the spin, while the least motion the other way round would cause it to capsize.

It is important to notice that if the gyrostat be placed on the trunnions, so that the axis of the wheel is in the plane of the frame, azimuthal turning in one direction causes one end of the axis to rise, or turning in the other direction causes the other end to rise. As I shall show presently, this means a reaction couple on the frame which must be balanced by a couple applied by the experimenter.

Better than anything else I know, this experiment of the capsizing of the gyrostat by azimuthal motion affords an example of the two forms of solution of a certain differential equation, which, when the gyrostat is without sensible gravitational stability, and θ is small, I may write

$$A\frac{d^2\theta}{dt^2} + \omega N\theta = 0,$$

where N is the angular momentum of the wheel, and ω the angular speed with which the tray was carried round. When the turnings were in the same direction, ω and N had the same sign, but when the turnings were in opposite directions the product ω N had a negative value. When the product is positive

[8] Abridged from the Sixth Kelvin Lecture, delivered at the Institution of Electrical Engineers, on January 28, by Prof. A. Gray, F.R.S. (Continued from NATURE, No. 2365, vol. xciv., p. 716.)

we have a solution giving oscillations about the vertical, in the period $2\pi\sqrt{A/\omega N}$: the equilibrium is stable. When, however, ω is reversed the product must be given the opposite sign, and we get a solution in real exponentials, starting falling-away from the upright position, which is continued until the opposite (stable) position is attained. N has now also been reversed in space, and the product ωN in the differential equation is again positive.

As I have already stated, the time integral of the turning motive about the vertical required by the gyrostat from the frame constraining it to move round in azimuth is $2N$; that is, $2Cn$, where C is the moment of inertia of the flywheel about its axis. There is thus at each instant of the turning in azimuth before the inversion has been completed a couple required from the frame, and this couple is greater the greater the angular speed n of spin.

The couple arises thus. Let the gyrostat axis have been displaced from the vertical through an angle θ about the trunnion axis. In consequence of the azimuthal motion, at rate ω, say, the outer extremity of the axis of angular momentum is being moved parallel to the instantaneous position of the line of trunnions, and thus there is rate of production R of angular momentum about that line; but there being no applied couple about the trunnions, the gyrostat must begin to turn about the trunnions to neutralise R. This turning tends to erect or to capsize the gyrostat according as the spin and azimuthal motions agree or are opposed in direction. In its turn, however, this involves production of angular momentum about the vertical for which a couple must be applied by the frame, and of course to the frame by the operator. This couple is greater the greater Cn, and therefore if the operator cannot apply so great a couple, an azimuthal turning at rate ω cannot take place. With sufficiently great angular momentum the resistance to azimuthal turning could be made for any stated values of θ and ω greater than any specified amount.

The magnitude of this couple which measures the resistance to turning at a given rate is greatest when the angle θ is 90°; that is, when the axis of the flywheel is in the plane of the frame.

Now I come to an interesting application of these ideas. You are aware that Lord Kelvin endeavoured to frame something like a kinetic theory of elasticity—that is, he conceived the idea that, for example, the rigidity of bodies, their elasticity of shape, depends on motions of the parts of the bodies, hidden from our ordinary senses, as the flywheel of a gyrostat is hidden from our sight and touch by the case. Look at this diagram of a web (Fig. 11). It represents two sets of squares, one shown by full, the other by fine, lines; the former are supposed to be rigid squares, the latter flexible. Unlike ordinary fabrics, which are almost unstretchable except in a direction at 45° to the warp and woof, this web is equally stretchable in all directions. If the web is strained slightly by a small change of each flexible square into a rhombus, or into a not-square rectangle, the areas are to the first order of small quantities unaltered.

Now imagine that a gyrostat is mounted in each of the rigid squares, so that the axis of the trunnions and the axis of rotation are in the plane of the square as shown in Fig. 12. If the angular speeds of the flywheels are sufficiently great, it is impossible to turn the squares in azimuth at any given small angular speed. Thus any strain involving turning of the small squares is resisted, and we have azimuthal rigidity conferred on the web by the gyrostats. There is, however, no resistance to non-rotational displacement of the squares as wholes.

To get a model in three dimensions Lord Kelvin imagined an analogous structure made up of cubes, each composed of a rigid framework to play the part of the squares, and connected by flexible cords joining adjacent corners of the cubes. In each cube he supposed mounted three gyrostats with their trunnions at right angles to the three pairs of sides. This arrangement would, like the web of squares, resist

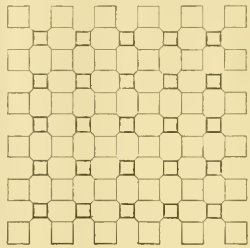

Fig. 11.

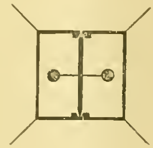

Fig. 12

rotation, but now about any axis whatever; and there would be no resistance to mere translation of the cubes as wholes. Thus the body so constituted would be undistinguishable from an ordinary elastic solid as regards translatory motion, but would resist turning.

It is convenient in this connection to refer to an arrangement—a gyrostatic imitation of a spiral spring—in which a constant displacement is produced and maintained by the action of a constant force in a fixed direction, involving the application of a couple of constant moment, though not of constant direction of axis. This gyrostatic spring balance is indicated in a paper entitled "On a Gyrostatic Adynamic Constitution for Ether," published partly in the *Comptes rendus*,[9] and partly in the Proceedings of the Royal Society of Edinburgh.[10] This is one of the many papers which Lord Kelvin published in the latter part of his life on a question that occupied him much from time to time, the nature of the æther as a vehicle of light and as the medium in which electric and magnetic phenomena are manifested.

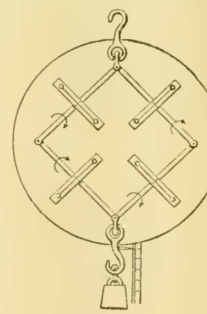

Fig. 13.

The spring balance is described in some detail in his "Popular Lectures and Addresses."[11] I had thought of realising the arrangement, which is shown in Fig. 13, but on consideration I found that though it would act as a spring, it would not, except under certain conditions, not easily realisable even approximately, possess the peculiar property of a spiral spring of being drawn out a distance proportional to the

[9] *Comptes rendus*, vol. cix., p. 453, 1889. Math. and Phys. Papers, vol. iii., p. 466.
[10] Proceedings of the Royal Society of Edinburgh, vol. xi., 1890.
[11] Vol. i., p. 237, *et seq.*

weight hung on the lower hook. The gyrostatic arrangement is very difficult to realise with ordinary gyrostats, but presents no difficulty with our motor instruments. You see what the arrangement is. A frame of four equal bars is constructed, by jointing the bars freely together at their extremities in the manner shown by the diagram. It is hung from a vertical swivelling pin at one corner, so that one diagonal of the frame is vertical, and another vertical swivelling pin at the lowest corner carries a hook. Four equal gyrostats are inserted, one in each bar, as shown, with its axis along the bar, and they have equal rotations in the directions shown by the circular arrows. Under the couples tending to change the directions of the axes of the flywheels, and applied by the weights of the gyrostats and bars, the system precesses round the two swivels, and so preserves a constant configuration. If now a weight is hung on the hook at the lower end, the frame is elongated a little, and a new precessional motion gives again a constant configuration of the frame, different, of course, from the former one. Two gyrostats, the upper or lower pair, would serve quite well to give the effect.

Lord Kelvin suggested that if the frame were surrounded by a case, leaving only the swivel-pins at top and bottom protruding, it would be impossible, apart from special knowledge of the construction of the interior, to discern the difference between the system and an enclosed spiral or coach spring, surrounded by a case and fitted with hooks for suspension and attachment of weights. But unless the masses of the gyrostats are very small (while their angular momenta are exceedingly great), so that the change of kinetic enegy due to the change in precessional motion may be put down entirely, or nearly so, to the work done by gravity on the weight carried by the hook, in its descent from one configuration of steady motion to another, the distance through which the frame is lengthened is not simply proportional to the load applied.

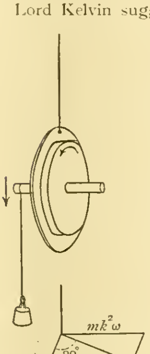

FIG. 6.

A fair idea of the action, and, indeed, an approximate realisation of the property aimed at, is obtained by means of the arrangement shown in Fig. 6 above. We have had it before. A gyrostat is hung with its axis horizontal by a cord in the same vertical as the centroid. The flywheel spins, but as there is no couple there is no precession. A weight mg is applied in a vertical line at distance l from the centroid, as indicated by the diagram; a slight, very slight, tilting of the gyrostat is produced, and the gyrostat moves off with not quite steady precession, of average angular speed μ. Neglecting the slight deviation now set up of the suspension cord from the vertical, and putting A for the moment of inertia of the gyrostat about a vertical axis through its centre, we get for the kinetic energy of the azimuthal motion the value $\frac{1}{2}A\mu^2 + \frac{1}{2}ml^2\mu^2$. The work done by the weight mg in its descent through the small distance h involved in the tilting is mgh. Hence we get $\frac{1}{2}(A+ml^2)\mu^2 = mgh$.

As we have already seen, however, we have in this case $\mu = mgl/Cn$. Substituting in the equation just found this value for μ, and supposing that A is great in comparison with ml^2, so that the term $\frac{1}{2}ml^2\mu^2$ may be neglected, we find after a little reduction the equation—

$$\frac{m}{h} = 2\frac{C^2 n^2}{A l^2 g}.$$

Thus h is proportional to m.

It will be evident that if on the right-hand side of the first equation there had been terms due to descent of the gyrostat through a distance of $\frac{1}{4}h$ or $\frac{3}{4}h$, this equation of proportionality could not have been obtained.

The idea, however, underlying the arrangement is very suggestive, and carries us a long way towards obtaining a definite notion as to how the elastic properties of bodies may be explained.

(A gyrostatic pendulum was here shown. See for figure and description NATURE, April 17, 1913.)

VII. *Vibrations and Waves in Stretched Chain of Gyrostats.*

[An account of this paper was given in the lecture, and will be found (with details of the mathematical discussion appended) in the *Journal* of the Institution of Electrical Engineers.]

VIII.—*Gyrostatic Observation of Rotation of the Earth.*

The famous French experimentalist, Léon Foucault, suggested two ways of determining the rotation of the earth. One was observation of the apparent turning of the plane of vibration of a long pendulum, suspended so as to be as nearly as possible free from any constraint due to the attachment of the pendulum wire to its fixed support. This classical experiment was carried out with fair success at the Panthéon at Paris, and was repeated under the domes of the cathedrals of Amiens and Rheims. If the exponents of "Kultur" in Northern France were aware of this fact, they seem to have attached to it just as little weight as they gave to the more sacred associations of the beautiful old church of the latter city.

Foucault's other method was based on the fact that a gyrostat, if mounted properly, retains unaltered the direction of the spin-axis when the supports are turned round. Here, for example, is our pedestal gyrostat, mounted freely in its enclosing frame which is carried by a vertical rod, swivelling in a vertical socket carried by the supporting stand (see Fig. 7 above). I can set the spinning gyrostat with its axis in any direction I please, and, when I turn the supporting stand round, a friction couple of some little magnitude is applied to the vertical rod. You see that I do not alter the direction of the spin-axis perceptibly. Yet the friction couple is sufficient to carry the gyrostat round with the stand when there is no spin. The spin results in a great increase of virtual inertia for turning displacements, as we shall see quantitatively in the case of one of Lord Kelvin's experiments, which I am about to describe.

In practice it is found desirable to subject the gyrostatic apparatus to a constraint which is perfectly definite; for example, the axis of spin may be kept horizontal. Solutions of the problem are to be found in the gyrostatic compasses now in use on the warships of various navies.

At the British Association meetings at Southport and Montreal, in 1883 and 1884, Lord Kelvin suggested methods of demonstrating the earth's rotation, and of constructing a gyrostatic compass. One of these had reference to the component of rotation about the vertical, the component, in fact, demonstrated by the Foucault pendulum experiment. If ω be the resultant angular speed, the component about the vertical at any place in latitude l is $\omega \sin l$, while the companion component about the horizontal there is $\omega \cos l$. Thus at London the component about the vertical is 0·78 of ω, and the period of rotation about the vertical is about 30·77 hours of sidereal time.

Lord Kelvin's method of measuring $\omega \sin l$ consists in supporting a gyrostat on knife-edges attached to the projecting edge of the case, so that the gyrostat without spin rests with the axis horizontal or nearly so. For this purpose the line of knife-edges is laid through the centre of the flywheel at right angles to the axis, and the plane of the knife-edges is therefore the plane of symmetry of the flywheel perpendicular to the axis. The knife-edges are a little above the centre of gravity of the instrument, which we suppose in or nearly in that plane, so that there is a little gravitational stability. The azimuth of the axis is a matter of indifference, as any couple due to the component of rotation about the horizontal is balanced by an equal couple furnished by the knife-edge bearings.

At points in a line at right angles to the line of knife-edges, and passing through it, two scale-pans are attached to the framework, and by weights in these the axis of the gyrostat (without spin) is adjusted, as nearly as may be, in a horizontal position which is marked. The gyrostat is now removed, to have its flywheel spun rapidly, and is then replaced. It is found that the weights in the scale-pans have to be altered now to bring the gyrostat back to the marked position. From the alteration in the weights the angular speed about the vertical can be calculated.

To fix the ideas, let the gyrostat axis be north and south, and let the spin to an observer, looking at it from beyond the north end, be in the counterclock, or positive direction. The rotation of the earth about the vertical carries the north end of the axis round towards the west, and therefore angular momentum is being produced about a horizontal axis drawn westward, at a rate equal to $C n \omega \sin l$, where C is the angular momentum of the flywheel. If the sum of the increase of weight on one scale-pan and the diminution (if any) in the other be w, and a be the horizontal distance between the points of attachment of the scale-pans, we have

$$C n \omega \sin l = w g a.$$

Thus if C and n are known, $\omega \sin l$, or ω, can be calculated.

Lord Kelvin does not give any figures as to the forces to be measured in a practical experiment; but I can supply these. We may take the mass of a small flywheel as 400 grammes, its radius of gyration as 4 cm., and its speed of revolution, if high, as 200 revolutions per second. If we take a as 10 cm. we obtain for London the equation

$$400 \times 4^2 \times 400\pi \times \frac{2\pi \times 0{\cdot}78}{80160} = 10 \times 981 \times w.$$

This gives $w = 0{\cdot}047$ gramme, or 47 milligrammes. It would require careful arrangements to carry out the experiment accurately, but the idea is clearly not unpractical. With some of the new gyrostats that we now have, the mass of the wheel is as much as 2000 grammes, and the radius of gyration is about 7·5 cm. These numbers bring w up to 0·82 gramme, at the same speed.

If the gravitational stability of this gyrostatic balance be removed, that is, the line of knife-edges be made to pass accurately through the centre of gravity of the system of wheel and framework, and the axis of the wheel be placed in a truly north and south vertical plane, so that the knife-edges are horizontally east and west, the gyrostat will be in stable equilibrium when the axis is parallel to the earth's axis, and is turned so that the direction of rotation agrees with the rotation of the earth. For we have then simply the experiment, described above, of the gyrostat mounted on trunnions resting on bearings attached to a tray which is carried round by the experimenter. The axis of the gyrostat was at right angles to the tray, and we saw that when the tray, held horizontally, was carried round in azimuth the equilibrium of the gyrostat was stable or unstable, according as the two turnings agreed or disagreed in direction. In the present case the tray is the earth, the position of the axis of rotation parallel to the earth's axis replaces the vertical position, and the earth's turning the azimuthal motion. If displaced from the stable position the gyrostat will oscillate about it in the period $2\pi\sqrt{A/Cn\omega}$, where A is the moment of inertia about the knife-edges, and the other quantities have the meanings already assigned to them.

If the line of knife-edges be north and south, the vertical will be the stable, or unstable, direction of the axis of rotation, and there will be oscillation about the stable position in the period

$$2\pi\sqrt{A/Cn\omega \sin l}.$$

The gyrostat thus imitates exactly the behaviour of a dipping needle in the earth's magnetic field, and thus we have Lord Kelvin's gyrostatic model of the dipping needle.

It is right to point out that these arrangements were anticipated by Gilbert's barogyroscope,[12] which rests on precisely the same idea, and applies it in a similar manner.

IX.—*Gyrostatic Compass.*

At Montreal Lord Kelvin described a "gyrostatic model of a magnetic compass." This was one of his gyrostats hung, with its axis of rotation horizontal, by a long fine wire, attached to the framework at a point over the centre of gravity of the system, and held at the upper end by a torsion-head capable of being turned round the axis of the wire. By means of this torsion-head any swinging of the gyrostat in azimuth round the wire was to be checked until, when the head was left untouched, the gyrostat hung at rest.

In small azimuthal oscillations of the gyrostat about the axis of the wire, the wire being fixed to the gyrostat at the lower end and held by the head at the upper, the virtual moment of inertia of the gyrostat about the wire is greatly enhanced by the rotation of the flywheel. If there were no rotation the moment of inertia would be A; with rotation it is virtually $A(1 + C^2n^2/AMag)$, where M is the whole suspended mass, a the distance of the point of attachment of the wire above the centre of gravity of the mass M. This will be found proved very simply in the Mathematical Appendix [see *Journal*, I.E.E.] to this lecture. It will be shown, moreover, that when the whole motion is considered—the tilting motion as well as the azimuthal—it appears that there are two fundamental periods of vibration. There is the long period due to the slight torsional rigidity of the long wire, and the enhanced moment of inertia pointed out by Lord Kelvin, and also a short period, the shortness of which is most properly to be reckoned as due to virtual diminution of the moment of inertia of the gyrostat, in the tilting motion, in exactly the same ratio as the other moment of inertia is increased. Both these periods are separately possible, and in

12 "Mémoires sur divers problèmes," etc. *Annales de la Société Scientifique, Bruxelles*, 1877–8.

the most general motion they are superimposed. This second curious effect was not referred to by Lord Kelvin, and I have not seen it noted before. The co-existence of long and short periods is, however, characteristic of rapidly spinning gyrostatic systems.

Now suppose that the wire so long and of so slight torsional rigidity that this rigidity cannot stabilise the gyrostat in the position of unstable equilibrium. Then the effect of the component of rotation of the earth about the vertical is to produce tilting of the axis of the flywheel from the horizontal position, since this turning gives a rate of production of angular momentum about a horizontal axis at right angles to that of rotation. A slight tilt suffices to give an equilibrating couple, and so we can have the gyrostatic axis in a north and south vertical plane, and nearly horizontal, while the wire is without twist. Into this position the gyrostat is guided by manipulation of the torsion-head. The effect of the horizontal component of the earth's angular speed is now practically zero.

If now by the use of the torsion-head the gyrostat axis be brought to rest in a nearly horizontal position at an angle ϕ with the north and south horizontal direction, the component of turning about this position of the axis is $\omega \cos l \cos \phi$, and about a horizontal line at right angles to the new position of the axis is $\omega \cos l \sin \phi$. The former has no influence on the gyrostatic axis, the latter gives a rate of production of angular momentum about the vertical amounting to $C n \omega \cos l \sin \phi$. Hence a couple of moment equal to this must be applied by means of the torsion-head to produce equilibrium, and this as we see is proportional to $\sin \phi$.

X.—*General Dynamical Theory of Gyrostatic System with any Number of Freedoms.*

I cannot do more than mention the gyrostatic investigations contained in the second edition of "Natural Philosophy." These were written while the proofs of § 345 of the book were in his hands, and consist of additional sections (§§ 345^{i}–345^{xxviii}) interpolated at that stage. From many points of view this part of the book is exceedingly interesting. It continues a subject which was also expanded in the same way on the proof-sheets (in §§ 343*a*–343*m*), that of oscillatory motion. Oscillatory motion for systems of two, three, four, six, or more freedoms with gyrostatic domination is enough to tax the skill of the most expert analyst, for questions arise regarding the roots of the determinantal equations and their interpretation, which require great care in handling. I may only quote the general conclusions as to gyrostatic domination.

Let the number of the freedoms be even (that is, the freedoms exclusive of those by which the flywheels have angular momenta about their axes). Let the equilibrium of the system when at rest (without spin of the flywheels) be either stable, or unstable, for every freedom. If the wheels are so linked up to the system as to render gyrostatic domination possible, then with sufficiently rapid spin the equilibrium becomes stable, with half the whole number, $2n$ say, of its periods of vibration exceedingly small, and the other half very large. Each set of periods is given by the roots of a determinantal equation of degree n. The latter periods are to the first degree of approximation independent of the applied forces, and were called "adynamic," the former periods were called "precessional," and do depend on the applied forces.

The first approximations to the fast and slow azimuthal motion of a top are in point. The angular speed $Cn/A \cos \theta$ does not depend on any applied forces, the other speed Mgh/Cn does.

XI.—*Difficulties of Mechanical Hypotheses and Models. Conclusion.*

I have now dealt with most of Lord Kelvin's investigations and theories. These were related in many ways to electricity and magnetism, and in all of them he ever sought some dynamical explanation that would work. This, indeed, was the distinguishing feature of all his researches, the bringing of everything down to dynamics, and the construction where possible of illustrative mechanical models. Electricity and magnetism are highly dynamical affairs; we send signals by wire or "wireless," we transmit power in a wonderful manner by an agency which we are still far from completely understanding, an agency which causes absorption of energy at one place on the earth's surface, and evolution again of a large portion ot that energy at another place. The vehicle is the æther, for, in spite of all that I have been able to learn regarding the new theory of relativity, I still believe in the æther's existence. In all this we are held fast by dynamical laws, no doubt not yet formulated in full detail, but to a considerable extent already correctly comprehended.

* * * * * *

Lord Kelvin certainly had confidence in his own theories and clung firmly to his conclusions. He was *tenax propositi*, yet he could on occasion acknowledge that he had made a mistake. His genius ranged over the whole field of physical science; no problem was too great or too small to attract his attention. No obstacles, no complications, daunted his spirit of inquiry. The thunders of Jove, the birth of the world and the cold death prepared for it by dissipation of energy, the harnessing of the energies of nature for the service of man, the guidance and safety of mariners, the genesis of waves and their breaking into spray and spindrift, all these questions, and many others, engaged his thoughts, to the lasting benefit of humanity and the increase of knowledge. Throughout all he was keen and calm and dispassionate, a truly unaggressive and kindly natural philosopher.

The function of science is to enable man to penetrate the secrets of nature, and to apply that knowledge to the promotion of the welfare and happiness of all living beings. No one would have repudiated with more scorn than Lord Kelvin that emanation of the Pit, the modern doctrine that culture—scientific, philosophical, or artistic—entitles a self-appraised and self-chosen nation to wade through seas of blood to the domination of the world.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

LONDON.—The report of the Military Education Committee to the Senate of the University for the year 1914 shows that very valuable service has been rendered to the country by the University Contingent of the Officers Training Corps. The number of cadets and ex-cadets of the Contingent gazetted to commissions between August 5, 1914, and the end of the year was 773, and the number of graduates and students of the University (not being past or present cadets of the O.T.C.) gazetted to commissions during the same period was 156. Allowing for officers commissioned from the O.T.C. before August 5, the total number of officers now serving, who are ex-cadets of the University of London O.T.C., or were recommended for their commissions by the University, is estimated at 1100. In addition, a large number of graduates and students of the University have been granted commissions through other channels or are serving in the ranks. We notice with regret that the following officers who proceeded to commissions from the University of London O.T.C. are reported killed:—2nd Lieut. T. R. Bottomley, Birkbeck College; 2nd Lieut. J. S. Paulson, University College; Lieut. C. D. Sneath, University College; 2nd Lieut. C. F. Shaw, King's College; 2nd Lieut. M. A. P. Shawyer, East London College; and 2nd Lieut. P. J. Whitehouse, East London College.

The Commanding Officer of the University O.T.C. Lieut.-Col. D. S. Capper, announces that a limited number of young men who are not students of the University will be enrolled for a course of continuous training with the view of qualifying for commissions. Candidates, who must be between the ages of 18 and 28 and suitable in every respect for commissions in the Army, should attend in person to see the Adjutant of the Contingent at the Headquarters, University of London, South Kensington. The next course of continuous training will commence on March 15.

The Senate on February 24 appointed Dr. C. K. Tinkler, D.Sc. (Birmingham), to the readership in chemistry, tenable in the home science department of King's College for Women.

The D.Sc. degree in biological chemistry was granted to R. V. Norris (Lister Institute), and in physics to A. H. Ferguson.

An interesting series of special lectures dealing with questions of social service is at present being conducted at the Municipal Technical Institute, Belfast. The problems created by the war have aroused much interest in social work, and have attracted into the field of social service large numbers of voluntary workers. Amongst these workers the need is being increasingly felt for a better understanding of the principles which should be followed and of the methods which should be employed in social effort, as well as for a fuller knowledge of the local facilities already existing for the amelioration of distress. It is to meet the urgent call for such knowledge that the authorities of the institute have established the lectures. The programme of the series, issued in pamphlet form and containing abridged syllabuses, shows that the course takes a very comprehensive view of the whole subject. The lectures fall naturally into three main groups. The first group deals with fundamental and general questions relating to social service, the second group deals with municipal and State effort, and the third group treats of voluntary agencies. The value of the programme is enhanced by the inclusion of lists of the books on social subjects which are available in the library of the institute and in the public libraries of the city. The first lectures of the series have been exceptionally well attended, and it is hoped that the outcome of the series will be the establishment of systematic courses of instruction in various branches of social science. More than six hundred members of the staff and of present and former students of the institute are serving with the naval and military forces of the Empire.

The debate in the House of Commons on Friday last on the vote for the Civil Service and Revenue Department was mainly occupied with the question of the alleged shortage of adult labour in agricultural districts and the attempt of farmers to induce the Boards of Agriculture and of Education to look with favour on the exploitation of children to take the place of men who have enlisted. It is satisfactory to learn that neither of the Boards in question shows much inclination to relax the conditions under which children are now allowed to leave school for full-time work, yet it is nevertheless disquieting to find that in some rural areas it is almost impossible to get magistrates to convict for breaches of the school bye-laws. The results of the war have not placed farmers in a disadvantageous position as regards prices; on the contrary, as is well known, the price of wheat and other produce has almost doubled since the war began, and the farmer has thus little reason to refuse a substantial advance in wages such as would induce the labourer in the town to return to the countryside. Moreover, the question as to whether there is a material shortage is not beyond doubt, since it is stated that not more than three per cent. of farm labourers have joined the forces. The cry for child labour comes mainly from the southern counties, where it is admitted that the rate of payment is greatly below that of the north and in Scotland. In any case, before the child is exploited the labour of women at an adequate rate demands to be considered. Having regard to the fact that this war is making a heavy drain upon some of the best elements of the industrial population the nation cannot be indifferent to the well-being of the children, both physically and intellectually. Everything that is possible, no matter how great the sacrifice of material interests, should be made to conserve both. We are at war with the best-instructed nation of the world, and we cannot be too considerate of the present welfare of the nation's children, having regard to the heavy responsibility the future will place upon them.

The second reading of the Universities and Colleges (Emergency Powers) Bill was agreed to by the House of Commons on Tuesday, March 2. The Bill gives the Universities of Oxford and Cambridge power to postpone the date of the determination of scholarships in order to enable their holders to enjoy them when they return from the war. In the same way, power is given to suspend the statutory conditions as to residence; to enable the richer colleges to make up the deficit in the tutorial fees by taking money from their endowments, and the poorer colleges to postpone repayment of capital; the power to make emergency statutes, and so on. In moving the second reading of the Bill, Mr. Asquith said that the total number of members from each University serving in the Army and at the front is approximately 6000. The total number of undergraduates in residence at Cambridge a year ago was 3181. It is now 1227. The figures for Oxford are approximately the same. This means that two-thirds of the undergraduates from the two great Universities have volunteered for service, and are now serving their country in the Army. Nearly all the physically fit undergraduates in residence both in Oxford and Cambridge have joined the Officers Training Corps, and many of the University buildings have been given up for military purposes. This transformation in the whole aspect and conditions of university life has exposed both the Universities as a whole and their constituent colleges to great difficulties and pecuniary embarrassments. At Cambridge the fees normally payable in the scientific department of the University are 26,000*l*. a year; and it is estimated that this year less than 15,000*l*. will be paid; while other fees, usually amounting to 35,000*l*., the University authorities estimate will be no more than 15,000*l*. In supporting the Bill, Sir Joseph Larmor said that when the war is over it will be the duty of the country to see that the standard of British learning and science is maintained before the world. It will be the duty of this nation more than ever before to see that the things of the mind are attended to after we have obtained success in the material prosecution of the war.

SOCIETIES AND ACADEMIES.

London.

Royal Society, February 25.—Sir William Crookes, president, in the chair.—Prof. L. **Hill** and J. F. **Twort**: The effect of the depth of pulmonary ventilation on the oxygen in the venous blood of man.—J. **Barcroft** and Toyojiro **Kato**: The effect of functional activity upon the metabolism, blood flow, and exudation in organs. The organ studies have been skeletal muscle and the submaxillary gland. (1) The oxygen used by these organs not only increases during their activity but outlasts it by some hours. The curve of oxidation usually shows two maxima, the first during the period of activity, the second much later. (2) water leaves the blood-vessels in much greater quantities during and after activity of the organs than before; a similar second maximum is sometimes seen in the case of the exudation. (3) In the case of muscle not all the exudation leaves the muscles as lymph. Of the right and left gastrocnemius muscles, the one which has been stimulated is heavier several hours after the stimulation, and of lower specific gravity than the unstimulated one. (4) The dilatation of the vessels of the organ outlasts the functional activity for two hours or more in the case of muscle which has been stimulated rhythmically for fifteen minutes. (5) The tenseness of the muscle caused by its distension with water would seem to be the physical basis of stiffness.—Miss D. Jordan **Lloyd**: The osmotic balance of skeletal muscle. In order to free the phenomena as far as possible from complications due to the formation of diffusion columns, a very small flat muscle—the sterno-cutaneous of the frog—was used. The results of experiments show that an oxygen-saturated muscle has an osmotic equivalent less than that of distilled water.—Dr. A. J. **Ewart**: The function of chlorophyll. Previous observations of the author have tended to support the theory that chlorophyll is a stage in photosynthesis. The present paper develops this idea further. By means of Wellstätter's methods of extraction and separation, chlorophyll, carotin, and xanthophyll were obtained in the pure state and used for the experiments. The following conclusions were reached:—(1) No peroxides, organic or inorganic, are produced during the photo-oxidation of chlorophyll, xanthophyll, and carotin. The oxidising effect of these latter substances on potassium iodide when they are undergoing oxidation in the light is due to the fact that in the presence of abundant oxygen they can act as oxidases, not only to themselves, but also to substances with which they may be in contact, such as hydriodic acid, litmus, or guaiacum. (2) Chlorophyll and xanthophyll decompose during photo-oxidation into (*a*) solids, and (*b*) a gas. The solids are colourless, waxy substances and hexose sugars. The gas is formaldehyde gas. With dry films in dry air free from CO_2 relatively more formaldehyde is produced and less sugar. (3) Carbon dioxide combines with chlorophyll, forming xanthophyll and a colourless waxy solid. The combination only takes place actively in the presence of water, and is accelerated by sunlight.—A. **Compton**: The influence of the hydrogen ion concentration upon the optimum temperature of a ferment.—M. **Back**, K. M. **Cogan**, and A. E. **Towers**: Functional œdema in frogs. If the gastrocnemius muscle of a frog be stimulated for fifteen minutes with forty induction shocks per minute it becomes heavier than the other. The difference in weight may amount to upwards of 20 per cent. of the weight of the muscle. The specific gravity falls correspondingly. This phenomenon may be noticed from fifteen minutes after the stimulation ceases to six hours. After sixteen hours the œdema has passed off.

Physical Society, February 12.—Dr. A. Russell, vice-president, in the chair.—A. **Campbell Swinton**: A galvanic cell which reverses its polarity when illuminated. If two plates—one of zinc and the other of tinned copper coated on one surface with selenium and varnished with enamel over the remainder of its surface—are immersed in tap-water, the electric current through a galvanometer connected to the plates shows that in the dark the zinc is electro-positive to the selenium, while the result of light falling on the selenium is to increase the effect. If, however, instead of zinc, carbon or copper is employed for the non-coated plate, the interesting result is obtained that, while the selenium proves to be electro-positive to the carbon or copper in the dark, it immediately becomes electro-negative to carbon or copper the moment it is illuminated, this being easily shown by the deflections of the galvanometer in contrary directions as the light is turned on and off.—Prof. S. P. **Thompson**: On the criterion of steel suitable for permanent magnets. Whatever the form to be given to a permanent magnet, the prime requisites as to the quality of the steel are (1) large remanent magnetism ($\mathfrak{I}_{\text{rem.}}$) and a high coercive (force $\mathfrak{H}_c$). Since Hopkinson's determinations of 1885 it has been supposed that for the purpose of making permanent magnets the best material would be that for which both of these quantities and, consequently, their numerical product, should be as high as possible. Recently Mr. J. A. Mathews and, independently, Mr. J. R. Ashworth, have proposed to take the ratio $\mathfrak{H}_c \div \mathfrak{I}_{\text{rem.}}$ or $\mathfrak{H}_c \div \mathfrak{B}_{\text{rem.}}$, which only differs in scale as the criterion. To decide as to the suggestion to take the ratio instead of the product a table giving the values of $\mathfrak{H}_c, \mathfrak{I}_{\text{rem.}}$ $\mathfrak{H}_c \div \mathfrak{I}_{\text{rem.}}$ and $\mathfrak{H}_c \times \mathfrak{I}_{\text{rem.}}$ for a number of steels is given, and it is clearly shown that the use of the ratio as a criterion of magnetic usefulness leads to most absurd results. As an example, annealed manganese steel (almost non-magnetic) should, judging from the ratio, be six times as good as Remy steel, whereas in reality, for equality of pull, a magnet of manganese steel would require to be 312 times the weight of that made of Remy steel. The qualities requisite in an ideal steel for permanent magnets are indicated.—A. B. **Wood** and A. I. **Steven**: An investigation of the photographic effect of recoil atoms. The ionising, phosphorescent and photographic effects of the α-particles from a radio-active substance entirely cease when the particle still retains about 40 per cent. of its kinetic energy. It appears possible, therefore, that the recoil atoms from a radio-active source should be able to affect a photographic plate, for though the range of a recoil atom is only about 1/500th of that of the α-particle shot off from it, the ionising effect has been shown by Wertenstein and one of the authors to be 10 times as powerful over the corresponding range as that of the α-particle. Attempts have, therefore, been made to demonstrate this action in the case of the recoil atom from polonium, this substance being chosen on account of the inactive nature of the recoiling atom. Two distinct methods were employed: (1) The recoil atom was "absorbed"; (2) the difference of deflection of the α-particle and the recoil atom in a strong magnetic field was utilised in order to attempt to separate their effects. "Schumann" plates were used as being most easily penetrable, but in all cases the results were negative or inconclusive. This is probably due to the fact that the recoil atoms are not able to penetrate sufficiently deeply into the sensitive layer to render the grains developable.

Linnean Society, February 18.—Prof. E. B. Poulton, president, in the chair.—Harold **Wager**: The action of light upon chlorophyll. By making a film of chlorophyll upon paper and on glass, by floating an alcoholic solution, and allowing it to dry, the author was able to bleach a portion under strong sunlight, and covering a portion by black paper; when this was tested by Schiff's solution, the exposed, that is, the bleached portion, became pink, the unexposed portion showing no colour change. Another experiment was made by subjecting similarly bleached portions of chlorophyll to the action of potassium iodide, when the exposed parts turned reddish-blue, in consequence of the liberation of iodine, which acts upon the starch on the paper. The experiments clearly show that the decomposition of chlorophyll is accompanied by the formation of an aldehyde and of something able to oxidise the potassium iodide and to set free the iodine. Instead of alcoholic extract of chlorophyll we may use dried leaves, or chlorophyll expressed from leaves, or layers of Euglena or algæ spread over the paper. The reactions also take place inside a leaf, if the bleaching has been efficient. Thus if sunlight is condensed by a lens upon a living leaf of *Oxalis acetosella* containing plenty of starch, the chlorophyll is bleached in a small area, and if treated with Schiff's solution, a strong aldehyde reaction results; if tested with potassium iodide the said area becomes blue. It having been stated that formaldehyde is produced when chlorophyll is exposed to sunlight in the presence of carbon dioxide, an attempt was made to determine whether such was the case in the present series of experiments, but the author was not able to satisfy himself on this point, though several of the tests succeeded even with so small an amount as one-millionth of formaldehyde. Hydrogen peroxide had been suggested as the gaseous oxidising compound of chlorophyll, but the result of many varied tests showed that this was not so.

MANCHESTER.

Literary and Philosophical Society, February 9.—Mr. F. Nicholson, president, in the chair.—Dr. T. Graham **Brown**: Note on the physiology of "walking," with especial reference to its occurrence in the unborn fœtus of the cat. The various reflexes have been examined in cat fœtuses. The red nuclei seem to be capable of stimulation, and evoke their characteristic movements of the fore-limbs. The limb reflexes are very similar to those of the adult cat. The ipsilateral flexion-reflex and the contralateral extension-reflex have thus been observed. In the former reflex an extension rebound effect has been seen. Reflex inhibition may be observed on pitting one reflex against another. If the fœtus is shelled out of the uterus without delay into warm physiological salt solution it may be regarded as still unborn. In these circumstances unmistakable movements of progression may be obtained on producing asphyxia by pressure upon the umbilical cord. They may sometimes appear to arise spontaneously. This observation shows that the mechanism for co-ordinate progression develops during intra-uterine life, and that the co-ordination of the mechanism is not conditioned after birth by a process of "learning." The observation also shows that the rhythmic activity may be evoked by the general stimulus of asphyxiation before it has been evoked or conditioned by any rhythmic self-generated peripheral stimuli such as those which play an important part in normal progression, but have been shown not to be its intrinsic factors. It thus also gives another demonstration of the similarity between the respiratory mechanism and that for progression.—Prof. G. Elliot **Smith**: The Darling Downs skull. Photographs were shown of a completely mineralised human skull, which had been found near Warwick in the Darling Downs of Queensland, and was described by Profs. Edgeworth David and Wilson at the recent meeting of the British Association in Australia. This important discovery of the earliest human remains yet known in Australia seems to prove that Man reached Australia at a time when the great fossil marsupials were still living.

DUBLIN.

Royal Dublin Society, February 23.—Prof. Wm. Brown in the chair.—Prof. Grenville A. J. **Cole**: The mode of occurrence and origin of the orbicular granite of Mullaghderg, Co. Donegal. The structure and mineral characters of this rock were described by Dr. F. H. Hatch in 1888. A recent visit by the Geological Survey has enabled large specimens to be procured, the surfaces of which have been polished. The nucleus in several of the large spherulites is seen to be a flake of schistose rock. In most cases, however, it consists of granite, somewhat poorer in biotite than the granite which includes the spherulitic bodies. The very local occurrence of this orbicular rock as a variation on the general red granite of the district leads to the conclusion that the spherulitic bodies represent inclusions from the roof of Dalradian schists which once overlay the granite cauldron. Such inclusions may have fallen in from a cold portion of the roof and thus promoted a rapid crystallisation of oligoclase round about them by interaction of their constituents and those of the granite magma. Blocks of already cooled granite may have fallen back also from the roof of the dome, and may have supplied nuclei for spherulitic growth. The occurrence of granite round about schist-fragments, and surrounded by a zone of radial oligoclase, suggests, however, an interchange of material between the granite and the schists. Granitic material seems to have soaked in while more basic material moved outwards to form the radially crystalline zone. Experiments by Tenow and Benedicks and by Endell are referred to: but no explanation can be offered as to why orbicular structure is so rare a phenomenon.

EDINBURGH.

Royal Society, February 1.—Sir E. A. Schäfer, vice-president, in the chair.—Mrs. Rosalind **Jones** (*née* Crosse): Studies on periodicity in plant growth. Part ii. Correlation in root and shoot growth. In a former paper the fact of a four-days' periodicity in plant growth had been established; and in the present continuation the subject was further investigated. It was found that artificial changes in environment as regards heating and illumination did not affect the periodicity, and that there was correlation in the root and shoot growths.—Dr. J. **Dawson**: The histology of disseminated Sclerosis. This investigation, which had been partly outlined by the late Dr. Alexander Bruce, was based on an extended pathological observation disseminated sclerosis. This investigation, which had been studied largely by the method of serial sections stained by modern neuro-histological technique; and complete sections through the cerebral hemispheres, or large portions of the central nervous system, had been used to elucidate the distribution of the patches. Although no complete interpretation of the subject could be given, or no uniform conception of the process offered, certain conclusions were formulated, of which the following may be noted. The process underlying disseminated sclerosis is a sub-acute disseminated encephalo-myelitis, which terminates in areas of actual and complete sclerosis. There is overwhelming evidence that the great majority of the areas arise on the basis of an evolution through a stage of fat granule cell formation. There is much to favour the view that true disseminated sclerosis is due to a specific morbid agent, the nature of which is quite unknown. Histological evidence suggests a soluble toxin, conveyed to the nervous tissues by the blood channel rather than by lymphatics. The fleeting early motor paralysis and psychical symptoms may be related to the presence of areas in association paths, their remission being possibly due to the linking up of other association paths, or their compensation to the opening up of new paths. Although approximate answers may be given to questions relating to the nature of the process, to its origin, and to certain aspects of the mode of action, we are still quite in the dark concerning the nature of the final causal agent, which determines a disease which, however variable the early symptoms, conceals its characteristic course only temporarily.

February 15.—Dr. Peach, vice-president, in the chair.—Dr. H. **Rainy** and Dr. J. W. **Ballantyne**: Skiagraphic researches in teratology. The paper dealt with the abnormal development of bones in the human fœtus, and was illustrated by a number of X-ray photographs of these abnormalities. The facts brought forward opened up important questions in heredity, as well as in development.—Prof. J. **Stephenson**: (1) On *Haemonais laurentii*, a representative of a little-known genus of Naididæ; (2) on a rule of proportion observed in the Setæ of certain Naididæ; (3) on the sexual phase in certain of the Naididæ. An account was given in these connected papers of the various systems of organs and of the process of fission in this group of worms. A curious feature in two of the species described was the degeneration of the alimentary canal as the worm approached sexual maturity. Dr. F. R. Cowper **Reed**: The Ordovician and Silurian Brachiopoda of the Girvan District. In this elaborate memoir about 250 species and varieties were described, of which some seventy were new to science. The greater number of specimens described were from the collection made by Mrs. Robert Gray of Edinburgh, and with these were joined specimens from various museums in Great Britain. The local facies of the fauna were strongly marked; but many of the species, particularly those of Ordovician age, resembled American rather than European types. A characteristic feature was the limitation of distinctive species to successive stratigraphical horizons, a fact which suggested a more extended use of brachiopods for zonal purposes.

PARIS.

Academy of Sciences, February 15.—M. Ed. Perrier in the chair.—L. E. **Bertin**: The transport of marine mines by currents under the action of the groundswell. The upward thrust on the mine due to hydrostatic pressure has been usually calculated from the value in water at rest. The alterations in the thrust due to an oscillatory motion of the water are calculated, and it is shown that to prevent the anchor being lifted its customary weight should be doubled.—C. **Guichard**: Surfaces such that the lines of curvature correspond on the primitive surface, and on the surface locus of the centres of the spheres osculating the lines of curvature of a series of the primitive surface.—Paul **Vuillemin**: The flower. A discussion of the flower in its relation to the leaves.—B. **Jekhowsky**: Observations of Delavan's comet, 1913*f*, made at the Observatory of Paris. Four positions given for January 8 and 11. The comet appeared as a rounded nebulosity of about 30″ diameter with a semi-stellar nucleus. Magnitude 7·5 to 8. No tail.—M. **Alezais**: A property of arithmetical progressions.—M. **Globa-Mikhaïlenko**: Ellipsoidal figures of equilibrium of a fluid mass in rotation when capillary pressure is taken into account. It is shown that the only ellipsoidal figure of equilibrium assumed by a fluid mass in rotation, if the surface tension is taken into account, is the cylinder of revolution.—A. **Guillet**: Wheel with harmonic teeth, application to the construction of a laboratory chronometer with a uniform and continuous movement.—E. **Mathias**, H. Kamerlingh **Onnes**, and C. A. **Crommelin**: The rectilinear diameter of nitrogen. The densities of liquid nitrogen and its saturated vapour were determined at temperatures ranging from −208·36° C. to −148·08° C., and the values of the ordinate of the diameter were found to be $y=0{\cdot}022904-0{\cdot}0019577\,\theta$. The angular coefficient of the diameter is $\alpha=-0{\cdot}0019577$, and the critical density $\Delta=0{\cdot}31096$. The critical coefficient $\frac{R\Theta\Delta}{\pi}$ is 3·421, or nearly the same as argon (3·424) and oxygen (3·419).—L. **Bouchet**: The deformation of vulcanised indiarubber under the action of an electrostatic field. The variable electrostatic pressures are sufficient to account for the observed facts without any additional hypothesis.—Keivin **Burns**: Interferential measurements of wavelengths in the ultra-violet part of the iron spectrum Data are given for wave-lengths between 2851 and 3701 on the basis of the value 6438.4696 for the red cadmium line.—Henry **Hubert**: Preliminary sketch of the geology of the Ivory Coast.—B. **Galitzine**: The earthquake in Italy on January 13, 1915. Particulars of the records on the seismographs at the Pulkovo Observatory. The position of the epicentre calculated from the seismograms coincided very closely with the region of greatest damage, and it is pointed out that observations from a single station were sufficient for this determination.—Ph. **Flajolet**: Disturbances of the magnetic declination at Lyons (Saint-Genis-Laval) during the second quarter of 1914.—Henri **Coupin**: A marine yeast. The first example of a yeast isolated from sea water, for which the name *Torula marina* is proposed.—M. **Coquidé**: Remark on the nitrification in the peaty soils in the neighbourhood of Laon. The experiments were made on virgin soil and included the addition of potassium chloride or kainit, sodium nitrate, and phosphate slag, the three types being used separately, in pairs, or all together, the last giving the best results. The effect of omitting nitrate was marked, and there appears to be little or no natural nitrification of the nitrogenous material in these soils.—J. **Bergonié**: The mobilisation in the tissues of magnetic projectiles by the repeated application of electromagnetism. To move deeply-seated metallic fragments repeated applications of an electromagnet may be required, leading ultimately to a swelling on the surface exactly localising the fragment, and permitting its easy extraction by a simple operation. Details of cases are given in which the original position of the piece of shell was too deep-seated for direct removal, or in which unsuccessful operations after X-ray localisation had been made.—Raoul **Bayeux**: The treatment of hydrarthosis and hæmarthrosis by intra-articular pneumatic compression by means of oxygen.—A. **Pezard**: The experimental transformation of the secondary sexual characters in the Gallinaceæ.—A. **Sartory**, L. **Spillmann**, and Ph. **Lasseur**: Contribution to the study of typhoid states. Although the causal origin of typhoid fever is the Eberth bacillus, it appears to be probable that the pathogenic power of this organism may be increased by the presence of other micro-organisms, such as *Proteus vulgaris*, a diplococcus described by the authors, and possibly other pathogenic species. It is also possible that life in the trenches may give rise to a new clinical type of typhoid fever.

February 22.—M. Ed. Perrier in the chair.—The president announced the death of E. H. Amagat, a member of the academy in the section of physics.—G. **Mittag-Leffler**: A new theorem in the theory of the series of Dirichlet.—J. **Tavani**: The integral $\Gamma(\rho)$ and its relations with other definite integrals.—Marcel **Baudouin**: The discovery and excavation of a menhir found upright and completely buried in a marine alluvium on the coasts of Vendée.—V. **Lubimenko**: New researches on the pigments of the Chromoleucites.—D. **Olaru**: The favourable action of manganese on the bacteria of the leguminosæ.—Louis **Roule**: A new genus of apodal fishes, and some peculiarities of the biology of these creatures.—G. **Daumézon**: The potato as an agent of dissemination of Friedländer's pneumobacillus in nature, and especially in water.

A TEXT-BOOK OF FORESTRY.

Elements of Forestry. By Prof. F. F. Moon and Prof. N. C. Brown. Pp. xvii+391. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 8s. 6d. net.

THE progress of forestry in the United States is remarkable. It is barely twenty years since the first forest reserve was set aside by the Government at Washington, which to-day controls with a trained staff of foresters about 186,000,000 acres of national forests. Forestry is now a matter of great public interest, and is taught in universities, colleges, and schools, there being no fewer than twenty-three institutions giving degrees in the subject. In addition to numerous bulletins and reports issued by the U.S. Bureau of Forestry, there now appear two professional journals, the *Forest Quarterly* and the Proceedings of the Society of American Foresters. Various text-books on special branches of forestry have been published, but no general handbook suitable to students in America has hitherto appeared.

The "Elements of Forestry," by Moon and Brown, is an attempt to supply this need, and it is very satisfactory as an elementary text-book. It will serve as a good introductory work for professional students of forestry, and covers about as much of the subject as is necessary for students in agriculture. The book is clearly printed and well-illustrated. All the usual divisions of the science and art of forestry are taken up in a series of simple and attractive chapters, at the end of each of which is a short and useful bibliography. Of chapters i. to xiv., which are of universal application, those devoted to the utilisation, technology, and preservation of wood are of special interest; and much praise must be given to the chapter on forest finance, in which the gist of this important matter is expounded in sixteen pages. The attention of landowners and practical foresters may be directed to the example on p. 265, which illustrates the most common problem in forestry finance in England, namely, the estimate of the cost of raising a crop of trees to any given number of years of age, and incidentally determining whether a plantation is a profitable investment or not.

Chapters xv.–xxii., entitled "Regional Studies," deal with the conditions of the forests of the United States, which are divided into seven regions. The description, silviculture, protection, and utilisation of the forests of each region are briefly but adequately dealt with. At the end of the book, in addition to a glossary, there is a collection of useful tables and statistics. The average rate of growth of the important species of trees in the various regions is given in Tables VII.–XI. From this it appears that the most vigorous conifers in each region are as follows, the figures being for average trees 100 years old and grown under forest conditions.

Region	Species	Height in feet	Diameter in inches at $4\frac{1}{2}$ feet up
Pacific Coast......	Douglas Fir	138	20·5
	Western Hemlock	110	15·2
Rocky Mountains	Douglas Fir	86	21·1
	Pinus Murrayana	73	11·2
Northern	*Pinus resinosa*	95	17·6
	Pinus Strobus	92	20·0
Southern............	*Pinus Taeda*	111	24·5

THE LANGUAGES OF SOUTHERN NIGERIA.

Specimens of Languages from Southern Nigeria. By N. W. Thomas. Pp. 143. (London: Harrison and Sons, 1914.) Price 4s. net.

MR. NORTHCOTE THOMAS has given us an exceedingly interesting piece of work in African philology by publishing for a reasonable price what might be called a sketch of the languages of Southern Nigeria between the frontier of the Bantu Cameroons on the east, and the Yoruba country on the west. The same ground was covered in 1888 by the writer of this review, but his work, which would be of interest in comparison with, and supplementary to, that of Mr. Northcote Thomas, was only privately printed by the Foreign Office. Perhaps some day it may be disinterred from a confidential blue-book and produced with other linguistic studies.

Mr. Thomas's specimens (prominent nouns, numerals, pronouns, and such syntax as can be illustrated by a variety of sentences) include nearly the entire range of the Ibô dialects, the languages of the Calabar and Cross River district; the Ijō of the actual Niger mouths, Yoruba of the Lagos vicinity, Sôbô and Kukurúku of the Bini-Edo group, Ibibio of the region between the Calabar estuary and Opôbô, and a number of very interesting semi-Bantu languages on the verge of the Cameroons frontier. Mr. Thomas does not attempt much in the way of classification, but would seem to indicate that he finds a connection more or less close between the semi-Bantu Yala, which lies far to the north of the upper Cross River, and the Edo or Bini group in the western part of Southern Nigeria. No evidence of very close affinity, or of affinity at all, is to be deduced from the actual vocabularies given. Personally, I should have been inclined to regard Yala (which is one amongst Koelle's many interesting vocabularies of 1854, hitherto difficult to locate geographically) as having nothing to do with Edo, but much with the more "semi-Bantu" speech contiguous to it on the east. Not the least interesting part of this useful manual is the identification *and* location of eighteen of Koelle's vocabularies, work which greatly enhances their value to the philologist. In addition, Mr. Thomas introduces us for the first time to several speech forms—languages and dialects—hitherto unknown.

Mr. Thomas's work throws a good deal more light on the semi-Bantu languages in addition to the not-sufficiently-known work of Mr. P. Amaury Talbot. The analysis of the material his vocabularies furnish induces me to account for the semi-Bantu group and cognate languages in two ways:—Some of them, especially in the east and south of their range, may be simply much-worn-down and corrupted real Bantu; relics of the comparatively ancient east-to-west migration, which finally carried a Bantu speech to the Island of Fernando Pô. But the balance of probability, especially in regard to the more northern groups of semi-Bantu, lies in the direction of their being descended from sister languages of the original Bantu mother tongue. They would thus have migrated from north-east to south-west. All such indications seem to lead to the theory that the original home of the Bantu was somewhere in the very heart of Africa, between the basins of the Benue, the Shari, the Mubangi and the Bahr-al-Ghazal. But Mr. Thomas's work further directs our attention to the existence of Bantu roots in Ibô and Gori; and this ancient Bantu influence can, I believe, be traced much farther to the west than the lower Niger.

H. H. Johnston.

HOUSEHOLD INSECTS.

(1) *Insects Injurious to the Household and Annoying to Man.* By Prof. G. W. Herrick. Pp. xvii+470. (New York: The Macmillan Co.; London: Macmillan and Co., 1914.) Price 7s. 6d. net.

(2) *The House-Fly,* Musca domestica, *Linn. Its Structure, Habits, Development, Relation to Disease and Control.* By Dr. C. G. Hewitt. Pp. xv+382. (Cambridge University Press, 1914.) Price 15s. net.

"HOUSEHOLD insects" have, for many years past, attracted the attention of entomologists in North America, and since the publication of the well-known Bulletins of the U.S. Department of Agriculture, by Dr. L. O. Howard and Mr. F. H. Chittenden, on pests of this nature, in 1896, much work of importance has been done, particularly with regard to house-flies and mosquitoes. Students of the subject should, therefore, be grateful to Prof. Herrick for providing a popular and trustworthy account (1) of our arthropodous "messmates" and parasites. In addition to insects in the zoological sense of the term, spiders, mites, ticks, solpugids, scorpions, and centipedes are passed in review, and the British reader cannot but feel that some compensation for not being an American is afforded by the comparatively scanty house-fauna of his native land.

The especial strength of Prof. Herrick's book lies in the directions given for dealing practically with the various pests; systematic and bionomic considerations are, throughout the volume, subordinated to the economic point of view. No fewer than one hundred pages are devoted to house-flies and mosquitoes; the disease-transmitting power of these insects is emphasised, albeit with the minimum of information as to the nature of the micro-organisms that they carry. Doubtless the author has been well advised to lay stress on the habits of the creatures that he describes in their relation to remedial and preventive measures, but if a little more space could have been devoted to the zoological aspects of the subject, the reader would take a more intelligent interest in the practical problems brought to his notice. Each chapter is followed by an "economic" bibliography, and the book is illustrated by more than 150 figures of somewhat unequal merit.

(2) Dr. Gordon Hewitt has, by his researches since 1907, made the House-fly (*Musca domestica*), to an especial degree, his own subject, and his transference from Manchester to Ottawa has not cut him off from an abundant supply of material of this cosmopolitan insect. In the handy volume now before us, all the anatomical and histological descriptions and figures from Dr. Hewitt's previously published works are collected in a convenient form, and a full survey of the latest literature on the house-fly and allied Diptera, together with an account of Dr. Hewitt's own recent investigations, will be found to furnish a store of information for the student. Interest in house-flies during recent years has centred around the possibility of these insects serving as carriers of disease-germs to human food-products, and the critical survey of the newest work on this subject—especially with regard to the prevalence of infantile diarrhœa during the fly season—forms a most valuable section of Dr. Hewitt's

book. Experiments carried on at Ottawa on the distances travelled by marked flies showed various ranges of flight up to 700 yards; observations quoted as made by Dr. Copeman in rural districts in Norfolk give a flight-range of 1700 yards. The book concludes with a discussion of the best methods for destroying fly-maggots and for checking the facilities for the breeding of the insects. Bavaria enjoys the reputation of a noteworthy paucity of flies, "perhaps due to the extreme cleanliness of Bavarian cities." Dr. Hewitt's book can be most heartily commended to all enthusiasts on behalf of public health, as well as to students of the anatomy and life-history of insects.

GEOGRAPHICAL TEXT-BOOKS.

(1) *A Geography of Australasia.* By Griffith Taylor. Pp. 176. (Oxford: Clarendon Press, 1914.) Price 1s. 6d.

(2) *The Pupils' Class-Book of Geography.* By E. J. S. Lay. England and Wales, pp. 80. Price 4d. The British Isles, pp. 118. Price 6d. The British Dominions, pp. 128. Price 6d. (London: Macmillan and Co., Ltd., 1914.)

(3) *Macmillan's Geographical Exercise Books.* With Questions by B. C. Wallis. i., The British Isles, pp. 48. Price 6d. ii., Europe, pp. 48. Price 6d. iii., The British Empire, pp. 48. Price 6d. (London: Macmillan and Co., Ltd.)

(4) *Bacon's Sixpenny Contour Atlas.* South-east England edition. Pp. 41. (London: G. W. Bacon and Co., Ltd.)

(5) *The Map and Its Story.* Pp. 44. (London: G. W. Bacon and Co., Ltd.) Price 1s. net.

(1) ONCE the pupil or student gets past the general outlines and principles of geography (which are so difficult for the author and teacher to lay down in terms that are otherwise than summary and dull), he ought to find out the real interests and fascination of the subject. A book like Mr. Taylor's will help him to do so. This writer has an unusual faculty for keeping steadily in view the interaction of those phenomena which geographers set out to study, and for picking out the right facts from the special departments of knowledge on which geographers have to draw. He also sets great store by the use of the map to illustrate special points, and in this direction shows considerable originality; the maps are generally clear, though sometimes injudiciously reduced, and occasionally rather severely generalised. The descriptive and explanatory writing could not well be clearer, and this being so, the author is safe in carrying his readers into such unaccustomed topics as that of the paragraphs in which he discusses the former history of river courses and the extent of land, a "journey into past geological times" which is justified, as he is able ingeniously to show the bearing of former physical conditions upon modern communications. This book would be an excellent introduction to Australasia as a special subject.

(2) Both the manner and the matter of Mr. Lay's three little volumes, according to their lights, are fairly satisfactory, and a large number of questions and exercises are provided, many of which will carry the pupil well beyond the scope of the work, and are properly suggestive. Others tend to throw back to the old narrow field of geographical teaching, demanding merely a list (*e.g.*, of "the highest mountains of the Pennine Chain"), while it is difficult to conceive in what possible geographical connection such a question is asked as, "Do you know the name of a Councillor? A Magistrate?" Pieces of poetry are set for learning, but the geographical value of poetry is too often doubtful, especially when its language is as difficult as that of W. J. Mickle's translation of Camoens. The text of these books illustrates at some points one of the geographer's besetting dangers, generalisation; such sentences as "Edinburgh, which is built on the famous Castle Rock"; "The Dominion of Canada is provided with a splendid system of waterways"; in the same country "the various minerals—with the exception of . . . gold and silver—are scarcely worked," are statements which, in the want of qualification, may be highly misleading.

The maps (black and white) in this series are commendable, though we should hesitate to subscribe to the claim that "no atlases or other maps" are "required." A point of some interest emerges on making a comparison of maps in this series in Mr. Taylor's book, and in "The Map and Its Story," presently to be noticed. The desirability is revealed of some attempt at standardising distribution maps. The maps illustrating the vegetation of Australia in these three books are, it is true, laid out on rather different systems, but their methods are sufficiently similar to show how widely divergent are the results obtained. A pupil comparing the three would be excusably "floored" in attempting to gather from them the extent and locality of forest and desert areas, and so forth, in Australia, and the differences are such that one or more of the maps must be very seriously in error.

(3) Mr. Wallis's "Geographical Exercise Books" consist of blank maps (sometimes with contour lines), and on the page facing each map a series of questions or directions as to filling it up and writing notes or exercises on the results obtained and the conditions revealed. Both maps and letterpress appear to be very judiciously chosen or compiled, and in the hands of a pupil of moderate capacity in draughtsmanship the finished product should possess a permanent value.

(4) Messrs. Bacon's "Sixpenny Contour Atlas" is very good, considering its price. It contains thirty-two coloured maps, showing the elevation of the land according to a recognised method, and dealing with the world and its various divisions, in addition to which there are a few maps of a special area, varying according to the pupil's requirements—*e.g.*, the edition under notice is that for south-east England, and contains special maps of that district, while editions for south Scotland, south Wales, and others are promised.

(5) The same firm's publication, "The Map and its Story," does not maintain the standard of the work previously noticed, so far as concerns its coloured maps illustrating climate, vegetation, etc. Some of the printing (*e.g.*, of the natural resources shown in red lettering) is bad, and some of the distribution colouring weak. But the distinctive feature of the work, the letterpress accompanying the maps, explains them very clearly, and ought to fulfil the purpose of guiding students as to what they should look for and find, not only on these, but on other maps.

OUR BOOKSHELF.

Huxley Memorial Lectures to the University of Birmingham. With an Introduction by Sir Oliver Lodge. Pp. 164. (Birmingham: Cornish Brothers, Ltd., 1914.) Price 5*s.* net.

OF the nine memorial lectures which have been delivered, the present volume contains only five. That by Prof. Joly on pleochroic halos does not even mention Huxley's name. Sir Oliver Lodge leads off with Huxley's own defence against the charge of materialism. "There is a third thing in the universe which . . . I cannot see to be matter or force, or any conceivable modification of either." This was consciousness. Sir Michael Foster found in Huxley the "conviction that what began as a search into things physical has become a search into things spiritual." Prof. Poulton points out that Huxley "never committed himself to a full belief in natural selection, and even contemplated the possibility of its ultimate disappearance." We come, in the remarkable paper by Prof. Percy Gardner, to the pith of the matter, "in regard to which words from Birmingham are greatly valued, the study of the subconscious side of man."

Prof. Bergson's lecture on life and consciousness traverses a field antipodal to that of Huxley. Consciousness is "the mind." It "and matter are antagonistic forces." It is at once a "creative force," a "vital impulse," and a "spiritual force." Life is "nothing but consciousness using matter for its purposes." It "cuts it up in order to bring about a greater precision." "The evolution of life . . . suggests to us the image of a current of consciousness which flows down into matter as into a tunnel." The final conclusion is "that with man consciousness has finally left the tunnel" to "pursue its path beyond this earthly life."

Dew-Ponds—History, Observation, and Experiment. By E. A. Martin. Pp. 208. (London: T. Werner Laurie, Ltd., n.d.) Price 6*s.* net.

A DIFFICULT problem has been attacked by Mr. E. A. Martin in this book. He defines a dew-pond as "one situated on the higher grounds, generally on the chalk downs of the south of England, which retains by some means or other a supply of water throughout all but the most prolonged droughts, whilst those ponds situated on the lower lands have consistently dried up." With the aid of continuous observation, and a grant from the Royal Society for experimental purposes, he has been able to throw much light on these curious ponds. He shows that "dew-pond" is a misnomer, for dew is quite insufficient to make up for loss by evaporation; and he inclines to the use of the term "mist-pond" as better explaining their origin. However, "dew-pond" is in common use, and when farmers speak of dew they include the condensation of mist and cloud also.

The author suggests that the small crystals of sodium chloride, found in sea air, have acted "as nuclei of condensation when the night-mists form on the downs, and as the mists blow up in the early morning from the sea they pass across the pond-depressions and are deposited in quantities there." Certainly it is to the morning mists drifting in from the sea that the replenishment of these ponds is mainly due. We would direct particular attention to some of the observations, in which are given actual measurements of the amount thus deposited. It is noticeable also what a large part is played by rushes or other vegetation in increasing the deposition. However, aspect, slope of ground, and other things all play their part, and great care is needed in the selection of a site.

We recommend this book to the notice of engineers and others who have to do with hilly regions where rain is deficient, but where heavy mists are common, as, for instance, the Pacific slopes of the Andes.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Resonance of Sodium Vapour in a Magnetic Field.

It is well known from the observations of Wiedmann and Schmidt, Wood, Dunoyer, and others that dilute sodium vapour contained in a glass bulb emits resonance radiation when a soda flame is focussed upon it. During the last few days I have examined the effect on the resonance radiation of putting the resonating vapour in a magnetic field.

If the exciting flame contains very little soda, the resonance radiation is diminished by the field.

If, on the other hand, the flame is rich in soda, the field greatly increases the resonance radiation.

It is too early to put forward more than a tentative suggestion towards the explanation of these effects. Each sodium line emitted by the resonating vapour is broadened by the Zeeman effect. The flame poor in salt gives a narrow exciting line, and magnetic broadening throws a part of the resonating line off the exciting line, thus diminishing the light.

Adding more salt to the flame makes each exciting line broader, and (it is provisionally assumed) reverses the middle of it. Thus magnetic broadening of the resonance line tends to bring the brightest parts of the exciting line into action, and increases the light.

It may be remarked that with an intermediate condition of the flame a moderate field would produce the kind of effect last referred to, while a very strong field would separate the side components so far as to throw them beyond the limits of the exciting line. An effect of this kind has been observed, though unfortunately the condition of the exciting flame at the time was not noted. The current was switched on, and as the field increased (this takes a perceptible time) the resonance radiation increased and then diminished again. On turning the current off, the light again passed through a maximum. The greatest strength of field used in this experiment was about 14,000 units. Brightening can be distinctly observed with 1000 units, when a well-salted flame is used.

I have not been able to find that any previous observations have been made on the resonance of sodium vapour in a magnetic field. Observations were made on mercury vapour by Malinowski (*Phys. Zeits.*, September, 1913). The present experiments were suggested by some made in this laboratory by Mr. F. S. Philipps on mercury vapour (see NATURE, December 4, 1913). His observations were independent of Malinowski's.

Imperial College, South Kensington, March 9.

The Spectra of Hydrogen and Helium.

DR. BOHR's letter in NATURE of March 4, although giving an interesting discussion of some aspects of this problem, does not meet the particular point which my letter was designed to raise. This point was solely that since combination series must be expected from the "4686" series in any circumstances, and since the lines so calculated occupy the positions in which lines have been found by Evans, they cannot be used to discriminate between theories of the origin of spectra, for we cannot prove that the observed lines are not these combination lines. It is true that Bohr's theory involves the combination principle, but so also does that of Ritz, who originated the principle.

My letter (NATURE, February 11, p. 642) took up this purely negative attitude, and was not intended as a criticism of the theory. It did not even advocate a hydrogen origin for the lines. Fowler's view, that the "4686" series is a 4N series analogous to that in magnesium, was, in fact, stated to have more evidence in its favour. Whether the origin be really hydrogen or helium is not actually relevant to my argument. Even if the origin is really helium, it was pointed out by Fowler in his Bakerian lecture that his results do not formally imply Bohr's theory. Since that time, the writer has published a proof that the theory cannot explain 4N series in general, for such elements as magnesium. It can only deal with helium, and the formal analogy between helium and magnesium would weaken, rather than strengthen, the theory.

The greater part of Dr. Bohr's letter does not bear on my original point, for he is seeking to discriminate between a hydrogen and helium origin, and between his view and Rydberg's, not directly by Evans's experiments, but by other considerations. At the risk of going further from the point at issue, I feel that some remarks on these considerations are necessary.

The references to Rau's experiments on voltages necessary to produce series are interesting, and if they have been interpreted correctly—there is some doubt of this—they show that the chemical origins of the series are those stated by Dr. Bohr, and by Stark and others. They show also that the electrons in Bohr's model atoms have the proper angular momenta. There are other reasons for believing that the relation of the atom to Planck's h is contained in the angular momenta, and such atoms were treated by the writer some years ago, but with a different kind of emission. Nevertheless, Rau's experiments have nothing to do with the mechanism of spectral production, and cannot support any theory of the mechanism of radiation. For the radiation problem is quite superposed on any specification of the steady configurations of non-radiating atoms.

The remarks concerning Rydberg's view proceed throughout on the supposition that the usual constant μ—Rydberg's phase—is *zero* in these series. No such case is known elsewhere in the whole range of spectra. It is quite easy to fit the "4686" series into a formula exhibiting it as a principal series of hydrogen, if this constant μ is not arbitrarily chosen as zero. There are other arrangements of the disputed series as hydrogen series which are formally possible, but their description would occupy too much space here. A full account of the whole problem will be published shortly, so that I propose to discontinue the present discussion with this letter. Meanwhile a protest must be urged against Dr. Bohr's conviction that the spectrum of atomic hydrogen consists solely of the Balmer, Ritz, and Schumann series. For MM. Fabry and Buisson have shown that a very large number of lines in the "secondary" spectrum are due to atoms of hydrogen. A correct model of the hydrogen atom must account for more emission spectra than have yet been deduced by Bohr's theory. Finally, I must again state explicitly that my present purpose is not to call the theory into question. My only concern is to show that no decisive factor has yet entered, and that judgment between theories must at least be suspended for the present. The importance to physics in general of the whole question of spectral emission is so great that a hasty decision must not be made. And the fact remains that all the present experimental results are explicable in widely different ways. The test mentioned at the end of my previous letter still appears to be an obvious crucial one.

J. W. NICHOLSON.

University of London, King's College, March 5.

A Neglected Correction in Osmotics.

In the dynamic method of determining relative vapour pressures, air, initially dry, is passed first over the solution and then over the pure solvent. When it leaves the solution it has taken up a quantity of solvent vapour l_1; on leaving the solvent it contains a further quantity, $l_0 - l_1$. While working on aqueous solutions at 0° C., Mr. Hartley and I had realised that the air when over the solution expands by an amount represented by the vapour pressure of the solution, similarly a further expansion takes places over the solvent, but as this further expansion is only that due to the difference of vapour pressures of the two liquids—say 1/10th of 4 mm. Hg—we had assumed that this small quantity was negligible in comparison with the total pressure.

Dr. C. V. Burton, of my laboratory, has pointed out to me that this assumption is not justified when osmotic pressures are to be calculated from the observed results. His discussion of the necessary correction is as follows. Let B be the barometric pressure and V the volume of air (measured when dry) passed through the system. The air in contact with the solution has a partial pressure of $B - \pi_\pi$, and the volume now occupied by it is increased to $VB/(B - \pi_\pi)$. Similarly, on leaving the solvent the volume has become $VB/(B - \pi_0)$. If ρ_1 and ρ_0 are the densities of the vapour in equilibrium with the solution and solvent respectively, the masses l_1 and l_0 are $\rho_1 VB/(B - \pi_\pi$ and $\rho_0 VB/(B - \pi_0)$.

Assuming that Boyle's law holds good for the vapour up to π_0, with sufficient accuracy for the purpose of the correction, we can replace π_π by $\pi_0 \rho_1/\rho_0$. We have then what amounts to a simple equation in ρ_0/ρ_1; its solution is $\rho_0/\rho_1 = l_0/l_1 - \frac{\pi_0}{B}\left(\frac{l_0}{l_1} - 1\right)$.

In the value deduced for the osmotic pressure, $\log_e(\rho_0/\rho_1)$, enters as a factor, and the corrected value of this factor is $\log_e(l_0/l_1) - \log_e\left[\frac{\pi_0}{B}\left(\frac{l_0}{l_1} - 1\right)\right]$.

The correction for a solution at 0° C., the osmotic pressure of which is 132 atmos., is −0·84 atmos., and for one the osmotic pressure of which is 41 atmos. it is −0·26 atmos.

Foxcombe near Oxford.

Chemistry and Industry.

In his admirable article in NATURE of February 18 under the above heading, Prof. Jocelyn Thorpe dealt in a very concise manner with the grave difficulty which must seriously hamper all the present efforts to establish chemical industries in this country in successful competition with Germany. Particularly his remarks that the scientific worker has found by sad experience that little financial profit accrues to him even though he goes to the trouble of obtaining patent protection for his discovery, are of interest.

In this country, when an inventor applies for patent protection, a novelty search is made by the Patent Office in respect of his invention, solely among British patent specifications published before the date of his application during a period of fifty years. In contradistinction thereto the examiners at the German Patent Office investigate all printed publications of the last one hundred years prior to the date of such application. These publications include not only German patent specifications, but patent specifications and text-books of every country in the world. The applicant's attention is directed to any prior publication or text-book dealing not only with the particular subject but containing even remote suggestions that may lead up to that particular discovery.

Now, while this somewhat gigantic problem of the German Patent Office cannot in all cases be efficient and free from fallacy, it is, nevertheless, quite clear that the result of such a search must in a large number of cases be of greater value than that of the limited search carried out by the British Patent Office. In this manner, therefore, the inventor, if his discovery is found novel and patentable in Germany, has not only the satisfaction of having his invention tested quasi from an international point of view, but what is more valuable to him, he has his attention directed to knowledge existing and discoveries made also outside his own country.

Due to this wide scope of the official search, apart from other stringent considerations connected therewith, fewer patents are, of course, granted proportionately in Germany than are granted in this country, and it would, indeed, be interesting to examine how many of the discoveries for which patents have been granted in this country, for instance, in respect of aniline dyes, have, in fact, been protected also in Germany. A number of these British patents on which royalties are probably being paid, or will be paid in the near future, would, perhaps, not stand a test before our courts, since prior text-books or a prior foreign specification may be relied upon in an action before a British Court, while the Comptroller-General of Patents has no right to consider such publications before granting a patent.

I have heard it argued that our limited search was good enough, because if there was anything worth patenting anywhere, it would certainly be patented in this country. I venture to suggest that this is as much an antiquated idea as prevailed, until this war opened our eyes to the present industrial situation, with regard to the industrial supremacy of these islands shortly after the time when Section 27 of the Patents and Designs Act of 1907 was called into being. In this connection it is interesting to recall a famous phrase uttered by Mr. Justice Parker (now Lord Parker) in his decision in the matter of the revocation of Hatschek's patents, Nos. 6455 of 1900 and 22,139 of 1900, viz.:—"However great may be one's belief in the industrial supremacy of the inhabitants of these islands, it would at least be somewhat arrogant to assert that wherever the manufacture of a patented article in the United Kingdom is less than one-half of the total manufacture of the whole world, there arises a presumption that British trade has not had fair play."

The decision involved a matter of great importance to patentees, manufacturers, and British traders, and it was justly stated that the whole industrial world was anxiously awaiting the dictum on that famous section of the Act.

The greatest anxiety, of course, prevailed in Germany, and this was natural in view of the many British patents taken out by German chemists and chemical concerns for the purpose of blocking the industry in this country rather than of developing it.

Now, why has that section failed to do that which it was actually framed for? To my mind there are several important reasons. The average manufacturer does not possess the knowledge that chemical manufacture cannot in these times be carried on without his close co-operation with highly trained chemists, and, true to old-established tradition, he is prejudiced to any such co-operation. Further, he is constantly faced by the danger of infringing existing British patents, and even though he may be aware that the patents blocking his way are mere "paper" patents and that he has every reasonable hope to succeed in an action for infringement or revocation thereof, the exceedingly high cost at present connected with any action must have an important effect on his hesitative attitude, and largely accounts also for the perpetual success of those whose business it is to defy the section and to maintain their "unworked" patents to the detriment of the British industry.

JUSTIN E. POLLAK.

London, March 4.

Measurements of Medieval English Femora.

PROF. KARL PEARSON'S criticisms are always welcome and stimulating to those strong enough to bear them though, since they are usually of the destructive variety, the fear of them undoubtedly prevents a good deal of work which would add to our knowledge being published. Let me deal, for instance, with the following criticism. "Looking at Dr. Parsons's results I can but conclude that his sexing is based on a fallacy, and the dip he has created in the Rothwell femora between those with 45 and 47 mm. heads—the range of Dwight's doubtful sex—is due to conscious or unconscious selection of his material; out of the great masses of bones available at Rothwell (which should have occupied in measurement of many characters and in their adequate reduction the whole time of a man for four or five years)."

By "conscious selection of material" I can scarcely think that deliberate fraud is suggested—I do not indeed know what it really means; while unconscious selection I suppose is covered by inaccurate measurements or by the absence of bones of a certain size which ought, mathematically, to be there.

At any rate, the impression conveyed by the stricture is that, from an enormous available mass of material, I have deliberately or unfortunately picked out a small selection which would bear out some object which I wished to prove

It is almost inconceivable that Prof. Karl Pearson would have mentioned the "great masses of bones available" unless he really knew what he was talking about, so that we may safely assume that he has been to Rothwell and satisfied himself on this point.

I can only say that I have spent a great deal of time at Rothwell, and that I found considerable difficulty in picking out 300 measurable femurs, and this was particularly the case with the slighter bones which, owing to the damp, snapped like carrots when touched.

I can assure Prof. Pearson that every measurable bone which could be extricated was welcome, and none were rejected because their sizes did not suit.

As to four years of a man's whole time being needed for the research, I can only infer that Prof. Pearson thinks that there is unlimited measurable material at Rothwell, and that, if I could not give the time he thinks necessary, I had better have left it to some other man who could. These really are the words of the "mere mathematician" ignoring all practical details. Did not Prof. Pearson observe when he went to Rothwell that the bones were rotting with damp—exactly the opposite condition, by the bye, to his Naquada bones and that the farther he worked into the stack, for he must have done this or how would he otherwise have known about the "great masses of bones available"? the more sodden and useless the material became? As no one else showed the least sign of spending even four weeks in working at the Rothwell bones, I did what I could while I could, for if I had left it for another ten years the available material would have been much less. Incidentally, I advised the restacking of the heaps, so that air now gets among the bones, and they will not disintegrate so rapidly. There is another practical point, too, about which Prof. Pearson is silent; it is the fact that the ordinary anatomist has difficulty in getting unlimited measurements recorded, and my contribution of sixteen sets of measurements on nearly 300 bones was all I could fairly expect our journal to print for me at one time.

In other points I think that Prof. Pearson and I are in practical agreement. We agree that neither of us can sex femurs with accuracy (I find that in eighty-two attempts I made seven mistakes), but that, when we have sexed them to our individual taste, the average difference in results is a fraction of a millimetre. We both agree that the head measurement alone is often liable to mislead, and that a series of secondary sexual tests of graded value are needed. These I have attempted to provide in a paper which will appear shortly, and of which I will not fail to send Prof. Pearson a copy.

Above all, I am glad to see that he tacitly agrees with me about the Rothwell bones being medieval, probably of the fourteenth and adjacent centuries.

F. G. PARSONS.

St. Thomas's Hospital, S.E.

The Green Flash.

PROF. PORTER'S interesting letter (NATURE, February 18, p. 672) on this subject must be my excuse for sending a summary of my own experience during the last eighteen years in which I have observed the flash more than a hundred times, and in no single case did I find anything not explainable by atmospheric dispersion, nor anything that could be put down as a subjective or complementary after-image.

I may add that I have observed with the naked eye, with an opera-glass (power 3), with binoculars (power 9), and with a telescope (power 100).

Whenever on a clear day a low sun is observed through a telescope, the upper limb appears bordered with a marine, *i.e.*, blue-green, fringe, the lower with an orange-red fringe, the side-limbs are unaltered. (The telescope should have a solar diagonal and other means of reducing the brightness of the sun.)

The marine upper fringe develops ultimately into the green flash, the blue element weakening as the sun descends. I have watched this change with the telescope, and it is perfectly continuous.

Again, if the sun descends behind a low cloud, parallel to the horizon, but with a clear space between, the base of the sun, just as it becomes visible, shows the red flash. I have seen this only thrice, as the necessary conditions are obviously seldom satisfied. The red flash seems inexplicable save by dispersion.

Under favourable conditions at sunset, as the upper segment of a yellow sun gradually diminishes, the right and left corners of the segment become green; this colour gradually spreads inwards, becoming marine, until finally the last tip of the sun may appear almost greenish-blue, and just as the sun has sunk, a very faint wisp of blue light is glimpsed directly above the point of disappearance. One friend even records a violet wisp.

But when the sun is orange the blue is replaced by green, and when the sun is really red no green flash at all is seen, the atmosphere cutting off the green as well as the blue rays. To see these changes it is desirable to use a power of 8 or 9.

Prof. Barnard, writing to me some years ago, said he preferred the title, "blue flash," as in sunsets seen over the Pacific from the Lick Observatory the final flash was usually blue. Doubtless this is due to clear atmosphere.

It is well known that at sunrise, when no exciting colour can be present, the flash has been seen, sometimes green, sometimes blue.

In the 1906 volume of *Symons's Meteorological*

Magazine appears correspondence on this subject by Dr. Rambaut, myself, and others, and the editor, Dr. Mill, in summing up the matter, decided strongly in favour of the dispersion theory. Capt. Carpenter, R.N., whose numerous observations appear in the *British Astron. Assoc. Journal*, holds the same view.

It is quite true that, if I look steadily at a bright red sun, and then close my eyes, I see a green after-image, but this is just what the observer of the green flash should not do. He should avoid looking at the sun when it is bright, and should wait until it is so low that the eye can easily bear the light—should wait, in fact, until only a very small segment is visible. As before stated, with a really red sun the flash fails to appear, so far as my experience goes. If proper precautions are taken I do not think any appreciable after-image will be present.

I may point out that the nature of the horizon, provided it is clean-cut and low down, makes but little difference. It may be of cloud, land, or water, and, of course, the last is the best. My experience relates to all three.

But few persons appear to have used a telescope for observing the flash. If those who have not done so would observe a low sun with a power of, say, 100, I think that they would be convinced that the true cause was atmospheric dispersion.

The real mystery about the flash is that it so often fails to appear, when apparently all conditions seem favourable. I have not yet found any explanation of this, but I am inclined to the opinion that at a clear sunset the flash could always be seen if a telescope were available, though it might be too feeble for the naked eye, for a telescope invariably reveals the upper green fringe when the sun is low. The telescope, of course, was achromatic, and showed no colour with a high sun. To the Journal of the B.A.A., to that of the Leeds Astron. Society, and to the *English Mechanic* I have contributed very numerous notes on this subject, but references to them would occupy too much of your valuable space. C. T. WHITMELL.

Invermay, Hyde Park, Leeds, February 22.

The Prices of Chemicals.

I HAVE had the same experience as "S. P." Since my letter of February 18 I have been able to purchase dulcite at 60*s*. an ounce from a firm of dealers in chemicals other than the one to which I referred. I cannot admit, therefore, that my complaint was unjustifiable. J. J.

University of Liverpool, March 2.

THROUGH SIBERIA.[1]

THIS book is the diary of a very interesting journey accomplished by the author in the course of the autumn of 1913. In fact, it describes four different journeys: one from Tromsö, *via* the Kara Sea, to the mouth of the Yenisei; then up the Yenisei to Krasnoyársk; next by rail across Transbaikalia and Manchuria to Vladivostók on the Pacific: and from this port to Petrográd, by the Usuri and the new Amur railway and the main Trans-Siberian line. A remarkable feature of this journey, during which more than 16,000 miles were covered, is that it was accomplished in less than three months, from August 5, when the party started from Tromsö, to October 27, when Dr. Nansen reached Petrográd.

We cannot expect to find detailed descriptions of the different portions of the immense continent thus rapidly crossed; but the book throughout has the greatest interest, owing to the human element it contains, and the unexpected glimpses it gives of the Canada of the East, with its wonderful development during the last fifteen years. In addition, it is illustrated by more than 160 beautiful photographs, taken by the author himself, most of which are worth pages of descriptions. The ethnographical remarks about the northern natives, whose encampments, or boats, Dr. Nansen always found time to visit, especially about the remaining members of that curious, once numerous, nation, the Yenisei Ostyáks, will be read with a special interest; while the photographs, as may be seen from the two accompanying specimens, give a clear idea of the ethnographical types of the different native tribes.

The really difficult part of the journey, from Tromsö to the mouth of the Yenisei, was made on the steamer *Correct*, with the experienced pilot Capt. Johannsen, without meeting with serious difficulties. There was a good deal of ice in the Kara Strait, and especially further east, so that the *Correct* had to enter the Kara Bay in order to follow the narrow, more or less ice-free channel close to the coast of the Yalmal peninsula. There was only one dangerous accident, when the steamer stuck on a mud bank close by the Devil's Island; but otherwise the journey was quite successful, and it took only eighteen days from the day the steamer entered the Kara Strait to the day it reached the port at Nosónovskiye Islands, in the Yenisei, under the 71st degree of latitude.

Once more the practicability of the northern route to Siberia was thus demonstrated. But it must be said that the conditions of ice along the northern coast of Siberia show great variations in different years, and in 1913 they certainly were by far not so favourable as they were in the years 1870–1871 and 1875–1878. A very valuable appendix, where the average summer temperatures on the shores of the Kara Sea and the conditions of ice in that sea are given for the last forty-one years, shows that while this passage was remarkably free from ice in the years named, as well as in 1890, 1897, 1900, 1901, and 1904, the conditions were not favourable for navigation in 1883, 1884, 1888, 1911, and 1913, unfavourable in 1895 and 1902, and most unfavourable in 1903 and 1912.

Still, Dr. Nansen is certain that the northern route may become a regular line of traffic if certain measures are taken. During his journey up the Yenisei, and later on along the Trans-Siberian railway, he had full opportunities to discuss such measures with M. Vostrótin, a Russian merchant and member of the Duma who has great knowledge of the Siberian north, and also made the journey on the *Correct*, and

[1] "Through Siberia, the Land of the Future." By Dr. F. Nansen. Translated by A. G. Chater. Pp. xvi+478. (London: W. Heinemann 1914.) Price 15*s*. net.

M. Wourtzel, the head of the traffic on the Siberian railway.

"We had," Dr. Nansen writes, "great deliberations in the saloon [of the train] as to how the trade route between Norway and the Yenisei could be best secured, and what were the first steps to be taken to this end. We discussed the best arrangement of wireless stations, the dispatch of motor sloops to investigate the extent of the ice in the Kara Sea, how aeroplanes might be used for constantly reconnoitring the ice-conditions of the sea, in connection with the wireless stations, and so on. The construction of an efficient harbour for discharging and loading in the northern part of the Yenisei and the transport up and down the river were discussed with Vostrótin, who has these questions at his fingers' ends. By degrees a whole programme was drawn up under the shrewd guidance of Wourtzel."

Group of Yenisei-Ostyáks. From "Through Siberia." By Dr F. Nansen. (London: W. Heinemann.)
(The figures in the background, left and right, are Russians.)

The journey up the Yenisei to the town Yeniseisk, made in a little motor steamer, *Omul*, offered Dr. Nansen the opportunity of making many fine remarks about a variety of subjects—Baer's law of excavation of the right banks of rivers; the first appearance of larches; the exiles scattered even within the Arctic circle and living in tiny primitive huts, the first appearance of agriculture and cattle-breeding, and so on. The rapid change on this journey, from the endless treeless *tundra* to the thick forests region, the gradual growth of the clusters of "snug, low timber buildings," into villages, and further south into towns, and the transition from the isolated native huts to Krasnoyársk, with its gilded cathedral, public park, museum, schools, and electric light in the streets—all the town profusely illuminated to welcome the Norwegian guest—all this, most sympathetically told by Nansen, is fascinating reading.

At Krasnoyársk Dr. Nansen took the luxurious eastern train which brought him in four days, from September 29 to October 4, to Vladivostók on the Pacific. Notwithstanding the rapidity of this journey, we still find in Dr. Nansen's book very interesting remarks about the condition of Siberia, the causes of its slow colonisation, and the rapid strides it has made since the Manchurian war.

Winter was rapidly setting in, and next day Dr. Nansen had already begun his return journey—this time on the railway which runs down the valley of the Usuri to the new town of Khabaróvsk, which I knew fifty years ago as a village of a score of houses. The great railway which is now built by the Russian Government along the left bank of the Amur had not yet reached this new capital of the Lower Amur region. An immense bridge, 7827 ft. long, on nineteen piles, is being built below Khabaróvsk across the Amur; and this bridge, as well as the lowlands on the left bank, representing an immense swamp for some 200 or 300 miles, often inundated during the monsoon rains, offer great difficulties to the engineers. The journey across this marshy region, as well as the crossing of the Little Khingán, were made by Dr. Nansen, partly in horse carriages, partly in trolleys run along temporary rails, and partly in a motor-car, until he reached, on the Zéya plain, about 420 miles from Khabaróvsk, a station where he could take the direct train to Petrográd. This station, from which Dr. Nansen could now travel by rail all the way to Petrográd, with but one or two interruptions at unfinished bridges, received from the local engineers the name of "Nansen's."

On October 18 Nansen was at Chitá, where he joined the Eastern Express. He passed Irkútsk at night, without stopping; six days later he was in the Urals, and on October 27 he reached Petrográd; and yet, notwithstanding the rapidity of the journey, his observations and remarks about Siberia, "the land of the future," "Russia in the East," and "The Yellow Question," and so on, are both valuable and interesting.

The book is richly produced, with numerous excellent reproductions of Dr. Nansen's photographs, and with three maps—one of the Kara Sea and adjoining lands, and two of Siberia. The transcription of Russian names, both in the text and on the maps, is quite correct, with the exception of a very few words, in which the German spelling has been followed (Tas, Seya, Syriansky, instead of Taz, Zeya, Zyriansky).

P. KROPOTKIN.

Men and women of the Yuraks and Yenisei Samoyedes. From "Through Siberia." By Dr. F. Nansen. (London: W. Heinemann.)

A BIOLOGICAL PUZZLE.[1]

DR. BRUN, of Zürich, has done a fine piece of work in devising an elaborate and ingenious series of experiments which enable us to come to a decision among the rival theories of way-finding among ants. Let us first illustrate the facts. If we pick up one of the higher ants from an ant-road, turn it about in a box, and then empty it out again near the place of its capture, it makes no mistake in hurrying homewards. When an ant goes off alone on an exploring adventure, it often keeps persistently in one general direction, in spite of many divagations to one side or the other, and when it turns its face homewards, it does not usually retrace its steps, but pursues a parallel course until it comes near the nest. If a higher ant, such as *Formica rufa,* be gently but firmly induced to travel on a path chosen for it and not by it, it makes straight for home when freed from coercion. It may run along a line which is the hypotenuse of the triangle the other two sides of which it was compelled to follow, or it may complete a polygonal figure and reach the nest. If members of such species as *Formica rufa* and *F. sanguinea* be lifted up and carried some distance and put down in hunting ground which they have

[1] "Die Raumorientierung der Ameisen und das Orientierungsproblem im allgemeinen. Eine kritisch-experimentelle Studie; zugleich ein Beitrag zur Theorie der Mneme." By Dr Rudolf Brun. Pp. viii+234+51 figs. (Jena: Gustav Fischer, 1914.) Price 6 marks.

not visited for a fortnight, they will return home, quickly, confidently, and by the shortest way.

These are four illustrative facts out of many, and the question is how they are to be interpreted. Some authorities still believe that there is no getting past the assumption of a non-analysable sense of direction, such as the Martian of Du Maurier's novel had of the North Pole. Others have swung to the opposite extreme of taking too simple a view, and maintain that it is altogether a question of scent: ants, like dogs, living in a smell-world. Others again lay too heavy a burden on muscle-memory, and others on visual impressions gathered by the way. Dr. Brun shows clearly, we think, that the power of way-finding is usually a composite product, and that there is no mysterious sense of direction.

Of course, there are ants and ants, and there is no doubt that the scent of the nest, of the food, and of the pupæ sometimes counts for much. If two adjacent sections of a pre-arranged ant-road be lifted and interchanged, the travellers go on just as they were doing; but if a section of the road—say a zinc plate—be lifted and replaced with its ends reversed, the ants seem to be perplexed at the boundaries, and there may be a temporary block. Facts of this sort have given rise to over-ingenious theories of polarised scent, of positive and negative scent, and so forth. This much seems clear, that the nest-smell gets fainter in proportion to the distance from home, and that the food-smell increases as the source of supply is approached; and it is very instructive to find that if an ant of one of the olfactory species be transported and placed in the middle of one of the ant-roads, it does not go home right away, but takes a tentative run first in the one direction and then in the other. In some genera, however, such as Formica, smell counts for little, and the obliteration of the scent by brushing the road or pegging down a spread-out newspaper does not disturb the homing. In connection with smell, it may be noted that the seat of the olfactory sense is in the tips of the mobile antennæ, where tactility is also located, so that tactile and olfactory impressions are closely combined.

To many ants the illumination is much more important than scent, as Lord Avebury proved long ago. He got his ants to make a path across a wooden disc, concentric segments of which could be rotated, and found that if he turned a ring so that an ant on its journey was made to face the wrong way, it righted itself and proceeded in the old direction. But this was not the case when he made the experiment in uniform shade, or when he shifted the light at the same time as he rotated a segment of disc. One of Brun's experiments with a species of Lasius is very instructive. It was marching with the sun directly in its eyes, when the experimenter put an extinguisher over it, and kept it prisoner from 3 to 5 p.m. When it was set free at five o'clock, it turned its back on the position which the sun had reached, moving through 30°, and set off in a straight line homewards, eventually turning sharply to the left to reach its original starting-point. Numerous experiments confirm the view that the direction of the light serves as a compass. When Santschi shut off the sun with a large shade and made a false sun by means of a mirror, he got the ants, even on one of their main roads, to march in a direction either at right angles to the original one, or opposite to it, according to the position of the mirror. If, in the absence of sunlight, there be equal bipolar illumination of a given area, there is in many species no orientation.

From waxing and waning scent and from differential illumination, ants seem to build up associations, but this is not all. There is evidence in some cases of a memory of muscular movements, especially of the distance traversed, as if the ant kept its eye on a pedometer. There is something very interesting, too, in the phenomenon technically known as Turner's curves. A solitary ant that has travelled successfully from a considerable distance reaches a point quite near the nest; but instead of going on confidently, it stops as if perplexed. In many instances—80 per cent. in *Cataglyphis bicolor*—it proceeds to describe concentric curves, it may be for 5–15 minutes, and gradually draws near to the door of its home. Is it seeking for a sign, which might be a shining stone among the sand, or a scent, or the faint stridulation of one of its kin? Is it pursuing a trial and error method, very willing to be helped by any hint or combination of hints?

In some cases, *e.g.*, *Formica rufa*, Brun has proved a baræsthesia, or feeling of gravity. A table was gently tilted, with the nest at the foot of the slope; a feast of honey was placed in the centre; the ants climbed straight up and straight down again. But if, while an ant was supping honey, the table was gently tilted in the opposite direction, so that the way to the nest was up-hill, the ant persisted in going down-hill as before—away from, not towards, home. Among the highest ants Brun finds distinct evidence of definite local memory, based on visual, topographical, and topochemical data, and lasting for two or three weeks at least. And only thus can we understand the confidence with which one of these creatures, transported to a distant part of its range, will make for home. There are ants which trust mostly to scent, and others which are largely guided by the direction of light, but for the higher ants the orientation is a complicated process, the outcome of the registration of manifold imprints received from the outer world—imprints relating to the quantity and quality of scents, the general direction of light, the illumination of particular objects, the slope of the ground, the feel of things, the distance travelled, the turns of the road, the direction of the wind, and even, perhaps, sounds. Individual ants hereditarily endowed with great sensitiveness, hereditarily attuned to receive certain kinds of tidings, serve an apprenticeship in the establishment of associations and reach a degree of perfection probably unsurpassed. Such is Dr. Brun's general position, which he defends with strong experimental evidence. There are still to be found old-fashioned fishermen who have attained within a certain range to a wonderful seamanship of an empirical sort; they have built up a body of associations from wind and from wave, from the sky and the "feel" of the sea, and they are seldom far out in finding their way home. And so it is with the higher ants, except that they work even more exclusively from an instinctive basis.

It must be remembered that the orientation power of ants does not stand magically alone. Even brainless animals adjust their body in a position of physiological equilibrium in relation to a stimulus of light or warmth or gravity—a static orientation. When there is direction of locomotion in relation to an external stimulus, we speak of dynamic orientation. This dynamic orientation may be direct or indirect. It is direct when the stimulus or goal is within the range of immediate sense-perception, and it must be noted that for ants this range is only about a yard. Of this locomotor orientation there are various grades—tropistic, reflex, instinctive, and acquired, the first three expressing a hereditary predisposition, the fourth expressing the results of the individual's own learning. On a higher level is indirect orientation, where the goal is beyond the range of direct sensory perception. A complex of imprints or memories, corresponding to the goal, functions in the animal's sensorium, and forms the unifying centre of a whole series of imprints of the environment of the goal. What leads the creature on from step to step—often quickly and, so to speak, unquestioningly, if no contradictory interruption occurs—is the recognition of localised stimuli corresponding to those of the unified reference series. The orientation implies a chain of recognitions, and the recognitions imply a registration of individual experiences. Without using Brun's somewhat forbidding mnemic terminology, we cannot do justice to his carefully worked-out theory, but we have indicated its general nature. It is essentially what may be called psychobiological, for he thinks of the organism as a historic being that trades with time, that enregisters imprints, and that has its past living in its present, as Bergson has accustomed us to say. These imprints, which the individual ant selectively accumulates, are not like sheets filed in a portfolio of reference; they are interpenetrated with and kept alive by their meaning for the actual everyday life.

PROF. JAMES GEIKIE, F.R.S.

BY the death of Prof. James Geikie, Edinburgh and its university have been deprived of one of the most prominent of its men of science, and geology has lost a distinguished investigator and successful teacher. The son of J. S. Geikie, of Edinburgh, whose literary talent found expression in a number of popular Scottish songs, the subject of this notice was educated at the high school and university of his native city, and in 1861, when only twenty-two years of age, received an appointment upon the Geological Survey of Scotland, a service in which his elder brother, Archibald, had already been engaged for five years. James Geikie's work as a surveyor lay chiefly in the south-west of Scotland, and in 1869 he was promoted to be a district surveyor; his studies seem to have been more particularly attracted, from a very early date, to the post-tertiary deposits, and in various papers in the scientific journals, as well as in the official memoirs of the survey, he published the results of his observations and his conclusions based upon them. Early in his career, James Geikie had become a great admirer and warm friend of Andrew Ramsay, then director of the English Geological Survey, and Ramsay's theoretical views and speculative suggestions found a stout supporter in the young Edinburgh geologist. In 1876 the Colonial Office requested Ramsay to proceed to Gibraltar in order to report on the important question of its water-supply, and James Geikie was chosen to accompany and assist him. In addition to the valuable report made to the Government, the two geologists were able to contribute to scientific journals memoirs dealing with the geology of Gibraltar, and especially with the superficial and cavern-deposits, and their bearing on the history of the Mediterranean in post-tertiary times.

In 1874 James Geikie had already published his conclusions concerning the history of the Glacial period in Britain in his well-known work, "The Great Ice Age," which has passed through three editions; and in 1881, after devoting his vacations to travel on both sides of the Atlantic, he extended the bearings of his views on the subject by the publication of his "Prehistoric Europe."

In the following year, however, James Geikie entered upon a new field of labour. The appointment of his elder brother to the directorship of the Survey necessitated his vacation of the Murchison professorship of geology at Edinburgh, and James Geikie received the appointment, resigning his position on the Survey. During his energetic and successful work of teaching, carried on for more than thirty years, he published a number of very valuable educational books: "Outlines of Geology," of which four editions were called for; "Fragments of Earth Lore"; "Earth Sculpture," two editions; and "Structural and Field Geology," three editions. His labours were not by any means limited to the special subject of his studies; he was one of the founders of the Royal Scottish Geographical Society, acting as editor of its journal, and for a time as president of the society. He was also for many years dean of the faculty of science in Edinburgh University. In 1875 he was elected a fellow of the Royal Society, and in 1889 received the Murchison medal of the Geological Society, while he was a member and correspondent of many scientific societies at home and abroad.

It was not only in his numerous scientific writings that James Geikie's hereditary literary instincts were exhibited, for he published in 1887 a series of translations from the German, "Songs and Lyrics by Heinrich Heine, etc." His frank manner and *bonhomie* won him many friends, and we may well believe that, though an ardent golfer, like so many other Scotchmen, he gave expression to the sentiment ascribed to him that he found a still more pleasant means of recreation in "loafing in pleasant places with a congenial friend." J. W. J.

EMILE-HILAIRE AMAGAT.

BY the death of M. Emile-Hilaire Amagat at his country estate at Saint Satur in the department of Cher, France loses one of her most distinguished physicists. Born in 1840, he held several minor teaching appointments before becoming professor at the Ecole Normal at Cluny. Here in 1867 he commenced his researches into the behaviour of gases under high pressures, which rapidly brought him into the front rank as an experimentalist. At Lyons, where he had become professor at the Catholic university, he utilised the tower of one of the churches as the site for a mercury manometer giving pressures up to 80 atmospheres, and in one of the coal mines of Saint Etienne constructed one up to 430 atmospheres. His observations on nitrogen at these pressures enabled him to use the nitrogen manometer in his experiments on other gases, on liquids and solids, and on the conditions of transition from one state to the other. By the help of a skilled mechanic he had himself trained, he was able to construct apparatus for observations at pressures up to 3000 atmospheres. His results, which appeared for the most part in the *Annales de Chimie et de Physique*, were summarised in memoirs of dates 1883 and 1893, and his curves showing the variation of the value of pv as p increases for hydrogen, nitrogen, and carbonic acid have been reproduced in standard text-books for the last twenty years.

In 1892 Amagat was elected an honorary member of the Literary and Philosophical Society of Manchester, and in 1897 a foreign member of the Royal Society of London. After going to Paris as examiner for admission into the Ecole Polytechnique, he was in 1902 elected member of the Académie des Sciences. In 1906 he was president of the French Physical Society, and soon after was elected one of its few honorary members. Although offered a professorship at the Ecole Polytechnique, he preferred his examinership, and continued to devote to research much of the leisure it allowed him. During the last few years his health kept him at his country house, and for several months before his death he was confined to his room. For a generation he had been one to whom younger men could appeal for advice and encouragement in their work, and many distinguished physicists of to-day recall with affection his kindliness, his sincerity, and his modesty. C. H. L.

NOTES.

THE prospectus of British Dyes (Limited), which was put before the public a few days ago, has evoked universal condemnation in the daily Press. As might perhaps have been anticipated, the board of directors does not include a single representative of science, whilst the directors appointed by the Government consist of a railway director and a civil engineer. This characteristic neglect of science, and its consequences, form the subject of two letters by Sir William Ramsay and Sir Henry Roscoe, published in Wednesday's *Times*. Sir William Ramsay gives numerous instances to show that scientific chemists *must* form an important part of the directorate if the scheme is to be a success. The Castner Kellner process has on its board Sir Henry Roscoe and Dr. Beilby. The ammonia-soda process, originally patented by Dyer and Hemming, was successfully introduced and managed by the late Dr. Ludwig Mond. The paraffin industry was due to the late James Young, at one time an assistant of Prof. T. Graham. Perkin's and Spiller's names are associated with the early days of synthetic colours. These men were both pupils of Hofmann at the Royal College of Chemistry. The firm of Spencer, Chapman, and Messel, which has for many years manufactured sulphuric acid by the contact process, owes its inception and success to Dr. Messel. Turning to metallurgy, Lowthian Bell and Bessemer were scientific chemists first; successful manufacturers after. In short, it would be difficult to discover a successful chemical industry which has not been initiated and controlled by a chemist. Unless "British Dyes (Limited)" copies this precedent, there is little hope for it.

SIR HENRY ROSCOE, in the letter referred to above, points out that it is not the manufacture of the well-known colours of indigo, alizarin, or methyl blue which will bring financial and final success to British Dyes (Limited). The preparation of these articles—which, like all complicated chemical processes, requires both knowledge and great care—is on well-known lines. It is the new thing which makes a business success. "In the colour industry it is then the research chemist, and he alone, who can keep the flag flying, for he alone can bring forward new forces and create new developments. Capital cannot do it, business capacity cannot do it, but the brains, the imagination, the skill, and the knowledge of the research chemist can." Yet though this is the case, so far at least, the research chemist is to have no voice in the direction of affairs in the new colour company, but merely to be called in as an expert when, in the opinion of his business superiors, he can help them to solve some difficulty. If this plan is persisted in and the scientific chemist is not given a voice in the management "success is improbable, if not impossible."

THE Bakerian lecture of the Royal Society will be delivered on Thursday next, March 18, by Prof. W. H. Bragg, upon the subject of "X-rays and Crystals."

WE regret to see the announcement that Principal Sir James Donaldson, Vice-Chancellor of the University of St. Andrews, died on Tuesday night, March 9, at eighty-three years of age.

THE death is announced, in his sixty-fifth year, of Prof. H. W. L. Tanner, F.R.S., formerly professor of mathematics and astronomy at University College, Cardiff.

WE learn from the *Morning Post* that Jean Maspero, the son of Sir Gaston Maspero, the Egyptologist, was killed in the Argonne on February 18 while leading his section into action.

PROF. SAMUEL W. SHATTUCK, for forty-four years professor and comptroller of the University of Illinois, died at his home in Champaign on February 13. Since 1868, says *Science*, Prof. Shattuck served the University of Illinois. For thirty-seven years he was head of the department of mathematics and from 1873 to 1912 he looked after the business affairs of the University.

ON Tuesday next, March 16, Sir J. G. Frazer will begin a course of two lectures at the Royal Institution on the belief in immortality among the Polynesians; and on Thursday, March 18, Dr. Aubrey Strahan will commence a course of two lectures on London geology. The Friday evening discourse on March 19 will be delivered by Prof. G. H. Bryan, on the modern piano-player—scientific aspects, and on March 26 by Sir J. J. Thomson on experiments in slow kathode rays.

WE regret to announce the death on March 6, in his eighty-seventh year, of Lieut.-General J. F. Tennant, F.R.S., past-president of the Royal Astronomical Society. When a young man, Lieut.-General Tennant was assistant to the Trigonometrical Survey of India. He served as Government Astronomer of Madras in 1859, and was afterwards transferred to the Public Works Department as an executive engineer, first, in Burma, then in the Punjab, and later in Bengal. He made observations of the solar eclipses of 1867–68 and 1871, and was in charge of those of the transit of Venus at Rurki and Lahore in 1876.

THE death is announced of Mr. Flaxman C. J. Spurrell, aged seventy-two. For many years he was interested in the geology of the Thames valley and co-operated with his father, the late Dr. Flaxman Spurrell, in collecting Pleistocene mammalia from the river-deposits at Crayford, Kent. In 1880 he described to the Geological Society his discovery at Crayford of a Palæolithic land-surface showing evidence of flint-implements in process of manufacture. The whole of the collection, both of mammalian remains and of flints, was presented to the British Museum (Natural History) in 1893 and 1895.

THE death is announced, at fifty-eight years of age, of Mr. William Willett, the promoter of the Daylight Saving Bill. The Bill proposed that clocks and other timepieces in Great Britain and Ireland should be put on an hour on the third Sunday in April of every year and put back again on the third Sunday in September. Mr. Willett was able to obtain support for this measure from many city corporations and town and district councils, in spite of the serious objections to it, but though the Bill was introduced into the House of Commons on two separate occasions it never reached the final stages. Mr. Willett was a fellow of the Royal Astronomical Society.

THE council of the British Association, in consultation with the local executive committee at Manchester, has decided that the annual meeting of the association shall be held in that city as arranged, in September next. Both the committee and the council have felt that it would be inexpedient under present conditions to offer an elaborate local hospitality in the form of social and other arrangements, which has been extended to the association on former occasions. The committee, however, expressed its desire that the long continuity of the yearly meetings should not be broken, and stated that it would "prefer that the meeting should be held although restricted to its more purely scientific functions."

THE War Office has just published the following table showing the distribution of the cases of typhoid which have occurred in the British Forces in the Field, between the categories of uninoculated, the fully inoculated, and the partially protected:—

	Cases	Deaths
Uninoculated	359	48
Fully inoculated within 2 years (two doses)	111	1
Partially protected (one dose) ...	136	1
Totals	606	50

LORD KITCHENER, Secretary of State for War; Dr. A. Strahan, F.R.S., director of the Geological Survey of Great Britain; and Prof. P. Vinogradoff, Corpus professor of jurisprudence at Oxford, have been elected members of the Athenæum Club under the provisions of the rule which empowers the annual election by the committee of three persons "of distinguished eminence in science, literature, the arts, or for public services."

WE learn that no fewer than thirty-seven members of the established staff of the Natural History Museum are at present serving with the naval or military forces, about half of them having joined their units at the front. Among these are Capt. E. E. Austen, who has for many years had charge of the Diptera in the museum; Lieut. C. Court Treatt, assistant in the bird-room, Mr. A. K. Totton, who was recently appointed to the invertebrate section of the department of zoology; Mr. H. F. Wernham, assistant in the department of botany; and Mr. W. N. Edwards, the newly appointed assistant for the study of fossil plants. In addition to the members of the established staff ten temporary assistants and forty-seven sons of the former class have joined the colours, while the museum has also furnished an efficient Red Cross Section and a platoon for the Volunteer Training Corps for Home Defence.

SOME few years ago the buildings of the Aquarium at Rothesay, which was for a time one of the well-known "sights" of the Clyde, were taken over by the Marquis of Bute. The buildings have, through the generosity of the Marquis, provided a local habitation for the Buteshire Natural History Society, of which Dr. J. N. Marshall is president, while they have also served to house a valuable and developing museum collection illustrative of the local fauna and flora. Lord Bute has now installed a small laboratory for biological research and provided the most necessary equipment, including a motor-boat. Mr. L. P. W. Renouf, of Trinity College, Cambridge, has been placed in charge, and as he is desirous of making the laboratory a thoroughly convenient centre for research work upon the wonderfully rich marine fauna and flora of the Clyde estuary, he will be grateful for the gift of books and pamphlets bearing upon marine zoology and botany. Any such gifts should be forwarded to the Bute Museum, Rothesay, N.B.

THE death is announced, in his seventieth year, of Dr. C. E. Bessey, professor of botany since 1884 at the University of Nebraska. For fourteen years previously he had held a similar post at the Iowa Agricultural College. From 1880 to 1897 he was botanical editor of the *American Naturalist*, and since 1897 he had been botanical editor of *Science*. Prof. Bessey had at various times occupied the presidential chair of the American Association for the Advancement of Science, of the Botanical Society of America, of the Society for the Promotion of Agricultural Science, of the American Microscopical Society, and of the natural science department of the National Education Association. He was the author of "The Phylogeny and Taxonomy of Angiosperms," "Plant Migration Studies," and "Outlines of Plant Phyla," as well as of several botanical text-books for schools.

WE referred in NATURE of February 4 (p. 622) to reports from a number of correspondents that the battle in the North Sea on January 24 was accompanied by much disturbance among pheasants in Lincolnshire, Yorkshire, and even in Cumberland. The disturbance was most noticeable between 9.45 and 10.30 a.m., that is, as we know from Sir David Beattie's report, at the time when the *Blücher* received its principal injuries before sinking. In woods near Burgh-le-Marsh in Lincolnshire, the guns were heard simultaneously with the crowing of the pheasants. Canon Rawnsley, who has collected many reports on the subject, infers that "the pheasant's ear is capable of receiving impressions from sound-waves that the human ear cannot respond to" (*Times*, February 22); but, in a later issue (March 6), Dr. Davison suggests that the disturbance might be caused by the sudden swaying of low trees and undergrowth during the passages of the air-waves. He directs attention to the fact (see NATURE, vol. lxii., pp. 377–9) that, during a naval review at Cherbourg on July 18, 1900, the reports were heard for 107 miles, while windows for another thirty miles were shaken by the inaudible air-waves.

ON Tuesday evening, March 9, Mr. George E. Brown, the editor of the *British Journal of Photography*, at a meeting of the Royal Photographic Society, described a method of colour photography that has recently been worked out at the Eastman Kodak Company's research laboratory at Rochester, N.Y. It is a two-colour method, and as blue is suppressed or represented in only a modified way, the process is not claimed to be suitable for other work than portraiture. The many fine examples shown prove that it gives excellent results, and that the lighter tones, such as those of flesh tints, white kid gloves, pearls, and so on, are particularly well rendered. The darker colours, such as the browns, are very rich, but in the absence of the original materials photographed, it is not possible to say how nearly the colours are imitated. The process consists in taking two negatives, one through a red and one through a green screen, developing and fixing them, then dissolving away the silver image, and staining the films, the red record green, and the green record red. The dyed plates are placed face to face (one is taken reversed to permit of this) and constitute the portrait. It has to be viewed as a transparency, those shown being adjusted in colour for incandescent electric lamps behind a diffusing ground-glass screen or its equivalent. If preferred, the original negatives may be kept as such, and ordinary positives prepared from them. These positives may then be made to furnish any number of negatives for conversion into colour portraits. We learn that the process has already been taken up enthusiastically by American portrait photographers.

THE most interesting contribution to vol. vii., part 4, of the Journal of the Gypsy Lore Society is the first part of an account translated from the Arabic of Father Anastas, the Carmelite, describing the Nawar or Gypsies of the East. The description of them is the reverse of complimentary: "swindling rogues, lewd adventurers, wicked nomads, heedless ruffians," preserving a language of their own but destitute of any religion—the last statement interesting if it be correct. They are believed to be a mixture of Indians, Persians, Kurds, Turks, and Tartars, with the off-scourings of the regions in which they have lived. Their name, Nawar, is, it is suggested a corruption of Lūr, the Persian wanderers who are noted for their skill in thieving, sleight-of-hand, and powers of witchcraft, and they may possibly be ultimately traced to the Indian peninsula. The author writes from personal knowledge of them, and he gives full references to the literature of the subject.

ACCORDING to the *Museum Journal* for September, 1914, a fine piece of art metal-work from the celebrated Dictæan Cave in Crete has found its way to the Philadelphia Museum. It is a unique bronze blade with incised designs, to which the nearest parallel is supplied by the inlaid daggers from the shaft graves at Mycenæ, but these are more elaborate in design and more beautiful in technique. The blade is 6 in. in length and is covered with a fine green patina. It probably belongs to the Late Minoan III. period. On one side a hunter is attacking a mighty boar with a spear, the jungle being indicated by a tuft of fern-like sprays between the sportsman and his victim. On the other side is represented the critical moment of an exciting bull fight, one bull clearly getting the worst of the encounter. Similar fern-like sprays on the quarters of one animal possibly represent the furry lines of his coat where the direction of the hair changes. The museum has also acquired a fine series of reproductions of the gems of Minoan and Mycenæan art—several swords and daggers, gold and silver cups from Mycenæ and Vaphio, faïence objects from the shrine of the serpent goddess at Knossos, and reproductions of some of the frescoes, including the famous cup-bearer.

AMONG the articles in the February number of the *American Naturalist* is one by Messrs. Castle and Fish on the black-and-tan rabbit and the significance of multiple allelomorphs, in which the origin of the breed is indicated.

IN vol. x., No. 7, of the University of California publications on archæology and ethnology, Mr. P. E. Goddard has collected a number of tales and legends of the Chilula tribe, a group of Indians now nearly extinct. The collection is a strange complex of primitive types of belief: animal tales, witchcraft, demonology, folk-medicine, and incidents of social life. It is well that the opportunity has been taken to place on record the language and folk beliefs of a people which in a few years it will be impossible to recover.

A PHOTOGRAPH of the European bison cow and calf in the Zoological Gardens is one of the features in the February number of *Wild Life*. Although this calf is the first of its kind born in the London establishment, cow-bison have produced offspring on more than one occasion in the Duke of Bedford's park at Woburn. In connection with a photograph of Canadian wild geese, Mr. S. J. Wigley states that the omission of these birds from the list of species protected in Alberta is a testimony to their alertness and cunning.

THE report of the Indian Museum for 1913–14 deals largely with last year's celebration of the centenary of that institution, of which a notice has already been published in our columns, and the inauguration of a series of public lectures. Much of the rest relates to administrative details and other matters of purely local interest; and attention has also been directed in NATURE to the biological survey of the Chilka Lake, which is discussed in the report under the heading of field-work. Among noteworthy additions to the zoological collections were specimens from the Chilka Lake, specimens received from the marine survey, mammal-skins sent by the Bombay Natural History Society, and a series of, chiefly fresh-water invertebrate, specimens from Kashmir.

NEW reptiles and amphibians from the Permo-Trias of South Africa are described by Mr. S. H. Haughton in vol. xii., part 2, of the Annals of the South African Museum. Very striking is a fine stegocephalian skull referred to the European genus Trematosaurus, under the name of *T. sobeyi*. A skull allied to Tapinocephalus is made the type of a new genus and species, with the designation *Struthiocephalus whaitsi;* and of two new therocephalians, one is regarded as entitled to represent a new generic type (Trochosaurus). Three dicynodonts are also described as new, in one of which it is shown that the bone in Lystrosaurus hitherto regarded as the exoccipital, really represents both that element and the paroccipital (opisthotic).

THE Journal of the Washington Academy of Sciences for January 19 (No. 2, of vol. v.) contains an interesting paper by Mr. H. S. Graves on the place of forestry among natural sciences. The importance of the forest as a distinct plant society and its connection with botany, plant geography, meteorology, sociology, and engineering is well put forward. In the same number Mr. P. C. Standley describes a new genus of Chenopodiaceæ from Arizona, under the name of Zuckia, which is most closely related to Atriplex.

PROF. H. H. W. PEARSON publishes an account of his observations on the internal temperatures of *Euphorbia virosa* and *Aloe dichotoma* in the Annals of the Bolus Herbarium, vol. i., part ii., 1914. The plants grow on the dry slopes of the Great Karasberg. The stem structure of the Euphorbia is remarkable from the large air cavities in the stem. The Euphorbia attains its maximum external temperature more rapidly than the Aloe, and temperatures as high as 51·5° C. were recorded when the black-bulb registered 65·8° C. On wounding, the temperature of the Euphorbia falls suddenly, and the fall is attributed to the expansion of the pith gases due to the withdrawal of latex. When a rubber pellicle has been formed over the wound by the exuded latex the fall in temperature ceases. In Aloe the lowering of temperature on wounding appears to be due to surface evaporation and the recovery in this case is slow, since there is no protective formation of rubber over the wound.

IN *Knowledge* for January Mr. L. Claremont describes the methods of ruby-mining in Burma, with the aid of a number of photographs, and of illustrations by Burmese artists. He deals also with the red spinels, or "balas rubies," of which a large example, presented to the Black Prince, occurs among the crown jewels of Great Britain. The possible sedimentary origin of the ruby-bearing limestone in Burma has been lately pointed out by Mr. T. H. D. La Touche (see NATURE, vol. xciv., p. 348).

THE *Revue Scientifique*, which continues its fifty-third volume in Paris, publishes (February 6) a lecture given in 1914 by Prof. Stanislas Meunier on "Le problème des montagnes." The author repeats his suggestion that earthquakes may be caused by the explosion of steam, when water-bearing blocks of the earth's crust slip down into regions of high temperature. He declines, however, to look forward, with Termier, to catastrophic displacements of the surface. We may note that the *Revue* invites records of Frenchmen destined for scientific careers, who have fallen, in heroic circumstances, in the present conflict. Two such obituaries are published in the number here referred to.

THE Meteorological Office with its recent *Weekly Weather Report* has issued a summary of temperature, rainfall, and duration of bright sunshine for the past winter, as comprised in the period for the thirteen weeks from November 29, 1914, to February 27, 1915. The temperature for the winter was in excess of the average over the whole of England, the greatest difference occurring in the east and south-east and in the midland counties, where the mean was approximately 2° warmer than the normal. In Scotland there was a deficiency of nearly 1°, and in Ireland the defect for the winter was about 1·5°. The duration of bright sunshine was not very different from the normal, the amount being slightly deficient in the eastern districts, whilst there was a slight excess of sunshine in the western districts. Excessive rains were recorded over the whole of the United Kingdom, the fall being heaviest over England, where the rains for the whole country were 196 per cent. of the average. In Ireland the rainfall was 152 per cent. of the average, and in Scotland 131 per cent. The greatest excess of rain occurred in the south-east of England, where the measurement, 17·19 in., was 248 per cent. of the normal, whilst in the east of England the record was 228 per cent. of the normal, and in the midland counties 196 per cent. The rainy days were in excess of the average over the entire kingdom, the excess being generally greatest in the English districts.

Symons's Meteorological Magazine for February gives the rainfall for January last at representative stations over the United Kingdom. The total at Camden Square was 4·12 in., which is 2·29 in. more than the average, and is 225 per cent. of the normal. This is the highest percentage of the average at any station given in the table, which, however, is only a tentative representation. Naturally there are many stations given with a larger rainfall, but the normals at these were larger. The map giving the Thames Valley rainfall for January, which in such times of flood as the present is of special interest, shows an area in the neighbourhood of Marlborough with a fall of more than 6 in., and fairly large areas are given with more than 5 in. The rainfall of 4·12 in. at Camden Square is said to be the greatest in January in the fifty-eight years' record, with the exception of January, 1877, when 4·74 in. was measured. Combining the records at Camden Square for the three months November, 1914, to January, 1915, the total measurement is 13·98 in., which is 56 per cent. of the annual average fall, and is 224 per cent. of the normal for the period. The rainfall for January is said to have been above the average over practically the whole of the British Isles, the excess being greatest in the south of England. On the Pennines 8 in. or more fell generally. A copy of a photograph is given showing the flooding of Salisbury Cathedral on January 5 and 6. In the neighbourhood the rainfall measured 16·86 in. from October 13 to December 31, and of this 2·93 in. fell in the last seven days of December, whilst an additional 2·06 in. fell in the first three days of January. The current number commences the fiftieth volume of the magazine.

THERE is a general belief that the paintings of old masters owe their success in some measure to secret processes or lost arts. A paper on the scientific aspects of this question is contributed by Dr. Maximilian Toch to the Journal of the Franklin Institute for January. Among other conclusions, the author points out that the painters only used a limited number of colours (madder being one) the permanency of which was well established, and that they avoided mixing those which were known to undergo chemical combination in each others' presence. As examples of scientific methods of detecting later day copies, some interesting examples are given. The use of zinc white instead of flake white, the presence of protoplasmic remains in the wood cells, and the transparency of the bitumen in the shadows are particular proofs that a picture is not a genuine antique. As regards deterioration, the author alludes to the serious effect of smoke and modern gas fumes, and further points out that while either light or darkness may bleach a picture, some that have been kept in the dark may be restored by placing them in bright sunlight. Finally, Dr. Toch condemns the style of modern painting, which substitutes the collapsible tube or palette knife for the brush, on the ground that the flakes of colour thus attached to the canvas will crack off and become detached. If, therefore, this method was ever used three hundred years ago, no traces of it would now be in existence.

DR. W. C. SABINE publishes an account of a recent lecture to the Franklin Institute on architectural acoustics in the Journal of the institute for January. The investigations referred largely to the lecture hall of Harvard University, in which an ordinary spoken word remained audible for about 5½ seconds. At first they were applied to determine the absorption only of a note of the pitch of violin C, but they have now been extended for three octaves in either sense. By introducing more and more cushions into the room a curve was plotted connecting the quantity of absorbing material with the duration of the sound, and was proved to be very approximately a rectangular hyperbola. Another curve shows that the absorption increases with the pitch. An interesting feature is the diagram showing the distribution of sound intensity in a room with a barrel-shaped ceiling, and though the curves look remarkably complicated, the author finds that it is easy to observe the maxima and points of zero intensity. In conclusion the author says: "While these several factors, reverberation, interference, and echo in an auditorium at all complicated are themselves complicated, nevertheless they are capable of an exact solution, or, at least of a solution as accurate as are the architect's plans in actual construction. It is entirely possible to calculate in advance of construction whether or not an auditorium will be good, and, if not, to determine the factors contributing to its poor acoustics and a method for their correction." It is a pity that these results are not generally applied, so as to prevent public halls being built in such a way that echoes make them almost useless.

M. HENRY LE CHATELIER has contributed an article on explosives to *La Nature* of February 20. In the article the general phenomena of explosion and the methods of measuring the relative value of explosives are discussed, much space being devoted to the phenomena of gaseous explosions. The general questions of the heat developed on explosion, the influence of mechanical forces, of chemical stability, and other minor points are touched upon. In conclusion, it is pointed out that the manufacture and employment of explosives are very complex questions, and demand long study; that in time of war it is not wise to introduce new explosives or great variation in methods of manufacture. Inventors and the public are apt to look more particularly for the production of explosives of enormous power without giving consideration to other all-important factors governing their production and application.

Engineering for March 5 contains an illustrated description of Lord Chetwynd's electrical steel-purification process, which has been in use for the past eighteen months at the Grimesthorpe Works, Sheffield, belonging to Messrs. Cammell, Laird and Co., Ltd. The steel is manufactured in the ordinary way in the Siemens-Martin furnace, and is then teemed into a special ladle. When teeming steel into a ladle in the ordinary way, a portion of the slag is drawn out with it, and becomes so intermingled with the steel in the ladle that it has no time to separate completely and to rise to the surface before the pouring into the ingot moulds takes place. Lord Chetwynd's process is applied to the steel in the ladle. Two graphite electrodes are made to rest in the layer of slag covering the molten steel in the ladle, and iron electrodes are fitted in the bottom of the ladle. As soon as the graphite electrodes are lowered into the layer of slag an electric current is made to flow through the steel, the effect of which is to raise the temperature of the metal, causing a rotating action throughout the molten mass, with the result that it is freed from the gases and slag particles which it contained in teeming from the furnace. The process lasts about thirty minutes, and the current expenditure is small. Test results show that the process has a marked refining action upon the metal in the ladle.

OUR ASTRONOMICAL COLUMN.

MELLISH'S COMET.—A note in the *Times* of March 10 states that the orbit of this comet obtained by Andersen and Fischer, of Copenhagen, places perihelion passage at about 1 p.m. on July 25 next, the distance being 110 million miles. The comet will remain visible to English observers up to the middle of May, by which time it is likely to be faintly discernible with the naked eye. It now rises about half an hour after midnight, the best time for observation being 5 a.m., when it is a little east of south. Its positions at 5 a.m. on the dates named are as follows:—

	R.A. h.	m.	s.	Decl. °	′
March 12	17	39	26	0	51 N.
16	17	44	16	0	29
20	17	49	5	0	4
24	17	53	50	0	22 S.

THE BRITISH ECLIPSE EXPEDITIONS OF 1914.—The January number (vol. lxxv., No. 3) of the *Monthly Notices of the Royal Astronomical Society* contains the preliminary reports of the various British expeditions which were dispatched last year to observe the total eclipse of the sun on August 21. These reports have now been issued also in a separate pamphlet, and distributed by the secretary of the Joint Permanent Eclipse Committee. Brief accounts of the work of each of these expeditions have already been given in this journal, so attention need only be directed to the handy collective publication mentioned above.

ASTRONOMY IN AMERICA.—With a strong editorial board the National Academy of Sciences of the United States of America has begun a publication of monthly proceedings. These proceedings will be official, and are intended to serve as a medium for prompt publication of brief original papers. It is intended that the papers will be shorter and less detailed than those published in journals devoted to special branches of science, and that they shall, if possible, include an introductory statement of the general aspects of the research, and of its relation to previous knowledge in the same field, so that its significance may be appreciated by those engaged in other branches of science. In the first number (January 15, vol. i., No. 1) astronomy is well represented by the following communications:—The radial velocities of nebulæ, by W. W. Campbell; Preliminary note on nebular proper motions, by H. D. Curtis; Discovery of the ninth satellite of Jupiter, by S. B. Nicholson; Spherical aberration in astronomical objectives due to changes of temperature, by F. Schlesinger; The relations between the proper motions and the radial velocities of the stars of the spectral types F, G, K, and M, by J. C. Kapteyn and W. S. Adams; and, finally, a critique of the hypothesis of anomalous dispersion in certain solar phenomena, by C. E. St. John.

GRUNDSPECTRA OF ALKALI AND ALKALINE EARTH METALS.—A research interesting to spectroscopists is that communicated to the *Astrophysical Journal* for January (vol. xli., No. 1, p. 16), by Mr. Edgar H. Nelthorpe. The work was carried out in the astrophysical laboratory of the Imperial College of Science and Technology, and deals with the observations of the *grundspectra* of alkali and alkaline earth metals. The term *grundspectra* refers to spectra obtained by Goldstein, who used a method by which line spectra of some elements were obtained which were totally different from their arc spectra and could not be arranged in series of the ordinary type. As Goldstein's method appeared in some cases completely to isolate enhanced lines (spark) from the arc lines occurring under the ordinary arc or spark conditions, the author of the present paper has repeated and extended this research, embodying some of the spectra of elements which are represented in stellar spectra. The elements here dealt with are sodium, potassium, rubidium, calcium, strontium, and barium. Mr. Nelthorpe describes the apparatus he employed, and gives the results of each element separately, accompanying them with a series of excellent photographic comparison spectra. The chief conclusion drawn is that the *grundspectra* obtained by Goldstein's method consist essentially of lines which are specially developed in the ordinary spark spectrum. In the case of potassium and rubidium the spectra consist entirely of enhanced lines, but with the calcium group the arc spectrum is not entirely absent.

ELECTRONS IN THE SUN'S ATMOSPHERE. In a paper communicated to the Tokio Mathematico-physical Society in October, 1914, Prof. H. Nagaoka directs attention to the important part which may be played by calcium in the production of electrons in the sun's atmosphere. In the flocculi so abundant in the photosphere it exists probably as calcium oxide, and the electronic emission of lime when incandescent is frequently utilised in laboratory work. At the pressure of one-tenth of an atmosphere which prevails in the calcium layer about a sun-spot, the electrical conductivity will not be too great to allow of considerable potential gradients which, according to their direction, will establish outward or inward electronic currents of considerable magnitudes. If, as seems most likely, the electric field is directed inwards, the electronic emission will be outwards and the regions of emission will be surrounded by electronic vortices with counter-clockwise rotation. Within the vortices magnetic fields will be produced, and the whole region will possess the properties found to exist in sun-spots. Comparisons of some of the consequences of this theory with observations are, it is hoped, to be carried out by the author and his pupils.

THE CHEMICAL INDUSTRIES OF GERMANY.[1]

THE interest and importance of the subject at the present time are sufficiently obvious. In outlining some of the origins of chemical industry in Germany, the lecturer pointed out how the royal house of Prussia had been frequently associated with chemical enterprise. The Markgrave John was actually surnamed "the Alchemist," the Great Elector was a patron of chemistry and provided a laboratory at Potsdam for the celebrated Kunkel, one of the first to discover phosphorus, and who also effected great advances in the manufacture of glass. Frederick the Great established the Royal Berlin porcelain factory, which still occupies some of the original premises. In the same reign also the chemist Marggraf made those classical investigations on the occurrence of sugar in the vegetable kingdom which later led to the foundation of the beet-sugar industry, which was initially subsidised by Frederick William III., the founder of the University of Berlin in 1809. (In 1914, the Berlin University had 12,585 students, and received an annual grant from the State of more than 200,000*l.*)

Great industries have developed out of these early steps. From the discovery of phosphorus came the match industry. German annual production of matches is 4,600,000*l.*; the British production in 1907 amounted to 775,000*l.*, whilst the British consumption in 1910 was estimated at 1,300,000*l.* Again, the porcelain and pottery manufacture had attained great dimensions in Germany, the exports in 1912 amounting to 3,556,000*l.*, whilst the glass industry was even on a larger scale, the recent annual exports being more than 7,000,000*l.* Great inconvenience in connection with all scientific work is at present being experienced through the absence of German glass. The important cyanide industry may be said to have taken its origin from the accidental discovery by Diesbach, of Berlin, of Prussian blue in the first decade of the eighteenth century. Germany's annual production of cyanides is now estimated at 10,000 tons (650,000*l*), or about one-half of the world's production.

The present position of Germany in the sugar industry of the world can be appreciated from the following figures:—

Total Sugar Crop, 1912–13.

	Tons
Cane-sugar	9 211,755
Beet-sugar, European (1/3 German) ...	8,310,000
,, United States	624,064
Total ...	18,145,819

The United Kingdom annually imports 1,700,000 tons of sugar (23,000,000*l.*).

	£		Acres
Germany annually produces	36,000,000	beet-sugar on	1,300,000
France ,, ,,	13,000,000	,,	570,000
All Continental countries	116,000,000	,,	6,000,000

The beet-sugar industry is of particular interest in connection with the present crisis because it is an example of an industry which received a most important impetus through the exclusion of British goods (colonial cane-sugar) from Continental ports during the Napoleonic wars.

This industry again exemplifies how agricultural production can be improved by systematic research such as has been bestowed on it by Germany, thus:—

In 1840	100 lb. of beet yielded	5·9	lb. sugar
1850	,, ,,	7·3	,,
1870	,, ,,	8·4	,,
1890	,, ,,	12·5	,,
1910	,, ,,	15·8	,,

Again in

1871	mean yield of beet per hectare of land was	246 quintals
1910	,, ,, ,,	300 ,,

And again in the economy of manufacture

In 1867	coal used on 100 lb. beet	35 lb.
1877	,, ,, ,, ...	24 ,,
1890	,, ,, ,, ...	10 ,,
1900	,, ,, ,, ...	7 ,,

As indicating the great and progressive attention devoted to agriculture, Germany's artificial manure bills for 1888 and 1912 were highly instructive:—

	1888. Tons	1912. Tons
Chile saltpetre ...	225,000	650,000
Sulphate of ammonia	50,000	500,000
Superphosphate ...	250,000	1,800,000
Basic slag	250,000	2,200,000
Crude potash salts ...	160,000	3,000,000
Lime...	— } 500,000	800,000
Other manures ...		500,000
Total value ..	£30,000,000	

The following comparison is also of interest:—

Use of Artificial Phosphatic Manures (per annum).

England	48 lb. per 1 acre cultivated
France	105 ,, ,,
Germany	105 ,, ,,

The former supremacy of Great Britain in the manufacture of the common chemicals—sulphuric acid and soda—was referred to, and compared with the production of these materials in 1910.

Production in Tons, 1910.

	Germany	England	France	U. States	World
Sulphuric acid	1,250,000	1,000,000	500,000	1,200,000	5,000,000
Soda	400,000	700,000	200,000	250,000	2,000,000

The substitution of the ammonia-soda for the earlier Le Blanc soda process, and of the contact for the time-honoured leaden chamber process of sulphuric acid manufacture, had no doubt greatly assisted both Germany and America in becoming independent of the British manufacture of these chemicals.

During the past twenty-five years the manufacture of chlorine and caustic soda by the electrolysis of common salt (sodium chloride) has been realised and rapidly extended. This process is carried out on a very large scale in Germany, where extensive use is made of liquefied chlorine. The production of electrolytic chlorine is attended with the simultaneous evolution of large quantities of hydrogen gas for which uses have been found; thus, for filling the dirigible balloons upon which such hopes of conquest have been based by Germany, whilst in the oxyhydrogen flame it has been employed for welding, for the cutting even of thick iron structures, and for the manufacture of artificial gems. The artificial production of gems—corundum, ruby, sapphire, etc.—was discovered in France by Michaud, Verneuil, and Paquier, and has been greatly taken up by the Elektrochemische Werke at Bitterfeld, in Germany. More than a ton of these gems, which are identical in chemical composition with the natural gems, are said to be annually produced. Other more important uses for hydrogen have been found for the hardening of fats, and still more recently for the synthetic production of ammonia to be presently referred to, and which is an industrial achievement of the first magnitude. Cheaper sources of hydrogen than the electrolytic method have been

[1] Abstract of a lecture delivered before the Society of Chemical Industry (Birmingham and Midland Section), in the University of Birmingham, on March 4, by Prof. Percy Frankland, F.R.S.

introduced, and notably that depending on the production of water-gas (consisting of equal volumes of hydrogen and carbon monoxide) from steam and coke at a red-heat, the carbon monoxide being subsequently separated from the hydrogen by liquefying it by means of the low temperature apparatus of Carl von Linde, of Munich.

The discovery of incandescent gas lighting by the Austrian, Count Auer v. Welsbach, and of the metallic filament incandescent electric lamp by the same inventor in 1903, as well as the improvements in the latter effected by Siemens and Halske in 1905 and 1906, have led to the production of these commodities on a very large and increasing scale in Germany, thus:—

	1911	1912
Incandescent gas mantles	126,000,000	135,000,000
Metallic filament electric lamps ...	47,000,000	76,000,000
Carbon filament lamps (production diminishing)	25,000,000	21,000,000

The following comparison of the estimated consumption of incandescent gas mantles in different countries for the year 1912 is interesting (Vivian B. Lewes):—

Germany ...	100,000,000	Belgium... ..	3,500,000
America ...	60,000,000	Italy	3,000,000
England ...	38,000,000	Russia	1,500,000
France ..	16,000,000		

Ammonia, Nitrates, and Fixation of Free Nitrogen.

During the past century the world's supply of ammonia has been almost exclusively obtained as a bye-product in the manufacture of gas, and latterly also from coke-ovens. So backward was Germany in the production of ammonia that as late as 1874 the ammoniacal liquor of their gasworks was allowed to run to waste. All the more remarkable is the state of affairs revealed by the following figures:—

	Tons
In 1890 the world's production of sulphate of ammonia	210,000
1900 ,, ,, ,, ,,	500,000
1912 ,, ,, ,, ,,	1,330,000
1910 Germany's ,, ,, ,,	300,000
1912 ,, ,, ,, ,,	400,000

The principal use of sulphate of ammonia is as a nitrogenous manure, as which it competes with Chile saltpetre (sodium nitrate).

Sulphate of ammonia contains 20·5 per cent. nitrogen
Chile saltpetre (sodium nitrate) 15 ,, ,,

It has already been pointed out that Germany imports 650,000 tons of Chile saltpetre for manure, hence by increasing their output of sulphate of ammonia they have been rendering themselves less dependent on foreign products (nitrate from Chile and sulphate of ammonia from England).

As is well known, one of the most important problems at the present time is to provide the world with nitrate when the deposits in Chile shall have been exhausted. The problem is bound up with the still wider one of the fixation of atmospheric nitrogen. This again, as is well known, is now accomplished on a large scale by the production of nitric acid from atmospheric nitrogen and oxygen by means of the electric furnace of Birkeland and Eyde, or by the production of calcium cyanamide by passing atmospheric nitrogen over heated calcium carbide. Both these processes involve the use of the electric furnace, in the former for effecting the union of the nitrogen and oxygen, and in the latter for the preliminary production of the calcium carbide. Abundant water-power being necessary for the economic operation of the above processes, Norway has become their chief centre, whilst Germany has sought other means of nitrogen-fixation which could be carried on within her own territories. The synthesis of ammonia from hydrogen and atmospheric nitrogen under a pressure of 200 atmospheres and at 500° C. in the presence of a catalyst, has been successfully worked out by Haber in conjunction with the Badische Anilin und Sodafabrik, and a plant capable of yielding 130,000 tons of sulphate of ammonia per annum was to have been ready in 1915. The second step in the German programme was to convert the ammonia into nitric acid by burning it in air in the presence of a catalyst. In this way it is hoped to make Germany independent of foreign countries for the nitrate required in the manufacture of explosives. It is asserted that this independence Germany has actually secured at the present moment.

Potash Salts.

The unique deposits of potash salts discovered at Stassfurth in 1857 have been exploited on an increasing scale and have furnished practically the whole world with potash; the output of crude salts was in

	Tons	£
1881	2,000	
1912	11,000,000	(8,800,000)

In 1911 America alone took potash salts to the value of 3,000,000*l.*

Explosives.

Of the modern high explosives, gun-cotton was discovered by Schoenbein and by Boettger in 1846. The manufacture of nitroglycerine (discovered by Sobrero in Paris in 1847) was first realised by the Swede, Alfred Nobel, in 1862, and it was Nobel who first adapted these powerful explosives for ballistic purposes. Trinitrotoluene, of which so much has been heard recently, was first proposed for filling shells by Haessermann in 1891. It is said to be surpassed, both as regards safety and disruptive effect, by tetranitro-aniline discovered in England by Dr. Fluerscheim. The great magnitude of the German explosives industry is seen from the following figures:—

	Tons
Total German production of explosives ...	40,000
or about 1/10th of the estimated world production.	
	£
Germany exported in 1908 to the value of	1,000,000
,, ,, 1912 ,,	3,000,000

Artificial Silk.

This remarkable industry, originated by Count Chardonnet in France in 1891, has also been largely developed on German soil. The German production amounts to about 2000 tons annually (1,200,000*l.*) out of a total world production of about 7000 tons. French, German, and British patents have largely contributed to the success of this industry.

Industries Dependent on Synthetic Organic Chemistry.

It is in respect of these industries that the world is learning that Germany holds the undisputed supremacy. It is in Germany alone that manufacturers have been found prepared to embark their capital and undertake industrial enterprises of the first magnitude on the advice of the organic chemist. The success which has been achieved by the German manufacturers of artificial dyestuffs, drugs, and perfumes, and the hegemony which they have secured in this branch of industry, has been the frequent subject of warning by professors of chemistry in this country for upwards of a generation. The seriousness of the situation which has arisen through the neglect of those warnings is seen from the following figures:—

		£
Annual value of dyestuffs used in England	...	2,000,000
,, trade in which these dyes are employed	...	200,000,000
Workmen dependent on this trade 1,500,000		
Total value of dyestuffs imported (1913)	...	1,892,055
,, ,, ,, from Germany		1,730,821

Thus less than 1/10th of the annual value of the dyestuffs consumed in England is produced in this country. Thus, by controlling the dyestuff industry, Germany indirectly holds in her grip the much larger textile industry.

The manner in which the coal-tar colour industry has extinguished the cultivation of madder more especially in France, since 1870, and has caused the cultivation of indigo in British India to dwindle almost to nothing since 1897, are now well-known facts in commercial history. They will be fully appreciated by a study of the following figures:—

At the time of the discovery of artificial alizarin (the dyestuff contained in madder) in 1869, the total production of natural alizarin amounted to between 500 and 750 tons (2,250,000*l.*), and in 1870 France had 50,000 acres under madder cultivation.

The production of artificial alizarin was

	Tons
In 1873	100
1877	750
1884	1350
1900	2000

(4/5ths of this produced in Germany).

Again, with regard to indigo, in 1896 the world's production of plantation-indigo was valued at about 4,000,000*l.*, of which four-fifths were obtained from British India.

Export of Indigo from British East Indies.

	£
1896	3,569,670
1899	1,980,319
1902	1,234,837
1905	556,405
1908	424,849
1911	225,000
1913–14	60,000–70,000

Since the introduction of artificial indigo the price of indigo has been reduced by more than one-half, but since the outbreak of the war the price of indigo has advanced by 350 per cent.

Much inconvenience has been experienced also in the shortage of artificial drugs and consequent high prices, more especially at the beginning of the war, as even the simplest of these products were almost exclusively made in Germany. The manufacture of some of these is, however, now being successfully carried on in England.

Again, the shortage of organic chemicals required for research purposes, which practically all come from Germany, is occasioning most serious difficulties in our university laboratories.

For the manufacture of dyestuffs and similar synthetic products Germany was formerly largely dependent on England for the raw material—coal tar. But in this case, again, the ambition of Germany to become in all respects independent and self-contained has led her in recent years to make the most strenuous efforts to recover the maximum amount of coal-tar both from the manufacture of gas and from coke-ovens, which endeavour has been assisted by the enormous growth in her iron and steel industries. Thus in 1897 Germany obtained only 52,000 tons of coal-tar from coke-ovens, whilst in 1908 she obtained no fewer than 632,400 tons from that source, besides 300,000 tons from the manufacture of gas. Thus at the present time the German output of coal-tar about equals, if it does not exceed, that of England.

The German production of artificial perfumes is said to amount to a value of about 2,500,000*l.* annually. In this department of applied chemistry, again, one of the first steps was made by the late Sir William Perkin, by the synthesis in 1868 of coumarin, the much-valued odoriferous principle of woodruff (*Asperula odorata*).

The great magnitude of the German coal-tar colour industry may be gathered from the fact that the two groups into which the principal firms are associated have at the present time a total share-capital of about 12,000,000*l.*, on which a dividend of about 28 per cent. is paid. In 1912 Germany produced dyestuffs to the value of 12,500,000*l.*, of which to the value of 10,000,000*l.* were exported.

The proposal of the Government to assist the British coal-tar colour industry is being watched with the greatest interest both by manufacturers and chemists. The problem of relieving the immediate shortage during the war must be carefully distinguished from the later problem of securing the independence of the home-industry after the war by greatly increasing the British output. The realisation of the latter object will be attended with the greatest possible difficulty. The industry will require "nursing" for a great many years. The undertaking must be possessed of such elasticity that it can ramify into other branches of chemical or other industry whenever advantageous opportunities arise for such departures. Chemists must form an integral part of the directorate, which must be prepared to spend large sums of money on judiciously conceived and well-organised research, for which the sum of 100,000*l.* in ten years, hitherto mentioned by the Government, is ridiculously inadequate. The undertaking must, moreover, be freed from all hampering legislation with regard to restrictions in the use of alcohol, ether, chloroform, and other chemicals. In short, the rehabilitation of the industry in this country will not be effected by following the precept "business as usual," but by pursuing a policy which is quite the reverse of what is implied by that undignified phrase.

BRITISH ASSOCIATION DISCUSSION OF THE NATURE AND ORIGIN OF SPECIES.

An outstanding feature of the Melbourne meeting of the British Association was the joint debate by Sections K and D (Botany and Zoology) on the nature and origin of species. Prof. F. O. Bower, President of Section K, took the chair.

Dr. A. B. Rendle pointed out the need of a working unit for the classification of the world's flora. A working systematist or monographer recognised certain characters common to a number of individuals as limiting varieties, species, and genera from one another. Such expert work was difficult, and inclined to be at times individualistic, but was necessary if systematic botany was to exist. Dr. Rendle showed himself a thorough supporter of the well-known Darwinian explanation of the origin of species by natural selection. The living organism is eminently adapted to its environment or is epharmonic. Slight gradual changes in the organism due to internal causes, influenced or not by slight changes in environment, accumulate and become inherited. If these changes are pronounced, *e.g.*, sports or monstrosities, they are likely to be detrimental to the individuals possessing them. To grow plants under alien conditions generally requires care and freedom from competition. He thought experiments conducted under control in the laboratory or greenhouse partook too much of the nature of hospital treatment, and that conclusions based on such work were scientifically unsound. The open field of nature was the more trustworthy as the interplay of forces there had nothing personal in it. He could not accept the theory offered by De Vries and others of the origin of species by mutation, namely, by the inheritance of striking changes suddenly appearing, that is to say, discontinuous variations, as distinguished from the non-heritable fluctuations of slight degree. The inheritance of the discontinuous variations gives rise by a process of segregation to the elementary species of De Vries. The Darwinian species arises, on the contrary, by selection by an aggregation of slight gradual epharmonic changes.

Dr. Rendle took as an example of the difference of interpretation under the two opposing views the work of Jordan on the Drabas and of Wettstein on alpine meadows. He showed no sympathy for Lotsy's view of the origin of species by crossing. The resulting forms would be in 90 per cent. of the cases of the nature of monstrosities, and incapable of perpetuating themselves. They would be too, as regards environment, unharmonic. In conclusion, he considered the latest suggestion made by Prof. Bateson, that new forms arise by the omission of a character, to be full of difficulties. On this view the highest phase of evolution would correspond with the disappearance of all characters, while the primitive organisms must have been inconceivably complex.

Prof. A. Dendy, President of Section D, considered that species arise by a process of fundamental evolution, in which environment plays a leading part, and that the adaptations are inherited. The epigenetic characters are, however, modified by sexual reproduction, giving permutations and combinations, following Mendelian laws, which are superposed on the modifications due to Darwinian evolution.

Prof. W. Bateson, President of the Association, did not himself attach so much importance as some of the speakers to the standardisation of the term species. He thought it hopeless to expect definite conclusions as to the nature and origin of species along the lines advocated by Dr. Rendle.

The reason that unquestionable judgments could not be reached was obviously that the physiological nature of specific difference was still unknown. In the absence of this knowledge the delimitation of species must be arbitrary. Many, following Darwin, hold that the distinction between species and variety was a matter of degree. That might be so, but he (the speaker) inclined to doubt it. No one, however, as yet had evidence on which a confident opinion as to that fundamental point could be based. Such evidence, if indeed attainable, could be reached only by physiological experiment—experiments in breeding providing as yet the most hopeful line. No amount of inspection of specimens, living or dead, could decide specific limits. Names must, of course, be given, and freely. Systematists perhaps do well to indicate which names they regard as prerogatively specific; but it should clearly be understood that these decisions were pragmatical and matters of convenience, and they should not be offered as indications of physiological significance.

Prof. E. B. Poulton thought there was too much assumption in the distinction drawn by De Vries between his non-heritable fluctuations and his discontinuous heritable variations as regards their heritability. He (Prof. Poulton) agreed with Prof. Dendy in laying stress on the importance of sexuality in producing new patterns by the endless combinations of units. He thought environment alone was not enough to account for the production and continuance of a variety. There must be selection too.

Prof. Benjamin Moore caused his audience much amusement by stating that although he had been compared in the President's address to Harry Lauder's schoolboy who took from his pocket a washer and said "that's to mak' a motor-car," yet if he were starting to collect materials for building a motor-car he would rather begin with a washer than a pot of enamel paint. Workers at different levels on the subject of evolution were apt to despise one another's work or misunderstand it. The problem of the origin of species, just like the problem of the origin of atoms, was fundamentally a chemical problem, and in its study the effects of energy transformations acting from without upon the living cell acting as a catalyst must be taken into account. The outside sources of energy formed the environment, and this environment acted as a directive, screening, and selective factor causing small variations.

Prof. E. A. Minchin said that speaking quite generally and ignoring for the moment intermediate and transitional forms, he believed that two principal grades of evolution would be recognised in the Protista, exemplified by the Bacteria and Protozoa respectively. In the bacteria the full structure of the cell has not been attained, and there are no sexual processes. In the Protozoa, on the other hand, the individual is a complete and typical cell, and sexual phenomena occur. In the bacteria the so-called species are groups of individuals in which the variability is indefinite and uncontrolled. In the Protozoa the variations are reduced to a common level by sexual blending, and fixed species occur. He believed that in the unicellular Protista one of the effects of the sexual powers is to produce true species by controlling and levelling down variability.

Mr. J. T. Cunningham expressed the view that recent discoveries concerning internal secretions or hormones gave evidence of a physiological process which would make the transmission of functionally produced modifications possible.

Dr. F. A. Dixey thought that the principle of segregation of the gametes, especially as reinforced by the President's suggestion of "fractionation," has thrown light on the persistence of some forms and the appearance of others. It would seem that adaptation can only be satisfactorily accounted for on the basis of selection applied to small inheritable variations.

Mr. R. P. Gregory and Dr. G. C. Druce also spoke. T. J.

FORTHCOMING BOOKS OF SCIENCE.

IN addition to the forthcoming books of science referred to in recent issues of NATURE we notice the following publishers' announcements:—*D. Appleton and Co.* The Fundamentals of Plant Breeding, J. M. Coulter; Psychology, General and Applied, H. Munsterberg; Sanitation in Panama, W. C. Gorgas. *The Cambridge University Press.*—The Teaching of Mathematics, Prof. T. P. Nunn (Cambridge Handbooks for Teachers). *J. M. Dent and Sons, Ltd.*—An Introduction to the Study of African Languages, Prof. Meinhof, translated by A. Werner; Elementary Experimental Statics, I. B. Hart. *G. G. Harrap and Co.*—Scientific Management in Education, Dr. J. M. Rice; An Industrial Geography of Britain, W. J. Claxton *T. C and E. C. Jack.*—German Culture, edited by Prof. W. P. Paterson, the aim being to give an estimate of what Germany has contributed to higher life and thought in the various departments of knowledge. The following subjects will be dealt with, among others:—German Science, Prof. J. Arthur Thomson; German Philosophy, Prof. A. D. Lindsay; Political Philosophy and Politics, Prof. D. H. Macgregor; German History and Character, Prof. R. Lodge; Modern Inventions, V. E. Johnson; Electricity, W. H. McCormick; Engineering, G. Knox. *Longmans and Co.*—The Development and Present Position of Biological Chemistry, Prof. F. G. Hopkins; The Polysaccharides, A. R. Ling; Colloids, W. B. Hardy; Respiratory Exchange in Animals, Dr. A. Krogh; Protamines and Histones, Dr. A. Kossel; Organic Compounds of Arsenic and Antimony, Dr. G. T. Morgan; Lecithin and Allied Substances, Dr. H. Maclean; The Ornamental Plant Pigments, A. G. Perkin; Chlorophyll and Hæmoglobin, H. J. Page (Monographs on Biochemistry); Electric Waves, Prof. G. W. Pierce; The Emission of Electricity from Hot Bodies, Prof. O. W. Richardson; Colloidal Solutions, Prof. E. F. Burton; Atmospheric Ionization, Prof. J. C. McLennan (Monographs on Physics); Electrolytic Dissociation Theory, Dr. J. C. Philip; The Physical Chemistry of Flames, J. E. Coates; Clays, Dr. J. W. Mellor; Catalysis of Gas Reactions, D. L. Chapman; The Electro-Chemistry of Non-Aqueous Solutions, J. W. McBain; Catalysis in Liquid Systems, Dr. G. Senter; Hydrates in Solution, Prof. E. A. Washburn; The Rare Earth Metals, Dr. J. F. Spencer; The Molecular Volumes of Liquid Chemical Compounds, G. Le Bas; Adsorption, V. Lefebure and A. M. Williams (Monographs on Inorganic and Physical Chemistry). *J. Nisbet and Co., Ltd.*—The Operative Treatment of Chronic Intestinal Stasis, Sir W. A. Lane. *Sir Isaac Pitman and Sons, Ltd.*—Experimental Physics, A. Cowling. *T. Fisher Unwin.*—Rubber Recueil: Papers on Rubber, its Botany, Culture, Preparation, and Commerce.

THE SECOND INDIAN SCIENCE CONGRESS.

THE second Indian Science Congress was held in Madras from January 14–16. It may be remembered that the suggestion to hold a Science Congress in India on the lines of the British Association was first made some three years ago by Prof. MacMahon, of Lucknow, and Prof. Simonsen, of Madras. The first meeting was held a year ago in Calcutta.

The Hon. Surgeon-General W. B. Bannermann, I.M.S., C.S.I., was president this year, and delivered on address entitled "The Importance of a Knowledge of Biology to Medical, Sanitary, and Scientific Men Working in the Tropics." After dealing with the scourges of India and recent research as to the nature of plague, malaria, and so on, the president remarked:—"It has been said that Indians have not yet distinguished themselves as they might in the domain of medical research. That is no doubt true, but the reason is not far to seek. The leisured and wealthy classes in India do not send their sons to our universities in any numbers, and when they do, certainly not with the idea that they should spend the rest of their lives in pure research work. Let us hope they will do so some day. It is, therefore, among the sons of the middle class and often poor community that we must look for the men with capacity and inclination for such work.

"But these are the very men who, not being in independent circumstances, must earn their living at the earliest possible time. They cannot, therefore, be expected to engage in scientific research which does not bring in money for daily bread or lead up to any permanent appointment. I would, therefore, appeal to our wealthy Indians to endow medical research, so that their poor but capable fellow-countrymen may have something to look forward to as reward for scientific toil. There are plenty of subjects for research which ought to be endowed, chairs in our medical schools and universities that ought to be established. All our Indian universities are at present mere skeletons; will no one here take up the rôle of beggar and try to extract a few lakhs of rupees from the hoards of his wealthy and aristocratic friends? We know that there is plenty of money to be had when the heart of the nation is touched, as witness the magnificent response to the appeals made for war funds by H.E. the Viceroy and our own Governor of Madras. It must be your part, gentlemen of light and leading, to inspire similar enthusiasm in the good cause of university endowment. India wants to have, not only more chairs and lectureships endowed, but also research scholarships or fellowships established; fellowships available for the student and the research worker, so that he may live in reasonable comfort, and be able to devote his whole energy to the work without anxiety for those depending on him.

"I should like here to point out that we in Madras have made a beginning in this direction owing to the enlightened liberality of the Rajah of Pithapuram, who has presented 50,000 rupees for the expenses of an inquiry into diabetes, that fell disease which carries off so many of the best brain workers in this part of India. This is an example which I trust will often be followed in the future; it can lead to nothing but good for India and her peoples.

"You will remember what our late beloved King-Emperor said with reference to tuberculosis:—'If preventible, why not prevented?' We may say the same of all these diseases—'They are preventible; why are they not prevented?' For their prevention we require research and research workers. Research workers are, after all, human beings and must be able to support themselves and their families by their labours. Who will come forward and help us? India needs this help, and we cannot look to Government for more than a small part of the money required. Government has done magnificent work of late years in establishing laboratories, and subsidising research all over the land, but much more is required. We want scholarships and fellowships with pensions for our best research workers. Endowments for this purpose will do more to keep alive the memory of the donors than the erection of chattrams or other traditional forms of charity. It will not merely do this but will confer an inestimable benefit on the inarticulate millions of India, who do not even know that they can be delivered from the various diseases that afflict them, and are scarcely conscious of their existence.

"But we not only require research workers, we want an organisation that will help to educate the people in the ordinary rules of health. There should be in each presidency an official whose business it is to look after the hygienic education of the common people. He should be in charge of a Bureau of Public Health, and his work should consist in preparing pamphlets and popular lectures with lantern-slide illustrations, which could be lent to lecturers who would undertake to itinerate in the villages and talk to the common people. He should organise classes for the teachers in our teachers' colleges, and he should gather together and popularise information from every quarter. Such an official—who would have to be very specially selected—would do an immense amount of good in educating the people, and without education we can hope for very little advance along the road to health.

"Until the usefulness of such a bureau is fully established, we can perhaps scarcely expect much help from Government, for it has plenty to do with the public revenues, but I am quite sure they would view any endeavour to educate the masses with a sympathetic eye."

After the presidential address it was decided to hold the 1916 meeting in Allahabad, and Dr. W. N. F. Woodland was appointed the local hon. secretary.

In the Agriculture and Applied Science Section Dr. H. H. Mann, of Poona, presided, and his address dealt with "The Lines of Development of Indian Agriculture."

Agriculture in India, he said, is of two kinds. On one hand you have an extensive agriculture, conducted without much capital, with primitive implements and methods, and yielding poor results when compared with any Western standard. On the other, you have a number of comparatively small, but highly organised industries, conducted largely by planters, growing special valuable crops, with adequate capital, and yielding exceedingly high returns.

It is not generally realised how unsatisfactory the results of the average Indian agriculture really are. We have no census of production in India as yet, and really satisfactory figures are not possible. But in a few cases it is possible to give figures which make us realise the position. In wheat production, for instance, the yield per acre is certainly not more than ten bushels per acre, and is probably nearer eight, or one-third of what might be considered as a good crop; more especially in this case where so much of the land devoted to it is irrigated and hence not dependent on a very variable rainfall. In the case of cotton, the figure is equally striking, and in this case the area and production are very fairly well known. From twenty-two million acres, the produce runs to above four million bales, or about 75 lb. of lint per acre, while in America, with an equally uncertain rainfall, the production reaches 200 lb. per acre. Again, if we take an intensive crop grown very largely under irrigation, like sugar-cane, the yield works out at under one ton of raw sugar per acre, as against a world's average of about two tons at least. In this case the average in India is very much lowered by the miserable outturn from Northern India, and the crop in Bombay and Madras is fairly up to the world's average. These figures are so striking that a newcomer to the subject is apt to think that improvement is easy, and that the raising of the standard of this cultivation towards that reached elsewhere is not very difficult.

This, however, is not the case. In no country perhaps is progress more difficult. One is hindered at every point by unexpected difficulties. The lack of anything more than a minimum of capital has been often considered as the most outstanding of these hindrances, and it is very important, though not the only one. The very great conservatism of the Indian cultivators has often, also, been mentioned. In this matter, it may be stated very emphatically that Indian cultivators are not more conservative than their situation demands. When a man is working on a minimum of capital, when any excess capital costs probably from 12 per cent. upwards for interest, when the money is turned over only once or at most twice in a year, it is the only policy to be extremely conservative.

Three methods of investigation seem important with a view of improving matters. One of these is the study of soil physics. It seems very important here, especially as several of our types of soil are peculiar, that the methods of increasing their absorbing and retaining capacity for water under our conditions required very careful investigation. A second investigation, that of implements, is one which is very much needed. A third method, to increase the utility of the water which actually falls in our drier tracts, is the development of drought-resisting varieties of plants.

Mr. F. M. Howlett, in his paper, termed "Chemical Entomology," stated that insects are usually easy to influence by one sense, and one alone. In the case of one small fly a small trace of *iso*valeric aldehyde will bring many thousands of them to a place in a short time, though none were present before. Among the fruit-flies, the maggots of which are found in many fruits, the scent is so well developed and so distinct that each species seems to be attracted by a different smell.

Dr. Coleman, of Bangalore, read two papers on the black rot of coffee, and the "koleroga" disease of the areca palm. He thinks that it is likely that by treatment with Bordeaux mixture black rot of coffee can be checked. The second paper, on the areca palm disease, told the story of one of the very few successful campaigns in India against a destructive disease of the betel nut, which threatened the industry in some districts of Mysore.

In the Physics Section, the contributions of the chairman, Mr. C. V. Raman, on the velocity of restitutions after impact between various elastic materials and his speculations as to the type of air disturbance involved in the click of two billiard balls, aroused a good deal of interest. Among other papers were:—Dr. D. N. Mallik, on a type of electric discharge in the neighbourhood of a permanent magnetic pole; Dr. Royds, on spectrum series; Mr. C. Michie Smith, on the climate of Kodaikanal; Mr. S. Appaswami, the Madras Physics Department, the motion of violin strings; Mr. J. Evershed, of the Kodaikanal Observatory, on sun-spots and prominences. In all twelve papers were read and discussed.

In the Chemical Section Dr. P. C. Ray, of Calcutta, presided, and fourteen papers were communicated. The chairman opened the proceedings by giving a brief account of his recent work on the use of nitrites and chloroacetic acid in causing tautomerisation in certain thio-derivatives, and in a further paper discussed the action of alkyl iodides on dimercuriammonium nitrite. Prof. J. J. Sudborough dealt with alcoholysis, and also gave an account of work which he was carrying on with his students on the replacement of sulphonic acid groups in aromatic compounds during halogenation. Prof. Neogi and Mr. Chowhari described their experiments on the conversion of aliphatic nitrites into nitro-compounds. Prof. Joseph, of Colombo, gave an account of his and Mr. W. N. Rae's work on chromium phosphate. Profs. Gibson and Simonsen communicated two papers on stereochemical problems, in one of which the resolution of β-naphthotetrahydroquinaldine was described.

The Section of Zoology was presided over by Dr. N. Annandale, of the Indian Museum. The two most important papers before the meeting were those on the autotomy and regeneration of the tail in the house-gecko and on the zoanthids of Madras. They were by Prof. W. N. F. Woodland, of Allahabad, and Prof. K. Ramunni Menon, of Madras, respectively.

Dr. C. A. Barber, of Coimbatore, the chairman of the Botany Section, in his opening address, took sugar and the sugar-cane as his subject. The history of the industry in Java was studied in detail as showing a fine example of the application of scientific work to sugar-cane problems. The question whether India (which now imports nearly a million tons each year) could hope to become an exporting country was answered in the negative. It was shown that India was a quarter of a century behind Java, and was, in fact, only just commencing scientific sugar-cane work. Recent work in India was discussed, especially the efforts to improve the local varieties and the raising of seedling sugar-canes in the newly founded cane-breeding station at Coimbatore. Mr. F. R. Parnell, of Coimbatore, read a very interesting paper on some Mendelian characters of the paddy plant. Dr. W. Burns and Mr. S. H. Prayag described experiments on inarching inflorescence of the mango when a union was made and the fruit of one tree was thus borne on a tree of another variety. Prof. P. F. Fyson discussed the phanerogamic flora of the patana regions of the Nilgiris and Pulney Hills, pointing out the affinities with Ceylon, the Vehasia, and Himalayan regions.

Other papers were by Mr. M. O. Parthasarathy Iyengar, on the defoliation of some Madras trees; by Dr. C. A. Barber and Mr. D. Vekataraman, on the depressed habit in the sugar-cane; and Mr. C. Tadulingam on the Madras flora.

The meeting of the Geological Section was presided over by Dr. W. F. Smeeth, State Geologist of Mysore, who read a paper on the geological history of southern India, and gave an account of the character and distribution of the various components of the great archæan complex as developed in Mysore. Babu H. C. Das Gupta described an occurrence of crystalline limestone from the Daltonganj coalfield. Mr. E. Masillamany dealt with certain basic dykes in Travancore, including gabbro, dolerites, and norites, the petrology and field relationships of which were discussed.

The Section of Ethnography met under the chairmanship of Mr. H. V. Nanjundayya, whose address was on some aspects of ethnographic work. He said that the lower castes are aspiring to a higher status; Gotras are claimed, and customs which enable the observer to recognise the lower caste are suppressed. According to legend the Castes claim descent from God, but actually Castes are considered to be tribal distinctions. By the adoption of Samskaras of higher castes and practising them for several generations higher status is claimed, and renders investigation a matter of considerable difficulty. Dr. Annandale, in a paper entitled "Anthropometric Notes of Calcutta Eurasians," dwelt on the importance of regarding physical anthropology from a zoological point of view. He expressed the opinion that the primary classification of the races of man should be conducted on exactly the same lines that would be adopted in investigating those of any other species. Unfortunately the characteristic features of the different human races were still very imperfectly known, and existing systems of anthropometry were unsatisfactory in many respects. He had no new system to expound, but laid stress on the value of a large series of photographs taken on a definite system and illustrating as far as possible the actual external structure. He put forward a proposal for a photographic survey of the people of Calcutta, and especially of those of mixed race. Dr. Ketkar, of Bombay, read a paper on Indian sociology as a theoretical and applied science. Dr. S. C. Roy read a paper on totem worship amongst the Oraons. The author showed that Kachchapa (tortoise) must have given rise to the Gotra, now known as Kasyapa. The existence of a wooden figure of the tortoise and pig seemed to bear out the theory suggested by him. Other papers in this section were contributed by Mr. Gopinatha Rau, on viragals and mastigals—the memorial stones set up in honour of heroes who fell in battle and women who died for their husbands; Mr. L. K. Ananta Krisna Iyer read papers on prehistoric monuments in Cochin, and on the Vettuvans of North Malabar.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The subject proposed for the Adams Prize Essay for the period 1915–16 is "The Course of Evolution of the Configurations possible for a Rotating and Gravitating Fluid Mass, including the Discussion of the Stabilities of the Various Forms." The investigation of the forms that can be assumed by a mass of gravitating fluid endowed with motion of rotation was initiated by Newton with reference to the figure of the earth, developed by Maclaurin, Clairaut, and Laplace, and extended by Jacobi. It was consolidated in Lord Kelvin's hands, as an example of the doctrine of the dissipation of energy, into a single problem illustrating the course of evolution of stellar and planetary systems. The sequence of the forms that can be assumed by a rotating fluid mass, first announced partially by Lord Kelvin, has been extended and systematised by the work of Poincaré, and expanded in new directions by Sir G. H. Darwin and other investigators. Further elucidation of this succession of forms, especially in the direction in which a tendency appears for the mass to divide into separate parts, is desirable, in view of its possible bearing on the modes of evolution of double and variable stars and the interpretation of other remarkable celestial objects. The case in which the mass is in whole or in part in the gaseous state may also present opportunities for investigations possessing astronomical interest. Some contribution to the further theoretical development of this subject is asked for. The prize is open to the competition of all persons who have at any time been admitted to a degree in the University. The value of the prize is about *220l.* The essays must be sent to the Vice-Chancellor on or before the last day of December, 1916.

OXFORD.—On March 9 Congregation approved the appointment of Dr. H. M. Vernon, fellow of Magdalen College, as University lecturer in chemical physiology for four years, in succession to Dr. Ramsden, fellow of Pembroke College, who has been elected to the post of Johnson professor of biochemistry at Liverpool University. Congregation has also approved the re-appointment of Dr. J. W. Jenkinson, Exeter College, as University lecturer in comparative and experimental embryology for five years.

The Hebdomadal Council has lately put out an important statement dealing with the financial position of the University as affected by the war. It is estimated that, after allowance has been made for a considerable saving in the conduct of examinations, the statutable and necessary expenditure for the current year will exceed the ordinary receipts by at least *15,000l.* This deficit may be reduced by various expedients, such as savings in respect of grants, and the suspension of repayment of loans (should the necessary powers be granted by the Bill now before Parliament), to a sum of about *6000l.* The remainder may ultimately have to be made good by borrowing; but before the necessity for this step arises, the situation will, it is hoped, be to some extent relieved by the voluntary contributions of many of the officers and other members of the University.

IT is stated in *Science* that Dr. William J. Mayo and Dr. Charles H. Mayo, of Rochester, Minn., the distinguished surgeons, have decided to establish a *200,000l.* foundation for medical research and to place the foundation, under certain restrictions, in the hands of the University of Minnesota.

We have received from the University Press of Liverpool a copy of a report of the Senate of the University upon research and other original work by members of the University published or completed during the session 1913-14. The titles of papers and other publications are arranged under faculties and numbered consecutively, those published during the session being placed first. The abbreviations adopted in the titles of scientific periodicals are those used in the "International Catalogue of Scientific Literature."

At a meeting held in New York, on January 27, in connection with the inauguration of the Engineering Foundation, it was announced, says *Science*, that the initial gift had been made by Mr. Ambrose Swasey, past-president of the American Society of Mechanical Engineers, who has given 40,000*l.* for "the advancement of the engineering arts and sciences in all their branches to the greatest good of the engineering profession and for the benefit of mankind." The administration of the fund will be entrusted to the Engineering Foundation Board, elected by the trustees of the United Engineering Society. From the same issue of our contemporary we learn that the sum of 8000*l.* has been given by Mr. Andrew Carnegie to Allegheny College for a chemical laboratory to replace that recently destroyed by fire; and that Mr. Patten, who has already given 100,000*l.* to the medical school of Northwestern University, has now added 5400*l.* for scholarships.

The Department of Agriculture and Technical Instruction for Ireland has issued particulars of the summer courses of instruction for teachers to be held this year in Ireland. The courses, with the exception of that in rural science for national school teachers to be held in August, will begin on July 6 and close on July 30. Among the courses arranged may be mentioned that on chemical manufactures intended for teachers of chemistry in technical schools who hold a university degree in chemistry or equivalent qualification; and those on the testing and working of electrical machines, practical mathematics and mechanics, hygiene and sick nursing, experimental science, and rural science (including school gardening). Teachers who attend the courses from the beginning to the end are allowed a sum of 3*l.* 10*s.* towards their expenses while living at the centre; and those who travel more than twenty miles to the centre of instruction are allowed, in addition, third-class railway fare for one return journey from the railway station nearest their school.

The metallurgy laboratory for the mechanical testing of metals and alloys, presented to the Sir John Cass Technical Institute by the Worshipful Company of Goldsmiths, was formally opened by Sir Boverton Redwood, Senior Warden of the Goldsmiths' Company, on March 3, in the unavoidable absence owing to illness of Sir Robert Mowbray, Prime Warden of the company. The work of this new laboratory, which will form an important extension of the metallurgy department of the institute, will be carried on from the metallurgical rather than from the engineering point of view, and will be closely related to the instruction already provided in connection with the metallographic and pyrometric examination of metals and alloys, including iron and steel and the materials used in the motor-car industry and in the construction of aeroplanes, high-speed machinery, and the like. Previous to the opening of the laboratory, Sir Boverton Redwood distributed the prizes gained by students of the institute during the past session, and delivered an address, the chair being taken by Sir Thomas Elliott, who has succeeded the late Sir Owen Roberts as chairman of the governing body. In speaking of the work of the institute, Sir Boverton Redwood said that such work as is being done was never more needed than at the present time. Among other things which the war has done for us, it has shown us that there must be a much more intimate relation between science and industry in this country; and it is to be hoped that the students will avail themselves to the fullest possible extent of the facilities which the institute affords them of becoming better qualified to discharge the duties with which they will be entrusted. If one result of the war is to bring about a better recognition of what is needed in this direction we shall have some compensation for the sacrifices which we are making. In referring to the courses on fuel and power, arranged at the institute, Sir Boverton pointed out the all-important part that is now being played by liquid fuel both in the Navy and on the field of battle on land, especially in connection with the "all-oil boilers" now in use on the battleships of the *Queen Elizabeth* class, all of which are driven solely by oil fuel.

SOCIETIES AND ACADEMIES.

London.

Geological Society, February 19. Annual General Meeting.—Dr. A. Smith Woodward, president, in the chair.—Dr. A. **Smith Woodward**: Presidential Address. The progress of geology depends on so many lines of research, that each specialist does well at times to pause and consider the relation of his own small part to the whole. The president therefore reviewed some results of his study of fossil fishes in their bearing on stratigraphy. However necessary detailed lists of species of fossils might be for comparative work with sediments in restricted areas, he hoped to show that in dealing with broader questions names were really of small importance. Certain general principles had been arrived at, which would serve for all practical purposes. Each successive great group of fishes began with free-swimming fusiform animals, of which some passed quickly into slow-moving or grovelling types, while others changed more gradually into elongated or eel-shaped types. There was also a constant tendency for the primitive symmetry of the parts of the skeleton in successive members of a group to become marred by various more or less irregular fusions, subdivisions, and suppressions. Some of the successive species of each group increased in size, until the maximum was reached just before the time for extinction. These and many other more special inevitable changes had now been traced in most groups, and the various geological dates at which they occurred had been determined by observations on fossil fishes from many parts of the world. Even fragments of fish-skeletons, too imperfect to be named, were often therefore of value for stratigraphical purposes.

Royal Anthropological Institute, February 23.—C. **Dawson**: Flint implement cultures of the Sussex Ouse Valley, with special reference to the Piltdown gravel-spreads and deposits. Among the exhibits were originals and casts of the rude iron-stained Palæolithic implements discovered at Piltdown. They are really large flakes worked on one face, rather after the Chellean culture. The other face is unworked, like those from the Mousterian cultures. The large elephant-bone implement trimmed to a point like a stake at one end, and roughly rounded by cuts at the other end, was exhibited. By comparison it is found that this implement is made from one of the thigh-bones of a large species of elephant not yet discovered later than Late Pliocene or Early Pleistocene ages. Mr. Dawson specially dealt with the "columnar" or "prismatic" flints of which the gravel-spreads of the neighbourhood is mainly composed. Among these flints have been discovered many of the Eolithic type forms and some *rostro-carinate* varieties.

Zoological Society, February 23.—Prof. E. W. MacBride, vice-president, in the chair.—Miss Kathleen **Haddon**: The methods of feeding and the mouth-parts of the larva of the glow-worm. External digestion is a phenomenon of fairly wide occurrence among various groups of insects, and the mouth-parts are in some cases specially adapted to this purpose. The larva of the glow-worm (*Lampyris noctiluca*) feeds on snails, of which it leaves no residue but an empty shell; it is unlikely that there is any preliminary anæsthetising as asserted by Fabre. The mandibles of the larva bite up the food and each mandible is pierced by a fine tube, through which a dark-coloured fluid is exuded. The bases of all the mouth-parts are covered with fine outwardly directed hairs, which are bathed in the juices of the snail whilst the larva is feeding; the juice is sucked into the œsophagus, which is extremely narrow, by the action of a pharyngeal pump similar to that found in other sucking insects.—Dr. J. F. **Gemmill**: Ciliation of asterids and the question of ciliary nutrition in certain species. The arrangement of the ciliary currents on the various surfaces of four widely different species of starfishes is described in detail. This arrangement is constant for all individuals in each of the species, and, except as regards external surfaces, is practically the same in all the species. Everywhere the arrangement is shown to be explicable by physiological needs. Ciliation in the perihæmal spaces is demonstrated.—R. E. **Turner**: New fossorial wasps. The wasps were mostly collected while on a recent expedition to Australia, but include a few received from the Queensland and West Australian Museums.—Lt.-Col. J. M. **Fawcett**: A collection of Heterocera made by Mr. W. Feather in British East Africa. The bulk of the species was taken at light during damp evenings, and perhaps the most interesting capture is that of a specimen of the celebrated *Actias besanti*, Rebel, a large and most beautiful Saturnid moth distinguished by its extremely long tails. This is a well-known rarity of the "first water," and only four specimens were previously known to have been taken, two of which are in the British Museum and two in Germany. Besides the forms described as new species, there are a good many previously described forms not as yet represented in the National Collection, which of itself is evidence of their rarity. Mr. Feather is to be especially congratulated upon the very perfect condition of his specimens and the very accurate record he has kept of the dates of their capture and the localities. Many of the forms dealt with in this memoir were only previously known to science through specimens brought from tropical West Africa, and were previously unrecorded from British East Africa. But this region still remains to be properly worked out, and a great field of research is in store for anyone who can find time to take the matter in hand.

CAMBRIDGE.

Philosophical Society, February 22.—Prof. Newall, president, in the chair.—Dr. **Arber** and R. H. **Goode**: Some fossil plants from the Devonian rocks of North Devon. In addition to the first record of an obscure plant specimen from the Lynton beds, some six other types are described from the Baggy or Cucullæa beds of the Upper Devonian. One of these, Xenotheca, is an entirely new fructification, consisting of thecæ with eight teeth, terminating the branches of a dichotomously branched axis. These thecæ are regarded as being probably of the nature of cupules. *Sphenopteridium rigidum*, Ludw., is recorded for the first time from Britain. The other fossils can only be identified generically as Sphenopteris sp., Telangium sp., Knorria sp., and Cordaites? sp. These are the oldest (in a geological sense) fossil plants of terrestrial habit yet known from England.—H. Hamshaw **Thomas**: Some new and rare Jurassic plants from Yorkshire—the male flower of *Williamsonia gigas*, L. and H. The female strobili of this species were described many years ago, but the male sporophylls have remained a matter for speculation. When examining the specimens in the Yates Collection in the Museum of Natural History at Paris, the author found an example showing an undoubted male flower of the same general type as *Williamsonia spectabilis*, Nath. Though not attached, there were strong reasons for regarding it as belonging to the species *W. gigas*. The flower was briefly described, and compared with other species in the genus.—Dr. C. E. **Moss**: Nomenclature of *Pteris aquilina*.

DUBLIN.

Royal Irish Academy, February 22.—Count Plunkett in the chair.—J. A. **McClelland** and J. J. **Dowling**: Some electrical properties of powders in thin layers. A very thin layer of a conducting powder, such as graphite, is formed on the surface of an insulator, usually paraffin. Tinfoil strips a few centimetres apart are fastened on the layer so as to make good electrical connection with it, and the conductivity of the layer measured. The strips being earthed, a high potential is applied to a plate parallel to the layer, a few millimetres of paraffin intervening between the plate and the layer. The conductivity of the layer is then found to be very much increased. The points of resemblance and of difference between this effect and the coherer effect are discussed in the paper, and the laws obeyed by the conductivity are studied in detail.

PARIS.

Academy of Sciences, March 1.—M. Ed. Perrier in the chair.—The President announced the deaths of George William Hill and G. F. J. Auwers, correspondants in the section of astronomy.—E. L. **Bouvier**: The adaptative forms of *Scyllarus arctus* and the post-larval development of Scyllarus.—Haton de la **Goupillière**: The sums of like powers of integral numbers.—J. **Guillaume**: Observations of the Mellish comet made at the Observatory at Lyons. Six positions given for February 20, 23, 25, and 26. The comet appeared as a circular nebulosity, diameter about half a minute of arc, with faintly marked excentric nucleus. Was about the 11th magnitude.—M. **Coggia**: Observations of the Mellish comet made at the Marseilles Observatory. Positions given for February 20, 23, and 25. W. **Sierpinski**: A curve of which any point is a point of ramification.—André **Brochet**: The catalytic reduction of indigo. In slightly alkaline solution indigo is rapidly reduced by hydrogen in presence of suspended metallic nickel. The indigo white obtained has the advantage of being free from saline impurities.—J. **Caralp**: A Permian melaphyre in the Ariège Pyrenees.—Marin **Molliard**: Free nitrogen and the higher plants. Experiments are described proving that the radish, grown aseptically, is incapable of assimilating atmospheric nitrogen.—Georges A. Le **Roy**: The use of low temperatures in toxicological analysis. The fine subdivision of tissues is facilitated by a preliminary solidification by freezing.

BOOKS RECEIVED.

The Carnegie United Kingdom Trust. First Annual Report. Pp. 34. (Edinburgh: T. and A. Constable.)

Memoirs of the Geological Survey of India. Palæontologia Indica. Vol. v. Memoir No. 2. The Anthracolithic Faunæ of Kashmir, Kanaur, and Spiti. By Dr. C. Diener. Pp. 135+plates xi. (Calcutta: Geological Survey; London: Kegan Paul and Co., Ltd.)

Twenty-seventh Annual Report of the Purdue University Agricultural Experiment Station, Lafayette, Indiana. Pp. 88. (Lafayette: Haywood Publishing Co.)

Clark University, Worcester, Mass. Register and Twenty-seventh Official Announcement. Pp. 112. (Worcester, Mass.: Clark University.)

Memoirs of the Geological Survey, Scotland. Explanation of Sheet 74. The Geology of Mid-Strathspey and Strathdearn. By L. W. Hinxman and E. M. Anderson. Pp. v+97. (London: H.M.S.O.; E. Stanford, Ltd.) 2*s*. 6*d*.

Memoirs of the Geological Survey, England and Wales. Explanation of Sheet 269. The Geology of the Country around Windsor and Chertsey. By A. Dewey and C. E. N. Bromehead. Pp. vi+123. (London: H.M.S.O.; E. Stanford, Ltd. 2*s*. 6*d*.

DIARY OF SOCIETIES.

THURSDAY, March 11.

Royal Society, at 4.30.—Contributions to the Study of the Bionomics and Reproductive Processes of the Foraminifera: E. Heron-Allen.—The Occurrence of an Intracranial Ganglion upon the Oculomotor Nerve in Scyllium Canicula, with a suggestion as to its Bearing upon the question of the Segmental Value of certain of the Cranial Nerves: G. E. Nicholls.—Experiments on the Restoration of Paralysed Muscles by Means of Nerve Anastomosis. III.—Anastomosis of the Brachial Plexus, with a consideration of the Distribution of its Roots: Prof. R. Kennedy.—On the Mechanism of the Cardiac Valves. A Preliminary Communication: A. F. S. Kent.

Institution of Electrical Engineers, at 8.—Electric Cooking, mainly from the Consumer's Point of View: W. R. Cooper.

Child Study Society, at 6.—*Discussion:* The Care and Development of the Child—during School Age—Treatment Centres and their Possibilities: Miss Margaret McMillan.—Care Committees: Mrs. Evelyn.

FRIDAY, March 12.

Royal Institution, at 9.—Back to Lister: Sir R. J. Godlee.

Physical Society, at 8.—(1) The Estimation of High Temperatures by the Method of Colour Identity: (2) The Unit of Candle-power in White Light: C. C. Paterson and B. P. Dudding.—The Relative Losses in Dielectrics in Equivalent Electric Fields, Steady and Alternating (R.M.S.): G. L. Addenbrooke.

Malacological Society, at 8.—*Helicella crayfordensis*, n.sp. from the Pleistocene deposits of S.E. England: A. S. Kennard and B. B. Woodward.—Further Notes on Radulæ: the Rev. E. W. Bowell.—The Editions of Swainson's "Exotic Conchology": A. Reynell.

Royal Astronomical Society, at 5.—Double Stars Measured at the Cape: J. Voûte.—Comet Westland: E. H. Beattie.—A General Solution of Hill's Equation: E. Lindsay Ince.—Note on the Comparison of Two Plates of the Same Region in the Vatican Zones of the Astrographic Catalogue: Ethel F. Bellamy.—*Probable Papers:* The Dynamics of a Globular Stellar System. II.: A. S. Eddington.—The Secular Acceleration of the Moon's Mean Motion, as Determined from the Occultations in the Almagest: J. K. Fotheringham and Gertrude Longbottom.—Micrometrical Measures of Double Stars made in 1914: Rev. T. E. R. Phillips.

SATURDAY, March 13.

Royal Institution, at 3.—Recent Researches on Atoms and Ions: Sir J. J. Thomson.

MONDAY, March 15.

Aristotelian Society, at 8.—The Philosophy of Values: Dr Tudor Jones.

Victoria Institute, at 4.30.—The Determination of Easter Day: Dr. A. M. W. Downing.

Royal Society of Arts, at 8.—House Building: M. H. Baillie Scott.

TUESDAY, March 16.

Royal Institution, at 3.—The Belief in Immortality among the Polynesians Sir J. G. Frazer.

Royal Statistical Society, at 5.15.—The Cost of the War: E. Crammond.

Illuminating Engineering Society at 8.—*Discussion:* The Marking and Rating of Lamps and the best methods of specifying their Illuminating Value.

Mineralogical Society, at 5.15.—The Dispersion of Adularia from St. Gothard, Felspar from Madagascar, and Moonstone from Ceylon: Dr. S. Kôzu.—The Meteoric Stone of Launton, Oxfordshire: Dr. G. T. Prior.

WEDNESDAY, March 17.

Institution of Electrical Engineers, at 7.45.—Students' Section Some Experiments on the Induction Generator: W. H. Date.

Royal Society of Arts, at 8.—The Industrial Uses of Coal Gas: H. M. Thornton.

Royal Meteorological Society, at 7.30.—The Meteorology of the Sun: Dr. W. Geoffrey Duffield.

Entomological Society, at 8.

Royal Microscopical Society, at 8.—A New Mitotic Structure Disclosed as the Result of New Technique: E. J. Sheppard.—Notes on the Structure of Tests of Fresh-water Rhizopoda: G. H. Wailes.

THURSDAY, March 18.

Royal Society, at 4.30.—Bakerian Lecture: X-rays and Crystals: Prof. W. H. Bragg.

Royal Institution, at 3.—The Form and Structure of the London Basin: Dr. A. Strahan.

Royal Society of Arts, at 4.30.—The Indian Army: Lieut.-Colonel A. C. Yate.

Institution of Mining and Metallurgy, at 8.—Annual Meeting.

FRIDAY, March 19.

Royal Institution, at 9.—The Modern Piano Player—Scientific Aspects: Prof. G. H. Bryan.

Institution of Mechanical Engineers, at 8.—The Chemical and Mechanical Relations of Iron, Cobalt, and Carbon: Prof. J. O. Arnold and Prof. A. A. Read.

SATURDAY, March 20.

Royal Institution, at 3.—Recent Researches on Atoms and Ions: Sir J. J. Thomson.

THURSDAY, MARCH 18, 1915.

SCIENCE AND INDUSTRY.

WHATEVER the political changes resulting from the present European struggle may be, it is certain that the industrial and economic changes will be of an equally striking and revolutionary character. Those of us who can remember Europe as it was before the war of 1870 and now look back upon the forty-five years which have elapsed since that fateful conflict, cannot fail to realise that the transfer of Alsace and Lorraine from France to Germany was an event of vanishing importance compared with the gigantic disturbance which has been brought about in Europe and throughout the world by the unprecedented industrial expansion of Germany which has taken place during the same period. Some idea of the stupendous magnitude of this rapid development in the matter of chemical industries may be gathered from the figures cited by Prof. Percy Frankland in a lecture recently delivered before the Society of Chemical Industry, and of which an abstract was published in our last issue. The magnitude and variety of the German chemical industries are surpassed in wonder only by the rapidity with which they have developed from the very small dimensions which they possessed prior to the war of 1870. Still more remarkable, however, is the fact that a similar investigation of many other activities, such as the textile, mining, metallurgical, electrical, agricultural, and shipping industries, would reveal developments almost equally startling.

It is this great industrial prosperity which has rendered possible the vast and amazing effort to secure German supremacy in Europe of which we are the spectators to-day. The older ruling class in Germany had but little interest in commerce and industry as such but it had the sagacity to see that its dreams of empire could only be realised by fostering industrial and commercial enterprise in every possible way. The ruling class, at bottom despising the tradesman in every shape and form, has had the wisdom to recognise that its prejudices must be concealed, and that everything must be done to put the wealth-producing classes into the most favourable position for competing with the similar classes of rival countries. The rulers of Germany had the discernment to apprehend that one of the most important weapons in that competition was education, and that education must not be of a uniform, stereotyped, and antiquated pattern, but must be elastic and carefully adapted to the needs of each particular class of the community. Education of every kind has been promoted, not only by pecuniary endowment but by the granting of exceptional privileges, both material and social, to those possessing attainments of a higher order, *e.g.*, by the reduction of military service to a period of one year only in the case of all boys who have passed beyond a certain school standard. Research of every description, not only in science but in every other branch of learning, has been fostered to an extent quite unknown in any other country.

This has resulted in Germany becoming beyond all other countries the land of the expert, "a country of damned professors," as Lord Palmerston once called it in the language of a bygone day. It is the country in which every man is proud of knowing his own particular business, nor will he be listened to on any other subject. In England, if a man succeeds in catching the public ear, his utterances on every conceivable subject will be accepted by thousands. Nothing is more astounding than the faith which large sections of people put in the omniscience of our prominent men. We can well remember how Mr. Gladstone, who had adopted the plan of replying by post-card to his innumerable inquirers, was once not only asked for his opinion on the efficacy of vaccination, but actually thought fit to express it. Other and much more recent examples of the faith reposed in self-constituted oracles amongst us will occur to most of the readers of NATURE. In Germany knowledge is so widely diffused, and it is so generally understood that real knowledge can only be attained by years devoted to some kind of research, using the word in its widest sense, that most educated Germans are aware that any given individual, however brilliant, can only be an authority in a comparatively limited field of knowledge. In Germany, therefore, it is only the opinion of the accepted expert that counts. If Germany is the land of experts, England is undoubtedly the land of amateurs, and, owing to the extraordinary genius of our countrymen, it is quite true that in the past most striking achievements must be credited to amateurs. Priestley and Cavendish were amateurs, as were Darwin and many others of high distinction that could be mentioned, but they assuredly became experts also in fact, if not in name.

Science is the dynamic and creative force in industry, and it is only through scientific discovery that industry can rapidly advance. It is this fact which has been freely recognised in Germany, whereas it is from this fact that the great majority of Englishmen instinctively shrink. The German believes in shaping his practice on theory, whilst the Englishman moulds his practice on tradition and instinct, and avoids all theoretical considerations as far as he can. In the earlier stages of chemical industry, and whilst chemical science was in a rudimentary state, much was accomplished by the eminently practical instincts of Englishmen, but with the increasing complexity and refinement of the problems involved, progress has only become possible through profound knowledge gained by unceasing investigation directed by theoretical considerations, and it has been during this later phase that such rapid strides have been made by the chemical manufacturers of Germany.

Of all the chemical industries, the one which depends most entirely on a far-reaching knowledge of chemical theory is that of Synthetic Organic Products (Artificial Dyes, Drugs, Perfumes, etc.), for it would certainly require instincts of even a super-British order to be capable of devising methods for the economic manufacture of such commodities as indigo, adrenalin, and ionone! It is not surprising, therefore, that this branch of chemical industry is almost entirely in German hands, whilst the other branches are, for the most part, gravitating in the same direction.

It is not the unexpected which has happened, for that the neglect of science by our manufacturers would inevitably lead to this result has been consistently preached by British chemists during the past forty years. The irony of the situation lies in the fact that this relative failure of our chemical industries to expand has gone on *pari passu* with a great increase in our output of chemical research, the quality of some of which has been of a particularly brilliant kind. That this capacity for research has remained almost wholly divorced from industry is due to the British manufacturer, who has almost entirely failed to attract into his works the more brilliant chemists trained in this country. The remuneration and prospects offered are in general of such a disadvantageous character that they cannot be entertained excepting as a last resort. It is, moreover, the absence of any prospect of reasonable remuneration in industrial chemistry that greatly limits the study of chemistry as a profession in this country. The Government and the municipal corporations, in their capacity as employers of chemists, are no better than the manufacturers.

That the British manufacturer is himself in general entirely ignorant of chemistry is the result of our antiquated system of education. Whatever school he may have attended will almost certainly have been presided over by a headmaster reared in traditions of medievalism, with the result that he probably imbibed the idea that the study of science would relegate him to an inferior position in the school; at the university, unless he were reading either classics or mathematics, he would not, even at the present day, be in the swim, and would find little or no favour with the head of his college, whilst until recently he would have been of no account at all. He would then pass into his hereditary position in the factory knowing nothing of the science upon which the business is based, and incapable of understanding even the alphabet of the language of the chemical officers it may possess. What wonder, then, that he distrusts and fears these chemists, who are the brain of his business, and that he prefers to confide in the engineers, who are but little less ignorant of chemistry than himself.

That this is the typical situation in the chemical industries of this country was revealed in a particularly significant manner in the House of Commons only a few nights ago, when the Government scheme of "British Dyes, Limited," was under discussion. At the conclusion of the debate, the Parliamentary Secretary of the Board of Trade said that the man who was conversant with the science and practice of dye manufacture was unfit to go on the directorate, because, as he would know something of the business, the whole of the other directors, being but business men, would be in his hands. We are thus authoritatively informed, from his seat in Parliament, by the Secretary of the very Board which is entrusted with the duty to look after the commercial and industrial interests of the country, that the first qualification of a director of a public company subsidised by the Government is that he must know nothing of the business in which that company proposes to engage. Surely the report of this speech must have escaped the astigmatic eye of the official censor, or he would have passed his pencil over a piece of information so gratifying and useful to the enemy! As Prof. Armstrong, in commenting on this utterance in a letter to the *Morning Post* on Saturday last, very truly remarks: "Our fate as makers of dyes is sealed. We, the taxpayers, can do nothing but look on while our million and a half is squandered by directors who now confessedly are to be men without business knowledge of the industry they control."

If we would take advantage of the great opportunity which this war affords for industrial and economic rearrangements, it is imperative that the ruling classes in this country should no longer continue in their present state of semi-education which passes as culture, and which permits them to go through life with little or no understanding of the vital importance of science to the State. If after the war we are to recover some of the chemical industries which we have lost, and even maintain those which we still possess, it is essential that the individual undertakings should be controlled by men who have a real and expert knowledge of the business in which they are engaged, and that our legislators should have had sufficient scientific education to enable them to understand such problems connected with these industries as may be brought before them. The experience of the past thirty years points unmistakably to the conclusion that industrial success is becoming more and more dependent upon the co-ordination of industrial effort, and the embarrassing position in which we find ourselves at the present moment, in respect of the supply of a number of chemical products, is largely attributable to the almost entire absence of any such organisation. In both France and Germany we understand that councils of experts have been appointed to inquire into the effects of the war on the chemical industries of these countries, and to report to their respective Governments as to what legislative measures are desirable for promoting their welfare. As the present crisis is on a scale which we trust may never recur in the history of the world, so the opportunity for discarding mischievous traditions, effete ideas, and clumsy methods of procedure is of such an altogether exceptional character that it is to be hoped we shall not allow it to pass unutilised through ignorance, lethargy, or divided counsels.

THE CHEMISTRY OF FOOD PRODUCTS.

Food Products. By Prof. H. C. Sherman. Pp. ix + 594. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 10*s*. net.

APART from the analytical side, chemistry in its application to food products is a neglected science in this country in comparison with the activity which exists in America. The neglect, however, has been, in the main, in official and public circles, as several of the British food manufacturers of repute have availed themselves of scientific help for some years past, and it may be claimed that the high—not to say world-wide—repute of the products of some of these firms is to some extent due to the resource of, as well as the control exercised by, their scientific staff. In the United States, legislation has been very largely the cause of the awakening of the public interest in its food, and in this connection the name of Dr. H. W. Wiley will be remembered with gratitude by present and future generations. Whatever the cause, the development of the investigation of the composition and value of food products has been exceptionally rapid during the past few years: it is manifested by such outward signs as the foundation of university chairs in food chemistry in America, and the publication of informative text-books.

As the moment is ripe for reform, the wisdom of founding such a chair at our own Imperial College of Technology may be urged: there is much to be done, for example, in educating the public as to the food value of many low-priced products from our Colonial Empire, which are at present neglected, and in showing manfacturers how to make better use of the available raw material.

Dr. H. C. Sherman, who occupies the chair of food chemistry at Columbia University, has produced an exceptionally informative book, in which he combines an account of the production and preparation of the various food products for the market, with statistical data, details as to their chemistry and physiology, and an outline of the latest scientific research and opinions.

The book also contains a large number of up-to-date tables giving the food values, protein content, and mineral constituents of all sorts of foods, and is, indeed, replete with information of every kind, so that it will be indispensable to every food chemist and manufacturer. All the principal food products are dealt with in turn, each chapter being concluded with a list of references to the literature. Though much of the information given is outside the ordinary scope of the college trained chemist, it corresponds exactly with the practical details which the actual worker requires, and we do not remember to have seen this given so succinctly anywhere else. The more advanced scientific sections are equally satisfactory, so that current views are expressed without undue dogmatism: this is especially the case in the more physiological sections.

A good deal of space is devoted both in an appendix and elsewhere to the rules and regulations for the enforcement of the Foods and Drugs

Act in America. These are of great interest to the British reader in view of the possibility of more drastic food legislation here, though fortunately the sale of inferior food materials is not tolerated to anything like the extent that existed in America. It is commonly understood that the most drastic legislation was necessary there to combat the existing evils, although its severity has to some extent acted in restriction of trade. In any case, such movement here should be official and under the guidance of responsible scientific opinion, and not sponsored by irresponsible "Pure Food Institutions."

The university courses of study are already so crowded that there is no time for the introduction of food chemistry into the degree course, nor, indeed, is such desirable. The would-be chemist, if he is to play his part in building up British industries, must be trained as a chemist first and as a specialist afterwards. Books such as this will be of the utmost service at the stage when the young chemist has to act on his own and to take responsibility. Prof. Sherman has done a great service to his colleagues. From the point of view here developed it is to be hoped that he will compress rather than enlarge future editions, so that the book may be read and not consulted as a dictionary. E. F. A.

APPLIED BOTANY.

(1) *A Text-book of Grasses, with Especial Reference to the Economic Species of the United States.* By Prof. A. S. Hitchcock. Pp. xvii+276. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 6*s*. 6*d*. net.

(2) *A Manual of Weeds.* By A. E. Georgia. Pp. xi+593. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 8*s*. 6*d*. net.

(1) ALTHOUGH we are disposed to welcome any innovation in the planning of text-books of applied science, we cannot congratulate the author of the work under review on the scheme which he has adopted. He divides his book into two parts, and treats first of economic agrostology, and subsequently, of systematic agrostology. As a consequence, the student who begins the book at the beginning reads of a considerable number of grasses, mostly called by their popular names, and if he be a novice, he must pause at each page to look up, in the systematic part, what these names signify. Moreover, whether he be novice or adept, he will find but little information of real value in the economic section. He will discover how much corn and wheat and barley and other cereals is grown in the United States, and how much each of these crops is worth; that America eats wheaten bread, and that the inhabitants of the "Old World" subsist on wheat, corn, and rice. Beside some useful general information, he will find a chapter on lawns, and a page or two on sand-binding grasses.

It may be that this somewhat discursive treatment is all that is possible in the present stage of "economic agrostology"; but whether it be so or no, we feel convinced that the proper place for it is at the end and not at the beginning of the volume.

Part ii. opens with an account of the morphology of the vegetative and floral organs of grasses. The descriptions are terse and clear, but their value is reduced very materially by the fact that not one figure is given by way of illustration, neither of the vegetative organs nor of the somewhat difficult inflorescence and flower. This is the more remarkable in that the succeeding taxonomic chapters are well and copiously illustrated.

The experience of the reviewer convinces him that it is impossible to teach the systematic botany of grasses unless the student has first mastered thoroughly the floral morphology of typical forms, and doubt may be expressed whether such mastering may be obtained by merely following the written text.

The taxonomical section, which occupies nearly half the book, follows in part the classification adopted by Bentham and Hooker, and, with respect to the "tribes," that of Hackel. The code governing nomenclature is not that laid down in the Vienna rules, but is "The American Code of Botanical Nomenclature." To criticise this decision scarcely becomes a non-American reviewer, but he may express a regret that systematists cannot come to a general agreement which will prevent these games of nine-pins with names. For example, all the gardens of Europe know Pampas grass by the name *Gynerium argenteum*. In this book it is called *Cortaderia argentea,* and no indication is given whether *Gynerium argenteum* is synonymous with *C. argentea,* or whether the latter is another plant under the same common name. Buffon said long ago that it was easier to learn botany than botanical nomenclature. The systematists seem to take a joy in maintaining the truth of the aphorism.

(2) M. Boutroux has insisted recently that sentiment no less than will and intellect must be reckoned with in the psychological make-up of mankind. No one who has fought with weeds, whether in the farm, the garden, or the golf-green will doubt it. The fight was stubborn and its fortunes varied, but whether won or lost, the

weeder left the field with a deep respect for his adversaries: so stubborn is the resistance that they offer, so various are the means by which they evade extermination.

Here they all are, hundreds of them catalogued and described in this book, and although the weeds treated of are those which trouble the American cultivator, the English farmer and gardener will recognise many of his old foes. He will also learn not a little of new ways of fighting them. For America takes its weeds seriously—more seriously even than the good farmer of this country. He tracks them to their lairs in the hedgerows and keeps a sharp look-out on them in his neighbours' plots. He even invokes legislation upon them. He needs be vigilant indeed, for field labour is not cheap or plentiful in his country, and the chief means of combating weeds—constant cultivation—cannot always be practised. We confess to a certain feeling of unmalicious pleasure, like that we have in the misfortunes of our friends, when we saw the weediness of the fields of certain parts of North America. Nevertheless, the American will win in his fight with weeds; for he threatens them with all the resources of organic chemistry. Not only are the sulphates of iron and of copper pressed into his service as weed-killers; but, and more recently, weeds are being attacked with fine sprays of kerosene or crude petroleum.

The author of this manual writes with sureness on her subject. She knows weeds well, describes them admirably, and gives much sound advice on the methods to be adopted for their eradication. In fact, this is the best book yet published on weeds and one that will prove of considerable service to cultivators in this country. High praise must be given also to F. Schuyler Mathews for the excellence of the 385 illustrations. Their value is enhanced by the fact that they face the page of text on which they are severally described.

One suggestion only would we offer in the interest of the busy reader of the book: that a new edition should include an appendix in which the means of control, and weeds controlled by these means, are classified.

LANTERN- AND MICRO-PROJECTION.

Optic Projection Principles, Installation and Use of the Magic Lantern, Projection Microscope, Reflecting Lantern, Moving Picture Machine. By Prof. S. H. Gage and Dr. H. P. Gage. Pp. ix+731. (Ithaca, N.Y.: Comstock Publishing Co., 1914.) Price 3.00 dollars.

THE use of the lantern in one of its many forms has become more and more general. In our younger days it was a great and exceptional treat to see a magic lantern entertainment, but now there are kinematograph theatres in all our main streets, and lanterns for the teaching of history, geography, and science in our schools, so that the younger generation look upon the lantern as a matter of course, and even the poorest of them go (perhaps too frequently) to the picture palaces.

The number of operators using the lantern has thus enormously increased in the last few years, and the lantern is acquiring quite a literature of its own. The volume under review treats the subject very fully, and collects into one volume a large amount of valuable information on every aspect of the subject. It is intended to be available to the ordinary unscientific rule-of-thumb operator, as well as to the manufacturer, and to the unscientific demonstrator or student. To meet the needs of the first of these, plain, practical directions are given in the earlier part of the book for using the direct-current arc, the alternating arc, the miniature arc, the lime-light, etc.; also practical summaries of what to do and what to avoid are added to each chapter, and there are similar practical instructions for using sunlight with a heliostat, for projecting opaque objects, for micro-projection, the kinematograph, and many other applications of the lantern. Presumably with the idea of making each section complete in itself, there is a great deal of repetition in these chapters. This will probably be of advantage to the practical man who is interested only in one form of projection, but it makes this part of the book tedious to read.

In the later part of the book there are many valuable tables and curves giving, for instance, the relations between current, voltage, and candle-power of the different forms of arcs and their distribution of light intensity; also the light and the energy absorption of the various media—glass, water, etc.—that are used in projection apparatus; and the reflecting powers and light distribution of lantern screens.

In the last chapter are some applications to physics. We should like to have seen this further developed; brief as it is, it explains how to demonstrate some beautiful experiments in advanced optics—experiments which are not often shown.

The instructions for adjusting the radiant are somewhat misleading. It is said that it should be placed at the principal focus of the first section of the condenser (§ 55), and it is said that there is a loss of light if the lamp is brought nearer. In almost every case this is not so, a bigger cone of light being embraced; in practice the second lens of the condenser is not made a weak lens, but the lamp is pushed up within the focus of the first lens, and it is very rarely that an operator changes his condenser when he changes his objective, as laid down in § 89.

The only other criticism is that in projecting the rings and brushes in convergent polarised light, the objective does not focus the back *lens* of the second convergent system on the screen, but its back *focal plane*; this mistake is, however, generally made in the optical text-books.

It should be added that there is a useful bibliography and a copious index.

MATHEMATICAL WORKS.

(1) *Elements of Geometry.* By S. Barnard and J. M. Child. Parts i.–vi. Pp. ix + 465. (London: Macmillan and Co., Ltd., 1914.) Price 4*s.* 6*d.*

(2) *A Foundational Study in the Pedagogy of Arithmetic.* By Dr. H. B. Howell. xi + 328. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 5*s.* 6*d.* net.

(3) *Constructive Text-book of Practical Mathematics.* By H. W. Marsh. Volume iii. Technical Geometry. Pp. xiv + 244. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 5*s.* 6*d.* net.

(4) *Algebraic Invariants.* By Prof. L. E. Dickson. Pp. x + 100. (New York: J. Wiley and Sons, Inc.; London, Chapman and Hall, Ltd., 1914.) Price 5*s.* 6*d.* net.

(5) *Plane Trigonometry and Tables.* By G. Wentworth and D. E. Smith. Pp. v + 188. *Trigonometric and Logarithmic Tables.* By G. Wentworth and D. E. Smith. Pp. v + 104. (London: Ginn and Co., 1914.) Price 5*s.*

(1) THIS is not a modified edition of the authors' well-known text-book entitled "A New Geometry for Schools." In form, grouping, method, and to some extent, subject-matter, it differs widely from their former work. The experience gained from eleven years' teaching on modern lines has led them to certain conclusions which they embody in the present volume. To some extent, they revert to older methods, as, for example, in the treatment of parallels, tangents, the early theorems of the second book of Euclid, and the grouping of cognate theorems. In other respects they adopt a more radical position by introducing trigonometrical ratios and sections on solid geometry (mainly numerical) at an early stage. They have compressed an immense amount of matter into a compact form, and the array of numerical and theoretical exercises is almost alarming in its extent.

(2) The science of pedagogy is arousing increasing interest in this country, although, curiously enough, less among those engaged in teaching at our public schools than at primary and other secondary schools. But the literature of the subject has received comparatively few British contributions. The object of the author is, in his own words, to summarise the anthropological, experimental, pedagogical, psychogenetic and phylogenetic resources now available, which bear on the part arithmetic should play in a scientific curriculum. His investigation is fourfold: (1) genetic, (2) psychological, (3) statistical, (4) didactical. Not the least interesting and valuable part of the book is the account of experiments, arranged and conducted by the author on the determination of ability in number apprehension and fundamental processes.

(3) It is strange to pick up a text-book on geometry and fail to find a single diagram before page 150. The explanation lies in the fact that the author believes that each student should, by his own researches, write his own text-book. That such a mode of procedure as is indicated by the plan and structure of this book has been in operation for nearly twenty years is conclusive evidence of the enthusiastic personality of the author: that many teachers, however, could adopt his method seems to us highly improbable. His purpose is to enable each pupil to build up for himself a logical geometrical structure, by the aid of appropriate suggestions made at the right time. The form these are to take and the quality of the work expected of the pupil is set out in great detail. We doubt, however, whether the author will make many converts.

(4) This monograph provides a simple and admirable introduction to the theory of invariants of algebraic forms. It is divided into three parts. The first deals with linear transformation from the point of view of (1) change of axes of reference, (2) projective geometry. Jacobians and Hessians are discussed, the latter in connection with the solution of the cubic and the points of inflexion of a cubic curve. The second treats of algebraic properties, such as weight, annihilators, reciprocity, differential operators, etc. And the concluding section introduces the symbolic notation of Aronhold and Clebsch. Some carefully selected sets of examples are provided.

(5) The form and plan of this text-book indicate that the changes in the teaching of elementary trigonometry have taken place along similar lines on each side of the Atlantic. The practical aspect of the subject is now regarded as requiring chief emphasis in the early stages and the abstract theory is postponed. Considerable space is de-

voted to applications involving only the use of the right-angled triangle; and identities occupy a subordinate position. The final chapter deals with complex quantities, Demoivre's theorem, and applications to analysis. The last hundred pages of the book are taken up with logarithmic and other tables, calculated to five figures. The first-rate quality of the type employed deserves special mention.

OUR BOOKSHELF.

Experimental Studies in Electricity and Magnetism. By F. E. Nipher. Pp. 73. (Philadelphia: P. Blakiston's Son and Co., 1914.) Price 1·25 dollars net.

THIS book consists mainly of descriptions of the author's experimental work, and summarises his reasons for accepting the one-fluid theory of electricity. Photographs of discharges across a spark-gap, and traces on a photographic plate due to discharges over its surface, constitute the major part of the evidence. Much work has been done, and many interesting plates are reproduced, but it is doubtful whether the experiments are quite so conclusive as the author believes. Several novel ideas are introduced, such as the existence of conducting lines or "drainage channels" round the positive or "exhaust" electrode in every kind of discharge, though it might be pointed out that this idea of a well-conducting channel is scarcely compatible with the considerable potential-slope which exists in the positive column of a discharge tube. The suggestion that gravitational attraction is due solely to the "corpuscular nebula" which permeates all matter is also novel; it is used to explain the explosive effect of discharging a Leyden jar through a wire.

Loosely-worded expressions as "the corpuscular nebula is set into a rhythmical vibration" abound, and the phraseology generally is scarcely so precise as that usually found in scientific publications. It is possible that the case made out by the author suffers considerably from the manner in which it is presented, but certainly simpler explanations than those given would seem to suffice for some of the phenomena mentioned. The deflection of a magnetic needle due to a gust of wind might conceivably be due to a magnetic storm produced by the wind, but it would be advisable to see that the oscillation box is hermetically sealed or even evacuated, before accepting the magnetic storm hypothesis!

The Principles and Practice of Judging Live Stock. By Prof. C. W. Gay. Pp. xviii+413. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 6*s.* 6*d.* net.

THIS volume is a very full compendium of all that belongs to a practice which has almost become a fetish in American agricultural colleges. To the student is given a card on which are printed the sections into which a horse, or some other animal, may be divided, and the marks to be awarded to each section. A draught horse, for instance, is divided into forty sections, and, as the marks total to 100, most sections get very small and none very large marks. The marks for some of the most important parts are these, given shortly: hocks, 6; hind cannons, 2; hind fetlocks, 2; hind pasterns, 3; hind feet, 4; hind legs, 4; walk, 6; trot, 4.

Some of us who have tried it would have been exceedingly glad had this volume contained some evidence as to the educative value of the score card, because it may be doubted whether good judges are produced by its use; and because it fails to make sufficient distinction between the good and the supremely good, or the fair and the useless animal. All this, however, is rather a criticism of the system, or at any rate, of the scale of marks.

If the system be admitted good and useful, Prof. Gay's book is also good and useful. It contains good illustrations, descriptions of many breeds, an appendix containing the card marks for different breeds, and much information as to yields of milk, butter, beef, wool, and so on.

J. W.

The Elements of Electro-Plating. By J. T. Sprague. Pp. vii+72. (London: E. F. N. Spon, Ltd., 1914). Price 1*s.* 6*d.* net.

THE publication of this little volume brings home to us the sparseness of literature on the subject of electro-plating. Its publishers have considered it worth while to re-publish, in this form, the intensely practical and well-written chapter dealing with the practice of the electro-deposition of metals which originally appeared in the late Mr. J. T. Sprague's "Electricity: Its Theory, Sources, and Applications." This classic was one of the best books of its kind when originally written, and the chapter on electro-plating was one of the best parts of the book. It is true that it is addressed "rather to experimentalists, students, and general readers" than to those "mainly intent on business considerations," and it is also true that as good electro-plating was done twenty-five years ago as now; yet one cannot but feel that the publishers would have done better to publish a new book than to re-publish an old one when dealing with a practical application of electricity. The reprint bears the new date 1914, and not the date of original publication, but perhaps some of our older readers may be able to make a rough guess at the latter from the clue given by the following passage: "It is impossible to urge too strongly, alike upon the learner and the practical operator, the advantage of keeping in circuit a suitable galvanometer . . . and galvanometers to show current in amperes are now easily obtainable." The book, old as it is, contains valuable directions and recipes, and if, instead of merely reprinting it, the publishers had employed a practical man of to-day to revise and re-write it, they would have deserved our unstinted commendation.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Supposed Horn-Sheaths of an Okapi.

Mr. R. Lydekker, F.R.S., lately directed attention in the columns of Nature to a specimen of the okapi sent home by Dr. Christy from the Congo State, which was stated to be provided with corneous sheaths to its horns, resembling those of an antelope. The specimen has been mounted by Mr. Gerrard, of Camden Town, and is still in his workshop, whilst the skull has been purchased by the Royal College of Surgeons. I have been given the opportunity of examining both the mounted skin and the skull. The skull is of an individual of nearly the same size and age as that presented to the Natural History Museum by the late Captain Boyd Alexander, carefully figured under my superintendence with many other skulls of the okapi in the atlas of my "Monograph of the Okapi," published in 1910 by the trustees of the British Museum. With the new skull acquired by the College of Surgeons, and apparently belonging to the same animal as the skin, is a pair of small ossicones, not yet ankylosed to the skull, measuring about 2 in. along the longer side from point to base. They are of the same shape and little shorter than those of Boyd Alexander's specimen. In neither skull is there as yet a tuberculated surface of the frontal bone developed for the attachment of the ossicone. In the Boyd Alexander specimen each ossicone stood up as a projecting cone, and was covered with the hairy skin except for a small area at the free end, where the hair seems to have been rubbed away, or removed in preparing the skin, as may be seen in the mounted specimen in the Natural History Museum. In Major Powell-Cotton's specimen, of which both skin and skeleton are in the museum, each ossicone is longer, slightly compressed from side to side, and claw-like in shape, the point curved downward and backward; and each ossicone rests on a pitted and tuberculated surface of the frontal bone, to which it is closely fitted but not yet ankylosed.

In older specimens, *e.g.* that in Paris and that in Edinburgh, figured in my atlas, there is complete ankylosis of the ossicone with the frontal bone, and a wide extension of its base. The ossicones of the Powell-Cotton specimen are $3\frac{3}{4}$ in. in length, and are closely covered with hairy skin except, for a length of about $\frac{1}{4}$ in., at the tip, which pierces the skin. This "tip" of the okapi's horn, or ossicone (not yet developed in the Boyd Alexander specimen), consists, as I have described in the Proc. Zool. Soc., 1907, of peculiarly dense bony substance, which acquires a bright polished surface, and is sharply marked off like a nipple, by its raised margin from the rest of the bony substance of the ossicone, as seen in all adult specimens, of several of which I have published drawings. It emerges through the skin as a tooth does, when it is said to be "cut."

It is only in their pointed claw-like shape and the penetration of the skin by the hard, tooth-like apex that the okapi's paired ossicones differ from the paired ossicones of the giraffe. It is, however, remarkable that the fœtal giraffe has already before birth two soft hair-covered growths corresponding in position and proportionate size to the paired ossicones of the adult, and that the bony ossicones develop in these soft up-standing structures soon after birth. The young okapi has no such tegumentary growths, and the ossicone makes its appearance when the animal is nearly full grown or completely so as a free button-like ossification lying beneath the integument, which is pushed upwards by it as it grows. The dense emerging point of the okapi's ossicone forms for the animal a very efficient weapon. The giraffe's ossicone never penetrates the skin, but its apex is broad and flat and clothed with a tuft of long black hair. The axis of the okapi's ossicone is not at right angles to the horizontal plane of the skull, but is directed backwards so as to form an angle of 45° with that plane.

Mr. Gerrard tells me that wrapped in the bundle with the skin of Dr. Christy's specimen as received by him were two hollow, bluntly ending corneous horn-sheaths of about $2\frac{1}{2}$ in. in length, which he was led to suppose belonged to the animal. He has mounted these two hollow horn-sheaths on the top of the animal's head over the holes in the skin made in originally clearing it from the ossicones (when the skin was prepared in Africa) which have gone with the skull to the College of Surgeons. These hollow horns do not fit well to the cut skin, and there is no intrinsic evidence forthcoming to justify the association of them with the okapi's skin. They have the appearance of young horn-sheaths of some species of antelope, and show a few ring-like markings on the surface. They taper only slightly from base to tip, and the tips are rounded and blunt. It is, I admit, conceivable that in the early period of its growth before the completion of its ivory-like point and the cutting by it of the skin, the ossicone of the young okapi might develop a temporary corneous sheath to be shed during further growth and replaced by hairy skin. The prongbuck sheds its horn-sheath yearly, and very young cavicorns have been observed to shed a first sheath before acquiring a permanent one. Hence it is not impossible that a temporary corneous sheath should develop from the skin covering the young ossicone of the okapi.

The real question in such a matter is what is the evidence in favour of the unlikely but possible occurrence? The fact that between fifty and a hundred skins and skulls of the okapi have reached Europe in the last twelve years, and that no such horn-sheaths have hitherto been seen or heard of, is important. It is also important to bear in mind that it is quite certain that when once the okapi is full grown and its ossicone is ankylosed to the skull, it is covered by hairy skin like that covering the skull, from which its naked ivory-like point emerges.

The evidence is as follows. Mr. Gerrard tells me that he was led to believe that the small horny sheaths sent with the skin of the okapi actually belonged to the specimen by the fact that when removed from the parcel a label was found tied to them on which was written, "Horns of the Okapi." This would certainly seem to justify Mr. Gerrard in mounting them on the head, as he did.

He has, however, since I saw the specimen, sent me a note just received by him from Dr. Christy. This is headed, "Details of Okapis obtained with numbers of cases and dates of dispatch." It is signed by Dr. Christy, and dated Khartoum, February 10, 1915. It appears that Dr. Christy has been employed on a mission in the Congo State during 1913–14 by the Belgian Government, and that he had forwarded during those years specimens collected by him to Brussels to be sent on to Mr. Gerrard, acting as his agent, in London. Seven specimens of okapi are mentioned in the list before me, and the date of shooting and the name of the ship and route by which they were dispatched are given. Some were sent off in 1913, others in 1914. Mr. Gerrard tells me that only one—the one he has mounted—has reached him in

London. It is impossible to say whether the others arrived in Brussels, and, if so, what has now become of them. Dr. Christy's list is a very interesting one, and I will venture to give extracts from it. The specimens are distinguished by numbers. "No. 507, ♂ juv., not full grown; shot by myself, April 10, 1913. Skin good, skeleton complete." "No. 531, ♂, full grown. Shot by a Congo official, out shooting with me, May 22, 1913. Horns 1¼ in., skin-covered. Skin good, skeleton complete." "No. 686, ♀, big. Shot by myself, October, 25, 1913. Skin good, skeleton complete." "No. 717, ♂, old. Shot by Reid. Skin good; horns and hoofs attached to skin. Skeleton complete. Horns 4 or 5 in. long, and bare at tips." "No. 532, ? ♂. Skin only: from natives." "No. 533, ? ♀. Skin only; from natives." "No. 695, juv., ? sex; half-grown, 1913. Skin dried by natives. Skeleton complete."

In this list it will be observed that nothing is said about "horn-sheaths." It is perfectly certain that, as a sportsman and naturalist acquainted with the okapi, and the only "educated" European who has himself shot the okapi, Dr. Christy would have directed attention in his notes to the presence of "horn-sheaths" if he had discovered such structures to exist.

Only one of the seven specimens mentioned in Dr. Christy's list has come through to London. I have no doubt that it is the specimen No. 531, shot on May 22, 1913, at Mawambi, by a Congo official out shooting with Dr. Christy. The horns (ossicones) are stated definitely to be *skin*-covered. This agrees with my inference from a comparison with the Boyd Alexander specimen and the state of growth of the ossicones. It makes the "horny-sheaths" impossible. The measurement given by Dr. Christy for the horns (ossicones) is 1¼ in. This is their vertical height from base to apex. As they are pyramidal in shape, the measurement along the side of the pyramid from apex to edge of the expanding base, is as given above by me, about 2 in.

I think that Dr. Christy's own notes settle the question against the horny sheaths which it was already really impossible to "fit" satisfactorily to the specimen with which they reached Mr. Gerrard.

As to how this label—with "Horns of the Okapi" written on it—became attached to these little horn-sheaths it is possible to form various conjectures. Perhaps some busy, well-intentioned servant, being told to be sure to see that the little horns (ossicones) were not omitted from the parcel, mistakenly picked up the small horn-sheaths belonging to some antelope skin, left by chance with other skins and skulls in the disorder of packing or preparing a mass of specimens, and conscientiously but erroneously labelled them "Horns of Okapi," and packed them with specimen No. 531, destined to produce astonishment and confusion on arriving two years later in London.

Dr. Christy is to be congratulated on the fine series of specimens of okapi which he obtained and sent to Brussels *en route* for London. We must hope that they may escape destruction or seizure by the enemies of mankind, and eventually yield their contribution to our knowledge of the okapi, especially since among them are the first specimens seen alive and shot by a competent European observer.

March 9. E. RAY LANKESTER.

The Spectra of Hydrogen and Helium.

MR. E. J. EVANS has described recently some interesting experiments on the "4686" and Pickering series, which were obtained from vacuum tubes containing helium from which hydrogen was apparently completely eliminated. Stark has also observed the "4686" line in a vacuum tube showing no trace of the hydrogen lines. The experimental evidence of a helium origin of the lines in question would thus appear to be strong, and Prof. Fowler, from analogy with the enhanced line series of the alkaline earths, has also concluded that the lines are due to helium. According to Dr. Bohr, who first suggested that the lines were due to helium, the series in question owe their origin to the binding of an electron by a helium atom from which two electrons have been removed. Dr. Bohr's theory involves a modified value of Rydberg's constant for these lines, and Prof. J. W. Nicholson, in a letter to NATURE of February 11, has pointed out that it can be put to the test by an accurate measurement of the lines of the "4686" series, from which the value of the constant can be calculated.

Although the spectroscopic evidence is in favour of helium as the origin of the lines, it may be pointed out that this evidence is not conclusive. Although 4686 does not appear in hydrogen in the absence of helium, the same may be said of ultra-violet members of the Balmer series, which do not appear in vacuum tubes containing pure hydrogen, but which make their appearance when helium is present. The difficulty of preparing vacuum tubes free from hydrogen is well known, and the fact that the ordinary hydrogen lines are absent from the spectrum cannot be taken as conclusive evidence that hydrogen is not present. In view of this fact, the writer has conducted experiments to determine the relative mass of the atom from which the "4686" series originates, by measuring the limits of interference of the "4686" line and the lines of helium and hydrogen. The circumstances which control the breadth of spectrum lines have been discussed by Lord Rayleigh in the current number of the *Philosophical Magazine*.

At low pressures the order of interference at which fringes are still visible is proportional to the square root of the atomic weight of the atom from which the radiation originates. It is hoped shortly to publish a full account of the experiments, but the following may be stated as a preliminary result. A vacuum tube containing helium and hydrogen at a low pressure was excited by an induction coil with capacity and a spark-gap in the circuit, the spectrum consisting of helium lines, 4686, and the hydrogen lines. With an interference apparatus giving a suitable difference of path, moderately sharp ring systems can be obtained for all the helium lines, whilst no trace of interference can be detected in the 4686 line or the hydrogen lines.

Further observations are required to determine the exact limits of interference of the 4686 line and the hydrogen lines, but the results indicate that the mass of the atom from which 4686 originates is definitely smaller than that of the atoms concerned in the production of the ordinary helium spectrum.

Musical Sand in China.

AMONG the immense mass of ancient Chinese records and manuscripts brought back from the buried cities and caves of ancient Khotan, in Central Asia, and now stored in the British Museum, is one called the Tun-Huang-Lu, a topographical description of part of Khotan itself. This little geography was written in the time of the Tang dynasty, in the seventh century, but probably contains matter from earlier authors.

Among the specially interesting natural phenomena of the country described in the Tun-Huang-Lu is a large sandhill, which at certain times gave forth strange noises, so much so that a temple in its vicinity was entitled the "Thunder Sound Temple."

The geographer, speaking specially of the sandhill, says:—"The hill of sounding sand stretches 80 li east and west and 40 li north and south. It reaches a height of 500 ft. The whole mass is entirely constituted of pure sand. In the height of summer the sand gives out sounds of itself, and if trodden by men or horses, the noise is heard 10 li away. At festivals people clamber up and rush down again in a body, which causes the sand to give a loud rumbling sound like thunder. Yet when you look at it next morning the hill is just as steep as before."

Mr. Lionel Giles, from whose translation of the Tun-Huang-Lu these extracts are made, mentions that this sounding sandhill is referred to in another old Chinese book, the Wu Tai Shih.

JOSEPH OFFORD.

94 Gloucester Road, South Kensington, S.W.

The Green Flash.

I CAN confirm Dr. Schuster's observation of the green flash at sunrise, as in September last I saw a green segment herald the sun as it rose from the sea into a sky which was free from atmospheric glare (see the *Observatory*, December, 1914). Observations had previously been made at sunset, in one of which the eye was unquestionably fatigued, and the green flash was seen upon turning *away* from the sun at the instant after sunset. In a later sunset experiment precautions were taken to prevent retinal fatigue, and again the flash was seen.

My opinion is confirmed by Prof. Porter's experiment that "the reason why doubt has been cast upon records of the green flash is that the colour may arise in two different ways (complementary colour due to retinal fatigue, or dispersion by the atmosphere), and that the observer has not always been careful to avoid retinal fatigue, as was the case in my first (sunset) observation."

My observation, No. 2 (*loc. cit.*), is also in agreement with Dr. Schuster's experience, that with a very red sun no flash is to be seen.

Measurements of Medieval English Femora.

As the Editor of NATURE has insisted upon the great pressure at present upon his space I propose to reply to Dr. Parsons's letter, in the issue of March 11, adequately elsewhere.

KARL PEARSON.

Galton Laboratory, March 15.

THE PRINCIPLE OF SIMILITUDE.

I HAVE often been impressed by the scanty attention paid even by original workers in physics to the great principle of similitude. It happens not infrequently that results in the form of "laws" are put forward as novelties on the basis of elaborate experiments, which might have been predicted *a priori* after a few minutes' consideration. However useful verification may be, whether to solve doubts or to exercise students, this seems to be an inversion of the natural order. One reason for the neglect of the principle may be that, at any rate in its applications to particular cases, it does not much interest mathematicians. On the other hand, engineers, who might make much more use of it than they have done, employ a notation which tends to obscure it. I refer to the manner in which gravity is treated. When the question under consideration depends essentially upon gravity, the symbol of gravity (g) makes no appearance, but when gravity does not enter into the question at all, g obtrudes itself conspicuously.

I have thought that a few examples, chosen almost at random from various fields, may help to direct the attention of workers and teachers to the great importance of the principle. The statement made is brief and in some cases inadequate, but may perhaps suffice for the purpose. Some foreign considerations of a more or less obvious character have been invoked in aid. In using the method practically, two cautions should be borne in mind. First, there is no prospect of determining a numerical coefficient from the principle of similarity alone; it must be found if at all, by further calculation, or experimentally. Secondly, it is necessary as a preliminary step to specify clearly *all* the quantities on which the desired result may reasonably be supposed to depend, after which it may be possible to drop one or more if further consideration shows that in the circumstances they cannot enter. The following, then, are some conclusions, which may be arrived at by this method:—

Geometrical similarity being presupposed here as always, how does the strength of a bridge depend upon the linear dimension and the force of gravity? In order to entail the same strains, the force of gravity must be inversely as the linear dimension. Under a given gravity the larger structure is the weaker.

The velocity of propagation of periodic waves on the surface of deep water is as the square root of the wave-length.

The periodic time of liquid vibration under gravity in a deep cylindrical vessel of any section is as the square root of the linear dimension.

The periodic time of a tuning-fork, or of a Helmholtz resonator, is directly as the linear dimension.

The intensity of light scattered in an otherwise uniform medium from a small particle of different refractive index is inversely as the fourth power of the wave-length.

The resolving power of an object-glass, measured by the reciprocal of the angle with which it can deal, is directly as the diameter and inversely as the wave-length of the light.

The frequency of vibration of a globe of liquid, vibrating in any of its modes under its own gravitation, is independent of the diameter and directly as the square root of the density.

The frequency of vibration of a drop of liquid, vibrating under capillary force, is directly as the square root of the capillary tension and inversely as the square root of the density and as the $1\frac{1}{2}$ power of the diameter.

The time-constant (*i.e.*, the time in which a current falls in the ratio $e:1$) of a linear conducting electric circuit is directly as the inductance and inversely as the resistance, measured in electro-magnetic measure.

The time-constant of circumferential electric currents in an infinite conducting cylinder is as the square of the diameter.

In a gaseous medium, of which the particles repel one another with a force inversely as the nth power of the distance, the viscosity is as the $(n+3)/(2n-2)$ power of the absolute temperature. Thus, if $n=5$, the viscosity is proportional to temperature.

Eiffel found that the resistance to a sphere moving through air changes its character somewhat suddenly at a certain velocity. The consideration of viscosity shows that the critical velocity is inversely proportional to the diameter of the sphere.

If viscosity may be neglected, the mass (M) of a drop of liquid, delivered slowly from a tube of diameter (a), depends further upon (T) the capillary tension, the density (σ), and the acceleration of gravity (g). If these data suffice, it follows from similarity that

$$M = \frac{Ta}{g} F\left(\frac{T}{g\sigma a^2}\right),$$

where F denotes an arbitrary function. Experiment shows that F varies but little and that within somewhat wide limits may be taken to be 3·8. Within these limits Tate's law that M varies as a holds good.

In the Æolian harp, if we may put out of account the compressibility and the viscosity of the air, the pitch (n) is a function of the velocity of the wind (v) and the diameter (d) of the wire. It then follows from similarity that the pitch is directly as v and inversely as d, as was found experimentally by Strouhal. If we include viscosity (ν), the form is

$$n = v/d.f(\nu/vd),$$

where f is arbitrary.

As a last example let us consider, somewhat in detail, Boussinesq's problem of the steady passage of heat from a good conductor immersed in a stream of fluid moving (at a distance from the solid) with velocity v. The fluid is treated as incompressible and for the present as inviscid, while the solid has always the same *shape* and presentation to the stream. In these circumstances the total heat (h) passing in unit time is a function of the linear dimension of the solid (a), the temperature-difference (θ), the stream-velocity (v), the capacity for heat of the fluid per unit volume (c), and the conductivity (κ). The density of the fluid clearly does not enter into the question. We have now to consider the "dimensions" of the various symbols.

Those of a are (Length)^1,
. . . . . . v . . (Length)^1 (Time)$^{-1}$,
. . . . . . θ . . (Temperature)^1,
. . . . . . c . . (Heat)^1 (Length)$^{-3}$ (Temp.)$^{-1}$,
. . . . . . κ . . (Heat)^1 (Length)$^{-1}$ (Temp.)$^{-1}$ (Time)$^{-1}$,
. . . . . . h . . (Heat)^1 (Time)$^{-1}$.

Hence if we assume

$$h = a^x \theta^y v^z c^u \kappa^v,$$

we have

by heat $1 = u + v$
by temperature $0 = y - u - v$,
by length $0 = x + z - 3u - v$,
by time $-1 = -z - v$;

so that

$$h = \kappa a\theta \left(\frac{avc}{\kappa}\right)^z.$$

Since z is undetermined, any number of terms of this form may be combined, and all that we can conclude is that

$$h = \kappa a\theta.F(avc/\kappa),$$

where F is an arbitrary function of the one variable avc/κ. An important particular case arises when the solid takes the form of a cylindrical wire of any section, the length of which is perpendicular to the stream. In strictness similarity requires that the length l be proportional to the linear dimension of the section b; but when l is relatively very great h must become proportional to l and a under the functional symbol may be replaced by b. Thus

$$h = \kappa l\theta.F(bvc/\kappa).$$

We see that in all cases h is proportional to θ, and that for a given fluid F is constant provided v be taken inversely as a or b.

In an important class of cases Boussinesq has shown that it is possible to go further and actually to determine the form of F. When the layer of fluid which receives heat during its passage is very thin, the flow of heat is practically in one dimension and the circumstances are the same as when the plane boundary of a uniform conductor is suddenly raised in temperature and so maintained. From these considerations it follows that F varies as $v^{\frac{1}{2}}$, so that in the case of the wire

$$h \propto l\theta.\sqrt{(bvc/\kappa)},$$

the remaining constant factor being dependent upon the shape and purely numerical. But this development scarcely belongs to my present subject.

It will be remarked that since viscosity is neglected, the fluid is regarded as flowing past the surface of the solid with finite velocity, a serious departure from what happens in practice. If we include viscosity in our discussion, the question is of course complicated, but perhaps not so much as might be expected. We have merely to include another factor, ν^w, where ν is the kinematic viscosity of dimensions (Length)^2 (Time)$^{-1}$, and we find by the same process as before

$$h = \kappa a\theta.\left(\frac{avc}{\kappa}\right)^z.\left(\frac{c\nu}{\kappa}\right)^w.$$

Here z and w are both undetermined, and the conclusion is that

$$h = \kappa a\theta.F\left\{\frac{avc}{\kappa}, \frac{c\nu}{\kappa}\right\},$$

where F is an arbitrary function of the *two* variables avc/κ and $c\nu/\kappa$. The latter of these, being the ratio of the two diffusivities (for momentum and for temperature), is of no dimensions; it appears to be constant for a given kind of gas, and to vary only moderately from one gas to another. If we may assume the accuracy and universality of this law, $c\nu/\kappa$ is a merely numerical constant, the same for all gases, and may be omitted, so that h reduces to the forms already given when viscosity is neglected altogether, F being again a function of a single variable, avc/κ or bvc/κ. In any case F is constant for a given fluid, provided v be taken inversely as a or b.

RAYLEIGH.

PERISCOPES.

WHILE the periscope of the submarine is developing in the direction of greater optical perfection and elaboration, there has been a return to the simplest and earliest types of periscope for use in land warfare. Some of these trench periscopes recall the polemoscope, described by Helvelius in the seventeenth century for military purposes; this polemoscope in its simplest form consisted of two mirrors with their reflecting surfaces parallel to each other, and inclined at 45° to the direction of the incident light. These mirrors were mounted in a tube and separated a convenient distance (Fig. 1).

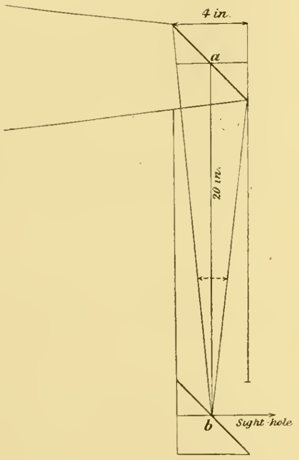

FIG. 1.

For modern trench warfare the convenient separation is about 18 to 24 in., and the mirrors are mounted in tubes, in boxes of square or oblong section, or attached to a long rod. In each case it is necessary that the mirrors should be fixed at the correct angle, and that there should be no doubling or distortion of the image.

The principal requirements of these trench periscopes are portability, lightness, small size and inconspicuous appearance, and large field of view. When there are no lenses the field of view is exactly the same as would be obtained by looking through a tube of the same length and diameter. Thus, with mirrors of 2 in. by 3 in. and a separation of about 22 in., a field of view of 5° would be obtained; and by moving the eye about, this field could be nearly doubled.

By using a box of oblong section the horizontal field of view can be increased without unduly increasing the size of the periscope. As the field of view is somewhat limited in any case, the principal objection to the use of a telescope or binocular, viz., the reduced field, no longer applies, and many periscopes are arranged to be used with a monocular or a binocular telescope.

Most periscopes can be used with a magnification of two or three, *i.e.*, with one tube of an ordinary opera glass; but when higher magnification is to be used the mirrors must be of better quality, both as regards flatness of surfaces and parallelism of the glass. When the mirrors are large enough—8 to 10 centimetres wide—both telescopes of the binocular may be used, but in this case the requirements for the mirrors are even more stringent, as the images formed by the two telescopes will not coincide unless the mirrors are plane. When suitable lenses are placed between the mirrors, the size of the mirrors can be reduced or the field of view increased; it is easy to provide a small magnification of the image or even to arrange for a variable magnification.

In such cases the lenses must be arranged to give an erect image, or mirrors or prisms employed to erect the image. An example of a periscope of this type is shown in Fig. 2, where the mirrors are replaced by reflecting prisms, and the prisms erect the image in much the same way as the prisms of a prism binocular.

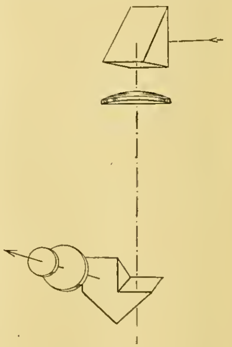

FIG. 2.

This arrangement is very suitable for a large magnification, but for larger fields the prism is unsuitable, unless it be silvered, and it is preferable to erect the image by means of lenses.

When longer tubes are used or larger fields are required, the design should approximate to that used in the submarine periscope.

This optical system has been steadily developed since its first introduction by Sir Howard Grubb in 1901.

The system consists of two telescopes, of which one is reversed, so that the image would be reduced in size, while the other magnifies this image, so that the final image is of the same size as the object, or is magnified one and a quarter or one and a half times. (As a very large angular field of view is required in these periscopes, the beam reflected into the tube must cover a large angle, and would soon fall on the sides of the tube; the reversed telescope, however, reduces the angle of the beam, and so enables it to proceed far enough down the tube to be received by the second telescope, and so transmitted to the eye.)

In modern submarines the tube has a length of from 16 to 24 ft., the diameter is from 6 to 9 in., while the field of view is about 65°. In order that objects shall look their real size, it is necessary to give a magnification of one and a quarter to one and a half.

Fig. 3 gives an illustration of a periscope in which three telescope systems are employed. The drawing is made from information published by Messrs. Goerz[1] of Berlin, and relates to periscopes made by them. It is, of course, undesirable to give any details of English periscopes at the present time.

An outer tube has a spherical glass cover. In the inner tube is the optical system, which can be rotated to face in any required direction; the eye piece, however, remains fixed.

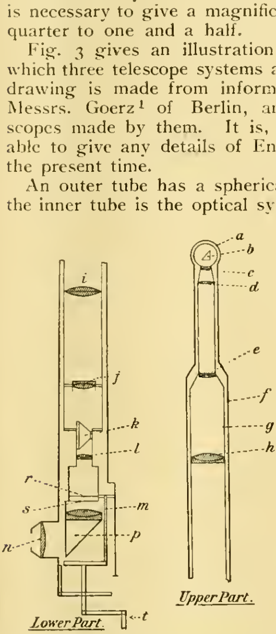

FIG. 3.—*a*, Glass cover; *b*, prism; *c*, *d*, and *e*, lenses of reversed telescope; *f*, outer tube; *g*, inner tube; *h*, *i*, and *j*, lenses of second telescope; *k*, reversing prism; *l*, *m*, and *n*, lenses of third telescope; *p*, prism; *r* and *s*, pointer and scale; *t*, rotating mechanism.

The optical system, which follows in its general principles Sir Howard Grubb's original design, consists of:—

(1) A reversed telescope, giving a reduction of about one quarter;

(2) A telescope, giving a magnification of about two;

(3) An erecting prism which can be rotated so that the image given by the system is correctly oriented;

(4) A telescope giving a magnification of about three.

This telescope includes a fixed eye piece and prism, so arranged that the observer looks horizontally at the object. At the focus of the eye piece are placed a scale and pointer to show the bearing of the object sighted, and a ruling to allow the distance to be estimated when the size of the object is known.

By the aid of a subsidiary system, special parts of the field can be further magnified to allow of objects being examined in more detail.

The continued use of the periscope is very trying to the eye, so that devices have been used to throw the image on to a ground glass screen. The ordinary eye piece and ground glass systems are made interchangeable, so that the observer can readily pass from one to the other; he may observe with the ground glass in the ordinary way, but examine special objects with the ordinary eye piece.

The field of view of the periscope is still limited, and various attempts to overcome this difficulty have been made. More than one periscope can be used and the images combined to form a complete image. A recent improvement consists in the use of a ring reflector which enables a view of the whole horizon to be obtained at once. The image formed by the ring system is much distorted, but when any object is picked up it can be examined by means of the ordinary system. These two optical systems are combined in one instrument, so that the two images are seen in the one field, the image formed by the ring system surrounding the other.

But these ring periscopes are still far from perfect, their distortion making it very difficult to identify objects; and this difficulty, though not so pronounced, occurs with the ordinary periscope. The point of view from which the surface of the sea and surrounding objects are seen is one to which the eye is not generally accustomed. The conditions of lighting, too, render it difficult to distinguish objects, especially when there is mist or spray, so that the effective use of a periscope requires considerable skill and training.

Trench periscopes may be obtained from most opticians, and the following are a few typical forms:—

The Hampson, wooden stake carrying two mirrors; price 7*s*. 6*d*.

The Adams, jointed rod; price 10*s*. 6*d*.

The Stanley; the support is in the form of lazy tongs, and is of a light alloy; price 25*s*.

These open-mirror types are light, portable, with good field, but the mirrors are not protected from rain, and the useful field is surrounded by bright sky.

Tube types are made by Messrs. Negretti and Zambra, Dixey, The Periscope Co., and many others; prices from 8*s*. 6*d*. to 15*s*., depending on the metal tube used. In these types the field is rather limited.

Messrs. Chas. Baker and Co. supply a type with large mirrors, which can be satisfactorily used with both barrels of a binocular. In spite of the large mirrors, the type is very portable; price 30*s*.

Many makers supply types in which the optical system is incorporated with the periscope, and the prices of these range from 28*s*. to 6*l*. 10*s*., according to the type of optical system used.

S. D. CHALMERS.

[1] Dr. Weichert, Jahrbuch der Schiffsbautechnischen Gesellschaft, 1914

OIL OF VITRIOL AS AN AGENT OF "CULTURE."

IN a former article under this heading (NATURE, December 31, 1914, vol. xciv., p. 472) we pointed out that Germany's ability to continue the war depended largely upon her power to maintain her supply of oil of vitriol, this product being absolutely indispensable in the manufacture of those high explosives upon which her artillery depends. We stated further that Germany's stock of the materials which are required to produce oil of vitriol is very limited, her sources of internal supply being almost negligible in comparison with the huge amounts demanded by her industries. An article by Dr. Reusch in a recent issue of the *Chemiker Zeitung* (vol. xxxviii., pp. 1241–43) is interesting at the present moment as showing that Germany is beginning to feel the pinch of necessity as regards this substance, and that, in view of the "reprisals" with which she is now threatened, as a consequence of her policy of "piracy and pillage," this necessity will become increasingly stringent.

We learn from Dr. Reusch's article that all export of sulphuric acid, sulphuric anhydride, and sulphurous acid from Germany is now prohibited. Before the war began she was a large importer of oil of vitriol—the imports in 1913 exceeding the exports by 65,289 metric tons—most of which came from Belgium. The total German production in 1912 is given as 1,649,681 metric tons, mostly made from pyrites, of which more than 80 per cent. was imported, mainly from Portugal, Spain, and France. Germany possesses deposits of this mineral, but they are of poor quality, and their working would present difficulties owing to scarcity of labour and other causes. She is now looking to Norway as a possible source, but if the policy indicated by Mr. Asquith is to be effective it should not be difficult to checkmate her action in this direction.

Another source of supply consisted in the working-up of zinc-blende, largely carried on in Silesia, principally on imported material, of which about 60 per cent. came from Australia alone. The only other main source would be natural sulphur imported through Italy, and principally of Sicilian origin, but here again, if the policy of "reprisals" is efficiently maintained, it should be readily possible for us to deal with this means of supply. It is interesting, in this connection, to note that in this respect, history repeats itself. During the Napoleonic wars the French occupied Sicily mainly with the view of cutting off our supply of sulphur for the manufacture of gunpowder in retaliation for our blockade of Pondicherry, upon which the enemy depended for his supply of nitre.

The sulphuric acid required for the manufacture of explosives is mainly employed in the production of nitric acid from nitrates, and from the point of view of hampering Germany in providing herself with the munitions of war it would be equally, if not more, effective to cut off her supplies of nitrates. As regards imported nitrates, and particularly Chile saltpetre, this may be practicable, and, indeed, cargoes of this material have already been stopped by our vessels on the high seas. But she has still certain internal sources of supply, as have most continental nations, and we now see that it is not for nothing that for some years past German chemists and engineers have, under the fostering influence of persons in high places, been straining every nerve to perfect possible synthetic processes of making ammonia and of converting it into nitric acid and nitrates, largely by the aid of the water-power of Norway.

Luckily for the Allies at the present juncture, certain of these processes, such as that of Ostwald, have turned out to be hopeless commercial failures, but there are others which would appear to have in them the promise of eventual and permanent success. We learn that the German Government has just introduced a Bill into the Reichstag providing for a State monopoly of the trade in nitrates for a period of seven years. The preamble explains that, at great expense, the Government has succeeded, in consequence of the stoppage of imports of Chile saltpetre, in establishing a chemical industry for the fixation of nitrates from the air, and that this industry is to be protected absolutely from all competition. Meanwhile, the price of nitrates, as of sulphuric acid, has steadily risen in Germany, and the shortage is becoming more and more pronounced. The process of depletion of sulphuric acid may be delayed by the action of the Government, which may be driven ultimately to commandeer all supplies in the interests of national defence. For the moment a certain amount is liberated in consequence of the diminished activity of various branches of chemical industry, as, for example, the dyestuff factories, and owing to the economy which has been enjoined in the manufacture of superphosphate manures, partly in consequence of the increased production of basic slag, due to the expansion of the iron industry. T.

PROF. H. W. LLOYD TANNER, F.R.S.

PROF. H. W. LLOYD TANNER, whose death on March 5 we announced with regret last week, was born at Burham, in Kent, on January 17, 1851. He received his school education at Bristol Grammar School, from which he proceeded to Jesus College, Oxford. At Oxford he came under the stimulating influence of Mr. John Griffiths, the mathematical tutor of his college. After leaving Oxford he held some educational appointments until the year 1883, when the University College of South Wales and Monmouthshire was founded at Cardiff. Of this college he was appointed Professor of Mathematics and Astronomy, and he occupied the chair at Cardiff until his resignation in 1909.

Cardiff University College now forms one of the constituent colleges of the University of Wales, but the Charter of the University was not granted until ten years after the opening of the college at Cardiff. In the interval the students of the college were prepared for the degrees of the University of London, and the courses of lectures in mathematics and other subjects were necessarily framed to meet the requirements of that University. After the foundation of the University of Wales the professors in the Welsh colleges enjoyed a degree of freedom in the choice and scope of the subjects they taught which had been denied to them when their students were reading for the degrees of an external university. Prof. Tanner took an active part in the arrangement of the mathematical work of the Welsh University in the early days, and the courses of study in pure mathematics still show the great influence he exerted on the general character of the mathematical teaching in Wales.

At Cardiff Prof. Tanner made a reputation for himself as an inspiring teacher and an excellent administrator. When the British Association visited Cardiff in 1891 he acted as one of the local secretaries, and the success of the meeting was in a large measure due to the thoroughness with which the secretaries carried out the necessary arrangements. After the death of Principal Jones he filled for some time the position of Acting-Principal of the college. In the year 1909 his health broke down, and he resigned his appointment as professor. In recognition of his services as head of the department of mathematics for twenty-six years, the Council of the college appointed him Emeritus Professor of Mathematics and Astronomy.

Amid all his varying activities in connection with his work in college, Prof. Tanner found time to engage in mathematical research, and he published in the Proceedings of the London Mathematical Society a series of valuable papers. His early papers, the first of which was written in 1875, dealt with the solution of partial differential equations, but his later papers were mostly concerned with the theory of numbers. These later papers were remarkable alike for grasp of principle, clearness of exposition, and elegance of method. The Royal Society recognised the value of his research work by electing him a Fellow of the Society in 1899. The University of Oxford also honoured him by conferring on him the degree of D.Sc., and by appointing him on one occasion an examiner for mathematical scholarships.

R. H. P.

NOTES.

The fifth annual May lecture of the Institute of Metals will be given on Wednesday, May 12, by Sir J. J. Thomson.

A special lecture on the septic infection of wounds will be delivered before the Royal Society of Medicine on Tuesday, March 30, by Sir Almroth Wright, who will deal with the results of his investigations and research with the Expeditionary Force.

A correspondent in Moscow informs us that the Imperial Society of Naturalists has removed the names of Prof. Haeckel and Prof. Ostwald from its list of members on account of their having signed the address, "To Civilised Nations," containing libels upon the Russian people.

The death is announced, at eighty-six years of age, of Dr. W. M. Dobie, who was associated with Charles Kingsley in founding the Chester Society of Natural Science, Literature, and Art, and was president of the society during the sessions 1893–94 and 1894–95.

The Board of Trade announces that in order to mitigate the effects of the dearth of indigo for dyeing purposes caused by the present war, and also to prevent any speculative holding up of natural indigo, the Government has acquired the greater part of the crop of natural indigo now coming forward for the use of dye-users in the United Kingdom.

The *British Medical Journal* has received a communication from a distinguished Scandinavian colleague in which he expresses the opinion that the reception accorded to foreign medical visitors in this country compares unfavourably with that they habitually receive from the medical profession in Austria and Germany. In these countries the practice of the large hospitals is placed at the disposal of foreign visitors without fee, whereas here fees more or less large are generally charged. This doubtless depends partly on the fact that our hospitals are voluntary and the staff is unpaid, whereas abroad the hospitals are Government institutions. The Germanic countries are also indefatigable in flooding the Scandinavian countries with their medical literature, while England and France, on the other hand, send scarcely a book for review to the Scandinavian countries. Here seems to be another opportunity for the extension of British enterprise.

Dr. Batschinski, of the University of Moscow, informs us that Prof. Nicolas Oumoff, whose death on January 15 was announced in these columns on January 28, was born at Simbirsk, East Russia in 1846. After passing through the University of Moscow he became lecturer and afterwards professor of theoretical physics at the University of Odessa. In 1903, after twenty-two years at Odessa, he was appointed professor of physics at the University of Moscow. Here, with the late Prof. Lebedew as his colleague, a large new physics institute was designed and erected. Prof. Oumoff was one of the Russian representatives at Lord Kelvin's jubilee, and received the honorary degree of LL.D. from the University of Glasgow. Along with many other Moscow professors, he resigned his position in 1911, and devoted himself to the Ledenzoff Society for assisting discoveries and inventions useful to humanity. He was very successful both as a university and as a popular lecturer. Of his published papers those on terrestrial magnetism are probably best known in this country.

The death is announced, at seventy-nine years of age, of Sir George Turner, whose researches relating to rinderpest, leprosy, and other diseases in South Africa are of high importance. Sir George Turner entered the Civil Service of Cape Colony as medical officer of health in 1895. The year after, rinderpest broke out in the Cape Colony. Koch had just devised a system of inoculation against this disease of cattle, and after three weeks' collaboration with him, Sir George continued the work, and before long devised a method of producing a lasting immunity by simultaneous inoculation with virus and serum. Within a year rinderpest in Cape Colony was stamped out; later, the same method was adopted in Egypt and Natal. In the South African war, on the outbreak of typhoid fever, he supervised the military hospitals and concentration camps. Afterwards he devoted his spare time to the leper asylum at Pretoria, and was assiduous in doing all he could to alleviate the lot of the inmates and in investigating the disease. On his retirement in 1907 he still continued his researches on leprosy in the laboratory, but after some years' work he noticed that he himself had contracted the disease which he had set himself to fight. Nevertheless, he still continued to work unswervingly amid the pain and beneath the shadow of a leper's lot.

THE arrangements which the Institute of Industry and Science (Aldwych Site, Strand, W.C.) has been making for some months past with regard to the holding of a conference in London of leaders of industry and science to discuss the British position, have now been completed, and a conference is to be held on Thursday, March 25, at the Mansion House. The proceedings will be opened with an address on the influence of science in political economy, to be followed by a discussion on the co-operation of science and industry. Many distinguished representatives of industry and science are expected to be present and to speak upon these and related subjects. A very effective organisation has already been created by the Institute of Industry and Science. At a meeting of the directors, held on March 10, it was resolved to place the organisation at the disposal of the Government without reservation, and this has already been done. A large number of the principal trade organisations are fully represented in the institute, and many eminent men of science and industry are taking an active part in its work. An important work, entitled "A Study of the First Principles of Production, and the Relation of Science to Industry," which has been in course of preparation for the last six months, by Mr. J. Taylor Peddie, will be published immediately by Messrs. Longmans, Green and Co., so as to be available before the conference. Attendance at the conference at the Mansion House is by invitation only.

IN the February number of the Journal of the Franklin Institute there is an interesting contribution by Dr. C. E. K. Mees under the title of "The Physics of the Photographic Process." He adopts Quincke's suggestion as to the sponge-like character of air-dried gelatine, with its cells and passages between them, and Joly's suggestion, which is confirmed by Nutting's calculation of the energy involved, that developable silver bromide is this salt which has lost one electron per grain (or particle). He thinks that reversal by the continued action of light is more likely due to the actual decomposition of the silver bromide, than to "self-neutralisation" brought about by the accumulation of the separated electrons in the gelatine surrounding the particles of silver bromide, as Joly and H. S. Allen have suggested, but we look in vain for any calculation as to whether the energy available is able to produce such a decomposition. He then considers the effects of the size of the grain, and states that a very fine-grained emulsion will never by cooking yield a very sensitive preparation. For this latter purpose one must *start* with a larger grain. In both cases sensitiveness increases as the grain grows. He considers, apparently favourably, the idea that greater sensitiveness is caused by the growth of the grain in size, and he illustrates by curves the effect of the gradation of grain size on the characteristic curve. An emulsion that is approximately homogeneous as to grain size gives a curve with a short "straight line" portion, while a larger proportion of smaller (less sensitive) grains, increases it, but a mixture of two emulsions, a low-speed fine-grained one with a high-speed, coarse-grained one, gives a very long under-exposure part to the curve. The author concludes with a short summary of recent work on the resolving power of plates.

PROF. J. STANLEY GARDINER, in lecturing on March 8 to the Royal Geographical Society on the geography of British fisheries, entered on a field which must have been as unfamiliar to most of his audience as it was interesting. After indicating the topography of the British fishing grounds, he illustrated the "correlation of habits with physical conditions" by discussing some of the remarkable facts in the growth, development, and movements of various food fishes which are gradually being brought to light. He mentioned the peculiar richness of the British fishing grounds as due largely to the quantity of organic remains derived from the land—indeed, he believed that drainage from the land would be found to be the "primary cause" of this richness, supplying the shallow seas with a substantial category of ingredients favourable to fish life. The varying character of the sea-floor, the movements of currents, and other phenomena were discussed as having important effects, some certain, some (so far as research has extended) no more than probable. Specially interesting was the reference to Dr. E. J. Allen's inquiry as to the relation between abundance of sunshine in early months of the year, the resultant rich cultures of diatoms, and the subsequent special abundance of copepods which feed on these, and of mackerel, which in spring feed largely on copepods. "We must regard as hopeful," he said, "the suggestion of physical data by which 'drifters' might be informed months beforehand of the probabilities of the fishery for the year."

PROF J. W. GREGORY, at a recent afternoon meeting of the Royal Geographical Society, discussed Suess's classification of Eurasian mountains. He contrasted it with other classifications, and commended it specially on the ground that "it separates the Himalayan line from the northern highlands, such as the Sayans, and from the north-eastern chains, such as the Yablonoi and Stanovoi mountains." Mountains widely different "in structure and geographical character," as these are, should be separated in classification, but Prof. Gregory stated that Suess did not always do this. He attached "excessive importance . . . to early earth movements which affected the foundations of the mountain areas," and his classification "does not serve ordinary geographical purposes, for it links together elements which are different in their topography and geographical influences, alike political, climatic, and biological; while it separates elements which have similar geographical influence." No doubt it was not primarily intended to serve these purposes, but Prof. Gregory adduced purely physical reasons—elevation at the same epoch, due to great crustal compression, etc.—for classifying together the Pyrenees, Alps, Dinaric mountains, the Caucasus, Himalaya, and others, whereas Suess's classification "represents the Alps as closer akin to the hills of Brittany than to the Himalaya, and makes the Dinaric mountains and the hills of Crete the European equivalents of the Himalaya," and "is obviously not intended as a guide to the comparison of existing earth forms."

AMONG many valuable contributions to our knowledge of the natural history of Gloucestershire contained in the Proceedings of the Cotteswold Naturalists' Field Club for 1914 is the account of an excursion to the Forest of Dean and a description of the work being done by the School of Forestry. Works have recently been erected containing a retort of large capacity for the carbonisation of wood, and the necessary plant for producing and working up charcoal, grey acetate of lime, miscible naphtha, and wood-tar. Mr. Hanson, a member of the school staff, among other interesting facts, remarked that after diligent search in the forest only fifteen mistletoe plants have been found, eight of which were on poplar trees and none on oak. This, he observed, tends to confirm the belief that the connection between the oak and the mistletoe in Druidic times is more mythical than real. He fails, however, to observe that it is the comparative scarcity of the appearance of mistletoe on the oak which would be likely to inspire a belief in its sanctity.

NEW material has enabled Mr. C. C. Mook (Ann. New York Ac. Sci., vol. xxiv., pp. 19–22) to formulate the distinctive features of Camarosaurus, described by Cope in 1877, and one of the first of the sauropod dinosaurs made known to science. It is now shown that Morosaurus, named by the same palæontologist about a month later, is really inseparable. It is also recalled that at first Cope believed these huge and unwieldy reptiles to be bipedal.

A LONG synopsis, illustrated by eight plates, of the British fleas, or Siphonaptera, by the Hon. N. C. Rothschild, renders the March number of the *Entomologist's Monthly Magazine,* about double the normal size, and the price is consequently raised in proportion to all save subscribers. It is the first attempt to bring a difficult subject up to date, and is consequently to some extent tentative. The descriptions are purposely brief, and the diagnoses of genera and species apply only to the British forms. The author remarks that in a considerable number of cases the same species of flea infests totally different kinds of animals, and that Carnivora frequently acquire such unwelcome guests from their prey, and may apparently retain them for a considerable time.

THOUGH the Scottish Zoological Park, near Edinburgh, has suffered from the effects of the war, it has been found possible to undertake during the winter several new works. The largest of these is the acclimatisation house, presented by Lord Salvesen, president of the society. Another is the construction of a pool for the society's valuable collection of penguins, which arrived from the Antarctic last spring. The pool is almost completed, and the penguins will be seen to much greater advantage than hitherto. The completion of the polar bear pool has also been undertaken. The formation of the polar bear pool was the first work undertaken by the society in the laying out of the park, but as it was not possible to have the pool, as originally designed, completed in time for the opening in 1913, a temporary barrier and cages were thrown across one side, so that the bears might be exhibited at once. The temporary wooden barrier has now been removed, and the rock on one side is being cut back, in order to enlarge the pool and at the same time afford a rock face of sufficient height to prevent the escape of the bears. The work on this pool will also be completed in a short time.

WE have been favoured with a copy of a richly illustrated memoir on the "Anthracolithic Faunæ of Kashmir, Kanaur, and Spiti," by Dr. C. Diener, published as vol. v., No. 2, of the new series of the "Palæontologica Indica." Fossils of a Permo-Carboniferous type were brought to light many years ago by Col. Godwin-Austen and others in Kashmir; and in the late 'seventies a fresh deposit of such fossils was discovered by Mr. Lydekker. The latter proved to be of the same type as those from the well-known Kuling shales of Spiti, and were therefore classed as Permian, while the great bulk of the fossiliferous deposits were originally regarded as Carboniferous; a third horizon, of presumed Carboniferous age, being indicated by a quartz-sandstone from Ladak containing a brachiopod first described by Dr. Diener as *Spirifer lydekkeri,* but now transferred to the genus Syringothyris. More important was the subsequent discovery by Dr. Noetling of plant-remains of a Gondwana type in the Kashmir beds. Dr. Diener's original memoir on the Anthracolithic series was published in 1899; the present one is based on new stratigraphical work and new collections, and contains descriptions of new species and revisions of others. As the results of his work, the author considers that the fossil evidence proves the Zewan beds of Kashmir to be the equivalent of the Upper Productus Limestone of the Punjab Salt Range and the Kuling Shales, this being confirmed by the presence in all of two distinctive Permian species.

DR. A. SMITH WOODWARD has written for the British Museum (Natural History) an inspiring illustrated "Guide to the Fossil Remains of Man in the Department of Geology and Palæontology," price 4*d*. Since the remains in other collections are here represented by casts, a comprehensive view can be obtained of the remarkable additions to our knowledge of human origins that have been made in the last eight years. One of the most interesting pictures is that showing the side aspect of the Piltdown skull, in comparison with that from La Chapelle-aux-Saints (Neandertal type) and with a modern human skull. Equally effective drawings are given of the skulls of chimpanzees, in young and adult stages. The possession of a complete skeleton of the Neandertal type has enabled M. Marcellin Boule to furnish a valuable comparison with that of the more erect modern Australian. The Piltdown type is regarded as even older than that represented by the mandible found at Mauer, near Heidelberg, in 1907. In stating that the immediate predecessor of modern man in Europe was of Neandertal type, Dr. Smith Woodward does not exclude the possibility of the contemporaneous existence of a type with less retreating forehead. The Transactions of the Perthshire Society of Natural Science (vol. vi., 1914) contain a paper by Dr. Lyell, in which the existence of man throughout the Glacial epoch is emphasised; and Mr. R. A. Smith's paper on prehistoric problems in geology, with the well-reported discussion on it (Proc. Geol. Assoc., vol. xxvi., 1915, p. 1) shows how far we have got from the old prejudices, which would have us believe that a deposit containing flint implements must necessarily be of post-Glacial age.

THE nature of "nardoo," the supposed nutritive food which led to such disastrous results during the ill-fated expedition of Burke and Wills, is discussed by Mr. E. H. Lees in the January issue of the *Victorian Naturalist*. It has been assumed that the true nardoo is made from the spores of a species of Marsilea growing in the swamps of Victoria. This, however, appears to be quite innutritious by itself, and nardoo made from leguminous seeds of various kinds is stated by the author to have been formerly supplied in establishments kept by natives. He maintains, in fact, that, in place of being the product of any one particular plant, nardoo is a compound made from several.

AN investigation into the limits within which the combined hysteresis and eddy current losses in iron per unit mass can be expressed by a single expression of the form, $W=cB^n$, has been carried out at Liverpool by Mr. N. W. McLachlan, who describes his results in a contribution to the Journal of the Institution of Electrical Engineers. Measurements were made by the Epstein alternating-current method with various brands of iron, and the curves obtained were analysed. It was finally found that such a formula would be accurate within from 1·5 to 2·5 per cent. for various materials tested, between the flux densities of 4000 or 5000 and 10,000 lines per sq. cm., and frequencies from 26 to 60 cycles per sec., the index n varying from 1·68 to 1·83, according to the material. Going closer into the matter, the constant c was found to vary directly with the frequency and the relation which exists between n and f was of the form $n=cf^{n_1}$.

THE results of a long series of researches on the conditions affecting the strength of wireless signals is published in a paper by Prof. E. W. Marchant, read before the Institution of Electrical Engineers recently. Daily observations, unhappily interrupted by the war, were made at Liverpool of the strength of signals sent out by the Eiffel Tower with a carefully calibrated apparatus and recorded by a suitable galvanometer. Attempts were made to draw general conclusions from the result, but in the opinion of several well-known wireless telegraph engineers who took part in the discussion, there was, in the absence of a control station near Paris, scarcely sufficient proof that the variations in received signal strength were due entirely to the degree of ionisation or other conditions in the intervening medium. Be this as it may, however, Prof. Marchant was able to show that the ratio between the day and night signal strength varies with the time of the year, and that the strengthening after sunset is less marked in rain than in clear weather, and is different in different directions. The greatest variations were observed at night. In his own opinion, moreover, the character and strength of the variations do point to the conclusion that the main factor which controls them is the state of ionisation of the atmosphere; he suggests that clouds of ionised air may exist in the upper regions of the atmosphere which act as mirrors for the waves and cause the sudden changes in signal strength that have been observed.

THE applications of electrical engineering to warfare formed the subject of an exceptionally interesting discussion at the Students' Section of the Institution of Electrical Engineers on March 3, under the chairmanship of Mr. W. Duddell. Mr. P. R. Coursey opened the discussion on "Communications," stating that the utilisation of the electrical telegraph for military purposes dated back only to the Boer war. In the Russo-Japanese war, field telegraphy and telephony, and also wireless telegraphy, were used; while in the present war not only do field telephones, and telegraphy with Morse sounders and "vibrator" instruments take an important part, but telegraphy is so much employed that transmission with Wheatstone automatic instruments actually finds useful application. Use is also made of wireless telegraphy. In the course of the discussion it was mentioned that, for wireless telegraph reception by airmen, pneumatic head-piece "shock-absorbers" are employed to deaden the noise of the engine. The subject of "The firing of mines and explosives" was opened by Mr. S. Killingback, who said that electric firing had the advantage over hand firing with time fuses, that it was more convenient and trustworthy, and also rendered possible remote control and the simultaneous firing of several charges. The standard electric fuses and detonators require about 0·8 ampere to actuate them, and are fixed either by accumulators or portable hand-operated service dynamos. One speaker in the discussion expressed the opinion that trinitrotoluene was superseding gun-cotton and gunpowder for the fuses, and another stated that electric firing had not been employed in the Russo-Japanese war, suggesting that its chief field in warfare was for the firing of mines for harbour protection for which more trustworthy and permanent cables could be laid. Mr. Duddell reminded the meeting of an exploder (of German make) captured from the Boers, which had been preserved in the Institution library.

THE harmful effects of aldehydes in soils are described by O. Schreiner and J. J. Skinner in Bulletin No. 108, Bureau of Soils, U.S. Department of Agriculture. In the course of examination of an acid garden soil for organic substances, salicylic aldehyde was isolated in amount sufficient to enable its effects to be tested on wheat plants grown in water culture. The harmful effect of the aldehyde, when added both to distilled water and to nutrient culture solutions, was so striking that an extensive series of experiments was undertaken in order to study the action of this compound on various plants and in various culture solutions, in soil in pots, and finally in the field. The plants used for the water culture experiments included wheat, maize, cow-peas, cabbage, and rice; for pot experiments trials were made with wheat, maize, and clover. In every case the depressing effect of the aldehyde was clearly shown. Thus in the case of wheat the addition of ten parts per million of salicylic aldehyde in distilled water reduced the growth by 31 per cent. compared with the control; with fifty parts per million the plants were killed. The experiments suggest that calcium carbonate and calcium phosphate restrain the toxic action of the aldehyde to a slight extent, but the cultures under alkaline conditions indicate that its harmfulness cannot be attributed to any slight acidity it may possess. Field trials made with cow-peas, beans, and garden-peas showed that these crops were all reduced when grown in soil treated with the aldehyde. Finally, seventy-four samples of soils, taken from various parts of the United States, were examined for aldehyde compounds; seventeen of these gave positive results. Ten per cent. of the soils known to be productive and 33 per cent. of unproductive soils contained aldehyde. The infertility of many of the soils is obviously due to causes other than the presence of toxic compounds, and especially of a particular toxic compound.

AN interesting letter from Prof. John Perry appears in *Engineering* for March 12. The subject dealt with is cheap and rapid gun-making, and Prof. Perry describes some experiments carried out under his instructions at Elswick, in which a cylinder of ordinary nickel steel, such as is used in guns, was constructed in such a manner that successive charges were exploded in it, finally reaching the high figure of 52 tons per square inch, without apparent damage to the cylinder. The cylinder was cast solid, or nearly solid, under pressure, and turned and bored not quite to the finished sizes. The ends were closed, and means adopted for filling it with fluid under pressure. The temperature was maintained by rings of gas jets outside (this prevents the yielding material from hardening too much). The internal pressure was raised rapidly to 17 tons per sq. in., and afterwards, during many hours, the pressure was increased gradually to 40 tons. It had been intended to increase the pressure until the outside diameter became permanently (and not merely elastically) larger. Prof. Perry gives a full account of the theory in his letter, together with tables of values of the internal stresses, from which the thickness of gun tubes can be calculated.

A PAPER was read by Sir Thomas Mason at the Institution of Civil Engineers on March 9, giving particulars of the improvement of the River Clyde and the harbour of Glasgow from 1873 to 1914. In 1873 the river from Glasgow to Port Glasgow had an average depth of 15 to 18 ft. below low water, and 25 to 28 ft. at high water. The largest vessels navigating the river had a draught of 22 ft. The total quayage of the harbour was 6410 yards in length, and the water-area was 76 acres. During the period considered, the Queen's Dock, Prince's Dock, Rothesay Dock, and several graving docks have been completed. Improvements on the river have had the effect of reducing the time of flow between Greenock and Glasgow; low water has fallen at Glasgow about 2 ft., and is now 5 in. lower than at Greenock. In 1873 springs rose 10 ft. 6 in.; now the rise is 12 ft. 2 in. The tonnage of trading vessels has increased by 325 per cent., length by 56 per cent., breadth by 69 per cent., and draught by 48 per cent. Quayage has increased three times; tonnage of goods handled four and a half times; and revenue nearly three and a half times. The water-area of harbour and docks is now 535 acres.

OUR ASTRONOMICAL COLUMN.

MELLISH'S COMET (1915*a*).—A recent number of the *Comptes rendus* (vol. clx., No. 9, p. 301) publishes observations of Mellish's comet made at the Observatories of Lyons and Marseilles. The observations at the former were made by M. J. Guillaume between February 20 and 26. The comet is described as of the eleventh magnitude, with the aspect of a circular nebula about a half-minute of arc in diameter, with vague boundaries, and with a condensation or very small nucleus excentric towards the sun. The note by M. Coggia on the observations at Marseilles describe the appearance of the comet as diffuse, irregular, without any brilliant part or condensation. Its magnitude is given as 11. The ephemeris given in this column last week extends up to March 24.

SUN-SPOT AND MAGNETIC ACTIVITY IN 1913.—Prof. A. Wolfer brings together in the *Astronomische Mitteilungen* (No. 105, p. 115) the very valuable statistics of the solar and magnetic acitivity for the year 1913. The statement is based on the large number of observations made at numerous observatories, and affords a ready means of comparing the relative changes which occur from one year to another. The year 1913 seems to have been a very quiescent one according to the value arrived at for the spot activity, and the diminution in activity from the year 1911 will be seen from the following figures:—

1911, 5·7; 1912, 3·6; 1913, 1·4.

This quiet state of spot activity is in close accord with the condition as deduced from the discussion of the mean areas and heliographic latitudes of sun-spots in the year 1913 at the Royal Observatory, Greenwich (*Monthly Notices*, R.A.S., vol. lxxv., No. 1, p. 16).

The value for the daily variation of magnetic declination, on the other hand, has shown a pronounced indication of activity for the year 1913, showing that the minimum took place in 1912, a year earlier than that of the sun-spot.

REPORT OF MOUNT WILSON SOLAR OBSERVATORY.—The annual report of the Mount Wilson Solar Observatory gives the reader a good insight into the remarkable activity that has been, and is, in progress. Before proceeding to give somewhat in detail an account of the work in the various departments, the director, Prof. G. E. Hale, enumerates in the fifty-nine brief paragraphs the principal conclusions to which the work of the past year have led. These are, of course, too numerous to give here, but many of the conclusions have been referred to in previous accounts of research work in this column. This report completes the first decade of operations on the mountain, and we are promised a brief outline of the work for this period. The past year is described as "one of the most productive of this period." We are told that solar research has progressed satisfactorily, that a beginning has been made in the application to solar phenomena of Stark's capital discovery of the effect of an electric field on radiation. One of the new conclusions in stellar astronomy promises to furnish the means of determining a star's distance simply by measuring its brightness and the relative intensities of certain lines in its spectrum. Laboratory investigations and the work of construction have gone forward rapidly. With regard to the last-mentioned, it is hoped to complete the dome for the 100-in. reflecting telescope next summer, and to set up the mounting in the autumn. The large mirror has already received an almost perfectly spherical figure, and preparations are being made for the work of parabolising it. The reader must refer to the report itself to note the progress made in the many and various investigations which are in operation, both on the mountain and at the base station.

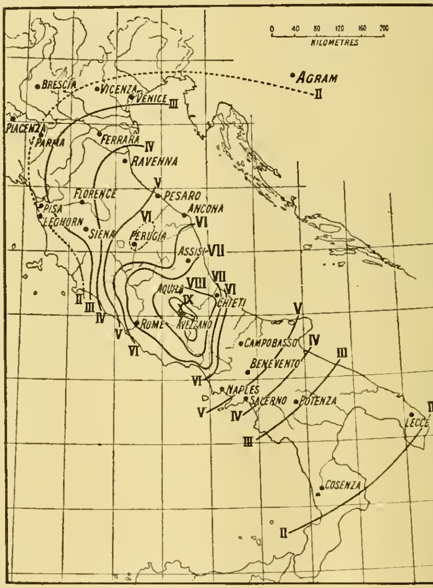
ANNUAIRE ASTRONOMIQUE ET MÉTÉOROLOGIQUE POUR 1915.—The fifty-first issue of the useful handbook entitled "Annuaire Astronomique et Météorologique" has just come to hand. M. Camille Flammarion, the originator and editor of this handy reference book, has, in spite of the recent difficulties met with in Paris, produced the volume up to the high standard of its predecessors. Most of the readers of this column know the arrangement and subjects of the contents so well that it seems necessary only to direct attention to the issue of the volume. Nevertheless it may be added that under the heading, "Scientific Notices," which is an annual review of the progress of astronomy, the reader will obtain a good broad view of the year's work, while in the numerous other sections dealing with the calendar, phenomena, astronomical tables, etc., illustrated by 120 figures of charts and diagrams, a mine of valuable material is included.

THE AVEZZANO EARTHQUAKE OF JANUARY 13.

FOR most of the details contained in the present paper I am indebted to the courtesy of Dr. G. Martinelli, of the Ufficio Centrale di Meteorologia e di Geodinamico at Rome, and of Dr. G. Agamennone, the well-known director of the Geodynamic Observatory of Rocca di Papa, near Rome.

The map of the isoseismal lines is a reproduction of that prepared by Dr. G. Martinelli from the numerous observations forwarded to the Central Office. The scale of intensity employed is that of the late Prof. Mercalli, which, in Italy, has superseded the Rossi-Forel scale. The degree X., for instance, represents the intensity of a shock capable of ruining many buildings and causing much loss of life; the degree VII. that of a shock that will throw down chimneys and produce slight cracks in numerous buildings; while the degree II. corresponds to a shock that can just be felt under favourable conditions by persons at rest. It will be seen that the isoseismal X. is an elongated curve including Avezzano at its western end. The isoseismal of intensity VII. is interrupted by the eastern coast of Italy, and extends beyond Rome to within a few miles of the western coast. The isoseismal of intensity II., which represents the boundary of the disturbed area, includes Parma, Mantua, Verona, and Venice to the north, and to the south approaches within thirty miles of Messina. Thus the area disturbed is not less than 550 miles in length. Its width is, of course, unknown, but, if the mean radius be taken as 275 miles, the total disturbed area must extend over about 240,000 square miles, an area about two-thirds of that shaken by the San Francisco earthquake of 1906.

Dr. Agamennone informs me that the first vibrations were registered at the Rocca di Papa Observatory at 6h. 52m. 54s. a.m. (G.M.T.), but the vibrations soon attained such strength that the seismographs there were thrown out of action. At Rome, a somewhat less sensitive seismograph registered the whole movement, though the pendular masses beat repeatedly against the screws which are arranged to protect the instrument from excessive oscillation. At Eskdalemuir, the first movement was recorded by the Galitzin seismograph at 6h. 56m. 45s., and the beginning of the principal portion at 7h. 1m., the instrument remaining in motion until 9h. 12m. Judging



from the seismogram obtained at this observatory, the epicentre was at the distance of 1930 km. in the direction 40° 50′ south of east; that is, in 42° N. lat., 14° E. long. The centre of the isoseismal line of intensity X. is in 42° 0′ N. lat., 13° 27′ E. long. According to a special seismological bulletin issued by the Georgetown (U.S.A.) University Department of Geology, the first tremors reached that place at 7h. 28m. 40s., and the first oscillations of the principal portion at 7h. 36m. 40s.

The Avezzano earthquake is noticeable for its extraordinary number of after-shocks. At Rocca di Papa, a sensitive microseismograph was at work again an hour after the principal shock, and, from January 13–29, this instrument registered more than 500 after-shocks. That the earthquake was tectonic in its nature is indicated by the extensive disturbed area, the registration of the movement at great distances, and the unusual frequency of the after-shocks.

The earthquake is being investigated by Dr. Mario Baratta on behalf of the Italian Geographical Society. A preliminary notice by Dr. G. Martinelli will appear in the next number of the *Bollettino* of the Italian Seismological Society, and will include the map of the isoseismal lines reproduced here, and also a map prepared by Dr. Baratta to illustrate the seismic history of the district. From the latter, it is evident that the epicentral area of the recent earthquake, though not far distant from the important seismic zone of Aquila, is one in which only earthquakes of slight intensity have originated in the past.

(Since the above was written, a short paper on the earthquake by Dr. G. Agamennone has appeared in the *Rendiconti* of the R. Accad. dei Lincei (vol. xxiv., 1915, pp. 239-46). The author states that the most sensitive microseismometrograph at Rocca di Papa (about forty-three miles from the epicentre) recorded 240 after-shocks from 8.37 a.m. to midnight (that is, from 7.37 a.m. to 11 p.m., G.M.T.) on January 13, and on each of the four succeeding days 120, 88, 38, and 30, the total number of after-shocks until February 6 being nearly 750, of which only about thirty were felt at the observatory or in the surrounding country.) CHARLES DAVISON.

SANITATION IN INDIA.[1]

WE have before us four volumes of papers presented to the All-India Sanitary Conference held at Lucknow in January of last year. Vol. ii. commences with an interesting account of the methods by which in Italy the silt of rivers is utilised for raising the level of the soil, while at the same time the level of the water is lowered by drainage. The system can be carried out with the primary object in view of reclaiming swampy land or the agricultural improvement can also be considered, an almost necessary procedure from the financial side. How far the method is applicable to India is a matter of great interest. One factor that has to be determined is the amount of silt in the particular river under consideration, and, secondly, if agricultural improvement is to be considered, whether the silt is of manurial value. The views of the agriculturist, the engineer, and the sanitarian all need consideration in a problem of this magnitude. How manifold and fundamental the problems are, a consideration of the papers dealing with malaria will show. It is indeed no little achievement that this immense malaria problem is now being studied in India in all its aspects, and that its solution has already progressed far from the facile position held not so long ago by many that the filling up of a few pools and ditches was the answer.

An anti-fly campaign was carried out in Delhi with considerable success, the methods employed being:—(1) Either the burning of rubbish or covering it with one foot of earth; (2) the trenches of trenching grounds were cut $1\frac{1}{2}$ ft. deep and covered with a foot of earth well-rammed down; (3) the use of incineration at the latrines; (4) the cleaning and sprinkling with pesterine of stables, cowsheds, backyards, etc.; (5) litter was removed daily or burned, bedding was changed at least once a week; (6) garden manure was not allowed to be exposed for more than four days—after this it must be dug into the ground and covered with a foot of earth; (7) butchers' shops and vegetable shops were dealt with; and (8) in private latrines, pucca floors and drains were made compulsory. The result of this campaign was that flies were "enormously reduced" and apparently the infantile mortality statistics. It was not, however, until the breeding-grounds within the city—*i.e.* those comprised under headings (4) to (8)—were dealt with that progress was made.

In England the essential points in the bionomics of the fly have been known for some years, but flies still infest our large towns. Is it the inadequacy of the powers possessed by the sanitary authorities that allows this insane condition to continue, or is it the apathy that allows us also almost without a murmur to permit foul smoke to be discharged from our chimneys?

The section on conservancy contains two interesting notes on the "pitting" of night soil, a simple and effective method of solving under certain conditions this ever-recurring problem. The essence of the method consists in sealing the pits from access of flies, etc., with road sweepings.

In vol. iii., the problems of tuberculosis and the very difficult one of a pure milk supply, water supply, notification of disease, and various questions in connection with sewage disposal, are discussed in several papers. An important one is the disposal of sewage sludge; the Grossman process in use in Oldham, where the sludge is dried and freed of its fat by passing steam through, yielding a valuable manure, seems successfully to solve the problem under certain conditions.

Vol. iv. The regulations for the control of malaria in Portuguese India are somewhat rigorous, *e.g.* all vessels intended to hold water will be closed and their contents changed *at least every two days.* Once a week at most is sufficient, as mosquitoes cannot develop from eggs in two days. Again, not only are ventilation outlets of drains to be furnished with wire gauze, but oil is to be poured into the openings to make assurance doubly sure, we suppose. A method for destroying larvæ that we do not remember to have seen mentioned before is contained in the following regulation. "Herds of animals will be introduced periodically (into ponds) to stir up the water, thus making it unsuitable for anopheline larvæ"!

In another paper figures are given which suggest that one species of malaria parasite prevails at one season of the year, another at another. If this is really so, and apparently similar results have been observed elsewhere, it would be important to know the reason for this.

A very interesting paper is that dealing with certain features of malaria in the island of Salsette. One main fact comes out, viz., that malaria increases as one approaches the hills. The study of the conditions in an island have always appeared to us especially interesting, and it is to be hoped that it can be repeated year after year. It shows clearly the great importance of an extended malaria survey of a district before houses are built anywhere and everywhere without consulting expert sanitary opinion.

Another interesting point is the effect of sea breezes in reducing the endemic index of malaria; "villages exposed to the sea-breezes have no spleen rate at all." Emphasis is also laid on that ubiquitous evil, the "borrow" pits along the railway track. Under existing conditions the only practical policy recommended is the abolition of these pits, the exposure of villages to sea breezes by the cutting down of grass and undergrowth, the institution of travelling dispensaries, and the proper control of new building schemes. A general attack on breeding-grounds in rural districts seems impossible. Certain areas of the island are free from malaria, and development should be recommended in these. The question of rice fields and malaria is one of first-rate importance. It would appear that we can get in a rice cultivation area three conditions:—(1) Healthy: spleen rate, 4·3 per cent.; (2) malaria endemic: 24·1 per cent.; (3) malaria hyperendemic:

[1] Supplement to the Indian Journal of Medical Research. Proceedings of the Third All-India Sanitary Conference held at Lucknow, January 19-27, 1914. Vol. ii., Papers, pp. ii+186. Vol. iii., Papers, pp. iv+220. Vol. iv., Papers, pp. iv+212. Vol. v., Papers, pp. iv+226. (Calcutta: Thacker, Spink and Co., 1914.)

70·5 per cent. The healthy areas are in the open plains, the hyperendemic areas at the foot of the mountains, where shade produced by forest, jungle, long grass, scrub, etc., exists, and (3) the endemic area with intermediate conditions. These data illustrate also the great value of malaria surveys before recommendations based simply on general principles are carried out.

Guinea-worm prevails to the extent of as much as 4 per cent. in some of the Indian jails. In a certain Bombay village over a third of the Cyclops in the village well contained larvæ, but the villagers put all the usual obstacles in the way of improving the well and their health.

Vol. v. contains an extremely interesting method of classification of Anophelines based on the distribution of "spots" on the wings; three main groups, Protoanopheles, Deuteroanopheles, and Neoanopheles, are easily separated.

The problem of the mode of dissemination of kala-azar is still *sub judice*; the balance of opinion favours the bed-bug as the agent. It has occurred to the writer as a not impossible hypothesis that perhaps this and some other diseases are not insect-man-insect diseases, but insect-man diseases only, *i.e.* the infecting agent is inoculated into man from and by an insect, produces its ill-effects, but is not further transmissible.

As regards the destruction of rats in plague prophylaxis, we have the merits of two methods put forward, viz.: (1) phosphorus, made up in attractive balls containing less than 3 per cent., and (2) hydrocyanic acid gas. This last kills not only rats but fleas, and its only drawback appears to be its very poisonous character. Its detection, however, is an easy matter, viz., by means of a paste which forms with it prussian-blue. The amount requisite is $\frac{1}{2}$–$\frac{3}{4}$ of an ounce of potassium cyanide per 100 cu. ft. It has many advantages over the sulphur dioxide or carbon monoxide methods.

There are many other subjects, such as vital statistics, water filtration, that we have not alluded to, but one would refer those who wish to obtain a general idea of the scope of these important conferences to the summary contained in the *first* volume. We ought to end with a word of congratulation on the splendid work that is being done.

J. W. W. S.

ORNITHOLOGICAL NOTES.

IN the February number of *British Birds* Miss M. D. Haviland continues her account of ornithological observations made in the delta of the Yenisei, dealing in this instance with the little stint. So fearless during the nesting season were these birds that it was with difficulty they were kept far enough away from the camera to admit of the taking of a satisfactory photograph; and a brooding cock captured by the author in her hands, when released returned to the young. In six out of eight instances the sitting birds were cocks, but whether both sexes take their share in incubation was not ascertained.

The distribution of birds in Ceylon, in relation to recent geological changes in that island, forms the subject of an article by Mr. W. E. Wait in *Spolia Zeylanica* for December, 1914. (vol. x., part 36). A large proportion of the resident birds, especially in the Kandyan provinces and the wet zone of the low country, are of a Malabar type; but in the north and north-west there is a nearer affinity with those of the Carnatic. Of the peculiar species, the greater number pertain to the Malabar type of the fauna, and have their headquarters in the wet zone, but there are also a few with a Himalayan or Malay *facies*, although none of the Carnatic types. As the theories advanced by the author to explain these peculiarities in distribution are confessedly tentative, quotation seems unnecessary.

In the *Zoologist* for February Miss W. Austen records the appearance of a flock of about thirty long-tailed tits in a garden at Maida Hill on October 1, 1914, an occurrence which the editor believes to be altogether unprecedented.

To the January number of the *Auk*, and likewise to *Blue-Bird* for the same month, Dr. R. W. Shufeldt contributes a note on the last survivor of the American passenger-pigeon, which died in the Cincinnati Zoological Gardens on September 1, 1914, at the age of twenty-nine years. Immediately after death the body, packed in ice, was forwarded to the National Museum at Washington, where the skin was carefully removed for preservation, doubtless in the study series. Before this took place a photograph of the head and neck was taken and coloured with Japanese tints from the specimen; this photograph, after the insertion of an artificial eye, being reproduced in colour in the aforesaid issue of *Blue-Bird*.

R. L.

NOTES ON GLASS.[1]

A CERTAIN amount of experimental work on glass-ware of various kinds has been carried out recently at the National Physical Laboratory, and it may be of interest to make known some of the results.

Chemical investigations have for some years been dependent on German glass; the publication of the analyses and of test results may, it is hoped, lead some English firms to produce articles which may replace those of German manufacture.

The first table gives the analyses of some thermometric and chemical glass-ware.

Analyses of Thermometer and Chemical Glass-ware.

	Thermometer Glasses		Schott and Gen., Jena		Chemical Glassware		
	Jena 59III	Jena 16III	Original	"New"	Resistance "R"	Kavalier's Bohemian	Thüringen

Analyses made with an asterisk have been made at the N.P.L. The other analyses are taken from a paper by Walker in the Journal Am. Chem. Soc., xxvii., 865, 1905.

(Bohemian and Thüringen glass is now rarely used in chemical work, but the analyses given are of the best material of that class.)

Resistance of Various Chemical Glass-ware to the Action of Chemical Attack.

The table below, taken from the work of Mylius and Foerster on this subject, gives the action of

[1] From the National Physical Laboratory, February, 1915.

various chemical reagents on glass used for chemical purposes (for analyses, see foregoing table):—

Beakers.

Type of Glass.	Water. 20°	Water. 80°	H_2SO_4	NaOH	Na_2CO_3
"R" ...	0·0054	0·0144	0	41	23
Jena ...	0·0071	0·0035	0	53	19
Bohemian	0·118	0·219	5	37	49

Flasks.

Type of Glass.	Water. 20°	Water. 80°	H_2SO_4	NaOH	Na_2CO_3
"R" ...	0·0128	0·0128	0	51	26
Jena ...	0·0063	0·0057	0	63	24
Bohemian	0·093	0·255	11	52	70

The figures are in milligrams per sq. dcm.

The solutions, viz. 2N.NaOH and $N.H_2SO_4$ were allowed to act at 100° for six hours, and $2N.Na_2CO_3$ for three hours.

The Jena glass used was probably of the composition given in the first foregoing table under description "Original." This glass is now not used, but has been replaced by the new Jena glass, an analysis of which has been made at the National Physical Laboratory. Soon after the introduction of this new Jena glass by Schott and Gen., viz., in 1910, some tests were made at the National Physical Laboratory. A special feature of the new glass was its increased resistance to attack; this was brought about by long exposure to sulphureous gases. The tests on the glass before and after such treatment are given in the table below. Several kinds of vessels were tested, and the results for all were substantially the same.

Tests made at the N.P.L. in 1910 on "New" Jena Glass.

Mark: (1) Vessels had received no annealing.
(2) Vessels had received ordinary annealing.
(3) Vessels had received special annealing in sulphureous gases for thirty-six hours.

Beakers.	Milligms. Na_2O per sq. dcm. given up to water at 20° C. in 1 week.	Milligms. Na_2O per sq. dcm. given up to water at 80° C. in 3 hours.
1 ...	0·0022 ...	0·0045
2 ...	0·0032 ...	0·0047
3 ...	0·0019 ...	0·0040

In the following table the figures give the loss in weight in milligms. per sq. dcm. after the treatment stated.

Beakers.	3 hours with 2N NaOH at 100° C.	3 hours with 2N Na_2CO_3 at 100° C.	6 hours with N H_2SO_4 at 100° C.

3 ...	71 ...	10 ...	nil.
Flat-bottomed Flasks			
1 ...	62 ...	8 ...	nil.
2 ...	71 ...	8 ...	nil.
3 ...	79 ...	6 ...	nil.

There was a small improvement as regards resistance to the attack of water, but no improvement to the attack of alkalies. Since its introduction this type of glass-ware has been used in the National Physical Laboratory and has given every satisfaction.

It is well known that alkaline fluids attack glass very markedly, and for that reason in chemical analyses prolonged contact is avoided. To do this is not always possible, *e.g.* in the estimation of zinc and manganese, especially in silicate analyses. It is necessary in the estimation of these metals to employ solutions containing alkaline chlorides and ammonium sulphide, and to allow the solutions to stand at a rather high temperature (50–60° C.) for sometimes as long as twelve hours. In these circumstances the glass is invariably attacked, and although no quantitative experiments have been made with the Jena glass, the resistance to the attack of these solutions is certainly not as good as with the alkaline solutions in the absence of chlorides and sulphides. In view of the fact that glass flasks have to be used for this purpose, it seems desirable to devise a test, in addition to the tests usually carried out, to determine the ability to withstand the joint action of alkaline chlorides and sulphides.

The new Jena glass examined at the National Physical Laboratory in 1910 possessed in a very high degree the ability to withstand sudden change of temperature. A glass flask filled with molten paraffin wax at a temperature of 250° C. broke when placed suddenly in water at 15° C., but only after successfully standing such a test at slightly lower temperatures.

Another question which is engaging attention is glass for miners' lamps, incandescent chimneys, steam gauge tubes, and other purposes in which a gradient of temperature is established between the inside and outside.

Analyses of some of these glasses are given in the following table:—

Analyses of Lamp Glasses.

	Jena Incandescent Gas (Schott & Gen.) Best Quality.	Miner's Lamp Glass. German Make. Mark A [1] B.	Miners' French Lamp Glass (Yellow).	Miners' French Lamp Glass (Colourless).	Austrian Lamp Glass "Sun Brand."

	100·00	100·00	100·00	99·76	100·14

It appeared, however, from Hovestadt's book on glass, and other information, that the additional strength of the German glass was conferred on it in great measure by its heat treatment, and tests were made to investigate the state of strain in the glass.

For this purpose the following glasses were examined:—

(1) A miner's lamp chimney of white glass of German manufacture.

(2) A miner's lamp chimney of yellow glass of French manufacture.

(3) A piece of "Durax" tubing as used for chemical purposes.

From each of these tubes two rings of about 1 cm. depth were prepared by making transverse cuts across the tubes; the plane surfaces of the rings were optically polished. One ring of each specimen had a piece cut out so that the ring was free to spring. Other pieces were prepared for the determination of the refractive properties of the glasses.

The three open and three complete rings were examined in plane polarised light for strain. The examination showed that in both rings of the French glass, and in the open ring from the German lamp chimney, the amount of strain was negligible. In the unbroken ring from the German chimney there was very decided strain. Strain was also present in both rings of the "Durax" glass, the unbroken ring of this material showing much more pronounced strain than any of the other rings. The appearance presented by the rings when examined in the dark field is a very strong and sharp black circular line in the middle of the glass with a decided black cross upon it, and the rest of the ring either white or milky.

The character of the strain present in the unbroken ring from the German chimney was determined by distorting the ring into an elliptical form by compression between two points at opposite ends of a diameter of the ring inclined at 45° to the plane of polarisation. By this means the milkiness could be made to disappear entirely from the regions about the diametrical plane perpendicular to the line of compression, but the strain in the neighbourhood of the points of compression was increased. This shows that the strain is relieved by an increase in the curvature, and augmented by a reduction in the curvature; in other words, the inner layers of the ring are in a state of tension, and the outer layers in a state of compression. The fact that in the open ring the strain throughout is practically entirely relieved suggests that these chimneys are made in one operation, and not by the combination of layers of material at different temperatures. It is evident that with the distribution of strain in the cold state indicated above, the chimney will tend to be relieved of strain when there is a radial temperature gradient throughout its substance with the outer surface cooler than the inner surface.

With the "Durax" tubing there is in neither ring freedom from strain. In the open ring the strain becomes worse on altering the curvature in either direction. Perhaps this indicates that the tube is built up of layers of the same or different materials, but brought together with one layer decidedly cooler than another. The presence of a thin white band in the substance of the glass may also indicate that the tube has been built up in the way suggested. An examination of all the rings in ordinary light showed the presence of striæ likely to prevent the formation of really sharp spectrum lines in the determination of their refractive properties. This expectation was fully borne out by the appearance of the lines in the refractometer. No indication was obtained that any tube consisted of more than one type of glass, but the want of sharpness in the lines was sufficient to obscure the difference between glasses of very nearly identical optical properties. The results obtained in these measurements are as follows:—

	n_D	$n_C - n_F$	ν
German chimney ...	1·4795	0·00729	65·8
French chimney ...	1·5748	0·01313	43·8
"Durax" combustion tubing	1·5156	—	—

The *optical* glasses which resemble the above in refractive properties are, for the German chimney one of the new "Fluor Crowns," for the French chimney a light flint, and for the "Durax" tubing a hard crown.

Experiments were made to determine possible variations in the strained condition of lamp chimneys due to internal heating and resulting temperature gradient across the glass.

Coils of wire were wound round a cylindrical metal core, the whole enclosed in asbestos paper and fitted closely (without mechanical strain) into the ring of the chimney examined. A thermo-couple was introduced between the lagging and the glass to enable the temperature of the latter to be determined on the passage of a current through the heating coil.

French Chimney.—This was initially when cool without strain. On heating up strain was found to develop progressively as the temperature rose, and there is no evidence that at any temperature the strain declines to a minimum again.

German Chimney.—When cool and at uniform temperature this showed very decided strain in the shape of a central ring and cross. On heating up the ring the strain was relieved, but the glass is never *entirely* freed from the strain as evidenced by a complete absence of the stauroscopic figure. The tendency is rather for the central dark ring to move outwards and to be replaced eventually by another ring moving out from the inner surface of the glass ring. There is nevertheless a decided minimum effect, *i.e.* minimum strain, obtained when the temperature of the inner surface of the glass ring is about 150° C. (±20°). The temperature gradient across the glass is such that in the steady state the temperature of the outer surface of the lamp, corresponding with the above internal temperature, is roughly 70°, within the same limits of accuracy. Excessive heating above these limits results merely in producing a more pronounced strain.

A further chemical analysis of the inner layers confirmed the view that the German miner's lamp chimney is of a single material.

The incandescent lamp chimneys are very thin and optical examination is not possible, but it appears fairly certain that in their case also the extra strength is attained by some process whereby the outside is chilled before the interior cools down. It seems possible also that the extra heat-resisting qualities of certain beakers, flasks, etc., of German glass may be due to the converse process, the interior being chilled previously to the exterior. All these glasses appear to be of the borosilicate type, such as is used for the well-known thermometer glass 59^{III}, but with somewhat more boric anhydride; the chemical glass contains zinc oxide, which is absent from the thermometer glass.

As already stated, the object of these notes is to put such information as is available before English manufacturers in the hopes of encouraging some of them to take up the manufacture of some of these glasses.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. R. TRAVERS SMITH has been appointed to the chair of materia medica, therapeutics, and pharmacology in the school of surgery of the Royal College of Surgeons in Ireland.

THE will of the late Mr. W. E. Allen, chairman of Messrs. Edgar Allen and Co., Ltd., of the Imperial Steel Works, Sheffield, who died in Jnuary last, provides that two-fifths of the residue of his property after the payment of numerous bequests to charities and employees, shall be given to the University of Sheffield, to be applied as to 5000*l.* to the Applied Science Department, and as to the balance, in the discretion of the University Council, in founding Edgar Allen scholarships or exhibitions for students of that University, of whom one-half shall be sons of workmen earning daily or weekly wages or foremen of workmen or managers. The gross value of the estate was 271,068*l*., and about 150,000*l*. is devoted to bequests for charities and employees.

THE annual gathering of the South-Western Polytechnic was held on Friday, March 12. The chair was taken by Archdeacon Bevan, and Mrs. Hayes Fisher distributed the certificates and prizes. The report of the principal showed that the chief feature of the session 1913–14 was the large number of scholarships gained by the past and present evening students. These scholarships included a Beit fellowship, the research studentship at Emmanuel College, Cambridge, a science scholarship and an art scholarship given by the London County Council. Amongst the degrees gained in London University were three D.Sc. degrees in chemistry. The principal also directed attention to the large number of present and past members of the institute who were serving with the forces. A vote of thanks was proposed by the Mayor of Chelsea, Principal Hudson, of St. Mark's College, and was seconded by Mr. J. B. Coleman, who gave some account of the present condition of chemical industries and of what the chemical department of the institute was doing to help those industries.

THE steady progress of education, and especially of scientific education, in India, has frequently been noticed in these columns, and we are glad to see confirmatory evidence in the *Presidency College Magazine*, issued from the Presidency College, Calcutta, and edited by Mr. Joges Chandra Chakravarti. The magazine contains some interesting papers and notes, and prominent among them is an article on Prof. H. E. Armstrong's visit to Calcutta as reader in chemistry to the University, when he delivered a course of five lectures. There is also a review of "Forty Years of Progress of Chemistry at the Presidency College," by Dr. P. C. Ray, showing how a school of chemical research is being gradually built up, of which Dr. Ray himself is the leader. A very appreciative obituary notice of Prof. J. A. Cunningham, who was professor of chemistry at the Presidency College from 1906–9 is given. Further, a series of notices of eminent Presidency College men is published, and the subject of the article in this number is Sir Asutosh Mookerjee, lately Vice-Chancellor of the University, who has done much for Indian education.

THE number of undergraduates in residence at Oxford and Cambridge, as stated in a note on March 4 (p. 24) is almost exactly one-third that of a year ago, the other two-thirds—about 2000 from each University—being on active service with the Army or Navy. According to the *Kreuz-Zeitung* there are upon the books of the twenty-two German universities—the twenty-second university being that of Frankfurt a/M., opened in October last—for the winter semester, including those at the front, 52,504 students, of whom 4000 are women, as against 59,600 and 3700 respectively last year. On leave—*i.e.* on military service—there are 29,882 students, including 300 women, mostly students of medicine. There are present in the universities 18,922 men and about 3700 women. Of those present, 1500, including several hundred women, are foreigners. The number of students on military service is, however, larger than appears from these statistics, since the Technical High Schools have not been taken into account. The real number is only obtained by subtracting from last year's number of German men students those of this semester, which gives about 32,000 students in the field. This does not even include those called to arms after the closing of the statistics Their number is at least one-third of those present, so that the number of students under arms must be raised by a further 6300. Seventy-five per cent. of the German students are therefore in the field. Of the German students of Technical High Schools about 80 per cent. are in the army.

THE War Office gives notice that an Army entrance examination will be held on June 29 next. At this examination there will be open to competition :—(*a*) Not fewer than 125 cadetships at the Royal Military Academy, Woolwich (for the Royal Artillery and Royal Engineers); (*b*) not fewer than 300 cadetships at the Royal Military College, Sandhurst (for the Cavalry, Foot Guards, Infantry, and Army Service Corps). The competition will be conducted in accordance with the regulations issued in November, 1911, except that no oral or practical tests will be included in the examination. To be eligible to compete for admission to the academy, a candidate's age must be such that he will have attained the age of 16½, and will not have attained the age of 25, on July 1, 1915. To be eligible to compete for admission to the college, a candidate's age must be such that he will have attained the age of 17, and will not have attained the age of 25, on that date. The contributions usually paid by parents of cadets will be dispensed with in the case of candidates admitted as a result of this examination. This will not affect the payment of 35*l*. required for the provision of uniform, books, etc. A sum not exceeding 3*s*. a day will be contributed from Army funds towards the cost of each cadet's messing, washing, and contingencies. Camp kits are issued in kind at the academy or college. Outfit allowance of 50*l*., from which the cost of the camp kit will be deducted, is issuable to cadets on appointment to commissions. A limited number of cadetships in the Royal Navy and supplementary first appointments in the Royal Marines will also be open to competition.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 4.—Sir William Crookes, president, in the chair.—Prof. W. A. **Bone**, Prof. H. L. **Callendar**, and H. J. **Yates**: A bolometric method of determining the efficiency of radiating bodies. In view of the increasing uses of incandescent surfaces in heating operations of all kinds, the authors have investigated, as a scientific problem, the measurement of radiant efficiencies of such surfaces, by a bolometric method, which can be standardised by direct comparison with a radio-balance, and which the authors propose to substitute for the existing *water-radiometer-cum-thermopile* method (known as the "Leeds method") used hitherto. The paper describes the construction and use of a new bolometer, specially designed for the purposes in view, in which the radiation from an incandescent surface, falling on a blackened coil of platinum wire, can be determined in absolute units for the increase in the electrical resistance of the receiving coil, the area of which is sufficiently small to allow of the instrument being standardised from a source of known intensity. And, by way of example, the application of the method to the measurement of both the absolute radiation of a gas fire and its "distribution factor," is described and discussed.—E. **Chappell**: The simplification of the arithmetical processes of involution and evolution. An arithmetical process can be said to be completely simplified when it is reduced to either addition or subtraction. The invention of logarithms completely simplified multiplication and division, but involution and evolution were only replaced by multiplication and division, so that these processes may still be laborious even with the use of logarithms. The paper describes a table of the logarithms of numbers recently compiled, by the use of which involution and evolution are also completely simplified. The frequency with which fractional indices, positive and negative, occur in most branches of modern experimental science gives rise to the hope that the tables in question will accomplish for the modern investigator what logarithms did for the man of science of the seventeenth century.—F. E. **Rowett**: The elastic properties of steel at moderately high temperatures. The difference in the behaviour of hard-drawn steel tubes, before and after annealing, under stress, led to the experiments described in the paper. At a suitable temperature a hard-drawn tube, which contains a good deal of amorphous material, behaves like a viscous fluid, that is, it flows more or less freely under stress, whereas, at the same temperature, an annealed tube being crystalline will flow in a much less degree, corresponding to the small amount of amorphous material in it. At a temperature of about 300° C. a hard-drawn tube shows properties similar to those of pitch at ordinary temperatures or of glass at a temperature rather below its softening point. It is still highly elastic under rapidly varying stress, but flows perceptibly when the stress is applied for a long time. On the other hand, in the annealed tube at 300° C. the energy dissipated in a cycle of stress is still almost independent of the time taken over cycle. At a higher temperature, for example, at 540° C., the hard-drawn tube flows rapidly and continues to flow for a long period, though at a diminishing rate, under a shear stress of less than one ton per square inch. Moreover, like pitch or glass, the steel at this temperature shows considerable elastic after-working. If the stress be suddenly removed the immediate elastic recovery is followed by a slow backward flow which persists for many minutes.—Prof. J. W. **Nicholson**: The laws of series spectra. The paper contains a critical analysis of the diffuse, sharp, and principal series of helium, especially in the light of recent interferometer measurements of the leading lines of these series. The investigation depends on a mode of accurate calculation of the limits of series, not dependent on the type of formula used. The limits of series with many lines, for which a Hicks formula is already known, can be calculated with extreme accuracy by a new method. Interferometer measures of leading lines of helium series enable the best form of the series to be obtained. This form is an extension of that of Rydberg, dependent on $m+\mu$ and not m. The value of Rydberg's constant, 109679·2, given by Curtis for hydrogen, is the true value for the arc spectrum of helium, and is, in fact, a rigorous constant for arc spectra. Spark spectra are not treated. The Rydberg-Schuster law of limits is exact for helium. It seems probable that μ is a simple fraction the denominator of which is a multiple of 5, as Halm has suggested. It is exactly 0·7 for the short series of helium.

March 11.—Sir William Crookes, president, in the chair.—E. **Heron-Allen**: Contributions to the study of the bionomics and reproductive processes of the foraminifera. The mechanical functions of the protoplasm in locomotion and food catching and its reaction to stimuli are considered. The phenomenon hitherto known as plastogamy is only fortuitously connected with reproduction, and is in most cases a budding-off of a daughter-individual from a parent shell. Certain species of foraminifera, if not all, vary the processes of reproduction by amœbulæ formed of protoplasm discharged from the shells, and by flagellispores, by the formation of fully formed and calcareously invested polythalamous young inside the parent shell which are set free by the resorption of the parent shell. The dual nature of the terminal chamber in *Cymbalopora brelloides*, d'Orbigny, is confirmed, and its functions in the life-history of the organism are discussed. A new species, *C. milletti*, Heron-Allen and Earland, is established. The species, *C. tabellaeformis*, Brady, is recorded as exhibiting a new phenomenon in the bionomics of foraminifera, namely, the excavation of crypts in suitable hosts where it passes its life, boring by chemical action tunnels for the protrusion of its pseudopodia. The secretion of calcium carbonate by porcellanous and hyaline foraminifera is considered, and the phenomena of "purpose" and "intelligence" are claimed as being exhibited by certain species of arenaceous foraminifera in the construction of their tests, either with a view to adaptation to environment or for defensive purposes. The "monadiform bodies" of Cymbalopora and the siliceous foraminifera from great depths, attributed to the late Sir John Murray, are explained by publication of his original notes made on board H.M.S. *Challenger*.—G. E. **Nicholls**: The occurrence of an intracranial ganglion upon the oculomotor nerve in *Scyllium canicula*, with a suggestion as to its bearing upon the question of the segmental value of certain of the cranial nerves. The occurrence of actively functional ganglion cells in large number, associated with numerous smaller and more deeply staining cells to form a small ganglion upon the oculomotor nerve in the adult *S. canicula*, has not hitherto been recorded. The true sensori-motor character of this nerve has recently been established by Sherrington and Tozer. This fact, in conjunction with the existence of the ganglion, becomes extremely significant, when it is remembered that the oculomotor plays an important part in the development of a related sympathetic ganglion (the ciliary). The author's suggestion is that the oculomotor be regarded as a distinct segmental nerve, not merely as a ventral root. From this it follows that the ophthal. profund. is not the dorsal root of the oculomotor neuromere, but has encroached upon that segment, while itself related to another (probably more posterior) head segment.—Prof. R. **Kennedy**: Experiments on the restoration of paralysed muscles by means of nerve anastomosis. Part III.—Anastomosis of the brachial plexus, with a consideration of the distribution of its roots. The experiments recorded consist of division of one or more roots of the brachial plexus and anastomosis of the divided root or roots either to another part of the plexus or to the spinal accessory. Restoration of function took place, and physiological examinations showed that this was due to the nerve which was substituted for the severed roots. When fewer than two roots were divided restoration of function took place much earlier, and was shown to be a spontaneous recovery due to the affected muscles being each supplied through more than one root.—A. F. S. **Kent**: The mechanism of the cardiac valves—a preliminary communication. The communication deals with the structure and mode of action of the auriculo-ventricular valves of the mammalian heart. Muscular tissue derived from the auricular wall runs for a considerable distance into the substance of the valve flaps, being situated principally towards their auricular surfaces. It is permissible to conclude that this muscle exercises an important function in connection with the closure of the valves. Receiving its stimulus from the base of the auricle, of which it is indeed an extension and with which it is directly connected, it comes into action at the appropriate moment in the cardiac circle, and contracts—and remains contracted—last of all the auricular muscle. Thus it keeps the valve flaps away from the ventricular wall, and ensures free play to the retro-valvular eddy right up to the time when the valve closure begins to be finally accomplished. The function of the muscular slips now described may be regarded as a double one—(*a*) to keep the flaps away from the ventricular walls, and thus to ensure the provision of an adequate space between the flap and the ventricular wall for the full development of the retro-valvular eddy, and (*b*) to afford by their contraction direct mechanical assistance in the raising of the flaps into the position of final closure.

Geological Society, February 24.—Dr. A. Smith Woodward, president, in the chair.—Dr. J. E. **Marr**: The Ashgillian succession in the tract to the west of Coniston Lake. The author has studied in detail the succession of the Ashgillian strata in Ashgill Beck and the adjoining tract. An account of the lithological characters and lists of the fossil contents of the various divisions are given, and confirmatory sections from Coniston Village to Appletreeworth Beck are described. A comparison is made with the beds of the Cautley district, previously described by the author. Some fossils which have not yet been found in the Lower Ashgillian of the Cautley district occur in the beds of that division at Coniston. From a study of the fossils of the Coniston tract and of other areas in Britain and the Continent, it would appear that a twofold division of the Ashgillian strata which is of more than local value may be made. The lower division is characterised by the abundance of *Phillipsinella parabola*, and the upper by the profusion of *Phacops mucronatus*.—H. S. **Shelton**: The radio-active methods of determining geological time. The author holds that the radio-active method of determining geological time, while of great interest, is not of such certainty as to be independent of confirmation from other lines of investigation. The various radio-active methods, helium ratios, lead ratios, and pleochroic haloes are severally examined, and the various sources of uncertainty, general and particular, are pointed out. The most important general cause of uncertainty is to be found in the fact that mechanical and chemical changes of composition in minerals are the rule rather than the exception; and, in instances where constancy of composition throughout long periods of geological time is asserted, the burden of proof lies with those who make the assumption. The attempt to assess exact, or even approximate times by means of lead ratios is premature and entirely invalid. At the same time, the weight of the evidence is such as to render it exceedingly probable, so far as radio-active evidence goes, that geological time must be reckoned at least in hundreds of millions of years. There is a high degree of improbability that the errors in the radio-active methods should always be errors of over-estimation. The next step in the investigation of the time problem is to be found in a reversion to other lines of reasoning. The sea-salt methods, and those based on the thickness of the sedimentary rocks in particular, need careful reconsideration. Reference is made to a number of papers which show that the first of these is worthless, and the second based on a misapprehension of the nature of deposition. The argument from tidal retardation is still of value, as also is that from the evolution of carbonate of lime. To the author radio-active experiments come as a confirmation of views held on other grounds, but are not sufficiently important in themselves to be authoritative against the balance of the evidence derived from other lines of investigation.

Mathematical Society, March 11.—Sir Joseph Larmor, president, in the chair.—Prof. E. W. **Hobson**: Some theorems in the theory of series of orthogonal functions.—Major P. A. **MacMahon**: Investigations in the theory of the partition of numbers by a new method of partial fractions.—Col. R. L. **Hippisley**: Reciprocal and parallelogram linkages.—Dr. J. R. **Wilton**: A pseudo-sphere the equation of which is expressible in terms of elliptic functions.—T. C. **Lewis**: Circles and spheres, etc., associated with a triangle, orthocentric tetrahedron, etc.

PARIS.

Academy of Sciences, March 8.—M. Ed. Perrier in the chair.—The President announced the death of Prof. Hittorf, foreign associate.—A. **Leduc**: Diffraction phenomena and the motion of the earth. Pointing out an error in the calculations of Mascart in his memoir on the modifications undergone by light by reason of the movement of the source or the observer.—Emile **Saillard**: Catalysis in the oxidation of the alkaline sulphites. The oxidation of alkaline sulphites is retarded by the presence of saccharose, invert sugar, and other bodies, and accelerated by rise of temperature. The practical bearing of these observations on the process of sugar refining is discussed.—Maurice **Lugeon** and Gerhard **Henny**: The Canavese zone and the southern limit of the Alps.—Med. **Gard**: A hybrid of *Fucus ceranoides* and *F. vesiculosus*.—M. **Weinberg**: Researches on gas gangrene. In the majority of cases the organism producing the disease is *B. perfringens*. A description of the preparation of a vaccine and an antiserum (through the horse) is given; the latter appears to offer the most promising results.—Agasse **Lafont**, M. **Desmoulins**, and F. **Heim**: Pneumokoniosis in metal polishers.

PSYCHOLOGY WITHOUT CONSCIOUSNESS.

Behavior: An Introduction to Comparative Psychology. By Prof. J. B. Watson. Pp. xii+439. (New York: H. Holt and Co., 1914.) Price 1.75 dollars.

BY the nature of its subject-matter, psychology has been more handicapped than any other science as regards both methods and aims. This is a truism which may qualify the following statement of Prof. Watson: "Psychology has failed signally during the fifty odd years of its existence as an experimental discipline to make its place in the world as an undisputed natural science." He is quite justified in saying that psychology "as it is generally thought of, has something esoteric in its methods. If you fail to reproduce my findings, it is not due to some fault in your apparatus or the control of your stimuli, but it is due to the fact that your introspection is untrained. . . . If you can't observe 3—9 states of clearness in attention, your introspection is poor. If, on the other hand, a feeling seems reasonably clear to you, your introspection is again faulty. You are experiencing too much." This kind of psychological method has been particularly exploited by the Germans. Again, the science has almost evaporated "in speculative questions concerning the elements of mind, the nature of conscious content (*e.g.*, imageless thought, attitudes and *Bewusstseinslage*, etc.)"; a practical result is that the concept of sensation is "unusable, either for the purpose of analysis or that of synthesis." Generally, the axiom that psychology is a study of the phenomena of consciousness has been thoroughly mischievous; no data have been accorded any importance except in so far as they throw light upon conscious states. Compromises have been attempted; a line has been tentatively drawn where "associative memory" in animals begins; consciousness has been assumed to commence where "reflex and instinctive activities fail properly to conserve the organism," or "whenever we find the presence of diffuse activity which results in habit-formation, we are justified in assuming consciousness." Not the least result of such pre-suppositions is the divorce of the study from practical human interests.

The new school of what Prof. Watson terms "behaviorism" has, as his volume well shows, thrown overboard much conceptual lumber of the sort sketched above, and comparative psychology is able to act untrammelled. "It is possible to write a psychology (as the 'science of behavior') and never go back upon the definition; never to use the terms consciousness, mental states, mind, content, will, imagery, and the like. . . . It can be done in terms of stimulus and response, in terms of habit formation, habit integration, and the like." The starting-point is the observable fact that "organisms, man and animal alike, do adjust themselves to their environment by means of hereditary and habit equipments; . . . . certain stimuli lead the organisms to make the responses." Thus, with the elimination of investigational reference to consciousness, mental state, or imagery (as previously such reference to soul and mind (its successor) had been discredited), the barrier between psychology and objective sciences is removed; "the findings of psychology become the functional correlates of structure and lend themselves to explanation in physico-chemical terms." "The behavior of man and the behavior of animals must be considered on the same plane."

This latest reforming of the comparative psychological front may be considered strategically sound, and should lead to advances along all the line. Little has been accomplished yet, but the resulting clearness of objective is already promising. For instance, Prof. Watson's discussion of the differences between man and animal; convolution of brain surface probably means nothing *per se*. Wundt assumed that the apperception centres resided in the frontal lobe; for this view there is no probability, but since the frontal lobe "was the last brain tissue put on in evolution, and is to be found chiefly in man, we have hastened to assign to its care all those functions in which man is thought chiefly to excel the brute." The break between man and brute is "the lack of well-developed speech mechanisms in animals and the consequent lack of *language habits*. . . . The lack of language habits forever differentiates brute from man."

The general reader and the beginner in comparative psychology will find this impartial and well-reasoned volume invaluable. Some of the best matter is the result of the author's own experiments, *e.g.*, with terns, monkeys, and rodents.

A. E. CRAWLEY.

WATER, SEWAGE, AND FOOD.

(1) *The Chemical Examination of Water, Sewage, Foods, and other Substances.* By J. E. Purvis and T. R. Hodgson. Pp. 228. (Cambridge: At the University Press, 1914.) Price 9*s*. net.

(2) *Water Supplies: their Purification, Filtration, and Sterilisation. A Handbook for the Use of*

Local and Municipal Authorities. By Dr. S. Rideal and Dr. E. K. Rideal. Pp. xii+274. (London: Crosby Lockwood and Son, 1914.) Price 7*s.* 6*d.* net.

These two books to some extent supplement one another, the former dealing with the analysis of water (among other things), while the latter treats mainly with the production of a pure and wholesome water supply; the one being designed for the analyst and public-health student, the other for local and municipal authorities.

(1) The volume by Messrs. Purvis and Hodgson, as its name implies, deals primarily with the chemical analysis of water, sewage and foods, and such allied subjects as the detection and estimation of preservatives, and the analysis of air, coal-gas and other gases, rag flock, and urine.

The opening chapter, which is by far the longest in the book, deals with the analysis of water, sewage, and sewage effluents. More or less detailed descriptions are given of the chief tests employed, and in this connection one might note the desirability of the standardisation of some of these tests, notably those for albuminoid ammonia, and oxygen absorbed from permanganate. Some of the tests, as described, do not appear to be capable of any great delicacy. This is particularly the case with the ammonia tests, which apparently are about ten times less delicate than those employed in the laboratories either of the Metropolitan Water Board or the Royal Commission on Sewage Disposal.

At the conclusion of the chapter the results of a series of investigations, chiefly by Mr. Purvis, are given dealing with the effect of mixing sewage with river water and sea water. Much of the work is obviously inspired by the eighth report of the Royal Commission on Sewage Disposal. The researches have resulted in some interesting information, but the manner in which the results are presented makes a full appreciation of them very difficult, and some of the results of an investigation of the changes which occur to a mixture of sewage and sea water in course of time show such wide variations that one is inclined almost to doubt the accuracy of some of the figures; for example, the albuminoid ammonia of a mixture of sewage and sea water analysed after 115, 165, and 176 days is given as 0·078, 0·002, and 0·13 respectively (Table F^1, p. 74).

The remaining chapters of the book consist of instructions for carrying out the analyses of the other substances mentioned above. The instructions are usually remarkably clear and concise, but occasionally they become much involved and even ungrammatical, suggesting that these parts have been hurriedly compiled. This, however, is a small blemish, and can easily be corrected in a future edition; it in no way detracts from a book which will undoubtedly be of great value both to the analyst and the student in a public-health laboratory.

(2) The second volume under review deals with the question of water supply in its widest sense, and only touches on the subject of analysis in the last chapter, and then more on the interpretation of the results than on the way these results are obtained.

The opening chapters deal with the inorganic and organic contents of natural waters, both useful (as in medicinal springs) and harmful (as in water from polluted sources), mention being also made of some of the living contents, particularly those grouped under the name of plankton. Following this preliminary matter, the book deals with the successive stages in water supply under the headings of sources of supply, distribution, storage, filtration, softening, sterilisation, and finally the analysis of water and interpretation of results.

There is so much of interest in this valuable book that it is difficult, in the space allotted, to more than mention many of the important subjects dealt with, but several points call for especial notice.

The chapter devoted to storage is full of interesting information, particularly with regard to the physical, chemical, and bacteriological changes which occur in water subjected to storage. It is pointed out, for instance, that while the changes which occur to an initially impure water are wholly or mainly in the direction of improvement, an initially pure water may considerably deteriorate owing to prolonged storage.

Before going into the important subject of filtration, the authors devote a chapter to preliminary purification, including precipitation and assisted sedimentation, deferrisation, and the abatement of nuisances arising from living growths in the reservoirs; this subject is treated very fully, and reference is made to the work of many investigators both English and foreign.

Chapters vii. and viii. deal in great detail with the question of sand filtration and mechanical filtration, chapter ix. with softening, and then follow two important chapters on sterilisation.

The authors enter a strong plea for the sterilisation of all supplies from polluted or pollutable sources. Against the contention that the expense of sterilising is prohibitive in a great many cases, the suggestion is put forward that there might be a dual supply for drinking and non-potable purposes, but the arguments in favour of this course do not seem to be very convincing; moreover, the alternative to sterilisation put forward by Dr. Houston in his reports to the Metropolitan Water Board—namely, adequate storage followed by efficient filtration—is not presented in its best light, and one is inclined to think a much better case could be made out from Dr. Houston's reports in favour of his suggestions than is conveyed by the somewhat meagre extracts given in the book.

The different means of sterilising water are very fully described and discussed, both chemical (peroxides, excess lime, chlorine, and hypochlorites, etc.), and physical and electrical (electrolytic hypochlorite, ozone, and ultra-violet light), and full reference is made to the places where these processes are practised.

The concluding chapter, on the analysis of water and the interpretation of results, is written more for the water authority than the analyst. It is not an easy subject to deal with, yet the authors appear to have done it very carefully.

There are numerous excellent plates in the book illustrating different works and processes.

DENISON B. BYLES.

RADIOLOGY IN THEORY AND PRACTICE.

(1) *X-rays: an Introduction to the Study of Röntgen Rays.* By Dr. G. W. C. Kaye. Pp. x+252. (London: Longmans, Green and Co., 1914.) Price 5*s*. net.

(2) *A Manual of X-Ray Technic.* By Capt. A. C. Christie. Pp. viii+104. (Philadelphia and London: J. B. Lippincott Company, n.d.) Price 8*s*. 6*d*. net.

(3) *Molecular Physics.* By J. A. Crowther. Pp. viii+167. (London: J. and A. Churchill, 1914.) Price 3*s*. 6*d*. net.

(1) THE discovery of X-rays has hitherto afforded an opportunity, probably unique in the history of science, for the production of that kind of literature which is distinguished more for its sensational character than for its accuracy or usefulness. If the numerous small books and pamphlets dealing with the subject and published between 1895 and 1898 do not seem to us now to possess any striking feature, they are at least remarkable for their resemblance to one another. They serve, too, as a measure of the wide popular interest aroused by Prof. Röntgen's work. Some of these publications actually reached the six thousandth edition before finally sinking into oblivion. When it was realised, however, that X-rays, in conjunction with the study of radioactivity, were destined to play a vital part in the elucidation of many problems hitherto considered insoluble, and a few well-known laboratories had successfully taken the matter in hand, the budding heralds of a new physics seem to have lost their spirit. It is noteworthy that from about 1898 until now, excepting some medical works, including an account of radiation treatment, no English book has appeared devoted solely to the systematic study of Röntgen radiation.

Dr. Kaye's book will therefore be welcomed by all who are engaged in work with the new radiations generally and with X-rays in particular, for it has appeared at the very moment when it is most needed.

The time has certainly come to take stock of our knowledge of this subject and to set forth clearly the relationship which connects the speed of the electron with the wave-length of the radiation resulting from its impact against a specific substance. Incidentally, it is seen that the production of a radiation identical with the gamma rays from radium is merely a question of overcoming certain experimental difficulties, and obstacles of this character generally disappear with the lapse of time. The first part of Dr. Kaye's book deals in an interesting manner with some of the early classical vacuum-tube experiments, and care is taken, by the aid of numerous asides in the form of footnotes, to give the reader many useful facts as well as references.

The fourth chapter deals with the X-ray bulb itself, and the progressive changes in its design are traced from the 1895 type, with flat electrodes, up to the somewhat elaborate modern apparatus. There are many excellent illustrations here, and the photomicrograph on p. 43, of an anti-kathode after prolonged use, is of great interest. A chapter follows in which the various high-potential generators of electricity are described. The references to influence machines, induction coils, and step-up transformers contain many practical hints, and the oscillograph records are well reproduced. Next follows an account of the various interrupters and their several virtues or drawbacks, and a chapter dealing with the actual manipulation of an X-ray apparatus, wherein we are told about the volatilisation of the anti-kathode, the coloration of the glass, and so forth—all of great practical interest and importance to these engaged upon this work. The rest of the book is concerned with the more theoretical part of the subject and methods of measurement, questions of wave-length, sparking potentials, absorption coefficients, and so on. The work of Barkla and others on the secondary and characteristic radiations are fully set out, so that the reader may be gradually prepared for the final sections dealing with the actual nature of X-rays and the discussion of recent work upon their reflection from the interior of crystals.

Although we do not agree with the footnote to p. 165, the application of X-rays to medicine is mentioned with a moderation which will be understood and appreciated by those who are expert in that branch of the subject. We have no hesitation in recommending that a copy of the book should be in the library of every medical practitioner who desires to master the fundamental ideas underlying the properties and actions of the radiation which he is putting to good use in the alleviation or cure of disease.

(2) The study of the clinical application of X-rays is more often than not approached from a purely medical point of view, and some there are who think that a wider scientific knowledge, especially of physics, should play a large part in the early training of the student of radiology. It is probable that with them at least this book will find no favour; indeed, were it not for the fact that the author states specifically in his preface, for whom this book is intended some doubt upon the point might reasonably have arisen.

It must be borne in mind, however, that we have to deal here with a manual intended to meet the "needs of the United States army," and, judging by the somewhat limited knowledge of the subject considered sufficient in our own service, a student who assimilates the contents of this work might be counted as one possessing exceptional qualifications.

If "brevity is the soul of wit," it may also be the source of much error, and the inadequate treatment of the elements of electricity and magnetism condensed into the first nine pages contains some misleading statements. From chapter iii. onwards, however, there will be found many useful practical hints as to radiographic technique, and the tersely written survey (which certainly covers a wide field) affords a suitable framework upon which to build by experience if supplemented by the study of more complete works dealing with the subject.

(3) It is noteworthy that in this small handy volume Mr. Crowther has succeeded in giving a remarkably complete survey of work dealing with the physics of the electron and atomic structure.

The treatment of the subject is naturally influenced very largely by the trend of researches carried out during the last few years at the Cavendish Laboratory, and the work therefore stands as an authoritative and connected account of the most important recent results which have emanated from Cambridge under the stimulating leadership of Prof. Sir J. J. Thomson. The new method of analysis, for instance, which depends upon the simultaneous deviation of positive particles by an electrostatic and magnetic field, is dealt with in considerable detail and the apparatus illustrated by photograph and diagrams. There are also chapters devoted to the nature and size of electrons, their group stability, cohesion, and adhesion, as well as the bearing of modern physics upon valency and other problems once thought to be the exclusive preserves of the chemist. In the midst of great detail the author has nevertheless marked out clearly the general lines upon which this important subject has rapidly developed in recent years, and has brought together into a connected whole the results of work from many sources. It is difficult to select any particular section for special mention where all are so well done, but the chapter dealing with the atom in vibration is certainly of particular interest.

The author then shows the far-reaching significance of these new experimental results by directing attention to their bearing upon the complex "molecular theory of matter" as applied to solids, liquids, and gases. In the later pages he refers to the kinetic theory of heat, the size of atoms, and many other questions of wide interest and importance at the present day. The book, so well conceived, is a veritable mine of information. It will be read by physicists with only one regret—the author has not included even the briefest index.

OUR BOOKSHELF.

Economic Cycles: Their Law and Cause. By Prof. H. L. Moore. Pp. viii + 149. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 8*s.* 6*d.* net.

In this volume Prof. Moore has undertaken to test statistically the theory that the fundamental cause of that curious swing in trade, which results in alternate periods of depression and expansion instead of steady growth or decline, is a corresponding cycle in the weather, operating through its effect on the crops. Rainfall data for the Ohio valley are subjected to harmonic analysis, and the periodogram shows principal periods of thirty-three and eight years. These periods and their semiharmonics applied to the statistics of yield and production for some of the principal crops suggest that they will also account for the principal fluctuations in quantity, as might be expected from the high correlation between the yield and the rainfall of the months that are critical for each crop. Changes in yield are also highly correlated with changes in price for the several crops, and hence the general relation of the crop-cycle to the cycle of prices and trade in general—though matters are not so simple as might be thought at first sight, for in some manufacturing industries, *e.g.*, the production of pig-iron, price and production rise and fall together.

As in the case of his volume on the "Laws of Wages," Prof. Moore brings a distinct freshness of view to his task, and has made an important contribution to the subject with which he deals. What one most misses is any reference to the labours of others who have preceded him in the same field, and rendered the hypothesis one that many have already accepted, though some of them may only be willing to regard the weather-cycle as a contributory cause.

Directions for a Practical Course in Chemical Physiology. By Dr. W. Cramer. Second edition. Pp. viii+102. (London: Longmans, Green and Co., 1915.) Price 3*s*. net.

THIS is a useful little laboratory manual, in which the author states he has departed from the method usually employed. This departure may be illustrated by an example; there are certain tests for starch; it is usual to take commercial starch and perform the tests with this; the student is generally instructed also to prepare enough starch from the potato to illustrate its microscopic appearances. Dr. Cramer adopts the method of starting with the potato, and instructs his pupils to prepare from it enough starch for macroscopic experiments also. The distinction between the two methods is rather apparent than real, and Dr. Cramer's method involves more trouble to the student, which may not be a bad thing. Another departure one notices is that the results of a reaction are not explained; he interpolates instead questions such as, what change occurs? or why is this? or explain the result. This plan of stimulating inquiry is an excellent one for the student above the average; but one fears that 95 per cent. of the class will leave the questions unanswered, and be content with their ignorance. The author, moreover, is not consistent in the use of this method of questioning; one notes, for instance, in such subjects as blood-clotting and nerve chemistry, subjects on which Dr. Cramer holds special views of his own, that the teaching is didactic; it would evidently be unsafe to leave students here free to pursue independent inquiry.

W. D. H.

Soil Conditions and Plant Growth. By Dr. E. J. Russell. Pp. viii+190. New edition. Monographs on biochemistry. (London: Longmans, Green and Co., 1915.) Price 5*s*.

THE first edition of Dr. Russell's book was reviewed in the issue of NATURE for October 24, 1912 (vol. xc., p. 215). To the new edition a chapter has been added on the relationship between the micro-organic population of the soil and the growth of plants, and also a number of sections dealing with recent developments of other parts of the subject.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Early Figures of the Opossum.

IN view of the fact that several communications have appeared in NATURE during the past year concerning the first mention of the American opossum in literature, it may not be inopportune to direct attention to some of the early illustrations of this animal in maps and in printed works. First of all, it should be stated that the earliest reference to the opossum is found in the famous collection of voyages known as "Paesi Novamente Retrovati," published in 1507. In chapter cxiii. of that work it is mentioned that a live specimen, taken by the Pinzons in Brazil in 1500, was exhibited in Granada.

In the Waldseemüller map of 1516 a drawing intended to represent the opossum, as indicated by its accompanying legend, is introduced in the Brazilian region of South America; and this figure is copied in a number of later maps, and also in the Italian edition (1558) of Sebastian Münster's "Cosmographia."

FIG. 1.

Under the native designation of "Su," a grotesque figure of the opossum was given by André Thevet, in his volume published in 1558, and in the same year appeared the "Wahrhaftig Historia" of Hans Stade, of Homburg, wherein occur (cap. xxxi.) two illustrations, and descriptions, of these Brazilian animals, one of which is called the "Servoy" (*Didelphis marsupialis*, L.) and the other "Dattu" (*Dasypus novemcinctum*). The descriptions read as follows:—

"There is also a kind of game, called servoy, which is as large as a cat, and has a tail like a cat; its fur is gray, and sometimes grayish black. And when it breeds, it bears five or six young. It has a slit in the belly about half a span in length. Within the slit there is yet another skin; for its belly is not open, and within this slit are the teats. Wherever it goes, it carries its young in the pocket between the two skins. I have often helped to catch them and have taken the young ones from out of the slit."

"There is another sort of animal found in this country which the savages call *dattu*; it stands about six inches high and is nine inches long; its body is covered all over, except underneath, with a kind of armor. This covering is horn-like, and the plates overlap one another like those of chain armor. This animal has a very long snout, and is usually found on rocks. It feeds on ants. Its flesh is sweet and I have often eaten of it."

Several species of American marsupials are figured by seventeenth-century writers, such as J. E. Nieremberg (1635), George Marcgrav (1648), César de Rochefort (1658), and others. An illustration given by the last-named author is here reproduced (Fig. 1).

C. R. EASTMAN.

American Museum of Natural History.

Differential Antiseptic Action of Organic Dyes.

AN important property of certain organic dyes is their differential antiseptic action. Thus, varieties of *B. coli* commonly met with in the intestine are more susceptible to the inhibitory action of the tetraethyldiamidotriphenylmethane derivative, "brilliant green," than are typhoid or paratyphoid bacilli. The use of a fluid culture medium containing this dye (along with telluric acid) facilitates greatly the isolation of scanty typhoid and paratyphoid bacilli from fæces, since the growth of the various members of the *coli* group can be restrained, while the organisms in question proliferate actively. The detection of cases of typhoid infection, *e.g.* in "carriers," which is frequently a difficult bacteriological problem, can be materially simplified by this procedure. But our supplies of brilliant green have hitherto been derived from Germany, and I shall be indebted to your readers for information as to whether this dye is prepared in a fairly pure state by anyone in this country.

The Physical Properties of Isotopes.

DR. LINDEMANN (NATURE, March 4) deduces that the vapour pressure of lead from radio-active origin, or of radium D, should be very considerably different from ordinary lead at comparatively low temperatures. It would be no easy matter to test this at such a low temperature as 100° C. However, it is being found possible to make measurements of the vapour pressure of cadmium down to 10^{-6} mm., and the method should be applicable to the point in question.

It is interesting to note in connection with the last paragraph of Dr. Lindemann's letter that the arc spectra of lead of radio-active origin and of ordinary lead show no difference, as Mr. T. R. Merton has recently found, further confirming the view that the external electrons are responsible both for the spectra and the individual chemical properties of elements.

ALFRED C. EGERTON.

19 Old Court Mansions, Kensington.

A Misprint in Halphen's "Fonctions Elliptiques."

HAVING recently had to use Halphen's multiplication formulæ for the special cases of the lemniscate functions ($g_3=0$), I have convinced myself that there is a rather serious misprint in his expression for ψ_4 (vol. i., p. 96), namely, instead of $+\frac{1}{32}g_2^3$ in the last term, we should read $-\frac{1}{32}g_2^3$. Thus with $g_2=4$, and this correction, we have

$$\psi_4=\wp'(-2\wp^6+10\wp^4+10\wp^2-2)$$
$$=-2\wp'(\wp^2+1)(\wp^4-6\wp^2+1)$$

where the factor $(\wp^2+1)$ can be foreseen from the theory. With the other sign we have no such resolution.

G. B. MATHEWS.

Early References to Musical Sands.

AN allusion to musical sands may be found in one of the tales from the "Arabian Nights"—"The Story of the Two Sisters who were jealous of their Younger Sister." Prince Bahman, who was journeying in search of rarities and treasures, reaches the foot of a mountain, and while ascending "was assailed with the most hideous sounds," while others who followed him heard "groans, shouts, and all sorts of insulting epithets." One of the wonders they were in search of was the "Singing Tree," which "commenced to issue a series of exquisite strains of music" as soon as the Princess Parizadé saw it.

CECIL CARUS-WILSON.

March 21.

TWO CHINESE TOURS.[1]

A SOMEWHAT unexpected sequel to the mission which Sir Francis Younghusband led to Lhassa in 1903–4 was the appreciation by Chinese officials of the fact that the trade in Indian opium, which has at times been held up as a reproach to England, was in reality due to the demand of China for the drug. It is interesting to reflect that the truth should first have dawned upon a Chinese envoy who had been educated in the United States. The novel idea took root and engendered a movement which spread in China with such rapidity that in 1906 an imperial edict dealing with the opium question was promulgated. This rescript embodied elaborate provisions for the immediate curtailment and the gradual extinction of the use of the drug. Necessarily, therefore, it took account not only of the enormous Chinese out-turn of opium, but of the smaller, though still important amount imported from India. Proposals and counter-proposals were accordingly formulated in 1907 by the Governments of China and Britain, and certain regulations, to remain effective for three years, were agreed upon by the high contracting parties and became operative in 1908.

Meanwhile the Government of the United States thought fit to initiate a movement of an international character which culminated in the assembly at Shanghai in 1908 of an opium commission, the findings of which reflect a desire to aid the Chinese authorities in their crusade against the opium habit; while, before the preliminary period of three years had expired, negotiations for a new agreement between China and the United Kingdom were set on foot. As a preliminary to the ratification of this agreement it was desirable that his Majesty's Government should know what had been the actual effect in China of the restrictive measures adopted there in response to the imperial injunctions of 1906. The officer to whom the important duty of reporting upon this feature of the case was Sir Alexander Hosie. No one better fitted for the duty of traversing the six provinces of China, known to have been the chief opium-producing areas in that empire, could have been selected. Sir Alexander had already travelled extensively, and in some cases, as an officer of the Chinese Consular Service, had resided in the provinces

[1] "On the Trail of the Opium Poppy. A Narrative of Travel in the Chief Opium-producing Provinces of China." By Sir Alexander Hosie. 2 vols. Vol. i., pp. viii+300. Vol. ii., pp. 308. (London: G. Philip and Son, Ltd., 1914.) Price 25s. net 2 volumes.

involved. During a sojourn of more than thirty years in China he had taken a keen interest in all the economic resources of the empire; he had, moreover, been one of the members of the International Opium Commission which met at Shanghai. The narrative and the results of the two official journeys, undertaken with the object of securing the information of which the British Government had need, are given in the volumes now before us.

As the author in his preface explains, the book is not devoted to the history of the opium question. Nevertheless, those interested in that question will do well to consult this work. The circumstance that such consultants may neither be inclined nor qualified to appreciate the whole of the contents has been forestalled by the provision, for their especial benefit, of a couple of appendices wherein the genesis of the anti-opium crusade is outlined, and the results of his own investigations of 1910–11 into the cultivation of the poppy are summarised.

As compared with various other accounts of recent Chinese travel, an outstanding feature of the present work is the extent to which it deals with the conditions and the appearance of long-settled and closely cultivated portions of that empire. Having regard to the primary purpose of his two journeys this was inevitable, nor can the reader be too grateful to the author for the care and precision with which he recapitulates the various crops observed in the course of a particular stage. Even in districts where tilth is most intensive, however, areas occur which are unfit for cultivation, and are under timber. The components of the vegetation in cases of this kind are as carefully assessed as the field crops. In one such passage the author warns the reader not to assume, because reference has been made almost exclusively to trees of economic importance, that species of less consequence were altogether absent. The same may be true of other stages, as to which no such reservation is made. But even when due allowance is made for this possibility, one of the most interesting impressions which the narrative of the author conveys is the extent to which species that are devoid of utilitarian interest and value have become eliminated. The naturally regenerated constituents of the woodlands on uncultivated mountain slopes appear in the main to be as strictly economic as the species planted along highways and irrigation channels.

The detailed descriptions of the various stages should render the work useful to those who may follow the author's route, but the general reader will be most interested in, and will profit most from, the incidental accounts of the configuration, the industries, and the polity of the provinces traversed by him. A passage which excites interest and arrests attention deals with the famous Nestorian tablet at Hsi-an Fu in Shensi, while the temperate but convincing reference to the shortcomings of European cartography, the uniformity and simplicity of Chinese delimitations and terminology notwithstanding, evokes the reader's sympathy. Space forbids more than a passing reference to a few of the interesting topics discussed in the work. Among these may be mentioned the cultivation of huskless grain, the use of the fibres quaintly known to European commerce as China jute and China grass, the preparation of varnish, the weaving of silk, the making of bamboo hats, the wood-oil industry, the smelting of copper, the mining of coal, the separation of salt, the planting of rice, the various contrivances for irrigation, the different types of bridges. With these and other equally interesting topics the reader may best be left to make himself acquainted by reading the book. One of the most interesting passages in the work deals with the familiar yet little understood *loess* formation (Fig. 1), so extensively represented in the area traversed during the author's northern journey. Another, taken from the southern journey, treats of the white-wax industry (Fig. 2),

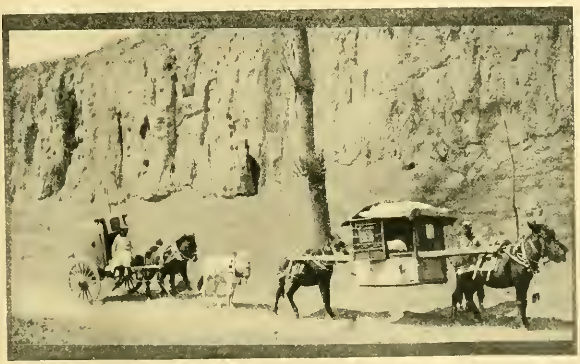

FIG. 1.—The loess formation, with mule litter and passenger cart, Shansi. From "On the Trail of the Opium Poppy."

FIG. 2.—Chinese ash (*Fraxinus Chinensis*) coated with insect white wax. From "On the Trail of the Opium Poppy."

for our knowledge of which we are mainly indebted to the author's powers of observation. These powers are so rarely at fault that it seems almost ungracious to indicate the only instance in which he appears to have been led into misapprehension; there is one passage in which what, from his succinct description, was obviously a silk-cotton tree has been confused with that—from a phytogeographical point of view—extremely interesting species, the tulip-tree of China. The book is admirably printed, and in its 600 or so pages we have noticed but one typographical error.

THE TELEPHONE IN SURGERY.

IN the *Lancet* of January 30 is published an address by Sir James Mackenzie Davidson, delivered before the Medical Society of London, on the telephone attachment in surgery. By this phrase the author refers to the attachment of a telephone receiver to a probe, or lancet, or other metallic instrument used by a surgeon when exploring a wound containing a bullet or other piece of extraneous metallic matter, in such a way that the sound heard in the telephone when the probe comes into contact with the bullet enables the surgeon to make certain of the position of the bullet in the wound.

As this matter appears to be of real importance at the moment to surgeons in the field hospitals of our armies abroad, we make no apologies for giving our readers a summary of the more salient features of Sir Mackenzie Davidson's address. His attention was first directed to the use of the telephone as an auxiliary in surgery thirty-two years ago, by the accounts of the attempts made by Graham Bell, to determine, by means of the induction balance, the position of the bullet in the body of President Garfield when he was assassinated in 1881. Speaking afterwards of these attempts, and of the difficulties attending the method—which had failed in that notable case to yield satisfactory indications—Graham Bell outlined another and simpler electrical method for the detection of bullets, as follows:—

> It consists of a telephone, to one terminal of which a fine needle is fixed, and to the other a plate of metal of the same nature as the needle. The plate is placed on the limb to be examined, and the needle is thrust in where the bullet is believed to be; and when it strikes the ball a galvanic battery is formed within the body. . . . *This will cause a click to be heard in the telephone each time the bullet is struck.* This is a far simpler apparatus than the induction balance, and one far more easily procured.

This method Sir Mackenzie Davidson tried in 1887 at the Aberdeen Royal Infirmary, in the case of a patient suffering from a revolver shot, using a silver probe joined by a wire to one terminal, and a silver plate, about 6 inches long and 4 inches wide, connected by wire to the other terminal of a telephone receiver. In subsequent years he employed the same method to verify the results of early X-ray localisations, and it enabled surgeons in the South African War to differentiate, as the common probe could not do, between a distorted and broken up Mauser bullet and a fragment of bone. Sir Mackenzie Davidson states that until quite recently he took it for granted that the same metal must be used—as Graham Bell stated—for the probing instrument and for the plate placed upon the patient's skin. But since the outbreak of the present war the difficulty experienced by skilful surgeons in finding bullets in wounds, even after the most precise localisation by means of X-rays, has caused him to experiment further, and to extend the method. Briefly, he finds, as the result of experimenting on different pairs of metals, that there is nothing so satisfactory as a plate of carbon, such as is used in an ordinary bichromate cell, to place upon the moistened skin of the patient as the auxiliary pole. The surgeon's metallic instruments are usually of steel, often silver-plated or nickel-plated. The metals to be sought for are lead, iron (and iron alloys), copper, and nickel. Carbon presents a sufficiently wide difference in its galvanic properties from any of these to render it suitable. The result is enhanced if the solution used to moisten the skin beneath the plate is the solution of iodine employed as a disinfecting agent, since iodine is also an excellent depolariser. A low-resistance telephone is better adapted than the more expensive high-resistance receivers used in wireless telegraphy, giving louder sounds besides being cheaper.

The form of telephone recommended is one with double receivers fixed to a flexible steel hoop that is placed on the head, so that each ear listens to its own receiver, and is protected from extraneous sounds. The operating surgeon places the auxiliary carbon plate upon the patient's moistened skin at some convenient spot near the place where the foreign object is supposed to be situated, and it may be held tightly against the skin by bandage or plaster. If a bare wire of silver is used as probe, it should, of course, be properly disinfected. Or the wire may be wound round an ordinary probe or needle or forceps which is used, or a spring clip may be employed to connect the instrument to the wire connected to the telephone. No battery of any kind is needed, owing to the galvanic action between the carbon-plate and the metal of the bullet. If, under these conditions, the instrument is introduced into the body of the patient, it will on the first contact with the bullet or other metallic body cause a most unmistakable click; while if the probe or scalpel is gently moved along the foreign body so as to make rubbing contact along it, an equally unmistakable rattling sound will be heard. Several examples of successful application, showing the advantages gained by the use of this method, are given by Sir Mackenzie, who states it to be his belief "that the time will come when no surgeon will attempt to remove a deeply embedded metallic body without having this telephone attachment at his command." He makes out an exceedingly good case for this application of the telephone to surgery.

The author's experience and ingenuity in applying X-ray methods to localise the position of foreign bodies are so well known that when he comes forward with improved methods of electric probing, which have the distinguishing merit of the utmost simplicity, we may be sure they will find immediate and extensive application.

GEODETIC SCIENCE.

NO. 3 of the new series of professional papers of the Ordnance Survey contains some excellent notes on the geodesy of the British Isles, by Colonel Close, R.E., which bring the position of geodetic achievement fairly up to date, and incidentally add some historical indications of the processes by means of which our position in the world of geodetic science has been secured. Their usefulness has been increased by the addition of a very ample bibliography of the science, and by simple diagrams illustrating certain special features affecting geodetic levelling, including the principal triangulation of Great Britain, the geographical position of the West European meridional arc, and of the European longitudinal arc. In the section of the pamphlet dealing with standard measurement it is interesting to observe that the national standard yard, which was legalised in 1855, consists of a marked length on a bronze bar bearing a definite relationship to the "international" metre (also a measured length on a bar), which was originally intended to represent one ten-millionth of the length of the earth's meridional quadrant.

Colonel Close's sketch of the various operations undertaken to determine the figure of the earth, dating from Airy's investigations of 1830 to Helmert's determination of 1906, proves incidentally the extraordinary value of the early investigations undertaken with inferior instruments. On Airy's figure the whole of the mapping of the United Kingdom still depends, nor have the results deduced from the reduction of the principal triangulation affected the map values. In the length of 700 miles from Shanklin to the extreme north of the Shetlands Airy's figure gives about four seconds in latitude too much, if we accept Helmert's figure as the criterion. This does not affect the linear accuracy of the map. Three figures were computed by Colonel Clarke (in 1858, 1866, and 1880 respectively) from the data furnished by the reduction of the principal triangulation. They are all in use, either in Africa or America. The mean value in length determined by Clarke of the semi-axis major of the ellipse, the revolution of which about its minor axis produces the spheroid of the earth's surface, is less than that of Airy and only slightly greater than that of Helmert. Colonel Close records his opinion that the probable value is somewhat greater than Clarke's mean.

Many people must have noticed the apparently haphazard way of recording "bench" marks by the Ordnance Survey to indicate altitudes determined by levelling. They are to be found on most unsubstantial walls, on milestones, and even on gateposts, and they must, many of them, inevitably be unstable. In the section of the pamphlet dealing with levelling, Colonel Close indicates the method by which, in future, such marks will be rendered permanent. Concrete blocks will be sunk on to hard rock foundations at intervals of about twenty-five miles all over the country; a bolt of bronze, with a knob of flint being embedded in the concrete. This section is also of interest as a record of the difficulties experienced in dealing with the adopted datum of mean sea-level. Indian survey investigations have contributed largely to the solution of this troublesome problem. It is in India, too, under Colonel Sir S. Burrard, that the most comprehensive investigations have been made in the matter of the deflection of the level, and the apparent eccentricities of the force of gravity, including the difficult problems which beset the speculative subject of isostasy; but Colonel Close's references to early English methods of determining the value of deflection due to local topography are extremely interesting as a record of the first steps taken in the evolution of this special branch of geodetic science. These plain and intelligible notes on a highly complicated subject, being entirely free from any affectation of technical specialism, should attract a much wider range of scientific interest than is indicated by the title of Ordnance Survey Professional Papers. T. H. HOLDICH.

SCIENTIFIC FACTORS OF INDUSTRIAL SUCCESS.

THE Institute of Industry and Commerce (now the Institute of Industry and Science), so the introductory leaflet states, is a counterpart of a German organisation known as the *Hansa Bund.* How the Hansa Bund arose or by whom and when it originated we have no knowledge. It is a confederation of important German firms for promoting, encouraging, and facilitating German home and foreign trade. It is proposed by similar means, but on somewhat "superior lines," to do the same for British industry, and the directors invite those interested in the development of our industries by the aid of science to enrol themselves as members. A portion of the revenue of each year is to be devoted to scientific research under the supervision of our most eminent men of science. Accompanying this leaflet are a number of brochures touching on the causes and effects of German commercial success and on the remedies for British commercial decline.

If "in the multitude of counsellors there is safety," in the diversity of their opinions there may also arise confusion. Sir W. Ramsay conceives that the main purpose of the Institute is to combat German industrial methods, which are said to be organised on a policy of dishonesty and trickery. This is to be undertaken by the State by adopting something of their methods, or by endeavouring to thwart them. Mr. S. Roy Illingworth, in his pamphet on "The Organisation of the Chemical Industries," advocates combination between different branches of industry, elimination of home competition, efficient advertising, the employment of highly trained chemists and engineers, reducing the cost of production, and finally some measure of protection. Sir George Watson, who also writes on "Chemistry and Industry," lays stress on the importance of highly trained chemists and the value of protection or some form of financial assistance for the newer industries. Mr. J. Taylor Peddie, in his review of "British Imperialism and German Culture," points out that although German ideals have been established upon sound democratic and Christian principles, and have had a vital, sustaining, and elevating influence, these ideals have been momentarily wrecked on the rocks of feudalism, absolute monarchism, and militarism. He realises Germany's intellectual superiority, for which we have no substitute, and demands organisation unrestricted by the State, which is too much dominated by the political party system. In a second brochure on "Finance and Industry" the same writer finds Germany's great commercial progress to be primarily due to the development of its financial system, and instances the advantages which the banks offer by advancing loans to industrial undertakings.

It will be seen from this rather brief epitome that whilst the writers unite in pointing out the unsatisfactory position of our industries, especially those into which science largely enters, they are not quite unanimous, either in regard to the cause of or the remedy for the present state of affairs.

It is no doubt true that our chemical industries have in the past been hampered by absurd duties and still more absurd patent laws, and that, speaking generally, the scientific industries have received little sympathy or encouragement from any Government, past or present. It is also true that German commercial acumen, not always over scrupulous, has succeeded in wresting from us a good deal of foreign trade. In this connection we are reminded of a chapter in Bagot's "My Italian Year," in which he describes how Germans have established themselves, as well as their goods, in the larger Italian cities, and that much of the trade formerly carried on by us has passed into their hands. All this is true enough, but there is another side to the picture. Our chemical industries have failed to prosper not because Germany has had special advantages in the use of cheap alcohol, or in its patent laws, or in its financial system or in its protective tariff, but because in recent years these industries have passed into the hands of men who have had no proper chemical training.

So long as this exists the industry will be run by rule-of-thumb methods; no advance can be made, because nothing new is being discovered or manufactured; for it must be remembered that it is not the old stereotyped products, but the novelties that bring the large profits. Where can we show such a record as that of the Baden Aniline Company, which laid out a million sterling on experiments carried out by a body of highly trained and *highly paid* chemists working unceasingly for ten years in elaborating the process for producing artificial indigo, which has now nearly driven out the natural product?

We lack knowledge first and last, as well as enterprise and that kind of adaptability which studies to supply the needs of foreign countries, and this applies to others besides the chemical trade. We remember an old Lancashire cotton weaver, whose trade, once a thriving one, gradually fell away because he insisted on always producing the same kind of cloth long after it had ceased to be in demand, for no other reason than that he had always done so.

We could point to many other industries which to-day are languishing or disappearing for the same reason. The heads of these firms do not keep pace with the time; they do not keep up any pace at all; they stand still. They stagnate in a backwater of ignorance, unconscious of the rapidly flowing stream of scientific achievement; which must in the future be the guiding current in every branch of industry if commercial success is to be attained.

It was announced on Monday that there has been such a poor response on the part of subscribers that the directors of the company British Dyes (Limited) do not feel justified in proceeding to allotment, and a meeting has been called to consider the situation. This state of affairs might have been anticipated from the amount of adverse criticism to which the Government scheme has been subjected. The scheme restricted competition at home, but made no attempt to safeguard future competition from abroad, and gave no guarantee in the constitution of the directorate that the industry would be conducted on a sound scientific basis. The question is still unanswered as to the best and safest means of resuscitating this moribund industry (if one may apply these terms to describe what has never been really alive for the last half-century).

Every chemist will admit that this is a problem which cannot be solved in a hurry. Owing to the complex nature of the products and the special character of the apparatus and machinery employed, a long period of patient experimenting under the control of the best chemists and chemical engineers that the country can provide will be required before success can be attained. It will naturally entail a heavy outlay in salaries and plant, and probably no profits for a long time to come. Who is going to undertake this whilst the textile industry with its millions of workpeople is starved for the want of dyes? If the country ran short of ammunition in the present crisis, the Government would at any cost be compelled to undertake its production.

The same kind of national crisis exists to-day in the dyeing industry, and the same remedy should be applied without further delay. The colour-makers have had their opportunity. They have been warned for years past what their fate would ultimately be if they neglected to develop their manufacture on a scientific basis. That opportunity has gone. The only practical plan would seem to be for the Government to take the matter in hand and independently of public financial assistance to obtain its staff of expert chemists under adequate scientific control, and by their aid to work out the initial experimental stages and afterwards either manufacture the dyes or make over the processes on certain conditions to private firms.

NOTES.

WE regret to see the announcement of the death, on March 21, in his sixty-fourth year, of Dr. A. A. W. Hubrecht, professor of embryology at the University of Utrecht.

THE honorary freedom of the Apothecaries' Company has been conferred upon Sir Ronald Ross, in recognition of the valuable services rendered by him to medical science, especially in the prevention of tropical disease.

IN recognition of their services as consulting surgeons to the British Expeditionary Force in France Mr. G. H. Makins and Sir Anthony A. Bowlby have been made Knights Commander of the Order of St. Michael and St. George (K.C.M.G.).

THE *Nieuwe Courant*, the Hague, of March 3, states that the van't Hoff fund committee of the Academy of Sciences of Amsterdam received five applications for grants. The only one awarded was for 600 francs to Dr. E. D. Tsakalotos, of Athens, in aid of his researches on the thermal properties, the viscosity, and the magnetic susceptibility of binary mixtures, capable of yielding endothermic compounds.

AT a meeting of the executive committee of the British Science Guild, held on March 16, it was resolved to send copies of a resolution formulated by the medical committee, advocating inoculation against typhoid fever, to the commanding officers of every regiment of the British Army. Reports on the question of the supply of optical glass and of glass for chemical purposes—formerly largely obtained from Germany and Austria—showing what has already been done in these matters, were also ordered to be widely circulated. The question of the shortage of microscopes was considered, and action is being taken by the guild in this matter.

THE death is announced, after a short illness, of Prof. W. Smart, professor of political economy at Glasgow University. Prof. Smart began his academic work in 1886 as lecturer on economics at University College, Dundee, and Queen Margaret College, Glasgow. On the affiliation of Queen Margaret College to the University, he became University lecturer on economics, and in 1896 was appointed to the Adam Smith chair of political economy. In addition to his professorial work, Prof. Smart translated Böhm-Bawerk's "Capital and Interest" and "Positive Theory of Capital," edited Wieser's "Natural Value," and compiled "Economic Annals of the Nineteenth Century." Among his other works are "Taxation of Land Values" and "The Return to Protection."

THE Geologists' Association has made arrangements for an excursion to Glasgow from April 2 to April 8. The object of the excursion is to examine the geology of the district around Glasgow. On April 2 Prof. J. W. Gregory will conduct the party around the Campsie Fells. On April 3 South Bute will be visited under the directorship of Mr. W. R. Smellie. Garabal Hill, Loch Long, and Loch Lomond will be studied on April 5 under the guidance of Mr. A. Scott; the Falls of Clyde, Cartland Gorge, and Kames of Carstairs on April 6, when Prof. J. W. Gregory and Mr. J. Stark will direct; Lugar and Mauchline on April 7, director, Mr. G. W. Tyrrell; Hamilton Park and Strathaven on April 8, directors, Messrs. Macintyre and Carruthers. Intending visitors should communicate with the secretary for the excursion, Miss G. M. Bauer, 16 Selborne Road, Handsworth Wood, Birmingham, from whom particulars as to trains and accommodation can be obtained.

THE death has occurred at Dartmouth, at the age of eighty-six, of Mr. E. W. H. Holdsworth, who will be remembered by his book, "Deep-Sea Fishing and Fishing Boats," published in 1874, which gives the best and most intelligent account of the British fisheries at that time which we possess. This book will always be of the first importance to those interested in the progress and development of our sea fisheries. Mr. Holdsworth wrote from great personal knowledge of the subject, as he had acted as secretary to the Royal Commission, of which Prof. Huxley was a member, which between 1863 and 1865 travelled all around the British coasts inquiring into the condition of the fisheries. At the close of the work of this Royal Commission, Mr. Holdsworth went for some years to Ceylon in order to conduct an official inquiry into the pearl fisheries. In 1883 Mr. Holdsworth took an active part in the International Fisheries Exhibition and contributed to the literature of that exhibition an important paper on apparatus for fishing. On the foundation of the Marine Biological Association he was for some years a member of the council. Previous to his work in connection with the fisheries Mr. Holdsworth took part in the management of the Zoological Gardens, Regent's Park, and the Proceedings of the Zoological Society contain several papers which he wrote, chiefly on anemones and corals.

MR. J. S. MACARTHUR, whose name is well known in connection with the cyanide process of extracting gold, has been engaged during the past two years in the extraction of radium from carnotite and similar ores at his factory at Runcorn. From a statement in the Press we learn that Dalvait, Loch Lomondside, has been selected as the site for a new factory, on account of the advantages offered by the purer air and water supply in this neighbourhood. The new factory is to deal with between five and six grams of radium annually, and will be a welcome addition to the country's sources of radio-active materials. Hitherto, with the exception of one concern, working up the pitchblende from the Trenwith mine, Cornwall, this country has been entirely dependent upon foreign radium. The output of another Cornish pitchblende mine is sent to France to be extracted, and the recently discovered source of pitchblende of very fine quality in India, seems, like the Indian monazite, to be controlled by foreign capitalists. The Glasgow and West of Scotland Radium Committee purchased from Mr. MacArthur last year the equivalent of 600 milligrams of radium bromide in the form of a barium-radium carbonate containing 20 milligrams of radium bromide per kilogram, finding it more advantageous to undertake itself the further fractionation of this material than to purchase from abroad at the inflated prices then obtaining.

IN the scientific world probably the highest distinction is the election of a man of science to foreign membership of the leading scientific society of a country not his own. Prof. E. C. Pickering has from time to time published lists of men of science who have received this honour from two or more of the seven great scientific societies, viz., the Imperial Academy of Petrograd, the U.S. National Academy, the Royal Prussian Academy, the Royal Academy of Sciences in Vienna, the Royal Society, the Institute of France, and the Royal Academy of the Lincei. The first such list was published in 1908, and since then more than a third of the men whose names were included have died. Prof. Pickering, in an article in the February number of the *Popular Science Monthly*, has brought the list up to the beginning of 1914, and analysed it according to societies, countries, and sciences. The men of science whose names appear in the list number 122, sixteen of whom are members of all seven societies, and fourteen of six societies. Four men of science in Prussia, namely, A. Auwers (since deceased), E. Fischer, van't Hoff, and R. Koch, and three Englishmen, namely, Sir A. Geikie, Sir William Ramsay, and Lord Rayleigh, are members of all seven societies. Taking two groups together, England leads with eight men of science who have achieved the distinction of election to foreign membership of six or seven national scientific societies, and is followed by Prussia, which possesses six such men. The average number of scientific societies for English members is 4·9, for Prussian members 4·2, and for Germany as a whole, 4·0. As regards the different branches of science, "In mathematics, the country most largely represented is France, with 5 members; in astronomy, United States, 5, England, 4; in physics, England, 5; in biology, Prussia, 5. Great Britain is the only country represented in each of the sciences. Prussia has no geologist, France no geographer, and the United States no mathematician, chemist, botanist, or biologist."

THE jubilee of the University of Melbourne Medical School was celebrated on April 25–May 2, 1914, and a memorial volume containing the history of the school and the jubilee addresses, and embellished with numerous plates of the buildings and laboratories and members of the staff, has been issued ("University of Melbourne Medical School Jubilee, 1914," Ford and Son, Melbourne). The University of Melbourne had been in existence for seven years when its medical school was opened on March 3, 1862. The school owed its inception largely to the energy of Dr. Anthony Colling Brownless, who became Vice-Chancellor of the University in 1858. In 1862 Dr. John Macadam was appointed lecturer on chemistry, Dr. G. B. Halford professor of anatomy, and Mr. R. Eades lecturer in Materia Medica. In 1863, the medical school buildings were commenced from plans prepared by Messrs. Reed and Barnes, the University architects. In 1864, the Melbourne Hospital opened its doors to receive the first class of third-year students, Messrs. Rees, Moloney, and Mackie. Although its career has been checked from time to time by lack of funds, the story of the school is one of continued progress. Opening in 1862 with four students, the students' roll now (1914) numbers 394 for the five years of the curriculum. The latest development is the establishment of a fund for clinical research, which now amounts to approximately 1000*l.* per annum.

THE forty-eighth report of the Peabody Museum at Harvard University is a record of active progress. Additions to the buildings now provide much needed accommodation for the collections. Exploration has been active in various regions—Mexico, Nebraska, New Jersey, Arizona, Syria, Palestine, and Egypt. Dr. E. A. Hooton conducted an expedition to England. Landing in July last, he worked for a month, when "he was forced to discontinue work because of the unsettled state of the country." He excavated without much success the alleged site of an early Saxon cemetery at Great Shefford, Berks, and then he turned his attention to Wexcombe Down, overlooking Salisbury Plain, where nine barrows were opened containing incinerated remains, Bronze Age potsherds, and surface finds of late Celtic and Roman pottery. One large cinerary urn and one La Tène III. bronze fibula were found. From Knowle Pit, Savernake, a series of River-drift implements was obtained.

CAPTAIN SIR G. D. DUNBAR in the February 26 issue of the Journal of the Royal Society of Arts describes some of the tribes occupying the northern frontier of Assam. Owing to the inaccessibility of the country and the savagery of its inhabitants, little is known about them. The tribes here dealt with are the Abors, Daflas, and Mishmis. The word Abor means "unfriendly," which well describes the character of the group. The general type is Mongoloid, and the writer suggests that the Abors and their brethren migrated from the Tibetan side of the Himalayas into the Dihang valley. They display remarkable industrial capacity in their bridges, irrigation channels, and ironwork. It is not possible to imagine a more democratic organisation than the constitution of these tribes. The village, not the clan, is the political unit, ruled by a headman, whose office is not hereditary, but he is retained in office only so long as he represents the views of the majority in their rather noisy meetings. Women exercise a marked influence. Other duties now prevent Sir G. D. Dunbar from preparing a book on these tribes, but it may be hoped that this intention is only for a time postponed.

IN the *American Museum Journal* for February Col. Theodore Roosevelt contributes an admirable article on the animals of Central Brazil, and Mr. L. E. Miller gives an account of the Roosevelt-Rondon

Scientific Expedition. The value of this exploration will be shown only when full studies have been made of the 2500 and more specimens of birds and mammals which have been collected. This will for the first time provide an outline of the mammalogy and ornithology of this hitherto unknown region, which includes a river as long as the Rhine, of which there appears to be no trace on the existing maps. Of special interest is the account of the man-eating fish, the piranha. "South America," Col. Roosevelt remarks, "makes up for its lack relatively to Africa and India of large man-eating Carnivora by the extraordinary ferocity or blood-thirstiness of certain small creatures of which the kinsfolk elsewhere are harmless. It is only here that fish no bigger than trout kill swimmers, and bats the size of the ordinary flittermouse of the northern hemisphere drink the blood of big beasts and of man himself."

In the Journal of the Straits Branch of the Royal Asiatic Society for December, 1914, Mr. J. C. Moulton, curator of the Sarawak Museum, continues his list of the butterflies of Borneo, dealing in this instance with the whites and swallow-tails, or Papilionidæ. No fewer than forty-three species, together with a number of subspecies of the true swallow-tails of the genus Papilio, are recognised, against twenty-nine in a list published by Dr. Russel Wallace in 1865.

To the March number of the *Irish Naturalist* Dr. R. F. Scharff contributes a tentative list of the native names of Irish mammals. There is a considerable degree of uncertainty with regard to the proper application of some of these names, and in a few instances, which may represent species now extinct, identification has not yet been practicable. Several names for the bear and the wolf are known, and it is possible that one or more of the unidentified terms may refer to the extinct giant Irish deer or "elk."

A striking coloured plate of the king-condor of the Andes forms the frontispiece to an article in the April number of *My Children's Magazine* on the vertical distribution of animal life on land and in the ocean. Most of the more striking instances of animals dwelling at great heights in the mountain-ranges of the world are mentioned, and the article as a whole is a mine of information. The artist cannot, however, be congratulated on his rendering of the red deer's antlers or on his so-called wild sheep and yak, which are obviously drawn from domesticated breeds.

In Mr. T. Southwell's report of the Bengal, Bihar, and Orissa Fishery Department for the year ending June 30, 1914, attention is directed to the extent of the area under the control of the Department, the smallness of the staff, and the difficulties encountered, in endeavours to improve the present condition of affairs owing to the indifference and lack of energy on the part of the fishermen. It is admitted that in Bengal the supply of food-fish, always short, is steadily falling, but since the occupation of fishing or dealing in fish is carried on exclusively by the lower classes the whole industry is left in the hands of people with no capital, no education, and no business capacity. In such circumstances it is scarcely to be wondered at that the fish-supply is scanty. In area and potentiality the fresh-water fisheries of Bengal are second to none; but the establishment of hatcheries for carp and other species of fish is highly desirable in order to mitigate the disaster to eggs and fry occurring annually in the big rivers during the rains. The rearing of eggs and fry removed from the mouth of the Damodar and their return to the river as young fish at an age when they are able to look after themselves, seems to be a step in the right direction, and one which should eventually give satisfactory results. As time and opportunity allow, the stocking of other small rivers will be carried on, where the necessity is indicated. The rearing of fry in special tanks will further enable small fish to be supplied for tank-culture throughout the province, at an age when they are unlikely to be devoured by voracious fish, whereby considerable improvement in tank-culture generally may be expected.

Among specimens received by the U.S. Museum from the Lower Eocene of Fort Union, Montana, particular interest attaches to the left half of the lower jaw of a small mammal described by Dr. J. W. Gidley in No. 2077 of the Proc. U.S. Nat. Mus. (vol. xlviii., pp. 395-402) as a new genus and species under the name of *Myrmecoboides montanensis*. The specimen, which retains the canine and seven cheek-teeth, is regarded by its describer as indicating a marsupial, which may be related to the Australian banded anteater (*Myrmecobius fasciatus*). The dentition presents the distinctly marsupial feature that all the last four cheek-teeth are molariform, and of the same general type, the first of the series being, however, slightly more complex than the other three. In many respects all the teeth present resemblances to those of Myrmecobius, although those with a molariform structure are relatively larger, and not separated from one another by intervals. If, however, the dentition of Myrmecobius be of a degenerate type, as is now generally believed, such differences are precisely those which would be expected in an ancestral form. What an important bearing such a relationship would have on the origin and dispersal of marsupials will be obvious. In addition to this, the Fort Union fossil may serve to solve a disputed point in regard to marsupial dentition. For, as Dr. Gidley points out, the first molariform tooth presents several features suggestive of its being a persistent milk-molar rather than a molar; and if this idea be well founded, there will be decisive evidence in favour of the view first suggested by Dr. Winge, and also arrived at independently by Mr. Lydekker in 1899, that the first molariform tooth of marsupials is a persistent milk-molar, and not, as previously supposed, a molar, and consequently that both placentals and marsupials normally possess but three pairs of molars.

We note with interest that the Lincolnshire Naturalists' Union is taking steps to preserve the ancient flora of Lincolnshire from extinction. Owing to cultivation, drainage of bogs, eating off by sheep, and the rapacity of trippers much has been lost. By educating the populace to respect the flora and by jealously guarding the habitats of the rarer plants, the Naturalists' Union should do useful work.

The *Indian Forester* for January, vol. xli., No. 1, contains a short account of the tali-pot palm (*Corypha umbraculifera*), which is indigenous in the Andamans and Southern India. Its uses are many; the pith is used for flour, some thirty headloads being yielded by one tree. The leaves, which were formerly used for writing upon, now serve for umbrellas and thatching, and the seeds are carved or made into buttons. At Honawar bats live under the protection of the leaves of the tali. When the lendi fruit (*Calophyllum inophyllum*) is ripe, the bats bring back large quantities to their palm and drop the hard drupes. As these contain oil, which is much prized, the bats serve a useful purpose, and natives are planting the tali-pot palm in order to obtain oil in this easy manner.

In an article reprinted from the *Botanical Gazette*, vol. lviii., No. 3, Dr. G. D. Fuller breaks new ground in plant ecology and presents results which, as in the case of much recent work in this subject, is of great interest to agriculturists and foresters as well as to botanists. He has made a detailed series of determinations at weekly intervals during the growing period (May to October) of the rate of evaporation and the amount of soil moisture in a series of plant communities which shows a gradual change or succession from exposed sand vegetation to moist beech-maple forest on the sand dunes near Chicago. The determinations, extending over three years, are presented in graphs; those of evaporation were taken with evaporimeters placed near the ground, those of soil moisture in the upper layers of the soil—in both cases the critical regions, since within them develop the seedlings which determine the character of the succeeding vegetation. The author introduces the term "growth-water" for the percentage of soil moisture in excess of that found by experiment to be present in the soil when wilting occurs in plants; and he finds that the differences in the ratio between evaporation and growth-water in the series of plant communities investigated are sufficient to be regarded as efficient factors in bringing about the succession or gradual change from the scanty drought-enduring (xerophytic) vegetation of the open sand to the moisture-loving (mesophytic) broad-leaved forest, which forms the climax of the series.

In vol. xiv., part 1, of the Annals of the South African Museum Mr. George Arnold, of the Rhodesia Museum, Bulawayo, commences an illustrated monograph of the ants of South Africa, which it is claimed will form the first collective account of the (approximately) three hundred known local species. Vol. xv., part 1, of the same is devoted to a continuation (part 7) of the Rev. T. R. R. Stebbing's account of South African Crustacea. Six species and two genera of Macrura are named as new, and certain emendations in pre-existing nomenclature suggested.

The association of geology, botany, and zoology in the domain of a State Survey is interestingly exemplified in the sixth biennial report of the Commissioners of the State Geological and Natural History Survey of Connecticut. The superintendent, Prof. W. N. Rice, points out the desirability of the maintenance of the survey as a permanent bureau of publication. Much of the work is done by men who are otherwise engaged for a large part of the year, and the annual appropriation of 1500 dollars may be considered modest for a State where a high level of general culture is ready to respond to scientific information.

The potash salts associated with the Cambrian rock-salt of the Cis-Indus Salt Range have been known since 1873; but a more complete examination of their extent has now been made by Dr. W. A. K. Christie (Records Geol. Survey of India, vol. xliv., 1914, p. 241). This author concludes, on account of the association of kieserite, sylvine, langbeinite, and rock-salt, that crystallisation finally took place under subterranean conditions at a temperature of about 80° C. It is interesting to note that the very soluble potash-salts have been preserved where a fine clay with sand-grains, probably wind-borne, was formed across the deposits of the evaporating lagoon.

An interesting rock is described by Dr. du Toit from the slope of Ingeli, in the extreme south-west of Natal (Geological Survey of South Africa, Annual Report for 1913, p. 99). In a stratum about 15 ft. thick, pellets of graphite, which may be as much as an inch in length, lie in a ground of oligoclase, quartz, cordierite, enstatite, and biotite; this ground has in part a micropegmatitic structure. This unique rock is ascribed to the partial absorption of a carbonaceous shale of the Ecca Series by an offshoot from the overlying intrusive sheet of norite. Kentallenite, the curious biotite-olivine-dolerite with soda-orthoclase, well known from its occurrence in Appin, is now recorded by Mr. S. Kôzu from Torigoé, Japan (Science Rep., Tôhoku University, Sendai, Japan, vol. ii., 1914, p. 1).

The South Wales tornado of October 27, 1913, which involved some loss of life, has been discussed by the Meteorological Office in No. 11 of its Geophysical Memoirs (price 6*d*.). Dr. Shaw states that a scientific assistant attached to the office, Mr. H. Billett, was sent to the neighbourhood to collect information on the spot. A severe thunderstorm swept the west of England and Wales from the south of Devon to Cheshire, and developed locally into a tornado of exceptional violence. The storm was intense for a distance of about 11 miles up the Taff Valley in Glamorganshire, for about an equal distance in Shropshire, and for about 5 miles in Cheshire. For several days before and after the occurrence, a high-pressure system was situated over Central Europe, and there was a low barometer centred over the Atlantic. The wind over the region affected was mainly from south-east or south, with the temperature decidedly above the average, and the weather unsettled. The rainfall was almost wholly limited to the south-western and western districts of England. Practically no damage was done outside the narrow limits of the storm, which nowhere exceeded 1000 ft. in width, but much destruction was wrought in certain parts of the track. In Cheshire, where the storm's track was about 450 ft. wide, the sound is described as that of "hundreds of motor-cars crashing through the trees." The storm occurred at about 4 p.m. in Devon, at 5.40 to 5.50 p.m. in South Wales, at 7.35 to 7.45 p.m. in Shropshire, and at 9 p.m. in Cheshire. The progress of the central area of the storm is given as 36 miles an hour No absolute measurement of wind velocity was secured, and a similar absence of barometer records is mentioned, with the exception of one station only a few yards from the South Wales track, where the record shows a fall of pressure from 29·20 in. to 28·91 in., followed by an almost immediate rise.

THE *Scientific American* for February 13 contains the third of the series of articles entitled "Doing without Europe," to which we referred in these columns a month ago. The principal object of the articles is to show how vast are the mineral resources of the country and how little they are utilised. The present article deals mainly with the barium salts used in the manufacture of paint. Up to the commencement of the present war these had been imported from Germany, but one of the largest paint manufacturers of New York has commenced manufacturing them from an ore found in Tennessee, and now turns out 15 tons a day. In respect to potash salts, of which the annual import from Germany exceeded 3,000,000*l*., the United States Government has directed attention to the natural deposit of the salts at Searles Lake, California, and a manufacturing plant has been set up there the success or failure of which will be watched with interest. Soda, magnesia, and several other substances are also mentioned as being found in abundance in the country, and as only requiring working to supply all requirements.

AN interesting paper on the internal-combustion engine in the oil field was read at the Institution of Petroleum Technologists on March 18 by Mr. F. G. Rappoport. It appears that the steam engine still largely holds its own despite its inefficiency, the reason for this being in the special character of the work to be done in boring and baling oil wells. Great flexibility in power and speed is required, and while electric power distributed from central stations is ideal from other points of view, electricity lacks that flexibility at the well which makes steam power so convenient. The oil engine has created a large and important sphere of its own by facilitating profitable operation of a large class of wells having a small yield. Such wells had formerly to be closed, and the advent of the oil engine with its low fuel-consumption has rendered possible their operation. The oil engine is well adapted for outlying districts and for prospecting work; the Binagadi oil field, without adequate water supply, is worked almost entirely by means of oil engines. The new Ural and Biellik districts in Russia are largely worked by oil engines. Applications of the gas engine are also discussed, and reference is made to an engine made by Messrs. Tangye, which can be run as a gas engine, or as an oil engine, by alteration of certain parts. Several of these engines are in successful operation on the Baku oil field.

MESSRS. W. HEFFER AND SONS, LTD., Cambridge, have just issued a classified catalogue of numerous scientific books, periodicals, and publications of scientific societies which they offer for sale, including large selections from the libraries of the late Sir Robert Ball and Dr. J. Reynolds Green. The catalogue contains titles and descriptions of many rare and valuable works which may be purchased at reasonable prices for private or public libraries.

OUR ASTRONOMICAL COLUMN.

COMET NOTES.—In the *Astronomische Nachrichten* (No. 4789) Dr. Elis Strömgren communicates an ephemeris up to March 29 for comet Mellish (1915*a*), computed by Herren J. Braae and J. Fisher-Petersen, from the parabolic elements given by the latter, with Herr R. Andersen. The data for the present week are as follows:—

	R.A. (true) h. m. s.	Dec. (true) ° ′	Mag.
March 25	17 55 53	−0 34·9	8·8
27	17 58 13	0 50·0

The comet lies approximately between γ Ophiuchi and η Serpentis.

Herr K. Hillebrand, in an Ephemeris Circular of the *Astronomische Nachrichten* (No. 478), publishes the elements and ephemeris of the periodic comet of Winnecke for its appearance in the current year. The latter extends from April 16 to the end of August.

A search ephemeris for Tempel's comet (Ephemeris Circular, No. 479) is given by Herr J. Braae. In 1910 this comet was not seen, but it is pointed out that this year it will be a little more favourable for observation. The ephemeris is extended to the end of June of the present year, and will be continued later.

THE STRUCTURE OF THE Hγ LINE IN STELLAR SPECTRA. —In this column for July 31 of last year attention was directed to a paper by Herr K. F. Bottlinger, in which was shown the result of a study of the intensity distribution of lines in many of the brighter stars. In a recent number of the *Astronomische Nachrichten* (No. 4788, vol. cc., No. 12) Dr. Adolf Hnatek gives his conclusions from rather a similar investigation. The author has measured both the intensity (Linientiefe) and breadth (Linienbreite) of the Hγ line in several bright stars, and summarises the values deduced according to the spectral types of the stars examined. Thus, in the case of the line-width the following are mean values in Ångström units which he has deduced.

Maury	Cannon	Width	Intensity
II–VI	B	16	0·55
VII–VIII	A	26	1·40
X–XI	F	17	0·81
XIII–XV	G–K	8	0·35

Summarising the values of the line-intensity (Linientiefe), he points out that they show also a similar relation to the spectral types; these intensity values are added in the last column of the above table. The paper contains also a number of curves of the Hγ lines in the individual stars arranged in groups according to their spectral classes. While the above investigation deals only with one line and a small number of stars, the author hopes to extend the research to more lines and stars in order to deduce results of a more definite and trustworthy value.

The Harvard College Observatory Report.—The annual report of the director of the Astronomical Observatory of Harvard College for the year ending September 30, 1914, indicates the completion of a large amount of work in both observation and publication. Prof. E. C. Pickering refers in the first place to the principal work of the observatory, namely, its publications and the importance of issuing these as soon as possible to prevent loss by fire. Thus observations from 1892–1912 with the 15-in. equatorial, from 1888–98 with the 8-in. transit circle, and from 1898–1912 with the 12-in. meridian photometer are now printed, and the discussions are in progress. The director directs attention to the improvement in photographic processes resulting in the replacement of practically all visual work. The report then describes in more detail the work of the Henry Draper Memorial, the principal research of which is the New Draper Catalogue; last year Miss Cannon classified 60,386 spectra, making a total of 160,541. The activities of the Boyden department, the Bruce photographic telescope, and the Blue Hill Meteorology Observatory are briefly summarised, while among the many items mentioned under the heading "Miscellaneous" the work of Prof. W. H. Pickering at the Mandeville Station, in Jamaica, is described, much time having been devoted to the study of the planet Mars during its recent opposition.

Star Charts for Meteor Observers.—One of the contributions to the January number of the Journal of the Royal Astronomical Society of Canada (vol. ix., No. 1, p. 7) is entitled "A Gnomonic Star Atlas," and contains a set of thirteen maps, prepared by Mr. Reynold K. Young, intended to facilitate the observation of meteors and the plotting of their paths. The method of the projection of the map is such that great circles in the sky are equivalent to straight lines on the map, thus making the plotting of the meteor trails more easy. The maps are devoid of unnecessary detail. The positions of the stars are given for the epoch 1900 correct to within one-tenth of a degree, and all stars down to 5th magnitude and the brighter variables are included. A good margin of overlap has been allowed in each map, which should prove very useful.

FLUCTUATIONS OF TEMPERATURE IN EUROPE AND AMERICA.

Mr. H. ARCTOWSKI, in a paper published in vol. xxiv. of the Annals of the New York Academy of Sciences, considers the problem of variation of temperature over the whole earth. After a brief statement of the general problem and the methods by which it may be attacked, he explains that he could not deal single-handed with the arrangement and discussion of the actual values even over the whole of the northern hemisphere, and confines himself to the detailed survey of the variations over North America and Europe. He also compares the results with one or two representative equatorial and southern hemisphere stations. From a study of the values at one of these, Arequipa, in Peru, he deduces that the temperature changes are partly of a short period of about fifty-five days, brachypleionian waves; partly of a long period of twenty years or so, macropleionian waves; and partly of an intermediate period of between one and two years, pleionian waves.

In dealing with the longer periods the normal annual variation is eliminated by taking a series of means for twelve months beginning with each consecutive month of time. For the European stations he finds that the continental ones resemble Arequipa in having marked pleionian waves, while those stations near the Atlantic are characterised mainly by brachypleionian variations.

In an earlier paper Mr. Arctowski dealt with the period 1891–1900, and he takes the mean values for this period as normals, and plots on maps the difference from normal of the values during each year of the decade 1900–09. The areas where the differences are positive he calls thermopleions, and the areas of negative differences antipleions. He finds that certain years, in particular 1900, 1908, are characterised by thermopleionian areas, while others, such as 1904, 1907, are years of antipleions. The most important cause of these differences is the variation of solar radiation, but there are also supplementary causes such as the presence of volcanic dust in large quantities, or exceptional ice conditions in the polar regions.

Many of the maps which illustrate the results of the investigation are on a very small scale; the course of the thermopleions and thermomeions is obscured by the attempt to show relatively microscopical geographical details.

Mr. Arctowski finds it astonishing that after all the efforts which are made to organise and maintain meteorological stations all over the world, the actual results of the work are so inaccessible. Even for the area with which he dealt he could only get much of the data by writing personally to the directors of the different meteorological institutes. This is a defect which will be remedied when meteorologists of different countries undertake to contribute to a central bureau representative regional values based on a selection of stations which can only be chosen satisfactorily by the local organisation.

There is another defect which is almost more serious, viz., the lack of continuity in the records for individual stations due to changes of situation or instruments. For example, Mr. Arctowski finds that the difference of temperature between Chicago and Milwaukee was nearly 4° F. in the decade 1873–82, while in the decade 1896–1909 the difference was only 2° F. The change is almost certainly due to change of instrument or site, and as it is of the same order of magnitude as the changes with which he deals, it indicates the need for great caution.

The difficulty of securing comparable continuous records is indeed one of the most serious problems with which organised meteorology has to deal.

E. G.

REFINING GOLD BY ELECTROLYSIS.[1]

THE problem presented by the necessity of refining gold was one for which a solution was sought at least as early as the time, about B.C. 700, when coins were first manufactured in the Western world. Apart from toughening or the removal of base metals, which was sufficiently cared for by the ancient process of cupellation, it is clear that some measure of success attended the efforts made to part gold and silver. Thus, some of the ancient Greek coins containing 997 or 998 per 1000 of gold. The earliest parting process used was one of cementation, which was succeeded by the nitric acid process. At the present day chlorine is the predominant agent for parting gold from silver in Australia, electrolysis in America, and sulphuric acid in Europe.

The electrolytic process was brought forward by Charles Watt, at Sydney, in 1863, and was first put into operation by Wohlwill at Hamburg in 1878 and by Tuttle at the Philadelphia Mint in 1902. In the gold chloride process the solution used in the bath

[1] Abstract of the presidential address delivered before the Institution of Mining and Metallurgy on March 18, by Sir T. K. Rose.

contains gold in the form of chloride and some free hydrochloric acid. Gold is dissolved at the anode, under the action of a current of electricity, and deposited in a pure state at the kathode. Other metals are also converted into chlorides at the anode, and either remain in solution, or pass into the anode slime. When silver is contained in the anode, it is converted into silver chloride which in part dissolves, in part falls to the bottom of the cell, and in part adheres to the anode, forming an insoluble coating. The result of the coating is that the free area of the anode is reduced, the density of the current becomes greater per unit area of effective anode surface, and chlorine is evolved unless a very small current is used. According to general experience, if more than 6 per cent. of silver is present in the bullion of the anode it is necessary to brush the silver chloride from the anodes, and accordingly this percentage is seldom exceeded in practice.

Photo] FIG. 1.—Electrolytic gold cells, United States Assay Office, New York. [*B. P. Wirth.*

The usual amount of free hydrochloric acid present in the bath varies from 3 to 10 per cent., but according to the results of experiments now put forward by Sir Thomas Rose some advantages are obtained by the use of stronger solutions. Thus in a bath containing 29 per cent. of free hydrochloric acid, a current of 5000 amperes per square metre of anode surface can be used without causing chlorine to be evolved at the anode. Under these conditions the proportion of silver in the anode may be raised to at least 20 per cent. without difficulties being encountered. The heavy current causes the silver chloride to split off from the anode, and also prevents gold from entering the anode slime, principally because no monochloride of gold is allowed to form.

Similar advantages occur in the deposition of gold at the kathode by the use of a solution containing 20 per cent. of gold as chloride instead of the usual 3 to 5 per cent. With a current of 5000 amperes per square metre, the gold is deposited in a coherent form, which is easily washed, and is malleable after being melted. The density of current now employed in practice is below 1000 amperes per square metre, and the anodes occupy about a week in being dissolved. With a current of 5000 amperes, the anodes would be dissolved within the limits of a working day and a saving in interest, and in the difficulties of daily stocktaking, would be effected.

One of the merits of the electrolytic process is that the refined gold is always malleable and fit for use in the arts, and another is that any platinum contained in the gold is extracted. This is becoming of some importance in view of the high price of platinum and of the fact that nearly all rough gold bullion, including that from the Transvaal, is now known to contain that metal. According to the experience in the United States mints (Fig. 1), it is cheaper to refine gold by electrolysis than by sulphuric acid.

BIRD-MIGRATION IN 1913.[1]

WE have before us the ninth of a projected series of ten reports setting forth the imposing mass of data regarding bird-migration collected by the committee appointed for the purpose by the British Ornithologists' Club. Once the final volume, dealing with the autumn of 1913 and the spring of 1914, has appeared, we may expect a publication of greater importance, summarising the vast amount of material collected by ten years' labour. In the meantime no attempt is made to draw conclusions from the facts which are published, but a few points about the movements of 1912–13 may here be selected for notice.

The autumn of 1912 appears to have been remarkable for the early dates at which the migrations of several species began. Thus a swallow was noted at the Bell Rock Light in the Firth of Tay on July 4, and willow-warblers at the same place two days later. As early as June 25 a large flock of starlings had been seen flying west in the evening at Spurn Head Light. On the nights of July 14–15 and 15–16 swifts were recorded from the Lundy North Light (British Channel) and the Hanois Light (Channel Islands) respectively.

The great movements, however, do not seem to have begun until mid-October, and the migrations observed during the first three weeks of November were of extraordinary magnitude. Almost every night during that period half-a-dozen different light-stations record the passage of large numbers of birds, notably skylarks, starlings, and various species of Turdus.

[1] Report on the Immigrations of Summer Residents in the Spring of 1913; also Notes on the Migratory Movements and Records received from Lighthouses and Light-vessels during the Autumn of 1912. (Bulletin of the British Ornithologists' Club, vol. xxxiv., December, 1914.)

The winter which followed was marked by comparatively high and uniform temperatures. Consequently many summer-visitant birds do not seem to have quitted some of the southern and western districts, while others were recorded as returning at unusually early dates. The spring immigration proper is stated to have lasted from March 6 until June 6, reaching its height between April 14 and May 11.

Attention is directed to the very long period covered by the immigrations of certain species as contrasted with those of others. On one hand we have swallow (March 8 to May 20), sand-martin (March 13 to May 15), chiff-chaff (March 6 to May 8), and wheatear (March 12 to May 12). On the other we have the reed-warbler (April 18 to May 5), wood-warbler (April 9 to May 11), and nightingale (April 13 to May 5).

A special feature of the report is the long list of records emanating from the Caskets Light in the Channel Islands. This station is exceptionally favourably situated, and was expected to furnish very important data. Unhappily, the committee had formerly been unable to induce the light-keepers to take the matter up. The desired result has been brought about, however, by the transfer to the Caskets of an enthusiast in the work, Mr. R. E. Wilson. His contributions to the present report are very valuable. A special summary of the records relating to this station is promised for the next report.

The publication under discussion is even bulkier than its recent predecessors, but the data are set out in the same clear and orderly manner. As usual there are numerous charts and a useful summary of the meteorological conditions prevailing during the period covered by the migration records A. L. T.

THE INSTITUTE OF METALS.

IN spite of the war, both the number and quality of the papers presented at the annual meeting of the institute on March 18 and 19 were well up to the average. Naturally, in the circumstances, the contributions were furnished mainly by what may be termed the "academic" workers in non-ferrous metallurgy. Moreover, although the attendance of members was small, the discussions were always interesting and well-sustained. Unfortunately the president of the institute, Engineer Vice-Admiral Sir Henry Oram was prevented by his onerous official duties at Whitehall from presiding at the proceedings, and his place was filled at the last moment by one of the vice-presidents.

The paper by Prof. A. C. Huntington, on the effects of heat and of work on the mechanical properties of metals, gave rise to an interesting debate, and a spirited reply by the author. It describes a machine devised by him several years ago for the purpose of investigating these effects while the metals are being subjected to alternating bending stresses, such as occur in the firebox of a locomotive. No attempt was made to reproduce the somewhat complicated movements which occur there, but the metal or alloy was held rigidly at one end, and "subjected to a to and fro movement at the other end in a single plane at right angles to its axis." Both as regards the extent of the movement and the range of temperature investigated, the experiments were made to conform broadly to the kind of conditions that obtain in locomotive fireboxes. Various kinds of commercial copper, and a copper alloy containing upwards of 5 per cent. of nickel and iron, were tested in this way. The outstanding feature of the curves, the co-ordinates of which are temperature and the number of revolutions required to crack and break the specimens, is the large number of maxima and minima which the author interprets from his data. For copper he gives five maxima and five minima. The fact, however, that these do not by any means always correspond to observed points gave rise to considerable criticism in the discussion and to a variety of alternative interpretations. From the fact that annealing greatly reduces the maxima and minima the author concludes that work plays an important part in emphasising transformation points, and goes so far as to say that "except in the case of phase changes in alloys, mechanical tests are to be preferred to heating and cooling curves as a means of studying changes of state with temperature." Even if this claim is admitted, it limits the application of such methods to ductile alloys, but not unnaturally objections were voiced to a statement which has certainly not been proved.

Dr. Rosenhain, in his paper, entitled "Some Appliances for Metallographic Research," described an optical instrument for the levelling of metallographic specimens, a new method of taking thermal curves, and a plotting chronograph, the last-named having been devised with the help of the Cambridge Scientific Instrument Co. These appliances have been originated by Dr. Rosenhain at the National Physical Laboratory. Great interest was expressed in them, particularly in the design of furnace for taking thermal curves. In order to obtain as nearly as possible a constant rate of heating or cooling of the metallic specimen a tubular furnace is erected vertically in which a "regular temperature gradient is established and steadily maintained while the specimens whose heating and cooling curves are to be taken are moved at any desired rate from the cold to the hot end of the furnace or *vice versa*." Heating and cooling curves obtained in such a furnace and in conjunction with the plotting chronograph show that very satisfactory results have been obtained. The power consumption with the hot end at 1000° C. is a kilowatt. No figures for higher temperatures have been given, and it will be interesting to have those stated when they have been determined.

With regard to the plotting chronograph, the author's endeavour has been to originate an instrument which shall furnish an inverse rate curve "plotted to an adequately open scale." The apparatus is not as yet entirely self-recording, but represents a considerable step in this direction, and it gives the curve obtained with no other human intervention than the periodic tapping of a key.

The paper by Prof. Read and Mr. Greaves, of University College, Cardiff, contains an account of their investigations on nickel-aluminium and nickel-copper-aluminium alloys, more particularly the light alloys of the last-named group, and is a continuation of their earlier work on the heavy alloys of the same metals. They find that, as regards the ternary alloys, copper and nickel can replace each other without the resulting properties being affected, and, in fact, that certain characteristics of the alloys are determined by the total percentage of copper and nickel present. As they point out, this is intelligible in view of the fact that the two metals possess almost identical densities and very similar atomic volumes. Moreover, micrographic analysis shows that the internal structure of the alloy scarcely alters when the one metal replaces the other. Inasmuch as nickel costs about three times as much as copper, and its melting point is nearly 400° C. higher, it is clear that it cannot compete with it economically in the case of such alloys, except perhaps in a few instances where the need for resistance to corrosion in certain liquids is sufficiently imperative to outweigh considerations of expense.

A very useful compilation of etching reagents and their applications to metallography was presented by

Mr. O. F. Hudson. This work had been undertaken at the request of the Publication Committee of the institute, and in preparing it Mr. Hudson received and incorporated methods adopted by well-known workers both in America and this country. The paper deals more especially with the final stage in the preparing of specimens for microscopic examination, but as the author points out, the effects of previous operations must always be borne in mind. There is now an increasing consensus of opinion among the most skilled metallographers that grinding on mechanically-driven discs produces too severe an alteration in the surface structure of a metal or alloy, which is likely to create difficulties in their microscopic interpretation after etching, and that hand grinding, although slower, is much more trustworthy. This is neither more nor less than a return to the technique of the late M. Osmond, whose skill in the preparation of a specimen for microscopic examination has never been surpassed. The discussion on Mr. Hudson's paper was in a high degree illuminating, and showed the institute members at their best. When the complete paper and discussion are published they will certainly be a standard work of reference.

Four other papers were submitted. Of these, that by Mr. Whyte, on the microchemistry of corrosion, and that by Mr. Haughton, on the constitution of the alloys of copper with tin, were read and discussed. The remaining two were taken as read, and will be discussed by written communications.

H. C. H. CARPENTER.

SUPPLIES OF LABORATORY AND OPTICAL GLASS APPARATUS.

REPORTS OF THE BRITISH SCIENCE GUILD.

THE British Science Guild has just issued two reports dealing with matters of national moment at the present time. One is concerned with the provision of glass apparatus for educational purposes, and the other with optical glass and the position of technical optics generally in this country. The reports are here reprinted, and it will be seen that they are both informative and helpful. First, with regard to laboratory ware, it appears that, as the result of an inquiry instituted by committees of the guild, working in co-operation with the Association of Public School Science Masters, about three-quarters of the schools or other bodies requiring laboratory glassware have undertaken to use British glass during the war, and for a period of three years after, provided that the price is not prohibitive. As explained in a letter to NATURE of February 18 (p. 670) the British Laboratory Ware Association has made arrangements for the supply of laboratory glassware and similar materials from British manufacturers. The British Science Guild has, by its action, presented the association and British glass manufacturers generally with an assurance of support which should be of the greatest value to them.

The report of the Technical Optics Committee of the guild should cause serious attention to be given to the establishment of a British Institute of Technical Optics. In the last annual report of the guild it was pointed out that this necessity had been impressed upon the education department of the London County Council continuously during the past twelve years. Scientific experts, leading members of the optical industry, and educational experts have combined to urge the paramount importance of the definite proposals which have been formulated, but the scheme still hangs fire. Meanwhile our scientific and industrial rivals on the Continent, taking note of successful developments on a small scale which have been originated here, have gone forward to new developments with increased vigour and with highly successful results.

(1) PROVISION OF GLASS APPARATUS FOR EDUCATIONAL PURPOSES.

In the past practically all the glass and procelain apparatus used in chemical laboratories in this country has been manufactured in Germany and Austria. As the supply is now cut off and the stocks held by British dealers are almost exhausted, the problem of obtaining apparatus for educational and technical purposes has become a serious one.

The Joint Committee is informed that efforts are now being made by several firms to introduce the manufacture of glass apparatus into this country, and being in hearty sympathy with these efforts, it has considered in what way the British Science Guild may best assist. In these efforts the committee has co-operated with the Association of Public School Science Masters, and has taken action along two main lines, viz. :—

(A) Endeavouring to obtain assurances of support for British makers of educational glass ware after the war as well as now.

(B) Obtaining information from educational institutions respecting the principal types and sizes of glass apparatus in greatest demand.

(A) *Assurances of Support for British Makers of Scientific Glass Ware.*

It is understood that the efforts during the last three months by certain British glass manufacturers have been attended with satisfactory results as regards the quality of the products. Economic and manufacturing conditions have prevented British glass apparatus being sold at so low a price as has been paid in the past for German material. As these conditions will probably remain unchanged, British manufacturers have been naturally disinclined to expend the necessary capital in establishing the proposed new industry here while there is every likelihood that they will be undersold in the British market by their competitors when the war is over. The Joint Committee is informed that this has acted as a strong deterrent to British glass manufacturers contemplating the production of scientific glass apparatus.

The Joint Committee therefore has endeavoured to ascertain how far it is probable that educational institutions would undertake to buy only British-made glass and porcelain apparatus during the war, and for a period of three years after.

Inquiries were made in this direction by the hon. secretary of the Association of Public School Science Masters, who is a member of the Joint Committee, from the headmasters of all schools represented on the Headmasters' Conference. Out of the hundred and ten (110) schools so represented, no fewer than seventy-eight (78), *i.e.*, 71 per cent., have definitely promised to authorise their science staffs to purchase, as far as possible, only British-made glass apparatus during and for a period of three years after the conclusion of the war. As these promises have been received from almost all the largest schools, both boarding and day, it may be assumed that manufacturers as well as dealers will receive adequate support from the "conference schools."

The guild also issued about 750 letters of inquiry to—

(*a*) Local education authorities.

(*b*) Governors of secondary schools.

(*c*) Governing bodies of technical institutions.

(*d*) Senates of universities and university colleges, and has received a very large number of replies.

The proportion of definite replies coming in at once has been smaller than in the case of the public schools from the fact that various committees have had to be consulted before definite promises could be given, but the replies which have been received have been quite satisfactory—of the definite replies received about 72 per cent. are sympathetic, and promises are given to purchase only British-made apparatus as requested, subject in many cases to the proviso that the increased cost is not prohibitive.

A considerable number of the replies, while generally sympathetic, give no guarantee, the reason being in most cases that the matter rests with a higher authority, such as a county council, or board of governors, from whom no definite reply had been obtained. Some authorities, also, while sympathetic, do not feel able to bind their successors, and one authority suggests that only the purchase of German and Austrian apparatus should be barred.

The endeavour to obtain the value of the apparatus used in such institutions has not resulted in any very precise information, but from the facts before the committee it is clear that the value of such apparatus must at least run to some thousands of pounds.

(B) *Types and Sizes of Apparatus most in Demand.*

Inquiries as to the principal types and sizes of apparatus most generally used have been made on behalf of the Joint Committee from public schools and technical schools. It was felt by the Joint Committee that this information would be of considerable value to glass-makers, as there is a very strong feeling among those concerned with the chemical apparatus trade that at the present time flasks, beakers, basins, etc., are supplied in an unnecessarily large variety of shapes and sizes.

Judging from the replies received from the institutions above referred to, the following represent the apparatus most in demand:—

TEST TUBES.—6 in. × $\frac{3}{4}$ in., 2 in. × $\frac{1}{4}$ in., and, in smaller quantities, 6 in. × 1 in., 5 in. × $\frac{5}{8}$ in., and 2 in. × $\frac{1}{2}$ in.

BEAKERS.—Squat form, lipped, 200 c.c., 300 c.c., and, in smaller quantities, 150 c.c., 500 c.c., 1000 c.c.

BEAKERS.—High form, in the same sizes as above, but in smaller quantities.

FLASKS.—Flat bottom, 100 c.c., 250 c.c., 500 c.c., and, in smaller quantities, 1000 c.c., 1500 c.c., 2000 c.c.

FLASKS.—Round bottom, 250 c.c., 500 c.c.

TUBULATED RETORTS.—150 c.c.

FUNNELS.—6·5 cm.

DISTILLING FLASKS.—100 c.c., 250 c.c., 500 c.c.

EVAPORATING DISHES.—50 c.c., 100 c.c., 200 c.c., and, in smaller quantities, 1000 c.c., and 2000 c.c.

CRUCIBLES.—15 c.c. and 25 c.c.

In conclusion, the Joint Committee desires to express its strong conviction that every effort should be made to facilitate and encourage the manufacture of glass and porcelain apparatus in the United Kingdom. It therefore urges the advisability of asking the Board of Trade to watch the new industry, and, if necessity should arise, to use its endeavours to modify any restrictions at present existing which may be detrimental to the carrying on and extension of the industry.

(2) THE MANUFACTURE OF OPTICAL INSTRUMENTS AND MATTERS RELATING THERETO.

NECESSITY FOR ACTION.

The British Science Guild, having inquired carefully, by means of a strong and representative expert committee, into the effect of the outbreak of hostilities on matters of national importance connected with the manufacture of optical instruments in the country generally, submits this report to the Government, and in doing so emphasises the pressing urgency of the subjects referred to.

Supply of Glass. (a) The General Case.

(1) In the first place the inquiry referred to was directed to the consequences of the *sudden stoppage of the supply of German optical glass* on which this country had increasingly relied for many recent years. A letter of inquiry asking for information on six specific points was addressed to representative firms in the optical trade. The results of these inquiries has been such as to satisfy the guild that the supply of optical glass available for the manufacture of telescopes, binoculars, range-finders, and other service instruments is sufficient for the purpose. Under this head there seems to be no call for any special effort to improve upon existing conditions, though the *supply of English glass has not always been adequate in quantity, and delays have been experienced in obtaining quick delivery.*

The representative of Messrs. Chance Bros., who was a member of the Technical Committee referred to above, has assured the committee that since the outbreak of hostilities the firm has considerably increased (in fact, quadrupled) the capacity of its plant for the manufacture of optical glass, and is fully prepared to extend this plant still further.

(b) Photography and Micrography.

(2) With regard to the manufacture of photographic and microscopic lenses the case stands otherwise. The requirements of the manufacturing trade in these respects are not definitely standardised as in the case of the instruments already referred to. To facilitate new and important developments it is necessary that the lens manufacturer should have recourse to a greater variety of glasses than are, in fact, manufactured at the present time in this country. It is further necessary that larger stocks should be held than is the custom at the present time of the various glasses produced. The guild, therefore, is of opinion that serious inconvenience is certain to result to the manufacturing trade if the supply of German glass is cut off for any considerable length of time. The amount of glass demanded, especially for photographic purposes, is very considerable, and the guild is of opinion that the attention of the authorities might usefully be directed to this opportunity for a considerable development of British glass manufacture in this direction. One difficulty the guild understands to be the defective supply of pure barium compounds.

(c) Variety of Glass Obtainable Inadequate.

(3) From a wider point of view and more generally, the variety of English glasses offered is not sufficient for all the requirements of optical instrument-makers, especially for the more recently developed and important optical designs. Thus, whilst the leading English firm listed only twenty to thirty types of glass, the leading German firm listed about seventy types, every one stocked. Barium glass of high refraction and low dispersion, *i.e.* having a high value of the "anti-dispersion" coefficient, is reported as specially difficult to obtain in England.

Research.

(4) The desirability of the provision of facilities for research upon the manufacture of optical glass has been carefully considered and has been found to be a difficult question. From the evidence submitted it appears that if one special object of research could be attained the result would be highly advantageous. This object is the discovery of a refractory lining of the melting "pot" which would resist the action, at

melting temperatures, of the materials used in the glass mixtures, and leave the contents of the pot uncontaminated at the conclusion of the operation. This research would probably be a long and costly one, and is such as might most appropriately be undertaken by the National Physical Laboratory, especially as certain details in the manufacture of optical glass may come under review during the inquiry.

Authoritative Testing of Glass.

(5) In another direction evidence was submitted to the guild to the effect that it would be distinctly advantageous to the optical trade if *increased facilities for the authoritative determination of the optical constants* and *relative absorption of samples of glass* submitted for test could be provided at the National Physical Laboratory

THE FUTURE.

Facilities for Education a Matter of Great Urgency.

(6) In still another direction evidence, additional to evidence collected before the outbreak of hostilities, was elicited that the *facilities for education in technical optics are very inadequate.* It was shown that not only could some of the present difficulties connected with the supply of optical glass probably be diminished, but that the output of optical instruments for national purposes would be increased, and that the optical trade would be substantially benefited in other directions if such facilities were largely extended. The Technical Optics Committee of the guild was originally appointed, early in the year 1914, for the purpose of "inquiring into the need of an Institute of Technical Optics and the steps to be taken in connection therewith, and in due course it submitted a "statement" on the subject, which was published in the annual report of the guild, 1914, pp. 31–34. The committee had further reported to the Executive Committee of the guild at its July meeting, and the report was adopted with a few alterations, and is printed at the end of this report.

(7) When the Technical Optics Committee met after the vacation, the other matters, apparently of more immediate urgency, referred to in this report, had arisen and took precedence of the earlier matter. In investigating these new questions it has become strongly evident that the earlier matter is of *supreme and pressing importance.*

The guild therefore recommends:—

(A) That better provision should be made at the National Physical Laboratory for the testing of samples of glass as to their physical and optical properties, and that the director of the National Physical Laboratory be approached on the subject.

(B) That facilities should be provided as speedily as possible for the carrying out, at the National Physical Laboratory, or elsewhere, of the researches connected with the manufacture of optical glass referred to in this report.

(C) That steps should be taken as speedily as possible to give effect to the recommendations of the previous report of the Technical Optics Committee of the guild in the direction of providing facilities for systematic, scientific, and manual training in technical optics, and the guild, recognising that educational training requires time, is strongly of opinion that this question is urgent and that the organisation of optical training should be taken in hand at once.

PREVIOUS REPORT REFERRED TO IN PARAGRAPH C, DATED JULY 14, 1914.

Proposed Establishment of an Institute for Technical Optics.

The British Science Guild has had under consideration for some time the inadequate provision for, and the unsatisfactory state of, the technical training in optics in the British Isles. The subject was brought to its notice by Sir Thomas Barlow, formerly president of the Royal College of Physicians, in a communication to the president of the guild, and was considered to be of such importance by the Executive Committee that a Special Committee was formed to deal with it. The Special Committee has now reported.

The establishment of such an institute has been under discussion for some years, and there is a remarkable consensus of expert opinion, both as to the necessity and the urgency for action, from many and diverse points of view, scientific, industrial, and national.

The London County Council, which has gone into the matter very thoroughly, has not felt itself in a position to provide from the funds under its control the initial capital expenditure of some 40,000*l.* for the erection and equipment of the proposed institute, although a site was actually purchased for the very purpose by the governing body of the Northampton Polytechnic Institute so far back as 1908. The Finance Committee of the council is understood to be of opinion that the project is so essentially of national importance that it would be unfair to saddle London ratepayers with the whole cost. It is, however, believed that if the question of capital expenditure can be solved, the maintenance of the institute could be assured by grants from the Board of Education and from the London County Council, and by students' fees. As an additional reason for expedition, it may be pointed out that the governing body of the Northampton Polytechnic Institute may not be in a position to carry much longer the heavy burden of the mortgage interest on the purchase money above referred to, and the amortisation of the capital amount.

GEOLOGY IN RELATION TO THE EXACT SCIENCES, WITH AN EXCURSUS ON GEOLOGICAL TIME.[1]

IT is often said that figures can be made to prove anything; and certain it is that a series of arithmetical operations does sometimes serve as introduction to very strange conclusions. The fault, of course, is not in the tool, but in the hand that uses it. In the larger issues of geology especially, where the gulf to be bridged between data and conclusions is so often a wide one, ingenuity of reasoning ought surely to be accompanied by a due sense of responsibility in the handling of figures. Calculation, in such applications, is by no means so simple an art as it may appear. In wrestling with problems of the kind indicated, and, I must add, in reading some very fascinating speculations by geologists of high standing, I have often wished that some obliging mathematician would put forth a small manual of applied arithmetic for the guidance of workers in the descriptive sciences. There are absolutely necessary precautions to be observed when calculation is based upon data always partial and at best roughly approximate, and these precautions are too often neglected. To be safe, we must have some conception of the probable error attaching to our observations, and we must note how the initial errors may be multiplied in the process of calculation. Especially there is the cumulation of error which must ensue when results obtained in this fashion are used as links in a chain of deduction. Here it is quite inadequate to say that the chain is no stronger than its weakest link; it is of necessity far weaker than its weakest link.

[1] From a Presidential Address delivered before the Yorkshire Geological Society by Alfred Harker, F.R.S. Reprinted from the Proceedings of the Society.

Without entering into these matters, some of which, as I have suggested, call for expert aid, I will take for illustration a single point, the frequent abuse of *the average*. Say that we wish to determine the amount of mud annually carried down by the Nile. Since there are variations, both seasonal and casual, we must take a sufficient number of observations, properly distributed in time, and an average, duly weighted, will then give us as good a result as the nature of the case admits. But now suppose that we wish to know the amount of sediment carried by all the rivers of the world. We have data for nine rivers, data which are likely to differ much in respect of probable error. Accepting them, however, as they stand, it appears that the water of the Rio Grande carries one part in 291 of sediment, that of the Uruguay River only one in 10,000, the other seven rivers giving intermediate values. The highest figure is thus thirty-four times as great as the lowest. Some geologists will simply take a mean of the nine figures, and proceed contentedly to use this result in the most far-reaching conclusions. I do not believe that a mean of nine figures so discordant can afford any information of quantitative value. The average must be extended over a much wider area, before a result is obtained of which we can legitimately make use.

Where dynamical principles enter into the problem, the pitfalls which await the unwary are sometimes less evident. I will take as an illustration the case of models, such as have been constructed to elucidate the mechanism of folding and faulting. In no case, so far as I am aware, have geologists had regard to the conditions which are necessary in order that a model may correctly represent the working of the original. The various forces concerned must bear their proper ratios. Since the weight (for a given material) is reduced proportionally to the cube of the linear dimensions, the other forces must be reduced in the same ratio; and it is, in fact, impossible to make this adjustment as regards the internal forces which resist deformation and fracture. Moreover, the velocities of the moving parts should be reduced in proportion to the square root of the linear dimensions; and this makes it hopeless to think of imitating the slow processes of mountain-building. Models of this kind may afford useful *geometrical* illustrations, but can throw no light on *dynamical* problems. The same remark applies to models of glaciers; but here there is no need to go to artificial models to illustrate my point. Some geologists still argue from the behaviour of an Alpine valley-glacier to that of a continental ice-sheet, without perceiving how completely the different scale of magnitude must modify the mechanical conditions.

Experiment has undoubtedly afforded valuable help in the study of particular questions in the domain of physical geology, and this is to be recognised with gratitude. As regards the larger and more complex problems, however, imitative experiment labours under the same disadvantage as mathematical analysis. Any concrete problem can be treated only in an arbitrarily simplified form, and among the conditions which cannot be realised in the laboratory may be some which in nature are of vital importance. Especially will this be the case where the time element enters.

There is, however, another department of experimental geology in which we are justified in expecting results of very high value. I allude to the study of the conditions of formation and stability of different minerals, with the object of elucidating the mode of origin of igneous and other rocks. The artificial reproduction of many of the rock-forming minerals has engaged the attention of chemists, especially in France, during the last hundred years. Fouqué and Michel-Lévy succeeded even in imitating some of the simpler types of igneous rocks. These researches have furnished the petrologist with useful information, but it is information mostly of a very general kind. The laborious investigations now being carried out, more particularly in the Geophysical Laboratory of the Carnegie Institution of Washington, are of a different order, systematic and precise to the highest degree attainable. Their chief object is to apply to the crystallisation of igneous rock-magmas the methods which have proved so fruitful in other branches of physical chemistry. This necessitates working over a far wider range of temperatures than is usual in laboratory operations, and must sometimes include high-pressure work also. It involves, too, other practical difficulties, arising especially from the slowness with which equilibrium is established in many of the transformations investigated. Owing perhaps to these obstacles, and partly, it may be, to the scarcity of enlightened millionaires—for expense is here a weighty consideration—research on these lines has not yet been widely taken up. Meanwhile it is scarcely too much to say that Dr. Day and his colleagues at Washington are already laying the foundations of an exact science of petrogenesis.

Of all geological questions involving the numerical element, none has been more frequently canvassed than the problem of geological chronology, and none has excited more general interest. Since, moreover, it introduces several points germane to my subject, a brief glance at its history and present state will not be wasted. I suppose it has happened to most of us, when relating how in past times the mammoth roamed the plains of Holderness, or how coral-reefs once flourished where the Craven hills now stand, to be met by the inquiry: How long ago was that? The answer was perhaps to the effect that geology does not deal with the ordinary measures of time, but has its own system of chronology, not translatable into years and centuries. I must confess, however, to a sense of inadequacy in such a reply, and some sympathy with the lay inquirer who is thus silenced but not satisfied. It seems a matter of reasonable regret that a science which deals with the history of past events should have no definite time-scale, by which those events could be ranged in a correct perspective.

No such reflection, it is safe to say, disturbed the minds of the early Uniformitarians, the founders of modern geology. Their reaction against the older catastrophic school led them constantly to lay great stress on the extreme slowness of geological processes, and they thus came to assume unlimited time for the past changes to which the stratified rocks bear witness. To Hutton there was "no vestige of a beginning, no prospect of an end"; in other words, he regarded geological time as infinite, and could no more contemplate reckoning it in centuries than numbering the sands on the shore. Later this position was reinforced from another quarter, as Darwin's doctrines gained acceptance; for these were held to push back to an immeasurably remote epoch the beginning of life on the globe. Geologists and biologists alike saw no reason for limiting their prodigal drafts on the bank of time.

From this comfortable attitude they were startled, as by a bombshell, some fifty years ago, when William Thomson, afterwards Lord Kelvin, published the first of his contributions from the mathematical side to this and cognate subjects. He pointed out that, apart from any changes on the surface of the globe, our planet as a whole must be undergoing a change of a secular, and so irrevocable, kind; viz., a continual loss of energy in the form of heat, as proved by the observed temperature-gradient. Since the store of energy cannot be inexhaustible, we must deduce both a beginning and an end of the existing geological *régime;* and Thomson endeavoured to set a limit to its past duration from a discussion of the rate of cooling of the globe. A parallel line of argument was based on the cooling of the sun.

Now as regards the validity of the general criticism there can be, of course, no doubt. Huxley's halting defence of what was then the orthodox position was easily broken down, and a wholesome check was given to the extravagance of the geologists. When we turn, however, from the destructive to the constructive part of Kelvin's argument, the case is different. The time to be allowed for the geological record was stated at first with considerable latitude, but was afterwards narrowed down, until, in 1899, Lord Kelvin concurred in Clarence King's conclusion that the globe was a molten mass about twenty-four million years ago. It is rather remarkable that so many geologists were found willing to submit to this narrow limitation. Doubtless they were impressed by the prestige of Lord Kelvin's authority, and perhaps some of them were influenced by a vague feeling that a result arrived at by strict mathematical reasoning is thereby entitled to credence. But, as has been so often pointed out, and so often forgotten, what you get out of the mathematical mill depends upon what you put into it. The reasoning may be unimpeachable, but it merely proves that, if certain assumptions be granted, certain consequences will follow. It may be that Lord Kelvin himself, in the enthusiasm of enforcing his conclusions, did not always recall the foundations on which they rested, and it is to be suspected that many geologists read no more than the conclusions.

Kelvin's argument was based necessarily upon a number of assumptions. At the present time, in the light of fuller knowledge, it is sufficient to note one, which in 1862 seemed little open to question. Kelvin recognised that, while the earth is certainly losing heat, "it is possible that no cooling may result from this loss of heat, but only an exhaustion of potential energy, which in this case could scarcely be other than chemical affinity between substances forming part of the earth's mass." This, however, he dismissed as "extremely improbable," and proceeded on the assumption that heat is the only form of energy to be reckoned with. Since the discovery of radium we have learnt that the earth possesses a vast store of potential energy in a highly concentrated form then unsuspected. Strutt has calculated, from data of a very simple kind, that the observed temperature-gradient can be wholly accounted for by radio-activity, if the rocks to a depth of forty-five miles contain as much radium as those at the surface. In other words, the heat generated by radio-active changes within this relatively thin crust will, on that supposition, be sufficient to compensate that lost at the surface. Clearly, therefore, the actual rate of cooling of the globe—if indeed it is cooling—must be far less than that adopted in Kelvin's calculation, and his estimate of the age of the earth must be enormously increased.

This is not all. A study of the various radio-active elements contained in minerals and rocks has shown that it is possible, in certain favourable cases, to calculate directly their age in years. Some estimates of this kind have been made, and the results are liberal enough to satisfy the most exacting claims of what may be called the reformed Uniformitarian creed.

With this turning of the tables one might suppose that the old controversy would come to an end. But the reversal of the situation is, in fact, more complete; for meanwhile there has arisen a formidable minority of geologists who contend, on geological grounds, for estimates of time no more elastic than Lord Kelvin's. The question is still, in great part, one between geologists and physicists, but it is now the geologists who offer us the stinted measure and the physicists the more liberal one.

It is not my purpose to discuss in detail the various geological arguments which have been advanced for limiting the age of the earth to a span of 80 or 100 millions of years. The method of procedure is broadly the same in all. A computation is made of the rate at which some fundamental geological process is going on; it may be the lowering of the land-surface by erosion, or its destruction by solution, or the deposition of sediment, or the addition of salt to the sea. Some estimate is then made of the total result of the process throughout geological time. Having the annual rate of increment and the total amount, simple division gives the measure of the time in years. The observational data employed in these calculations are of a very precarious kind, and it would not be difficult to point out instances of that levity in the handling of figures to which I have adverted. But the fundamental weakness of all such reasoning lies in the assumption that the present rate of any of these geological processes can be adopted as equivalent to its average rate throughout the whole time.

The existing configuration of the globe, and all the physical conditions that go with it, have been attained in consequence of a prolonged evolution. If we believe that, as the net result of all its vicissitudes, the land-area has on the whole been growing in extent, in complexity of distribution, in boldness of relief, we must believe also that differences of temperature, of humidity, of climate generally, between different parts of the globe have become progressively more accentuated, and that all geological activities have been quickened as the world has grown older. While there is difference of opinion concerning these *secular* changes, there can be no doubt as regards the great *cyclical* changes which have been repeated several times in the history of the earth: the cycle beginning in each case with an epoch of important crust-movements and including the train of consequences which follow upon this new step in the evolution of the earth. Such a cycle was initiated at an epoch not long remote by geological reckoning, and we are living in consequence in a time of more than ordinary geological activity, with the continental masses rising higher than their average level, and with large tracts of newly deposited strata exposed to the attack of destructive agents.

For these reasons I am of opinion that the present rate of erosion, and of its correlative sedimentation, is much higher than the average rate, and that any calculation based upon it must greatly under-estimate the duration of geological time. I do not ask you necessarily to concur in this conclusion, but at least to suspend judgment in the matter: for it will assuredly be a misfortune if geology, so lately freed from one bondage, should fall straightway into another no less galling. This at least is certain, that every one of the various geological processes which have been discussed in this connection, is controlled by conditions which cause its rate to be very variable. It is a clock which now hurries and now creeps, or stands still, and it can never be trusted as a time-keeper. Even for the most recent chapter of geological history we can make no approach to certainty on these lines. Attempts have been made, for example, to estimate the time since the final retreat of the ice in North America from the rate of recession of the falls of Niagara; but the evidence shows that this rate has varied widely even during the last half-century, and Gilbert, after a careful study of all the data, refrains from offering any opinion on this point.

Must we then abandon all hope of any practicable measure of time in geology? I do not draw this conclusion, but rather that we must search outside strictly geological phenomena for some physical process of which the rate is not affected by any disturbing conditions. There are, I think, only two classes of changes for which so much can be claimed—the transformations of the radio-active group of elements and the astronomical movements. It seems not improbable that in one or other of these two directions the solution of the problem may eventually be found.

The chemists have taught us that radium is derived from the spontaneous breaking up of uranium, the change taking place apparently in two stages and involving the liberation of three atoms of helium. But radium itself disintegrates spontaneously, giving the radium-emanation named niton and liberating another atom of helium. Niton in its turn undergoes disintegration, and so on through a succession of changes. The final product is lead, and in the gradual conversion of uranium to lead eight atoms of helium in all are set free. Of these various spontaneous changes some proceed with extreme slowness, others with comparative rapidity; but in each case there is a constant rate which, so far as experiment has tested it, is independent of temperature or pressure.

Prof. Strutt has shown that this gradual liberation of helium can be made the basis of a method of estimating the absolute ages of minerals and rocks. For example, phosphates and some iron-ores are rich in radium, derived from uranium. They also contain helium, and the ratio of helium to uranium is found to be higher in the older deposits. Estimates of age calculated from these data give high figures: *e.g.* the age of the hæmatite overlying the Carboniferous Limestone in Cumberland is given as 140 millions of years, and even that of the Eocene iron-ores of Antrim thirty millions. The results show some irregularities, and it is, of course, admitted that the method has its own difficulties. If, however, the chief source of error is, as appears probable, the loss of helium by leakage, the figures found will be under-estimates. Helium comes from the thorium series of derivatives as well as from the uranium series, and this is to be taken into account where thorium is found. Zircons from various igneous rocks have also been examined by Strutt, and found to give consistent results as regards the helium-ratio. Mr. A. Holmes has approached the question in a different way, by considering the ratio of lead to uranium in various minerals rich in the latter element. The igneous rocks of the Christiania district, of Devonian age, are in this way calculated to be about 370 million years old. For the Archæan rocks of different countries the estimates range from 1000 to 1600 millions of years. Holmes's results are in general nearly twice as high as those of Strutt; but, if we bear in mind the error due to the escape of helium, which is proved to take place, a discrepancy to this extent is no more than should be expected at this early stage of the inquiry.

The other method which has been suggested for obtaining an absolute measure of geological time is of a more speculative kind, although the principle of it is sufficiently simple. It consists in detecting some clearly marked rhythm or cycle in the geological record, and correlating it with one of the known periodic movements of the earth. It was on these lines that Croll attempted to explain the recurrent glacial epochs; but more to our present purpose is the theory which Blytt has based upon a study of the alternations observed in a succession of sedimentary strata. The most important astronomical cycle of long period is doubtless that which depends upon the precessional movement, by which the relation of summer and winter to perihelion and aphelion is gradually changed. This involves a change in the relative lengths of summer and winter, and must undoubtedly exercise a marked effect upon climatic conditions, though there is much difference of opinion concerning the exact nature of this effect. Changes of climate may in their turn cause differences in the nature of the sediments deposited successively at a given place, differences which will repeat themselves in a cycle corresponding with that of the precession. Probably the most noticeable effect will be a recurrence of limestones and chemical deposits alternating with detrital sediments.

If the matter were no more complex than this, it would be sufficient, where such alternations can be detected, to count them, as we count the rings of growth of a tree, and reckon 21,000 years for each sedimentary cycle, that being the period of the precession corrected for the movement of the perihelion. If the alternations can be distinguished only in some parts of the succession, some hypothesis must be devised to take account of the intervals. Gilbert has discussed in this way a succession of beds, 3900 ft. thick, forming part of the Cretaceous system in Colorado. Alternations of calcareous beds with shales come in four times, being separated by unbroken thicknesses of shale. Gilbert calculates for the part of Cretaceous time represented a duration of about twenty million years, with an uncertainty indicated by the number 2 as a "factor of safety."

We have to remember, however, that sedimentation is controlled by other conditions besides climate, and climate depends upon other causes besides the precession of the equinoxes; and, further, that most of these contributing causes cannot be described as periodic in any intelligible sense. There is, it is true, a second astronomical movement to which both Croll and Blytt have made appeal, viz., the variation in the eccentricity of the earth's orbit. This goes through a period of about 90,000 years; but there are considerable irregularities which repeat themselves in the course of 1,450,000 years, giving a larger cycle which embraces sixteen of the smaller cycles. The change of eccentricity must modify the effect of the precessional movement; but Blytt argues that it will also react on the ellipsoidal shape of the globe itself, and so give rise to a displacement of shore-lines. He claims to have traced this effect, as well as the climatic cycle, in such cases as the succession of the Tertiaries in the Paris basin and the Isle of Wight. His conclusion is that Tertiary time comprises two of the larger cycles, *i.e.* about three million years.

It has usually been assumed that the year is too short a period to leave any recognisable mark on the geological record. This is probably true in general, but in certain favourable circumstances it may perhaps be possible to count annual layers of sediment. De Geer has recently attempted this in the case of certain finely laminated clays of late Glacial and post-Glacial age in Sweden. The material was brought down by sub-glacial streams at a time when the ice had retreated to the higher ground. Consequently the seasonal variations were strongly marked, and the accumulation of sediment was rapid enough to yield an appreciable thickness in each year. From such data De Geer has estimated that the recession of the last ice-sheet occupied a duration of about 5000 years; and he further gives 7000 years as the lapse of time since the recession of the ice.

As regards the longer astronomical cycles, it is clear that the argument involves a large element of hypothesis, and its application, as Blytt allows, is beset with practical difficulties. It possesses a special interest as lending a new significance to the details of stratigraphy, but as a means to the establishment of a geological chronology its value is at present only potential. The radium method of evaluating geological time seems to offer more immediate promise.

In conclusion, it is pleasant to note how these applications of chemistry, astronomy, and meteorology, not merely to general principles of geology but to a definite geological problem, emphasise the fundamental unity of the sciences, and illustrate the powerful aid that may be rendered by one to another.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. H. ROY DEAN, professor of pathology in the University of Sheffield since 1912, has been appointed to the chair of pathology and pathological anatomy in the University of Manchester.

DR. ADA E. MILLER has been appointed lecturer on school hygiene by the Edinburgh Provincial Committee for the Training of Teachers, in succession to Dr. J. Douglas Cameron, who has resigned.

IT is stated in *Science* that the committee on education of the United States House of Representatives has reported favourably a Bill establishing a National University in Washington. According to the Bill an initial grant of 100,000*l.* would be made. The university would be devoted to research and graduate work and no degrees would be conferred.

A REUTER message from Delhi reports that on March 22 Sir Harcourt Butler introduced in the Imperial Legislative Council a Bill for constituting a teaching and residential university at Benares, with special facilities for instruction in the Hindu religion. He referred to the scheme as the commencement of a new era in university organisation in India.

DR. ALEX. HILL, principal of the Hartley University College, Southampton, is reported by the *Times* to have said in an address on Monday that he had recently been preparing a war-roll of the Empire universities, and had found that the average contribution in men from universities and university colleges was just above 50 per cent. He added:—"It is a surprising fact that the contribution of German universities to the forces of the German Empire in the field is less than 20 per cent." This statement as to German university students is not, however, correct, judging from the statistics we gave last week (p. 81). Seventy-five per cent. of the students of German universities are in the field, and about 80 per cent. of the students of the Technical High Schools are also on active service.

SIR PHILIP MAGNUS retires, we understand, to-day from his official connection with the City and Guilds of London Institute. It is now no fewer than thirty-five years ago since he was appointed organising director and secretary of the institute, a post which he held for eight years, during which he was responsible for the initiation of the institute's work and for the schemes of the Finsbury College and Central Technical College, which have since developed so successfully. In 1888 his activities were transferred to the examinations department, or, as it is now known, the department of technology of the institute, where they found a wider field in assisting and guiding the development of technical instruction all over the country. The ability of his organising powers is sufficiently evidenced by the manner in which the department, without any assistance from Government and without the power of the purse possessed by a department of State, has made the name of the City and Guilds of London Institute known to technical schools all over the British Isles, and, indeed, in the Dominions beyond the Seas. To the work of Sir Philip Magnus in the office which he is vacating, his careful insistence on the necessity of making technical instruction a true education in principles, his continual study of the best means of adapting courses to the needs of students and manufacturers alike, and his unceasing endeavours to raise the standard of teaching, the progress of technical education in this country is greatly indebted.

THE first annual report, for the period ended December 31, 1914, submitted by the executive committee to the trustees of the Carnegie United Kingdom Trust has now been published. Mr. Carnegie during many years prior to 1912 gave large sums to local authorities in this country for the erection of public libraries, and to churches for the acquisition of organs. As the applications for these grants increased and their administration became more difficult, Mr. Carnegie decided to place the future administration of grants under the control of a permanent body of trustees. In 1913 he placed 2,000,000*l.* in trust so that the income of about 100,000*l.* a year should be available "for the improvement of the well-being of the masses of the people of Great Britain and Ireland." The report is full of interesting particulars, but attention can be directed only to a few typical facts. Organ grants are to be discontinued for the present. Mr. Carnegie has already expended 550,000*l.* in this direction in the acquisition of some 3500 instruments. A total expenditure of nearly 2,000,000*l.* has been incurred already on the erection of public libraries in the United Kingdom. The executive committee has, we notice, intimated to the authorities of the Household and Social Science Department of King's College for Women, London, that it is prepared to meet half the cost of the erection of a library building, on certain conditions. The committee has also made an offer in the direction of endowment to the Central Bureau for the Employment of Women. The report throughout gives the impression of wise and sympathetic administration of a princely endowment.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 18.—Sir William Crookes, president, in the chair.—Prof. W. H. **Bragg**: Bakerian Lecture: X-rays and crystalline structure. The atoms of crystal may be conceived—in various ways—as arranged in a series of parallel planes, each capable of reflecting a small fraction of an incident pencil of X-rays. If the spacing of the planes is d, the wave-length λ, and the angle between the rays and the planes is θ, and if the relation $n\lambda = 2d \sin\theta$ is satisfied, where n is any integer, then the various reflected pencils are in the same phase and combine to give an obvious reflection of the X-rays. If this relation is not satisfied there is no reflection. The X-ray spectrometer is designed to measure the various values of θ at which reflection occurs in a given case. The angle can easily be determined to a minute of arc. Given d we can compare the wave-lengths of different X-rays. Given λ we can compare the spacings of various sets of planes of the same or of different crystals. By certain considerations the experiments can be made absolute and not merely comparative. In this way the structures of several simple crystals have already been found, such as rock-salt, diamond, iron pyrites, and so on. The reflections for various values of n, the integer in the formula, or, as they may be called, the spectra of various orders, differ amongst themselves in a surprising way. The intensities in the case of the most important planes in Iceland spar have recently been determined and give very interesting results. In the case of two pairs of planes the spacing is the same but the arrangement of atoms is different. This gives an opportunity of comparing the effect of arrangement apart from spacing, and it appears that the *intensity* of the reflection in any order is proportional to the weight of the planes which contribute to that order. Again, there are three calcite planes for which the arrangement of the atoms is exactly the same, but they differ in their spacings. The relative intensities follow a rule which has already been stated, viz., that the intensity in a reflection at an angle θ is inversely proportional to $\sin^2\theta$, other things being the same. Rules of this kind are needed if the method is to be used in the examination of more complicated crystals. The physical meanings that may be attached to these rules are of considerable interest.

Physical Society, February 26.—Dr. A. Russell, vice-president, in the chair.—Dr. C. **Chree**: Magnetic "character" figures, Antarctic and international. The paper makes use of magnetic "character" figures "0" (quiet day), "1" (moderately disturbed day), "2" (highly disturbed day) to investigate whether the incidence of disturbance at the base station of the Scott Antarctic Expedition, 1911–12, did or did not accord with the incidence of disturbance in temperate latitudes; also whether the "27-day period" could be recognised in the Antarctic data. The incidence of disturbance in the Antarctic was found to agree closely with that shown by the international lists, in spite of the fact that the disturbances in the Antarctic were much larger and more persistent than at any of the stations co-operating in the international scheme. The "27-day period" was clearly visible in the Antarctic records both in summer and winter, being as well developed there as elsewhere.—Dr. P. E. **Shaw**: The electrification of surfaces as affected by heat. The paper deals with anomalous electrical behaviour of various substances when subjected to heat. For example, a glass rod rubbed with silk is normally left positively electrified, but if the rod be passed through a bunsen flame, or heated in an electric furnace, and then allowed to cool it will be found on again rubbing with the silk that the glass becomes negatively electrified. Similar results were obtained with a number of materials, and various experiments are described which aim at determining the cause of the phenomenon. These seem to show that it is not due to the formation or removal of layers of any substance, solid or gaseous, but is probably due to surface strains in the material.—Prof. J. W. **Nicholson**: Electromagnetic inertia and atomic weight. The paper contains a mathematical deduction of a simple formula for the combined mass of two electrical charges when in proximity to each other. This mass is not the sum of their individual masses when far apart, if it be supposed that all mass of positive electricity, like that of electrons, is of electromagnetic origin. Applications are made of the formula to questions of atomic constitution and of radio-activity. A discussion is given of the evidence leading to the conclusion that the nuclei or cores of positive electricity in atoms are complex structures of electrons and even smaller positive nuclei. On this basis, emission of an α particle by an atom does not decrease its atomic mass by 4, a correction being necessary for the "mutual mass" of the α particle and the rest of the core. Estimates of the magnitude of this correction, in the case of radium and thorium passing into lead by the emission of particles, are given. From the value given by Soddy for the atomic weight of thorite lead we can deduce the average distance apart of the components in a radium nucleus. It is of the same order as the radius of an electron. Suggestions of further interesting applications of the precise formula for mutual mass are also contained in the paper

March 12.—Dr. A. Russell, vice-president, in the chair.—C. C. **Paterson** and B. P. **Dudding**: The estimation of high temperatures by the method of colour identity. Preliminary experiments are described in which the temperature of incandescent substances is estimated with a very fair accuracy by matching their colour with that of incandescent filament lamps working at appropriate efficiencies. These have previously been calibrated by comparison with a "black body" over a large temperature range. The comparisons are made in the field of a Lummer Brodhun photometer, and the method is shown to give the correct result for the melting point of platinum.—C. C. **Paterson** and B. P. **Dudding**: The unit of candle-power in white light. The paper describes the methods adopted at the National Physical Laboratory for minimising the difficulty of photometric comparison of white lights of different hue. A series of six sets of electric sub-standards are described varying in the tint of the light radiated from that of the pentane lamp to that of a tungsten vacuum lamp operating at 1·5 watts per candle. The absolute value of the unit of candle-power has been re-determined, as have also the corrections for humidity and barometric changes, while the probable existence of a temperature correction is discussed.—G. L. **Addenbrooke**: The relative losses in dielectrics in equivalent electric fields, steady and alternating (R.M.S.). After references to former work, especially on surface leakage, tables are given showing an intimate connection between the losses in steady and alternating fields, and that one can be predicted from the other to a first approximation. Exceptions are mentioned, and it is shown that there is heterogeneity in these cases. Curves of the losses from 1 to 4 seconds to 40 ~ are given for specimen dielectrics. Above 8 to 12 ~ both for "good" and "poor" dielectrics, these become rising straight lines. The salient features lie below about 16 ~. The formula $a+bn$ applies to all dielectrics for frequencies above about 8 ~, but not below. The a constant is always larger than, and bears only a very indefinite relation to, the steady voltage loss. Liquid dielectrics behave similarly to solid with certain differences, particularly that for a given resistance the ratio of the steady to the alternating loss is less than with solids. There is a great difference in the comparative ranges of the losses. For the dielectrics tabulated these vary in a steady field from 1 to 1,300,000, but the corresponding alternating losses vary only from 1 to 1,100.

Linnean Society, March 4.—Prof. E. B. Poulton, president, in the chair.—A. W. **Hill**: The germination of the cucurbitaceous genus Marah. The genus Marah includes some eleven species practically confined to the Pacific watershed of the western States of North America and the islands of Lower California. The genus is distinguished from Echinocystis and other genera with similar floral characters by its enormous tuberous root, associated with which is the peculiar mode of germination of the seeds. The petioles are fused to form a tube, and on germination this tube grows out, carrying plumule and radicle some distance into the ground, the cotyledons remaining hypogeal. The plumule finally bursts through the petiolar tube, and grows up into the air with sharply bent over tip. The petiolar tube is covered with hairs which appear to function as root-hairs.—Dr. Marie C. **Stopes**: New types of stem-anatomy in Cycadeoidea, with a well-petrified new species. A short account was given of two species of Cycadeoidea in which the internal anatomy is partially preserved, and also of a well-petrified new species showing very curiously alternating series of wood zones.—W. E. **Collinge**: A new genus and species of terrestrial Isopoda from British Guiana.—Dr. **Stapf**: Inflorescences of the Carob tree (*Ceratonia siliqua*) representing the several sexual conditions in which the tree occurs. Reference was made to Cavanilles's observations in the Carob groves of Valencia and the work done by Heckel and Schlagdenhauffen on the French Riviera, and by Gennadius in Cyprus. According to these authors most of the apparently female trees, that is, trees with very small subsessile anthers, are in reality hermaphrodite (brachystemonous hermaphrodites in contradistinction from the rare dolichostemonous hermaphrodites). But Dr. Stapf pointed out that no anthers containing pollen could be found in the "brachystemonous" specimens in the Kew Herbarium, in spirit material recently received from the Italian Riviera, and in preparations of such flowers obtained from Cyprus. In spite of Heckel's, Schlagdenhauffen's, and Gennadius's excellent work, there is still some mystery surrounding the pollination of the Carob tree which is certainly worth studying on the spot.

Zoological Society, March 9.—Mr. R. H. Burne, vice-president, in the chair.—R. I. **Pocock**: The feet, perfume-glands, and other external characters of the Viverrinæ. The term Viverrinæ was used by the author in a restricted sense for the typical Civets and Genets referred hitherto to the three genera, Viverra, Viverricula, and Genetta. He pointed out, however, that a new generic term must be introduced for the African Civet (*V. civetta*), which differs from the Oriental species (*V. zibetha*), the type of the genus Viverra, in the presence of a small metatarsal pad, the absence of skin-lobes protecting the claws on the fore-feet, the nakedness of the area of the feet round the plantar pad, the structure of the perfume-gland, etc.—Mary L. **Hett**: New Pentastomids from the lungs of snakes. The snakes from which the material was obtained had died in the society's gardens. There is great difficulty in establishing diagnostic characters for the separation of species in the Pentastomids. Size and number of annulations have generally been used as standards of comparison and they hold good in a certain number of cases; but in many forms both these characters are so variable as to afford no sound basis for classification. This is illustrated by *Porocephalus bifurcatus* and three allied forms which are here described as varieties. They were all obtained from the lungs of snakes from different regions. An average specimen of each form differs from the other varieties in length and number of rings, but intermediate forms occur which almost bridge the gap between them in both particulars. Hence it is difficult to regard them as separate species. If, however, the differences should prove to be of specific value, the four species, together with one other, should certainly be united in a new genus, as they differ from all other Pentastomids and resemble one another in several important particulars.—Reports on the collections made by the British Ornithologists' Union Expedition and the Wollaston Expedition in Dutch New Guinea:—G. J. **Arrow**, G. A. K. **Marshall**, and C. J. **Gahan**: Coleoptera.—F. W. **Edwards** and E. E. **Austen**: Diptera.—H. **Campion**: Odonata.—Dr. L. Cognetti de **Martiis**: Vermes.—G. **Arnold** and Dr. C. L. **Boulenger**: The fresh-water Medusa recently discovered in the Limpopo River system. This jelly-fish is referred to the same species (*Limnocnida rhodesiae*, Boulenger) as the form described from a tributary of the Zambesi River in 1912. Species of Limnocnida are now known to occur in the five principal river systems of Africa as well as in the Bombay Presidency of India. The paper contains descriptions of the structure and habits of the jelly-fish, and attention is directed to the occurrence of parasitic Infusorians of the genus Trichodina on both the African species, *L. tanganicae* and *L. rhodesiae*.—F. F. **Laidlaw**: Bornean dragonflies collected on Mount Kina Balu. Two new genera and seven new species were described.

Geological Society, March 10.—Dr. A. Smith Woodward, president, in the chair.—C. **Reid**: The plants of the late Glacial deposits of the Lea Valley. Large collections of plants from the Lea Valley deposits, already described, have been made by Mr. S. H. Warren, Mr. E. T. Newton, and Mr. Wrigley. The localities from which the plants were obtained are Angel Road, Hedge Lane, Ponders End, and Temple Mills. A list from Ponders End has already been given by Dr. Lewis, but the new collections include many unrecorded species, several of which have not previously been noted as British fossils. Although there are slight differences, the collections from all four localities are so similar as to leave no doubt that the deposits are contemporaneous. The whole assemblage points to a very cold climate, though perhaps not quite so cold as that indicated by the Arctic plants found at Hoxne, in Suffolk. Among the more interesting novelties may be mentioned *Armeria arctica*, a species of thrift now confined to Arctic America, although it has also been recorded as a Pleistocene fossil from the continent of Europe by Dr. C. A. Weber.—S. **Smith**: The genus Lonsdaleia and *Dibunophyllum rugosum* (McCoy). The present paper discusses the literature, structural characters and development, descent, classification, and distribution of the corals constituting the genus Lonsdaleia; it includes also a description of *Dibunophyllum rugosum* (McCoy).

Royal Meteorological Society, March 17.—Dr. W. G. **Duffield**: The meteorology of the sun. An account was given of methods and results of spectroscopic and other observations of solar phenomena. Abbot's work on the variability of solar radiation opens up the prospect of further discoveries in connection with solar and terrestrial phenomena, the most important practical problem in the region of physics or meteorology. It is the hope of astronomers that the earth will be completely girdled by observatories which will take part in the international scheme of co-operation in solar research. The promise of such observatories in Australia and New Zealand is welcomed by all interested in the development of solar and terrestrial meteorology.

THE DEVELOPMENT OF THE INVERTEBRATES.

Text-book of Embryology. Edited by W. Heape. Vol. i. Invertebrata. By Prof. E. W. MacBride. Pp. xxxii + 692. (London: Macmillan and Co., Ltd., 1914.) Price 25*s*. net.

THE appearance of Balfour's great work on comparative embryology in 1880 marked an epoch in the history of zoology. Since then not only has a vast quantity of new information been acquired, but whole new branches of the study have been developed. For instance, we now have the science of experimental embryology, which aims at discovering the conditions and regulative processes of differentiation and development—a science founded by Roux, Driesch, and others; while to E. B. Wilson and other American observers we owe the study of cell-lineage, whereby the prospect is opened up of being able to trace back homologous organs not merely to germ-layers, but to corresponding individual cells in the early history of the embryo. To give a clear and concise account of these modern researches is indeed a difficult task. Prof. MacBride is the first Englishman to make the attempt, and it may be said at once that he has been, on the whole, most successful.

The descriptions are remarkably lucid, and easy to understand with the help of an abundance of really excellent illustrations. Each chapter deals with a separate group. After a brief introduction, it begins with as complete an account as possible of the whole development of a typical example, from egg to larva, and from larva to adult. Other forms are then briefly compared with the type, and there follows a discussion of the general features of the embryology, of their phylogenetic significance, and of the affinities of the group. There is much to be said for this mode of treatment. The story of the development is continuous, and the reader is presented with a very complete picture of the ontogeny of a representative of each group. At the same time there is some danger that he may not fully realise how much diversity of development there often is among closely allied animals; and that the type chosen may be, and indeed often is, the most specialised. Following the history of normal development, we also find in many chapters an interesting discussion of the results of experimental embryology. Here and there the text is varied with useful notes on the occurrence and habits of larvæ, and on methods of collecting and preserving material.

Such a work is bound to show weak points, and the chapters are certainly of unequal merit. Readers will turn with special interest to the part devoted to Echinoderms, since Prof. MacBride's important researches on these animals are well known. They will not be disappointed, but will find, we think, the best account of the embryology of the Echinoderms yet published in any text-book. On the other hand, certain obscurer groups are altogether omitted, or are scarcely mentioned. Considerations of space may, no doubt, have compelled the author to aim rather at giving a full history of the more important forms than at completeness. But we venture to think that it would have been better to devote more attention especially to organogeny in the earlier chapters, and to have collected the parts dealing with experimental work into a separate volume. For the general questions, which the experiments are designed to elucidate, are far better discussed as a whole than piecemeal in the various chapters. Want of space has also prevented Prof. MacBride from giving any historical account of the subject, from referring in most cases to any but the most recent publications, and from providing a fuller bibliography.

Knowing what difficulties the writer of a text-book has to contend with, it is an ungrateful task to find fault with so excellent a work. Yet some points may be mentioned which might well be improved in a second edition. We doubt whether the reader of the chapter on the Porifera would gather that there takes place in many sponges the remarkable developmental process known as the "inversion of the layers," so well described by Delage, Minchin, and Maas. Since he admits, we believe quite rightly, that the Ectoprocta and Endoprocta are independent phyla "not descended from a common fixed Polyzoon ancestor," why has not the author the courage to separate them, following the example of some of his predecessors? Again, we find the Opisthogoneata and the Progoneata still joined in the artificial group Myriapoda. Such conservatism obscures the issue, and hinders progress. We wonder, also, why he retains the word nephridium, even in inverted commas, for the segmental ducts of Peripatus, derived from the cœlomic wall, and not homologous with the nephridia of the earthworm to which Lankester first gave the name. Indeed, the whole question of the nephridia, their development and homology, seems to be very inadequately treated. Here the author appears to be treading on unfamiliar ground, and to be insufficiently acquainted with the literature on the subject. Even less satisfactory is Prof. MacBride's discussion of the cœlom. Its origin is vaguely referred to the radial enteric chambers of some remote Cœlenterate ancestor. The author appears to forget that these chambers are formed in a fundamentally different way and order, by the ingrowing of mesenterial folds. Moreover, one of the many serious objections to this theory is that it fails utterly to bridge over the gap between the Cœlenterate and the Cœlomate, and leaves quite unexplained the structure of the Platyhelminth and Nemertine. It is just here that the Gonocœle theory has proved so valuable, giving the only intelligible interpretation of the morphology of these lower forms, founded not on vague speculations, but on the comparison of well-established facts in comparative anatomy. This theory, founded and supported by Hatschek, Ed. Meyer, Lang, and many others, Prof. MacBride dismisses with scorn, and the remarkable statement that any vogue it has obtained "is only in consequence of the myopic concentration of attention on the facts of development in a limited number of groups, and the neglect of the facts of development in other groups" (p. 166).

The suggestion made on p. 661 that the diverticula of the gut in the Platyhelmia represent the cœlom takes us back some thirty years to a time before the structure of these animals was understood, besides being in direct opposition to the teaching of cell-lineage so clearly described in this very volume. The determination of the homology of the mesoblast cells in Platyhelminths, Nemertines, Annelids, and Molluscs is surely one of the most important contributions of modern embryology to the morphology of the Invertebrata.

The author is less happy in his phylogenetic speculations than in his descriptions of development. So much is he under the influence of the recapitulation theory that almost all free-swimming larvæ appear to him as scarcely modified ancestral forms. It need scarcely be pointed out that the mere prevalence of a common larval form in one or several groups of animals does not in itself prove that this larva closely resembles the adult common ancestor. It may be taken as good evidence that the ancestor also possessed such a larval stage, and is therefore an indication of the close affinity of the animals concerned. Beyond this it is unsafe to theorise without other evidence from comparative anatomy or palæontology. It should never be forgotten that ancestors were not larvæ, but self-supporting adults capable of reproduction. Prof. MacBride would have done better to follow the example of Sir Ray Lankester, who long ago, when he reconstructed his famous Archi-mollusc, took as his model not the trochosphere nor even the veliger larva, but a creeping animal. If we adopted the author's theories as to the ancestral significance of larval forms, we should have to suppose that a large number of the characters held in common by the various groups have been independently developed, a conclusion for which there would seem to be no justification.

When discussing general questions in a final chapter Prof. MacBride appeals to hormones as affording a rational explanation of the *modus operandi* for the supposed "inheritance of acquired characters." This view is, of course, not new; Delage, Vernon, and Cunningham have in turn supported it. But, quite apart from the evidence of such inheritance, it is difficult to see how these internal secretions could become incorporated into the blastogenic factors of development.

We congratulate both the author and the editor on the production of this handsome text-book. It will doubtless be warmly welcomed by all English-speaking students and teachers of embryology, and take the place it deserves among the standard works on the subject.

E. S. Goodrich.

THE BUTTERFLIES OF AUSTRALIA.

The Butterflies of Australia: a Monograph of the Australian Rhopalocera. By G. A. Waterhouse and G. Lyell. Pp. vi+239+plates. (Sydney: Angus and Robertson; London: Oxford University Press, 1914.) Price 42*s*. net.

The scientific study of the butterflies of Australia is certain to be greatly advanced by the appearance of this admirable work, although it is to be feared that the high price will tend to prevent a very wide circulation. It is obvious, however, that a costly book is implied by the presence of forty-three excellent quarto plates, of which four are coloured. In addition to this abundant and most necessary illustration in plates, the reader is provided with numbers of text figures as well as a valuable map-index of localities. One of the plates is devoted to larvæ and pupæ, one coloured plate to the variations of the Satyrine butterfly *Tisiphone joanna*, the three others to special Satyrinæ, Lycænidæ, and Hesperidæ. The remaining thirty-eight uncoloured plates contain 793 figures, all natural size, of the 332 species recognised by the authors as at present known in Australia.

Especial attention has been given to geographical distribution, and the authors have made a point of examining long series of specimens wherever available. In this work they have received help from many students of the Australian Rhopalocera, while Mr. Waterhouse's extremely fine collection, seen by the present writer during the recent visit of the British Association, has clearly been developed with the object of producing this volume.

The trinominal system of nomenclature, the principles of which are clearly explained in the introduction, is followed by the authors as by most naturalists who have made a special study of geographical distribution. At the same time, new subspecies or geographical races have only been created when plenty of material was available. The authors have wisely deemed it "preferable that a race should continue undetermined rather than the racial characters should be wrongly described or a new race erected on insufficient grounds."

The exigencies of space prevent any detailed discussion or description of the work, but it must be mentioned that the remarkable *Euschemon* is considered as a "Skipper" (Hesperidæ) and not as a moth. This conclusion appears to the present writer to be entirely sound, although the primary division of Lepidoptera into "butterflies" and "moths" is, of course, artificial and merely a matter of convenience.

In addition to the description of the species and the groups to which they belong, occupying nearly the whole of the volume, there is an introductory section with a brief historical account of Australian work and an excellent general description of the Lepidoptera, together with the anatomical features relied upon by the systematist. A concluding section, with "Notes upon Collecting and Collections," complete the work by rendering it a sufficient guide to the beginner.

The keen Australian naturalist is now provided with a foundation upon which to build. The present work will tell him what he is dealing with, and will indicate much of the work that remains to be done. Blank records of food-plants and of larval and pupal stages will suggest, to those interested in breeding, one of the most fascinating of all inquiries. We may hope that the bionomic problems presented by the Australian Lepidoptera, as yet scarcely attacked at all, will now receive attention; that geographical variation, so specially studied by the authors, will forthwith be advanced by the efforts of a band of new observers.

The naturalist living in the cooler parts of Australia need not be discouraged by comparing his species with the grander forms of the tropical north. These latter are for the most part identical with or very closely allied to Papuan species, while his own less magnificent butterflies are characteristic of the great southern continent. At the same time, the resident in northern Queensland has the opportunity of solving complex problems of tropical life with its elaborate inter-relationships—an opportunity of which Mr. F. P. Dodd has taken such great advantage. With the present work as a guide we may look forward to a rapid advance along many lines in our knowledge of the butterflies of Australia.

E. B. P.

PHYSICAL ANTHROPOLOGY.

Lehrbuch der Anthropologie in Systematischer Darstellung. Mit besonderer Berücksichtigung der anthropologischen Methoden für studierende Aerzte und Forschungsreisende. Von Prof. R. Martin. Pp. xvi+1181. (Jena: G. Fischer, 1914.) Price 35 marks.

IN these later years the Anthropological Institute of the University of Zürich has acquired a very high reputation amongst anthropologists. The success of Zürich as a centre of anthropological research and teaching is due to Prof. Rudolf Martin who, these twenty years past, has gathered round him and trained a band of young men, who are now spreading abroad the reputation of the new Swiss school.

In the work under review, Prof. Martin gives a systematic account of twenty years of experience as an expert anthropologist, detailing his methods of measurement, his manner of making records and describing the principles on which his methods are based. His text-book is much more than a technical manual; it is really an encyclopædia of knowledge relating to the size and shape of body in all races of mankind. There was great need for a standard work on physical anthropology; Prof. Martin has supplied that need.

The modern conception of the scope of physical anthropology and the relative importance attached to each of its branches will be made clear by a summary of the contents of Prof. Martin's text-book. The largest section is given to the skull; 422 pages out of a total of 1069 are devoted to the methods and results of craniology. The next important section is that which deals with the living body—its measurements, proportions, pigmentation, growth, etc.; to this subject considerably more than a third of the total book is assigned. A separate section is devoted to a consideration of the skeleton—189 pages. Thus, the major part of this work is devoted to the skull, skeleton, and external characters of the body.

The two opening sections, although condensed—amounting altogether to 102 pages—are both useful and important. These opening sections deal with anthropological methods, particularly with the best means of expressing results in graphic and in mathematical forms. The classification of human races, the relationship of man to other mammalian forms, and the origin and progress of anthropological knowledge are discussed briefly but yet at sufficient length to meet the needs of the average student. A. K.

MONOGRAPHS AND TEXT-BOOKS OF CHEMISTRY.

(1) *Nucleic Acids: their Chemical Properties and Physiological Conduct.* By Prof. W. Jones. Pp. viii+118. (Monographs on Biochemistry.) (London: Longmans, Green and Co., 1914.) Price 3*s.* 6*d.* net.

(9) *A Manual of Chemistry: Theoretical and Practical, Inorganic and Organic.* Adapted to the requirements of students of medicine. By Dr. A. P. Luff and H. C. H. Candy. Pp. xix+660. Fifth edition. (London: Cassell and Co., Ltd., 1915.) Price 8*s.* 6*d.* net.

(1) and (2) THE subject of biochemistry, like many other branches of knowledge, has already extended to dimensions which effectively prevent any one author from doing justice to more than a part of the subject. Under these conditions it has been usual to witness the production of a text-book in which a general editor has distributed the work amongst a number of colleagues. The two monographs now under review are excellent examples of a better method of treatment. The publication of a series of smaller monographs provides just that flexibility which is required by a rapidly-growing subject; topics which are not yet ripe for description in a text-book can be held over to await further development, whilst individual sections can be revised and brought up to date without rendering obsolete a whole edition of many volumes.

Prof. Jones's monograph on the "Nucleic Acids" provides a fascinating story both for chemists and for physiologists, and affords a revelation of the amount of definite knowledge that is now coming into existence in reference to the chemical composition of plant and animal bodies.

It is very interesting to watch what materials are used in nature for the building up of living tissues. In the present case one of the most important sugars has been proved to be *d*-ribose (hitherto not known to chemists), whilst the bases belong to the pyrimidine series or are related to uric acid; the formula for the last substance is written in an unfamiliar form, with a hexagonal nucleus, which suggests a real analogy with the bases of the indol and skatol series. The inclusion of a bibliography covering sixteen pages of text will show how extensive is the literature on which this compact volume is based.

Prof. Barger's monograph covers a more extensive field, and is based on a bibliography which extends over 44 pages of text. These simpler bases are related in some ways to the alkaloids. They are distributed much more widely, but must be extracted by different methods. For this reason they were not recognised until a much later date; but, once identified, they are often capable of synthetical preparation on a large scale. Few things, in the recent growth of biochemistry, are more remarkable than the proof that has been given of the simple chemical character of many substances of intense physiological activity. The most striking case is that of adrenaline, but there is reason to believe that other internal secretions owe their activity to bases of comparatively small molecular weight. If this should be the case, the study of these bases may prove to be of even greater importance than that of the amino-acids which bulk so largely in the structure of the proteins.

(3) The appearance of a second edition of Prof. Soddy's monograph on the radio-elements is an indication of the rapid growth of the subject with which it deals. Many new members have been added to the disintegration-series, but there is reason to think that something approaching completeness has now been attained, and that further study will be devoted mainly towards an increased

knowledge of these elusive elements, some forty of which are crowded into ten places of the conventional periodic classification.

(4) The French book on analysis and synthesis is the fifth volume of an Encyclopædia of Applied Chemistry. It includes five sections on "Organic Analysis," by M. Hanriot; "Pharmaceutical Products," by P. Carré; "Synthesis of Colouring Matters," by A. Sergewetz; "Production of Perfumes," by E. Charabot; "Saponification," by A. Hébert. It is therefore in reality a series of five monographs, bound together in one volume and grouped under a convenient general title. It forms a companion to a similar volume on the theory and practice of mineral analysis, but might with advantage have been issued in separate parts, as it is unlikely that many workers would attempt to cover the wide field included in this volume.

(5) Prof. Ostwald's "Principles," of which a fourth edition is now published, is an inorganic chemistry written from the point of view of the physical chemist. The ionic hypothesis occupies a place of honour throughout the volume. In the new edition a final chapter on the radio-active elements contains a somewhat full account of the three chief disintegration-series of radio-elements.

(6) Mr. Williams' book on the cyanogen compounds contains a detailed description of this important series of compounds, arranged somewhat in the manner of a dictionary. Thus under the heading of "Thiocyanates," details are given as to the composition and properties of thirty-two simple salts and a far larger number of double salts. The author has made a number of experiments himself, the results of which are now described for the first time, the "petty restrictions" and "stereotyped methods" of the scientific societies having prevented him from publishing them through the usual channels. Fortunately, he has been able to avail himself freely of the work of others who have faced these obstacles. The book is therefore generously supplied with references to original literature, which render it a valuable guide to the subject with which it deals.

(7) Mr. Oscroft's book suffers from an unfortunate title. Intended primarily for senior classes of boys, it is described in the title as an "advanced inorganic chemistry," and in the text as a "Chemistry for advanced students." Such a description is misleading in the case of a book which devotes only one page to the Periodic Law, four pages to radio-activity, and five pages to spectrum analysis. Apart from this obvious error the book is a good example of the class of school text-books to which it really belongs. The author is in touch with the historical treatment, which is now becoming so important in the teaching of elementary chemistry, and promises also to effect, on the theoretical side, an improvement comparable with that which has resulted from the introduction in the laboratory of experiments based largely on the classical work of Scheele, Cavendish, and Priestley. The illustrations are scarcely equal to the standard of the text, and are not improved by labelling the gases as H, N, O, etc., in direct defiance of their recognised molecular formulæ. The formulæ given on p. 223 for persulphuric acid should be H_2SO_5 (monobasic) and $H_2S_2O_8$ (dibasic), and the preparation on p. 242, described and indexed under persulphuric acid, refers obviously to pyrosulphuric acid.

(8) The instructions used in the chemical laboratories at Leeds in the teaching of elementary students have been expanded by Mr. Lowson into a small volume intended primarily for local use, but likely to prove acceptable in other laboratories where similar work has to be carried out. The book consists mainly of simple preparations, which are described in detail in order to economise the time of the teacher and to enable him to accommodate the course to the varying abilities of different students. Theoretical questions suggested by the experiments are, however, referred to from time to time, and a large number of additional exercises are provided in connection with the different preparations.

(9) Luff and Candy's "Chemistry for Students of Medicine" shows a marked improvement in each successive edition. The condensation of the whole of the chemical theory, including the periodic classification of the elements, into one preliminary section does not provide a practicable basis for actual class-teaching; but it may well prove convenient to a student who wishes to revise what he has learnt in a course of lectures arranged on a gentler gradient. Historical references are more frequent than in the earlier editions, as the author has found that these interest the student, and also enable him to trace the evolution of the fundamental principles of chemistry, and thus appreciate their full significance. T. M. L.

OUR BOOKSHELF.

The Germ-cell Cycle in Animals. By Prof. R. W. Hegner. Pp. x + 346. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 7s. 6d. net.

In this interesting book Prof. Hegner gives a very complete and clear account of the origin, structure, and continuity from generation to generation of the reproductive cells of the Metazoa. Owen appears to have been the first clearly to point out that the fertilised ovum gives rise to two kinds of cells: the first destined to form the differentiated tissues of the new individual, the second remaining relatively unchanged and destined to propagate the race. Recent investigations, to which the author has made valuable contributions, tend to show that the distinction, once established, is irrevocable, and that germ-cells are derived from pre-existing germ-cells in an unbroken stream—the germ-track. Modern methods have enabled investigators to trace the appearance of germ-cells to earlier and earlier stages in development, thanks to certain distinctive characters of the cytoplasm or nucleus. The name keim-bahn determinants, or germ-track determinants, as we should prefer to call them, is given to such recognisable features in the cells. Although in some animals, such as Ascaris and Sagitta, the germ-cells have been traced back to the very early embryo consisting of only a few cells, the complete segregation of the germ-forming substance has not yet been observed in the first cleavage of the egg into two cells.

Having given an excellent review of the evidence on this subject, Prof. Hegner proceeds to discuss the significance of the germ-track determinants, the chromosomes and mitochondria of germ-cells, the determinants of sex, and kindred questions. No doubt the most interesting problems relate to the possible identification of factors which determine the fate of cells—whether they will become germ-cells or body-cells, ova or spermatozoa, and also the fate of individuals—whether they will become males, females, or hermaphrodites. Through no fault of the author these problems are left unsolved. But concerning the germ-plasm theory itself he is confident that it rests on a firm basis, while inclined to believe that the germ-plasm resides not in the nucleus or chromosomes alone, but also in the cytoplasm.

Quain's Elements of Anatomy. Eleventh edition. Vol. iv, Part 1. *Osteology and Arthrology*. By Dr. T. H. Bryce. Pp. viii + 329. (London: Longmans, Green and Co., 1915.) Price 12*s*. 6*d*. net.

IN the latest (eleventh) edition of "Quain's Anatomy"—a standard work—there have been several alterations, one of them being the inclusion of the chapters giving a descriptive account of the joints with the volume devoted to the skeleton of the human body. Part 1 of Vol. iv., which has just appeared under the editorship of Prof. T. H. Bryce, thus gives a systematic account of the bones and joints of the human body. We are very glad to note that the editor gives a fairly full list of the more important of recent publications—an essential feature of a standard work. Prof. Bryce has done well in retaining the excellent drawings which Mr. D. Gunn, Dr. T. W. P. Lawrence, and Prof. G. D. Thane contributed to the last edition, and has improved the chapters dealing with the joints by the use of new coloured plates prepared by Mr. A. K. Maxwell. Another decided improvement is the introduction of an account of the development of the various parts of the skeleton in the chapters devoted to descriptions of the bones. The investigations of Prof. Fawcett and of Dr. Alex. Low have been incorporated in the new text. Altogether, this volume of the new "Quain" will be welcomed by teachers and students of anatomy.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Rules of Zoological Nomenclature.

As one of the British members on the International Commission for Zoological Nomenclature, I have frequently been asked where copies of the rules as revised and adopted at the Monaco Congress are to be obtained in separate form. May I therefore use your widely-read columns to inform zoologists (including palæontologists) that a translation into French, the official language, has been made by Prof. R. Blanchard, in agreement with the secretary to the Commission, and has been published in the *Revue critique de Paléozoologie*, edited by Mr. Maurice Cossmann, 110 Faubourg Poissonnière, Paris X? Reprints may be purchased, at a price of 4*s*., from Messrs. Dulau and Co., Ltd., 37 Soho Square, London, W. Mr. Cossmann has added some useful notes, especially from the point of view of the palæontologist, but these, it should be remembered, have no authority from the Congress or the Commission.

Natural History Museum, South Kensington, S.W., March 30.

The Preparation of Anhydrous Solids.

THE following method may perhaps be of use to chemists and biologists who are concerned in the preparation of solid compounds in the anhydrous state for analysis, or in obtaining anhydrous tissues for moisture determinations, etc. It consists in utilising Prof. S. Young's process for the purification of alcohol from all water by distilling it through his evaporator still-head, with the previous addition of a suitable quantity of benzene.

The tissue or compound to be dehydrated is placed in the distillation flask with alcohol and benzene in the proper proportions. When all the turbid ternary mixture of constant boiling point has been removed, by distillation from a water-bath, the remaining mixture of alcohol and benzene may be rapidly distilled away, and the last traces can be removed in a vacuum desiccator. By adjusting the quantities either alcohol or benzene can be obtained as the residual liquid, and the complete removal of either of them is far more readily effected than is that of water owing to their lower boiling points and greater volatility.

The method avoids all risk of oxidation, a source of serious error when plant tissues are dried at 100° C. in air. It appears that this procedure can be adopted for quantitative determinations in many cases, and may throw light upon the existence of water as "water of crystallisation" or as "water of constitution." These points are at present being studied by Miss E. G. Wilson and the writer.

W. R. G. ATKINS.

University Chemical Laboratory, Trinity College, Dublin.

THE WAR AND BRITISH CHEMICAL INDUSTRY.

OWING to the urgency of the aniline dye question and the discussion which has been taking place on the Government scheme, it has been thought expedient to issue part iv. of a memorandum dealing with the entire question of the "War and British Economic Policy." It is published by Messrs. P. S. King and Son, of Westminster, and a brief summary of it is given in the *Chemical News* of February 26. British industries use annually dyes to the value of nearly 2,250,000*l.*, of which about 1,750,000*l.* come from Germany, about 150,000*l.* from Switzerland, and only about 200,000*l.* are of British home production. Aniline dyes constitute an indispensable material in many branches of the textile, leather, paper, and other industries, and the annual value of the goods in which they are an essential or important part is estimated at 200,000,000*l.*

The opinions of a large number of firms interested in the use or manufacture of aniline dyes are given in the memorandum in question, and emphasis is laid on the fact that the dependence upon German supplies is so great that the present capacity of British dye works is totally inadequate to fill the gap. During the past few weeks the Government scheme has formed the subject of numerous articles and letters to the Press, and a brief review may here be given of these, so far as they deal with the general question of the relationship between science and industry in this country, and ignoring all problems of a political nature, such as the question of the necessity for a protective tariff for the proposed new industry.

Prof. Armstrong, in a letter to the *Morning Post* of February 27, after considering the report of the debate on the Government dye scheme in the House of Commons, concludes that the "situation is an almost hopeless one owing to the lamentable ignorance of our public men of matters scientific." He illustrates this want of knowledge by a criticism of Mr. Runciman's recent pronouncement that in organising the new scheme the Government "had at their elbows two, at least, of the greatest chemists of Europe," a description which, it is contended, will "scarcely pass muster."

> If the production of dyes is to be taken in hand seriously, and the foundation laid of a permanent industry, men must be chosen to manage the enterprise who are as able as was my dear old friend, now deceased, Dr. H. Caro, who played so great a part in the development of the Badische Anilin Company, or as his eminent successor, Prof. Bernthsen is, or as is Prof. Duisberg, who has brought the Bayer Company to its present proud position, and now dominates the whole industry. . . . We have in our ranks men of their type who would be immediately available. But apparently the advisers of the Government want subordinate intellects, not leaders.

Dr. M. O. Forster, in a characteristically ironical letter to the same journal, points out that the establishment of an indigenous dye industry "is, has been, and ever will be as much a question of education as of trade. Education of legislators, Government officials, manufacturers, and merchants." It was to have been wished that before taking any steps towards organising the new scheme, every member of the Cabinet, together with the other Ministers, "could have been transferred bodily to Ludwigshafen and personally conducted through the Badische Anilin- und Soda-Fabrik." Dr. Forster depicts with considerable humour the astonishment that Mr. Runciman and the others might have expressed at the organisation and laboratories of this firm, and especially on finding some actual chemists on the directorate.

Several columns are devoted by the *Financier* of February 12, 23, and March 12 to interviews with Mr. W. P. Dreaper, who, as chemist to the Silk Association, speaks with some authority on the practical side of the question. Mr. Dreaper also most strongly emphasises the necessity that the board of the proposed company should contain a scientific representation, and the absolute importance of securing the best scientific knowledge which is available. He protests against the policy of training chemists of the "second class," of which Mr. Runciman seems to consider that we have an insufficient supply, and against the general lack of understanding which exists amongst manufacturers as to what a chemist is "owing to the demand that has sprung up in certain directions for the 70*l.* per annum variety."

The lack of appreciation in this country of the services of the chemist and the absolute ignorance on the part of the Government of what remuneration should be given him is admirably illustrated by the letter of Sir William Tilden in the *Chemical News* of February 26, protesting against the salary offered by the Royal Arsenal, Woolwich, to assistant chemists in the inspection department. At a time when the nation is spending 1,250,000*l.*, and will soon be spending 1,750,000*l.*, per diem on maintaining our army in the field, the utmost that the War Office can afford to give a chemist who has "had a thorough training in inorganic and organic chemistry," and is "a university graduate or member of the Institute of Chemistry," is the sum of 2*l.* 0*s.* 6*d.* per week! Such an advertisement "gives one to think," and is, indeed, a striking object lesson of the fact which Prof. Armstrong deplores—"we have had no public use for science in our country, and we are blind to our needs and as to our opportunities."

The whole question of the utilisation of science in industry is indeed closely wrapped up with that of the miserably insufficient remuneration given in the majority of cases to science and scientific workers, which Sir Ronald Ross has so strongly emphasised in recent numbers of *Science Progress*. So long as the prospects of the young chemist and the remuneration that he receives are of the order indicated in the above advertisement there is little hope of developing in this country industries that require the services of large numbers of highly-trained scientific workers.

It is interesting to find a politician like Mr. L. G. Chiozza Money, M.P., emphasising the same lesson in an article in the March *Fortnightly Review* on "The War and British Industry." Mr. Money comments that "we have been content to leave the development of many old industries and the establishment of many new industries to foreign hands," owing to our "normal" disregard of science.

Let us not deceive ourselves into believing that "science" or "chemistry" affects a limited number of subsidiary industries. There is no industry in the world, from building construction to coke-making, from artillery construction to the making of explosives, from dyeing to leather tanning . . . which has not been in recent years turned inside out by science and invention. We have been content in too many matters to let the world go by us.

Even in the matter of preparation for war Mr. Money, quoting from the address delivered before the Mathematical Association on January 9 by Sir George Greenhill (see NATURE, January 21, p. 573), gives a melancholy contrast between the conditions under which German and British artillery officers have been trained in their science at the Military Technical Academy of Berlin and at Woolwich.

The neglect of science in industry and in public affairs, which is characteristic of this country, culminated in the prospectus of British Dyes (Limited), on the board of which science is entirely unrepresented. The opinions of Sir Henry Roscoe and Sir William Ramsay on the scheme, expressed in the columns of the *Times*, have already been given in NATURE (March 11, p. 41), whilst Prof. Armstrong, in the *Morning Post* (March 13), considers that "our fate as makers of dyes is sealed." The failure of the scheme to attract sufficient capital from investors to justify the directors of the company in proceeding to allotment was referred to last week (p. 94). A meeting of representatives of the textile and dyeing trades was held at Manchester on March 24 to consider the position, and a resolution was adopted in favour of proceeding with the company if certain modifications were made in the business part of the programme. There is no doubt as to the national necessity for such work as the Government scheme is intended to promote, but to expect that a company without a single industrial chemist upon its board of directors will be able to compete with the highly organised coal-tar colour industry of Germany is to show complete want of understanding of the scientific problems which must be faced if permanent success is to be assured.

How little Germany fears competition in this field in the future from English manufacturers, even though aided by the resources of the State, can be gathered from an admirable article by Prof. O. N. Witt in the *Chemiker Zeitung* for February 13. In this article are given the real reasons why Germany has been able to outstrip all competition and to secure practically a monopoly, and why the foundations of the industry are so solidly based that the prospects of the British scheme having anything like a permanent success seem altogether illusory. It must be remembered that the German chemical industry (with one or two exceptions) has never received any protection whatever from tariffs. How futile such protection as that afforded by patent laws can be in comparison with the results obtained by the organisation of science in the service of industry is emphasised by a report to Congress, which is reprinted in the *Chemical News* of March 5. In the United States a 30 per cent. duty on some coal-tar dyes for more than thirty years has not produced a real coal-tar dye industry. Germany, on the other hand, has succeeded because she has placed science on a sound business footing, of which the fair remuneration of the scientific worker has been a striking feature. The part played by the German banks, often with men of considerable scientific attainments on their boards, in developing German industry is emphasised by Mr. W. P. Dreaper in an article on Industrial Research in the *Financier* of March 12.

Germany, in short, has succeeded in the past because she deserved to succeed. Not only has she organised scientific effort on the manufacturing side, but she has organised equally effectively her commercial relations with foreign countries. This side of the question, which has played no small part in attaining the final result, is dealt with in the current *Bulletin* of the Société d'Encouragement (vol. cxxii., p. 33), by M. Lindet, who gives as an example an account of the methods adopted by Germany in Rumania.

The Germans present to the Rumanians objects specially manufactured to satisfy the local requirements, sold at a price which is lower than ours because they are manufactured more cheaply and because they bear lower charges for transport. The German and Austrian merchants and manufacturers interested in Rumanian business have formed a syndicate with its representative at Bucharest. They obtain in this way facilities for transport in common which we do not possess. They have at Bucharest banks which allow long-date credits, and they have representatives and travellers who without intermission pursue their clients. They advertise widely, and have inaugurated at Bucharest a museum of their goods.

It is an organisation of this kind, highly developed on both the manufacturing and commercial sides that we have to prepare to face in the future, after the war has ended and Germany is left free to resume her usual activities.

DR. A. S. LEA, F.R.S.

THE ranks of those who took part in founding the Cambridge Physiology School grows thin. But a few months ago we recorded the death of Dr. Gaskell. We have now to record the death, on March 23, of Dr. Arthur Sheridan Lea at sixty-one years of age.

Lea entered Trinity College, Cambridge, in 1872, he became Foundation Scholar of the College, and in 1875 he took a First Class in the

Natural Sciences Tripos. His bias was to the chemical side of physiological problems, and, in consequence, on Foster's advice, he began research with Kühne at Heidelberg. Kühne combined in a rather unusual manner the study of physiological chemistry with that of histology, and Lea's work with him developed, as it chanced, mainly on histological lines. Kühne and Lea were the first to observe satisfactorily with the microscope the changes taking place in a living gland—the pancreas—with intact circulation, and to note the special vascular supply of the Islets of Langerhans. One of the figures illustrating their paper is given to this day in most text-books of histology and physiology.

Lea, after his return to Cambridge, specialised in physiological chemistry though he gave instruction to pupils in the whole range of physiology, and to him was due the development in the Cambridge laboratory of advanced teaching in this subject. In the successive editions of Foster's "Text-book of Physiology," Lea wrote the part dealing with physiological chemistry, and in the fifth edition (1892) this part, revised and enlarged, appeared as a separate volume entitled "The Chemical Basis of the Animal Body." His research work was chiefly on the chemical changes in food during digestion, and on the action of rennet and fibrin ferments.

Lea's first post was that of demonstrator of physiology for Dr. Foster. In 1881 he became director of medical studies and assistant lecturer at Gonville and Caius College. In 1885 he was elected fellow of the college, and soon after became bursar. He was appointed university lecturer in 1884. His career in the university and in science was cut short by the development of a spinal disease—signs of which had long been present—making walking at first difficult and later impossible. None of his friends can forget the astonishing fortitude with which Lea met this shattering of his chief interests. He had always led an active outdoor life; he had cruised about the coasts in a yacht whenever opportunity offered; he was Captain in the Cambridge Volunteers, had taken special courses of instruction at Aldershot, and was a good rifle shot. Since he could no longer carry on these pursuits, nor continue his research in the laboratory, he decided after a time to break entirely with the old life. He left Cambridge and settled at Sidcup in Kent.

Rarely then or later did Lea rail at fate. He put on a cheerful countenance, and made the best of what was left him. He kept in touch with his old friends, revised the proofs of their books as occasion offered, and occasionally made small pieces of apparatus for them with the mechanically-driven lathe which served to keep up the cunning of his hands. Before leaving Cambridge he had married, and had one son. In a letter written shortly before he died, Lea expressed pleasure that his son had volunteered for the Army and was serving in the trenches. In this as in other matters he kept his private anxieties to himself.

J. N. L.

PROF. A. A. W. HUBRECHT.

The death of Prof. Hubrecht at his residence in Utrecht on March 21, in his sixty-fifth year, removes another link between the zoology of the present day and the zoology of what may be called the great epoch of Huxley and Balfour. His earlier work dates back to 1874, and was of an anatomical character; it was only in the later part of his career that he devoted himself to embryology, and advocated views which led to lively controversy, and were provocative of good work, both on his own part and on the part of those who opposed him.

Speaking broadly, Hubrecht's name will survive as associated with thoroughly sound work and with the elucidation of a large number of most important new facts, even if the deductions which he drew from them no longer find favour with zoologists. So far, indeed, as theories are concerned, Hubrecht's mind continued to reflect the mental attitude of the zoological world in which his youth was passed; it was, indeed, a time of the "faith that moves mountains." Ardent naturalists were applying the Darwinian doctrine of evolution to every part of the animal kingdom; with the enthusiasm of pioneers they were tackling the most obscure and difficult problems of the natural relationships of animals; the deep abysses which separate different phyla of the animal kingdom were traversed by their soaring imagination, for were not the powers of variation limitless? and did not the principle of "change of function" enunciated by Dohrn authorise one to homologise any organ of any animal with any organ of any other animal to which it bore the slightest resemblance? So Hubrecht, to whom we owe the first thoroughly satisfactory account of the anatomy of the Nemertine worms, was convinced that Vertebrata were descended from a Nemertine worm, and that the Nemertine proboscis represented the Vertebrate notochord.

In his later years Hubrecht devoted himself principally to mammalian embryology, and made a series of most valuable observations on the relations between placenta and young in the eutherian mammals. He was led by these observations to a theory of the origin of mammalia, which has not been borne out by the work of other embryologists or by palæontologists. He supposed that the higher mammalia were directly descended from amphibia, and that the monotremata, the anatomy and embryology of which betrays in an unmistakable manner their reptilian affinities, were secondarily modified forms. Here, again, Hubrecht's firm faith carried him over all difficulties. These remarks are not intended as any disparagement of the methods of comparative anatomy or embryology, but are merely designed to emphasise the fact that in these, as in all other sciences, sound inductions are only possible on the basis of an immense accumulation of facts. Modern zoologists addicted to Mendelism would do well to remember that "of making many factors there is no end, and formulæ are a weariness to the flesh."

Hubrecht was a firm friend of England and a constant visitor at scientific meetings here; he could speak English like a native, and his death will be felt as a personal loss by a large circle of friends in this country. E. W. M.

NOTES.

The following resolution of the council of the Royal Geographical Society has been accepted by the fellows of the Society: "The council, having become aware that Sir Sven Hedin, K.C.I.E., a subject of a neutral State, has identified himself with the King's enemies by his actions and published statements, orders that his name be removed from the list of honorary corresponding members of the society." Dr. Sven Hedin has also been excluded from the Russian Imperial Geographical Society.

The council of the Royal Geographical Society has made the following awards of medals and other prizes to be presented at the anniversary meeting on May 17: Founder's Medal to Sir Douglas Mawson for his conduct of the Australian Antarctic Expedition of 1911–14; Patron's Medal to Dr. Filippo de Filippi for his expedition to the Karakoram and Eastern Turkestan in 1913–14; Victoria Research Medal to Dr. Hugh Robert Mill for geographical research extending over many years; Murchison Award to Captain J. K. Davis, who commanded the S.Y. *Aurora* during the time of the Australian Antarctic Expedition; Back Grant to Mr. C. W. Hobley for his contributions to the geology and ethnology of British East Africa; Cuthbert Peek Grant to Mr. A. Grant Ogilvie for his work in geographical investigation and research; Gill Memorial to Colonel Hon. C. G. Bruce for explorations in the Himalayas.

The annual general meeting of the Chemical Society was held at Burlington House on Thursday, March 25. The Longstaff medal for 1915 was presented to Dr. M. O. Forster, and the retiring president, Prof. W. H. Perkin, then delivered his presidential address on "The position of the organic chemical industry," an abstract of which appears elsewhere in this issue. A vote of thanks to the president was proposed by Prof. H. E. Armstrong and seconded by Sir William Tilden. The new officers and members of council elected were:—*President,* Dr. Alexander Scott; *Vice-Presidents,* Prof. F. R. Japp and Prof. R. Threlfall; *Treasurer,* Dr. M. O. Forster; *Ordinary Members of Council,* Mr. D. L. Chapman, Prof. F. G. Donnan, Mr. W. Macnab, and Dr. J. F. Thorpe.

The sixty-eighth annual meeting of the Palæontographical Society was held in the rooms of the Geological Society, Burlington House, on March 26, Dr. Henry Woodward, president, in the chair. The report stated that most of the authors for whom space had been reserved in the annual volume, had failed to contribute owing to the circumstances of the war, and an instalment only of Mr. F. W. Harmer's "Monograph of Pliocene Mollusca" would form the issue for 1914. Messrs. John Hopkinson, Clement Reid, S. Hazzledine Warren, and Henry Woods were elected new members of council. Dr. Henry Woodward was re-elected president, and Mr. R. S. Herries and Dr. A. Smith Woodward were re-elected treasurer and secretary respectively.

The seventieth annual general meeting of the Ray Society was held on March 25, the president, Prof. McIntosh, in the chair. The report for 1914 stated that the number of members had increased and the finances were satisfactory, but a diminution of income was to be expected this year owing to the loss of German and Austrian subscribers on account of the war. For 1914 the "British Marine Annelids," vol. iii., part 1, by the president, had been issued, and for 1915 two volumes were in preparation: the "British Fresh-water Rhizopoda," vol. iii., containing the filose Conchulina, by G. H. Wailes, and the "Principles of Vegetable Teratology," vol. i., containing non-vascular plants and the root, stem, and leaves of vascular plants, by W. C. Worsdell. Prof. W. C. McIntosh was re-elected president, Dr. F. Du Cane Godman treasurer, and Mr. John Hopkinson secretary.

We notice with regret the announcement of the death on March 27 of Mr. J. J. Beringer, associate of the Royal School of Mines, and principal of the School of Metalliferous Mining, Camborne, Cornwall

The death is announced of Prof. F. A. Sherman, professor of mathematics at Dartmouth College, New Hampshire, from 1871 until his retirement as professor emeritus in 1911. Prof. Sherman died on February 25 in his seventy-fourth year.

We learn from *Science* that the Rockefeller Institute for Medical Research has made a grant of 4000*l.* to be used under the institute's direction to further medical research work under war conditions, and is equipping Dr. Carrel's new hospital in France with apparatus for research work in pathology, bacteriology, and surgery.

The death is announced, in his seventy-seventh year, of the Rev. Dr. S. J. Coffin, professor of astronomy since 1873 at Lafayette College, Pennsylvania, in which institution he also occupied the chair of mathematics from 1876 to 1886. He was the author of a treatise on conic sections, and had revised "The Winds of the Globe," by his father, Prof. J. H. Coffin.

The *Times* correspondent at Ottawa states that in the Canadian House of Commons on March 27 Mr. Hazen, Minister of Marine, expressed the opinion that Mr. Stefansson, the Canadian explorer, had been lost with his two companions. The Government, he said, is doing everything of a practicable nature to find the missing men, and three steamers now in the Arctic will set out to the rescue of the expedition as soon as the ice breaks up in the spring.

The American Association of Immunologists will hold its annual meeting at Washington on May 10 next, under the presidency of Dr. G. B. Webb, of Colorado Springs. The association was founded in 1913 for the purpose of bringing together the medical men of the United States and Canada who are engaged in the scientific study of immunity and bacterial therapy; to study the problems of immunology; and to promote scientific research in this department; to spread a correct knowledge of vaccine therapy and immunology among general medical practitioners.

The Board of Agriculture and Fisheries announces that with a view of obtaining further information on their growth, migrations, and general life-history, a number of salmon and sea trout have been marked by means of a ring or wire, with or without a label or tag attached. Rewards will be paid for all such marks returned to the Board, with or without the fish, with information as to the date, time, place, and method of capture. When the entire fish is not sent full particulars of its weight, length, sex, and condition should also be given, and a portion of the skin or flesh of the fish to which the mark is fixed should be cut out. Postage and carriage need not be prepaid, and parcels and letters should be addressed to the Board at 43 Parliament Street, London, S.W.

Prof. H. Robinson, who occupied the chair of civil engineering at King's College, London, from 1880 to 1902, died on March 24, at seventy-eight years of age. From a short obituary notice in the *Times* we learn that Prof. Robinson had charge of many important works, including railways, water supply, sewerage, and electric lighting, an example of the latter being the successful installation at St. Pancras. He engineered the first public hydraulic power scheme in this country at Hull, and took an active part in promoting the distribution of energy in other towns by hydraulic power, compressed air, and electricity. Prof. Robinson was a fellow of King's College, of the Surveyors' Institution, and of the Sanitary Institute, and a past-president of the Society of Engineers.

We notice with much regret the announcement of the death, on March 23, at fifty-three years of age, of Dr. S. G. Rawson, principal of the Battersea Polytechnic, London. Dr. Rawson was educated at Charterhouse School, the Royal College of Science, University College, London, and University College, Liverpool. He afterwards became lecturer in chemistry at University College, Liverpool, and in 1895 he was appointed principal of the Technical College, Huddersfield. In 1903 he was appointed director of education to the Worcestershire County Council, and in September, 1907, he became principal of the Battersea Polytechnic. Dr. Rawson was a doctor of science of the University of London, an associate of the Royal College of Science, fellow of the Institute of Chemistry and of the Chemical Society, and, since January, 1914, was chairman of the council of the Association of Technical Institutions.

We regret to announce the death of Mr. James Kearney, who for the last thirteen years has been inspector in charge of the photo-engraving section of the Egyptian Survey Department. He was originally in the Royal Engineers, and accompanied Sir G. Graham's expeditionary force to the Sudan in 1885 as photographic expert. He was then for several years attached to the Solar Physics Committee at South Kensington, and will be remembered by many old students of the Royal College of Science, London. In 1893 he went to West Africa with the British Eclipse Expedition as expert photographer, and again in 1906 he was with the party who observed the solar eclipse at Aswan. During this period he several times received the thanks of the Royal Society. From 1893 to 1902 he was one of the instructors at the School of Military Engineering at Chatham, which he left to go to Egypt. His wide experience of his subject and originality have largely influenced the development of the reproduction of maps by the Egyptian Survey Department, and practically all their maps now are reproduced by the photo-metal process.

The following are among the arrangements for lectures at the Royal Institution after Easter:—"The Animal Spirits," Prof. C. S. Sherrington; "Advances in the Study of Radio-active Bodies," Prof. F. Soddy; "The Evolution of Steel: Influence on Civilisation," Prof. J. O. Arnold; "The System of the Stars: (1) Star Colour and its Significance; (2) The Stellar System in Motion," Prof. A. S. Eddington; Advances in General Physics," Dr. A. W. Porter; "The Movements and Activities of Plants," Prof. V. H. Blackman; "Method of Presenting Character in Biography and Fiction," Wilfrid Ward; "Modern Artillery," Lieut.-Col. A. G. Hadcock; "Photo-electricity" (the Tyndall Lectures), Prof. J. A. Fleming; "Colouring Matters of the Organic World: (1) Colouring Matters of Nature; (2) Dyes, the Creation of the Chemist," Dr. M. O. Forster. The Friday evening discourses will begin on April 16. Mr. Stephen Graham will deal with "The Russian Idea" and Major P. S. Lelean with "Military Hygiene at the War"; they will be followed by Canon Pearce, Sir John Jackson, Sir Ernest Rutherford, Dr. H. Walford Davies, Profs. F. G. Donnan and O. W. Richardson, and Mr. Edward Heron-Allen.

It is an axiom in business that to be successful the merchant must provide what the public wants. He may try to educate the public by advertisement and other means, but it is the public demand alone that regulates the quality of the supply. The population of this country demands a white loaf of light texture made from the finest portion of the wheat berry, and bakers and millers have made it their business to supply this want. Even at the height of the standard bread boom it is stated that the demand for this article did not reach 5 per cent. of the total. Whether the public taste is the most satisfactory on scientific grounds is possibly open to question; the subject was discussed in an article in these columns on January 7. In the opinion of nearly everyone qualified to judge, our bread is good enough in quality, and the fact remains that the public will take no other. The Bread and Food Reform League holds the contrary view, and recently presented a memorial to the President of the Local Government Board. The *Times* of March 26 reports the presentation of this memorial under the heading, "A Notable Protest." The list of signatories contains a number of notable names, but those of experts who can speak with authority upon the subject are not prominent, which is typical of the national attitude towards scientific knowledge. Mr. Samuel expressed the opinion that it is impracticable to undertake at the present time legislation on the lines suggested by the memorial.

We regret to record the death of Lady Huggins, at Chelsea, on March 24, after a long illness. From the time of their marriage in 1875, Lady Huggins was the able and unwearying assistant of her distinguished husband, the late Sir William Huggins, and was definitely associated with him as joint author of numerous original papers on astrophysical subjects. Among the investigations in which she took special part were those relating to the spectrum of the great nebula in Orion, the photographic spectra of Uranus and Saturn, absorption bands in the spectrum of Mars, the spectrum of Nova Aurigæ, and the spectra of Wolf-Rayet stars. In laboratory work she collaborated in investigations of the effect of density on the intensities of the H and K lines of calcium, of the modifications of the magnesium line 4481 under different experimental conditions of the spark discharge, and in photographic studies of the spectrum of the spontaneous luminous radiation of radium. Lady Huggins was also joint author of the well-known "Atlas of Representative Stellar Spectra" (1899), which includes the later work of the Tulse Hill Observatory, and a general discussion of the problem of stellar evolution; initial letters and other drawings by Lady Huggins add much to the beauty and interest of this volume. She also acted as joint editor of "The Scientific Papers of Sir William Huggins," published in 1909. In recognition of her valuable services to astrophysics, Lady Huggins was elected an honorary member of the Royal Astronomical Society in 1903.

The death is announced, after a short but painful illness, of Prof. Eberhard Fraas, curator of the geological section of the Royal Natural History Museum, Stuttgart. Prof. Fraas, who was born in 1862, was the son of Prof. Oscar F. von Fraas, whom he succeeded in the curatorship at Stuttgart in 1897. He was a student of Prof. Karl A. von Zittel, of Munich, and devoted his special attention to vertebrate palæontology. His first important work was a memoir on the Labyrinthodonts of the Swabian Trias, published in the *Palaeontographica* in 1889. This was followed in 1891 by a separate volume on the Ichthyosauria from the Jurassic of Würtemberg. In 1894 he first announced Mr. B. Hauff's remarkable discovery of the integument and fins of Ichthyosaurus, and during following years he described several fossil fishes and reptiles obtained by Mr. Hauff from the Upper Lias of Holzmaden. As a curator of the Royal Museum, Prof. Fraas made a special effort to collect systematically the fossil reptiles from the quarries in the Triassic sandstones round Stuttgart, and met with great success. He not only discovered unusually fine examples of Dinosaurians and Crocodilians of known species, but also obtained several new skeletons throwing light on the ancestry of the Chelonians. Most of this collection still awaits detailed description. Prof. Fraas also interested wealthy friends in the Tertiary mammalia of Egypt, and among the specimens obtained was the skull of the most primitive known whale, which he described in 1904 under the name of *Protocetus atavus*. He showed that this skull was intermediate between that of ordinary early toothed whales and that of the early land carnivores (Creodonta). In 1907 ill-health caused him to visit German East Africa, and while there he discovered the first remains of the gigantic Cretaceous dinosaurs, which have subsequently proved to exceed in size even the largest of the dinosaurs known from North America. Prof. Fraas's excellent scientific work will remain as a permanent memorial of his acumen and industry.

The large Australian collections of stone implements are little known to ethnographers. During the recent visit of the British Association, Miss A. C. Breton carefully examined the local museums, and in *Man* for March she gives an account of them. The finest collection, that at Melbourne, has been carefully arranged by Messrs. A. S. Kenyon and D. J. Mahony, who will, it may be hoped, publish an account of it. Their researches tend to show that, as in other countries, the *coup de poign*, once invented, was never forgotten. As other forms became known, all continued in use together until something more serviceable was introduced.

The question has often been asked: Was there an earlier race in occupation of the area in Africa at present held by the Bantus? In *Man* for March Mr. W. H. Beech reports that in the Kikuyu country some ancient pottery has been found, said to be the work of a people called Gumba, who displaced the Maithoachiana, cannibal dwarfs. These Miathoachiana are now believed to be earth-gnomes, skilled in the art of iron-working. Mr. Beech, with some amount of plausibility, suggests that they were possibly Bushmen, Pygmies, or both, and that they were a local indigenous race of the Stone age, who used the flint implements often found in the Kikuyu country. The Gumba are said to have made pottery and to have taught the Kikuyu the art of smelting. They may have been pre-Bantu Hamite invaders; but of this there is no evidence, and the legend may tend to show that the first discovery of iron was made in Africa.

Irish Gardening for March, 1915, contains several useful horticultural papers. One on the different species of Hamamelis, or witch hazel, hardy in the British Isles, is appropriate as these interesting shrubs from China and Virginia are so valuable in the garden in full flower in mid-winter. *Hamamelis mollis*, from China, with its fragrant flowers, is the most beautiful species. *H. virginiana*, from eastern North America, was introduced so long ago as 1736, and is further of interest since witch hazel snow or hazelene snow is prepared from an extract of the bark.

The annual note on the ornamental waterfowl at Kew is always of interest, since so many species breed there in captivity. In 1914 the following birds were reared:—Carolinas; mandarins; common, red-crested, white-eye pochards, and tufted ducks; common sheldrake; Brazilian, common, and Chilian teal; bar-headed, white-fronted, and other geese; and a black-necked swan. Several geese having been destroyed by a badger which took up its abode in the gardens it was decided to dig him out and deport him. When digging him out, his earth was found to be carpeted with bluebell leaves and flowers, and many shovelsful were thrown out.

The *Kew Bulletin* (No. 1., 1915) contains an account of additions to the gardens, museums, library, and herbarium during the past year. Among many interesting presentations to the gardens the most valuable was the fine collection of botanical orchids presented by Lady Lawrence. Collections of filmy ferns in excellent condition have also been received from the Director of Agriculture, Jamaica, Dr. L. Cockayne, New Zealand, and the Assistant-Director of Agriculture, Trinidad. The herbarium has acquired no fewer than 25,500 specimens as donations or exchanges, and 13,500 by purchase. Among the former, Mr. Crossland's collection of British fungi, with drawings, presented by the Bentham Trustees, is one of the most important additions. The Bentham Trustees have also enriched the library with several rare books, and Miss Willmott has presented a copy of her fine work on "The Genus Rosa."

The Canadian Department of Mines has published a Memoir (No. 20-E) upon the goldfields of Nova Scotia by Mr. W. Malcolm. This forms a large volume of some 330 pages, and gives a detailed description of the various gold-producing areas, which together include about one-half of the entire province of Nova Scotia. These descriptions are mainly of local interest, but a good deal will be found of importance to the student of ore deposits, owing to the fact that these particular deposits present a number of specially interesting features. The report shows clearly that the veins belong mainly to the type known as bedded veins—that is to say, mineral veins which are interstratified with, and generally conformable to, the country rocks, though some fissure veins that cross the formations are also met with. To the former class belong the numerous saddle veins, and especially those curious corrugated saddle veins, to which the name of "barrel quartz" is given locally; the peculiar structure of these veins has long attracted the attention of geologists. The memoir has been compiled with great care, the detailed statistics of production being amongst its most welcome features, and it forms a very valuable contribution to our knowledge of these goldfields.

The wet winter of 1914–15 is dealt with in *Symons's Meteorological Magazine* for March in a preliminary way, it being as yet too early to prepare any complete account of the rainfall. Taking the British Isles as a whole, the four months, November and December, 1914, and January and February, 1915, are said to have been all wet, and of these December and February were, relatively to the average, the wettest. November rainfall was below the average in the south of Ireland and in the south-west of Wales, while December was wet everywhere, especially in the south. More than two and a half times the average fell in the south-east of England, and more than three times the average in Sussex. The rainfall of January was double the average at a few stations in England, again chiefly in the south-east. In February more than twice the average rainfall was recorded in the south of England and Wales, in Yorkshire, and in the south and east of Scotland. The rainfall for the four months was 168 per cent. of the average over England and Wales, 139 per cent. over Scotland, 150 per cent. over Ireland, and over the British Isles as a whole it was 155 per cent. of the average. No previous winter seems to have been so wet. In the Thames Valley the general rainfall for the four months was 19·19 in., which is 205 per cent. of the average, and previous records, which exist for thirty-two years, show no aggregate general rainfall for four months over the Thames Valley so much as double the average.

The stability relations of the ternary system $CaO-Al_2O_3-SiO_2$ are studied by Mr. G. A. Rankin in the *American Journal of Science*, vol. xxix (1915), p. 1. Photographs of models, due to the ingenuity of Mr. England, are given; in these, the horizontal positions represent the compositions of the ternary mixtures and the vertical measures give the corresponding melting temperatures. The result has some resemblance to the surface of a mountainous country, the peaks of which represent the melting points of compounds stable at their melting points. The base is an equilateral triangle, the heights above its angles being the respective melting points of the three members of the system, *i.e.* CaO, 2570°; Al_2O_3, 2050°; SiO_2 (cristobalite), 1625° C.

The Washington Bureau of Standards has carried out a useful investigation of the familiar "basic lead acetate solutions." Mr. R. F. Jackson, in Bulletin No. 232, has given a complete equilibrium diagram for the system $H_2O | PbO | PbC_4H_6O_4$. In addition to the free base, $Pb(OH)_2$, and the neutral acetate, $PbC_4H_6O_4$, two double-compounds may exist in equilibrium with the solution. The most important of these has the formula $PbC_4H_6O_4,2PbO,4H_2O$, but there is a narrow range of compositions within which the compound $3PbC_4H_6O_4,PbO,3H_2O$, is the stable phase.

The chemical and mechanical relations of iron, cobalt, and carbon formed the subject of a paper read by Prof. J. O. Arnold at the Institution of Mechanical Engineers on March 19. The paper gives account of research work on the influence of cobalt, from which it appears that the tensile strength increases with the percentage of cobalt present. In annealing tests, with 2·68 per cent. of cobalt present, very little of the combined carbon was precipitated as graphite; two-thirds of the combined carbon passed into the graphitic form in specimens containing 5·5 per cent. cobalt, and in specimens having a higher percentage of cobalt, annealing caused the whole of the combined carbon to pass into the graphitic form. Dr. Arnold, in his remarks, pointed out that there were three true steels: (1) the old iron and carbon steel; (2) the true iron and carbon steel with 5 per cent. of vanadium; in this steel carbide of iron ceased to exist, carbide of vanadium is present; (3) iron and carbon steel having 11·5 per cent. of tungsten; the tungsten expels the carbide of iron, giving the true tungsten steel. Iron and carbon steel hardens at 730° C., vanadium steel at a temperature just before the melting point (1450° C.), and in tungsten steel hardening starts at 850° C., and is not completed until nearly 1200° C.

MESSRS. HENRY SOTHERAN AND CO., of 140 Strand, W.C., and 43 Piccadilly, W., have issued in two parts —Nos. 754 and 755—a catalogue of important works in natural history, including zoology, botany, gardening, farming, microscopy, and geology. The library of the late Prof. Howes is included in the collection. Owing to the war, the volumes are being offered at very low prices.

THE reference in NATURE of March 25 (p. 96) to "three Englishmen, namely Sir A. Geikie, Sir William Ramsay, and Lord Rayleigh," who are members of seven national scientific societies, has brought the inevitable letter from a correspondent suggesting injustice to "Scots." In the case of Prussia we used deliberately the phrase "men of science in Prussia," knowing, of course, that Prof. van't Hoff, though he lives in Berlin, is not a Prussian. It would perhaps have been better to have used the word "Britons" instead of Englishmen in the note, or to have said "men of science in England," as the comparative statement holds good only by taking the place of residence of each person.

OUR ASTRONOMICAL COLUMN.

COMET 1915*a* (MELLISH).—The following is the ephemeris for Mellish's comet for the current week as computed by Messrs. Braae and Fisher-Petersen :—

12h. Berlin Mean Time.

	R.A. (true) h. m. s.	Decl. (true) ° ′	Mag.
March 31	18 2 51	−1 23·1	
April 2	5 9	1 41·2	8·5
,, 4	7 25	2 0·5	
,, 6	9 40	2 21·1	8·3
,, 8	18 11 55	−2 43·2	

The comet is in the constellation of Serpens, and lies a little to the west of the star Eta. It is approaching both the earth and sun, and it will be nearest the earth in about the middle of June. Unfortunately it will be too far south to be seen from these latitudes, but its increasing brightness will make it a conspicuous object for observers in the southern hemisphere. Elements and ephemeris slightly different from the above appear in the Lick Observatory Bulletin No. 268.

THE NINTH SATELLITE OF JUPITER.—An account of the discovery, observations, and orbit of the ninth satellite of Jupiter is given by Seth B. Nicholson in No. 265 of the Lick Observatory Bulletin. The discovery of this faint object (about 19 mag.) was made with the Crossley reflector at the Lick Observatory on plates taken on July 21 and 22 of last year. A series of photographs was being made to secure positions of the faint satellites of Jupiter, and it was on the first plates taken for the eighth satellite that the new member was found. The plate was so exposed that the photographic image of the eighth satellite should not be elongated, and a similar exposure was made on the following night. A comparison of the two plates indicated the image of an almost circular object on both plates near the eighth satellite. Further photographs on July 23 and 24 corroborated the reality of the images in question, and in consequence the discovery was publicly announced. The present bulletin is accompanied by a plate showing reproductions of the photographs taken on July 22, 23, and 24, indicating the eighth and ninth satellites. Mr. Nicholson next describes the computation of the orbit of the new body by Leuschner's method, and gives the approximate elements calculated by him, together with those of the eighth satellite derived by Crawford and Meyer for comparison. These serve to establish the identity of the object and to describe the nature of its orbit. The motion, like that of the eighth satellite, is retrograde.

RELATIVE PROPER MOTIONS OF THE PLEIADES.—In the *Astronomische Nachrichten* No. 4790 Dr. R. Trümpler gives details of an interesting investigation on the relative proper motions of the Pleiades group. The work is based chiefly on a previous research (1901) by J. Lagrula entitled "Etude sur les occultations d'amas d'etoiles par la lune avec un catalogue normal des Pléiades," in which the differential positions of 102 stars in the Pleiades group in relation to the central star of η Tauri were determined. Dr. Trümpler derives the following conclusions from Lagrula's proper motions of forty-three stars. The relative proper motions of the eleven brightest stars are very small. The relative motions of the fainter stars have larger velocities than the bright stars, and exceed the limit of errors of the determinations. The proper motions of the fainter stars indicate a systematic variation from those of the brighter stars, or, in other words, the system of the fainter stars appears to displace itself with regard to the system of the brightest stars. In the case of the fainter stars there is indicated a movement of rotation in the direction of decreasing position angle, one rotation being of the order of two million years; the brightest stars appear to take either no part or only a very small part in this movement. The point of radiation for the proper motions of the Pleiades cannot be deduced with certainty. It can only be said that from the observed radial velocities of the brightest stars the parallaxes of the Pleiades must be smaller than 0·1″.

REPORT OF THE STONYHURST COLLEGE OBSERVATORY.—The report of the director of the Stonyhurst College Observatory for the year 1914 consists for the main part of the results of the meteorological, magnetical, and seismological observations. Reference to the astronomical work accomplished during the past year is incorporated under the heading, "Report and Notes by the Director." These include, first, the results of the measures of the disc areas of sun-spots as measured from drawings. It is shown that the year 1913 was the minimum year of sun-spot activity, while the year 1912 was the minimum year for the mean range of magnetic declination. These results are in accordance with those published in this column for March 18 (p. 75). An account is also given of the expedition to Hernösand, Sweden, to observe the total solar eclipse of August 21, 1914. Reference is made to the record of the strong red radiation coronal line 6374·3, which is described here as "a strong member of a band or fluting. . . ." The presence of this coronal radiation was first announced by M. Deslandres (*Comptes rendus*, November 16), and was soon corroborated by M. Carrasco by the examination of his own eclipse spectrograms.

RECENT WORK OF THE UNITED STATES GEOLOGICAL SURVEY.

IN No. 82 of the handsome series of Professional Papers published by the United States Geological Survey, Myron L. Fuller describes "The Geology of Long Island, New York." This suburban island, from the lively beach of Coney Island on the west to the old-time refinements of Easthampton, protects the Connecticut coast for more than a hundred miles. Its core consists of sandy strata, which are now recognised as Cretaceous; these appear at the base of the bluffs of the north coast and in wells in the interior. The early events of the Ice age piled the Manhasset Formation across them, and on the somewhat irregular plateau thus built up two great moraines were deposited as records of the Wisconsin epoch of ice-advance. One of these appears conspicuously along the axis of the island, while the younger moraine lies near to the north coast. The sandy plains formed by the outwashed material from these ridges cover a large part of the country. The present memoir, with its two large folding maps, may not appeal to the motorists who denude the roads on Sundays; but it will be prized on the shelves of those cultured citizens who have built their summer homes among the gracious woods and inlets of the sound.

It is a long stretch from the New York shores to the shifting mouths of the Mississippi. E. W. Shaw, in No. 85-B, deals with the mud lumps that attracted Lyell as examples of the seaward growth of land, and concludes that they arise from the creep of semi-fluid clay from beneath the land and the shallows, under the pressure of new alluvium deposited by flooding. Where currents sift the delta-material, leaving sandy banks behind, the resistance to outward flow is sufficient to cause the moving clay to rise up to the surface. Some of the lumps stand 8 ft. above the water. Unless they subside, they are worn away by the sea in a few years. The reader of this paper must remember that a "pass" in the delta is not a passageway, but a delta-finger dividing one bay from another.

Oklahoma, the paradise of protected Indians, is being explored for oil-pools, and the illustrations in Bulletin 547 introduce us to the broad alluvium-filled valleys of the country, in which the rivers may run almost dry, while sand-dunes (p. 31) may gather near their banks. The conditions remind us of those of Permian times in England. Another interesting view of river-action in easily denuded strata is given in Bulletin 575, where the Grand River, a tributary of the Missouri in South Dakota, is seen meandering on a great plain of level Pierre Shale, leaving outliers of the more resisting Foxford Sandstone, the highest marine Cretaceous deposit, standing out above it. To the west, in Wyoming, the Cretaceous beds, though still frequently horizontal, are associated with mountainous outcrops of contorted Carboniferous rocks, and the rainfall allows of a thick growth of trees across them (Bull. 543, "Lincoln County, Wyoming," by A. R. Schultz). In Professional Paper 78, W. H. Emmons and F. C. Calkins guide us through a high and ice-carved region around Philipsburg in western Montana, which was lifted from the sea with the central Rocky Mountains in earliest Eocene times. Pre-Cambrian rocks here come to light, and it is interesting to note that features of stoping and intimate penetration, resembling those so well seen in Finland, have arisen in them by the intrusion of Cainozoic granodiorite during the general uplift (Fig. 1). A careful description is given of the products of contact-metamorphism and of exhalation from the igneous invaders. The district includes ores of gold and silver, imported by these early Cainozoic intrusive bodies (p. 186). The first mining operations were undertaken twenty-five years before the arrival of the railway, and exploitation has now so far worked away the ores that the small town of Philipsburg may look forward to relying on its agricultural industries. The usual beautifully printed maps accompany this memoir.

Early Eocene granite appears on the west flank of the mountains in Idaho (Bulletin 528, "Geology and Ore Deposits of Lemhi County," by J. B. Umpleby), and it suffered from erosion in Middle Eocene times

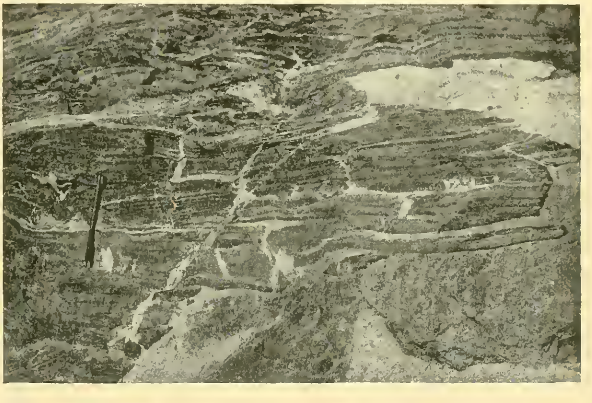

FIG. 1.—Stoping and absorption-features at contact of Cainozoic granodiorite and Algonkian sediments, Storm Lake, Montana.

(p. 43). Gold-bearing veins are associated with the rhyolitic lavas that broke out in the area in the Miocene, and possibly the Pliocene period, and this bulletin is largely concerned with mining. The main routes for traffic are eastward; the differences of elevation cause a great variety of climatic conditions in Lemhi County, but the photographs around Salmon City have a distinctly pleasing air. The same author describes a somewhat similar region in Bulletin 539 ("Some Ore Deposits in North-Western Custer County, Idaho"), where the open season lasts from the beginning of May to the end of October, and where tetrahedrite and galena are mined at 8000 ft. and upwards above the sea. A remarkable erosion-surface, developed near base-level in Eocene times, has left traces that are now elevated to 9600 ft., with valley-floors 5000 ft. below them. The mines on Poverty Flat thus stand at 9500 ft., on the margin of a partly wooded plateau covering twenty-five square miles, which has been worn as a peneplane across steeply tilted Palæozoic rocks. As a result of elevation, valleys were developed in the Miocene lacustrine strata to a depth of more than 4000 ft., prior to their occupation by the post-Pliocene glaciers (p. 17). These figures serve to illustrate the removal of Flysch beds and other Cainozoic strata during Pliocene times from the surface of our European Alps.

B. S. Butler, in Professional Paper 80, reports on the copper and other ores of the San Francisco district in Utah. The mines lie in the arid Great Basin, near the south end of the lost Lake Bonneville. The block-structure of the country is rendered all the more interesting by the continuation of the faulting into recent times. The intrusion of quartz-monzonite in a Cainozoic epoch (p. 70) has produced diopside as a common contact-product in the early Palæozoic limestones, and an example (pl. xii., Fig. A), where this has become altered into serpentine is of interest for comparison with various "eozoonal" rocks.

"The San Franciscan Volcanic Field, Arizona," described by H. H. Robinson (Professional Paper 76), lies three hundred miles farther to the south, beyond the Grand Canyon country, but sufficiently near to allow of a confusion of the mountain names. San Francisco Peak, rising 12,611 ft. above the sea, retains its general form as a great volcano with secondary cones, and fine igneous studies can be made in the ravines upon its flanks. It is believed (p. 52) to have originally risen 8800 ft. above the plateau of horizontal Carboniferous rocks, and to have lost 3000 ft. by denudation. This region stood close to sea-level in late Pliocene times, and then became deluged by flows of basalt; elevation by faulting followed, and rhyolites and andesites appeared on the surface as it underwent dissection. The great volcanoes belong to this epoch, at the opening of the Quaternary era. A far greater elevation, amounting to thousands of feet, then took place, introducing "the present or canyon cycle of erosion" (p. 93), and scattered vents emitted basalt and built up lava and scoria cones (see Fig. 2). The railway across the Colorado Plateau, from which a branch runs north to the Grand Canyon, gives access to this volcanic field. The great cone of Bill Williams Mountain, named after a scout killed in Indian warfare, is already ascended by a tourist-track, and in time we may hope that Flagstaff Station will be as famous among geologists as Mont Dore. Visitors will pass on, however, to the canyon country, and L. F. Noble (Bulletin 549) revives our memories of Dutton's survey in the fine illustrations to his work on "The Shinumo Quadrangle." In the region treated there is only one permanent habitation. Plate xviii. shows the geological history of the country, concerning which much has been learnt since Dutton's work, as recorded in a natural section rising a mile above the river. A hill of inclined Algonkian quartzite is seen half-way up, buried by horizontal strata from Cambrian to Upper Carboniferous. H. H. Robinson, the author of the paper on the San Franciscan volcanic field, is cited (p. 91) as providing the most recent summary of the physical history of the canyon country.

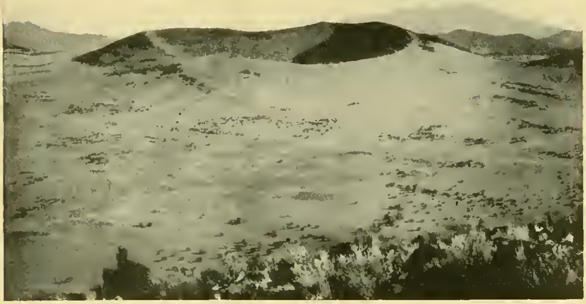

FIG. 2.—Recent cone formed of ash with lava above, north-east edge of the San Francisco volcanic field.

Alaska, which is being explored so conscientiously, is represented by nine bulletins published in 1913 and 1914. While these are mostly concerned with mining prospects, glacialists will appreciate the evidence of the forward movement of ice across forests in Bulletin 526, and of the formation of "push moraines" 25 ft. high, where a glacier-nose impinges upon beach-deposits. Though boulder-clays are rarely specifically mentioned, it is clear that a large part of the Alaskan "moraine" material is of this character. In Bulletin 534, for instance (p. 43), on the Yentna district, we read that "deposits of glacial till of the ground moraine type are widespread," up to 75 ft. in thickness, with particularly abundant striated pebbles and boulders.

Among publications dealing with minerals, we may note the illustrated descriptions of Ferberite, or wolfram free from manganese, by F. L. Hess and W. T. Schaller, in Bulletin 583. The latter author investigates the crystallography of the species. Alunite attracts attention in Bulletin 540 ("Contributions to Economic Geology, 1912," published in 1914, p. 347). Numerous saline deposits have been prospected without results for potash salts on a commercial scale (p. 406). The phosphatic shales at the top of the Carboniferous beds in Idaho, and probably of Permian age, are described in Bulletin 577. No. 585 consists of a list, with localities, of all the useful minerals and rocks of the United States, arranged under the States in which they occur. H. S. Gale refers the calcium borate, Colemanite, of southern California to the emission of boric acid from basaltic lavas into travertine deposits of Miocene age (Professional Paper 85-A, p. 8).

THE POSITION OF THE ORGANIC CHEMICAL INDUSTRY.[1]

THE value of the colouring matters consumed in the United Kingdom is 2,000,000*l.* per annum, and these dyes are essential to textile industries, representing at least 200,000,000*l.* a year, and employing 1,500,000 workers, and to many other industries, such as the wall-paper, printing, and paint industries, requiring lakes and pigments. In recent years Germany has supplied this country with nearly all these dyes, with organic chemicals required for photographic purposes, with the natural and artificial products used in the manufacture of scents and perfumes, with synthetic and other drugs and disinfectants, and

[1] Abstract of the presidential address delivered before the Chemical Society on March 25 by Prof. W. H. Perkin, F.R.S.

with nearly all the fine chemicals. As a result of allowing these trades to pass so much out of our hands, we are faced with the position that stocks are rapidly diminishing and prices are rising to such an extent as seriously to hamper many of our industries.

The great dyeing industry has been lost to this country because we, as a nation, and our manufacturers in particular have failed to understand the extreme complexity of the scientific basis of organic chemical industry. Science has been neglected in the works, and the chemists trained in organic chemistry necessary to carry on the industry in successful competition with Germany were not to be found in our universities. In 1870, the time when this industry commenced to be transferred to Germany, organic chemistry was not recognised by our older universities, and the newer universities, which since then have done so much for the progress of science, did not exist.

Many of our universities, and particularly those of Oxford and Cambridge and those in Scotland, contributed practically nothing to the advancement of organic chemistry in the latter part of last century, and even now their output of research is far less than it should be; while in Germany, as soon as the importance of the subject became apparent, schools especially devoted to the subject were founded by such great teachers as Liebig, Wöhler, Kekulé, and Baeyer. Every effort was made by the establishment of laboratories, aided by the State, to help forward the new movement, and the step which assisted more than anything else was the provision that in every German university, research must be an essential part in the training of every student of chemistry, who, in order to obtain his degree of Ph.D., spends at least one and generally two years in research; whilst in this country, students obtain their B.Sc. honours degree after a course of three years' study, and the majority are under no obligation to do any original research during their university career.

The recognition of the necessity for research forming an essential part of the training of the student in science has been responsible for the large output of original work in Germany as compared with this country. The B.Sc. degree, and certainly the B.Sc. honours, should not be conferred except on those who have undergone a course of research work, and the necessity for a change in this direction is now being recognised, though the proportion of graduates who engage in research in these circumstances is small compared with the number of Germans who qualify for the Ph.D. degree. Had there been a supply of first-rate chemists at the disposal of the manufacturers of this country there can be no doubt that such industries as the aniline dye industry and the coal tar industry would still be in existence and flourishing here.

Germany has recognised the value of the closest possible contact between the industries and universities, and the majority of the professors and privatdocenten keep in touch with the large factories. Appreciation by the manufacturers of the value of science in connection with industry is one of the reasons for the development of the German chemical works. To obtain a share of the wealth and prosperity opened by this vast industry, our manufacturer must so conduct his works that research is going on unceasingly; his laboratories must be properly equipped and staffed by research chemists of ability, with a scientific leader to direct the work; for the first essential for the success of a chemical works is for it to be under chemical control, and every department must be in the hands of an expert. Recognition of the soundness of this principle is one of the main reasons for the success of the works in Germany, where all the principal dye works are under chemical control; chemists are the heads of departments, and are included in a large proportion on the board of management.

In order to deal with the problem of the shortage of dyes in this country, schemes have been proposed by the Government to ascertain the best means of obtaining sufficient supplies of chemical products. The first scheme recommended by the special committee appointed by the Government was not cordially received, and in explanation of this it should be pointed out that the committee consisted entirely of business men. Had a chemical expert been present, such a scheme would not have been placed before the public. In the memorandum of agreement it is stated that the company has been incorporated for the purpose, amongst other things, of manufacturing and selling dyes, colours, and other chemical substances which, previous to the war, were exclusively or principally manufactured in Germany, and no mention is made of the main object of such a company—namely, the employment of a large staff of research chemists under leaders of ability for the purpose of making discoveries in every possible direction.

It is not merely a question of producing the dyes that are required during the war; the company must be able to compete successfully with the German industries after the war. No greater mistake could be made than to think that in order to manufacture a dye it is only necessary to follow the directions given in the patent, for the patent is so worded that while it satisfies the requirements of the patent laws of the countries in which it is taken out, it gives as little information as possible, and contains no indication of the process used in the actual manufacture. In the first place the methods of manufacture and the utilisation of by-products must be worked out until they have arrived at the same state of efficiency as in Germany. Another point to be borne in mind is that the Germans supply dyes to practically all the other nations, and could well afford to sell dyes at a loss to themselves in this country until the English company had been ruined. And what will happen after the war with regard to using German patents? Will these patents again become the sole property of the Germans and be workable in this country only on the payment of royalties or licenses?

The application for shares in the proposed company was unsatisfactory. The Government withdrew the first scheme and substituted an amended proposal which is a proof of a desire to meet in a generous spirit the criticisms raised against the first scheme. The grant of 100,000*l.* which the Government proposed to make to the company for research purposes would be better employed in subsidising the research laboratories of those universities and colleges willing to specialise in organic chemistry and to train a certain number of students with a view of their entering the service of the company.

The existing dye works in this country compare very unfavourably with those in Germany, where experience has been in favour of building large works and against spreading manufacturing operations over small works situated in different parts of the country. Moreover, in the manufacture of any substance by-products result, which must either be recovered or used in the manufacture of other saleable products, and in order that these by-products may be used to the best advantage, the dove-tailing operations should be carried out on the same site, and thus save transporting the by-products from one works to another, an operation that must entail loss. The proposal of the Government, therefore, to take over the existing works in this country appears a doubtful policy.

The German works with which the new British company must compete are enormous organisations controlling almost unlimited resources, and if after the war these organisations continue to work with the same efficiency as before, some years must elapse before we could compete successfully with them. Failure to develop on research lines is scarcely conceivable if the works are in the hands of a highly trained chemical staff; but if the new industries get into the power of the business man who wants an immediate return for his outlay and fails to appreciate the vital importance of scientific control, then no protection by a tariff on the import of German dyes and other organic products can avert disaster.

THE CO-OPERATION OF SCIENCE AND INDUSTRY.

A DISCUSSION upon the above subject took place at a conference held under the auspices of the Institute of Industry and Science at the Mansion House on March 25. The chairman, Mr. Frank Warner (president of the Silk Association), in opening the proceedings, dealt with the crying need for a greater application of science to industrial problems and for the need of the organisation of industry. The two main objects of the Institute of Industry and Science he defined as the organisation of capital for industrial purposes, and the bringing about of those working conditions in which science and industry are in closer contact.

Mr. Taylor Peddie, chairman of the Institute, stated that the Institute aimed at embracing within its membership the trade organisations of the country, and that already much progress had been made in this direction and with the formation of a trade bank. Prominent men of science had joined the court of directors of the Institute, and by development of this scheme it was hoped to bring science into intimate contact with industry. Mr. Peddie then opened the discussion by reading a paper upon "The Influence of Science upon Political Economy," in the course of which he demonstrated from comparative statistics the large reductions in the cost of production that had been brought about by the application of science to processes of manufacture.

Sir Philip Magnus stated that the output of research work from the English universities was equal to that of Germany, and that their graduates were as capable and as well trained as those from the German universities; but that, owing to our lack of appreciation of science, we made practically no use of our research work, nor of our trained men. He felt that any movement trying to bring about a more marked sympathy between science and industry was worthy of the greatest support.

The Earl of Portsmouth, in moving a resolution to the effect that the meeting supported the organisation of capital for industrial purposes, and that it agreed that a closer co-operation of science and industry was essential, stated that he was of opinion that in the near future the people now drawing their income from land and property would by force of circumstances be compelled to turn their attention to industrial affairs.

The Hon. F. Mackenzie (Agent-General for New Zealand), in seconding the resolution, expressed the opinion that we were too prosperous in this country to appreciate the need for organisation. He stated that twenty-five years ago agriculture in New Zealand was at a very low ebb, farmers were selling sheep at the rate of 18*s*. 9*d*. a gross, butter was 4*d*. a lb., but now, through careful organisation and the application of science to agriculture, New Zealand was a prosperous country, exporting a considerable amount of produce to England.

S. R. I.

THE INSTITUTION OF NAVAL ARCHITECTS.

THE spring meetings of the Institution of Naval Architects opened on Wednesday, March 24. Owing to the war, the meetings were curtailed somewhat; eleven papers were read and discussed at morning and afternoon meetings on Wednesday and Thursday. The Marquis of Bristol was re-elected president for the ensuing year, and in his opening address made reference to Germany's methods of submarine war. He suggested that, in order to obtain reasonable protection from submarine attack, it might be advisable to arm all merchant vessels to an extent which would render them dangerous to submarines.

Prof. J. J. Welch's paper on the watertight subdivision of ships was limited to a discussion of the orderly subdivision of ships, particularly as effected by transverse watertight bulkheads. The paper included a historical sketch leading up to the work of the bulkhead committee of 1912. One of the difficulties which had to be faced by this committee was the question of permeability. The same ship, whilst loaded to the same water-line, might carry cargo of very different density, so that with the same arrangement of bulkheads different standards of safety would obtain on the two voyages. Ultimately the conclusion was reached that a fair average permeability for cargo spaces was 60 per cent. Spaces devoted to passengers are taken at 95 per cent. permeability, and machinery spaces at 80 per cent. The paper goes on to discuss the recommendations of the bulkhead committee's report on oversea passenger vessels, and the author considers that the proposals in the report represent a very decided step forward.

An interesting paper on the influence of discharging appliances on the design of large ore carriers was read by Mr. John Reid. The shipment of ore on the Lakes Superior and Erie route has reached in one year the enormous total of nearly 50,000,000 tons. The author gives a description of the Hulett unloading machine, an appliance which has enabled a cargo of 10,000 tons of ore to be unloaded on the Great Lakes in less than three hours. Unloading and loading machinery of this description has led to the design of ore-carrying steamers in which the greater part of the length of the vessel is taken up with cargo holds, and practically the whole deck is covered with hatches. The rapid loading of such vessels is apt to produce great strains; a speaker in the discussion instanced a case of one of these vessels acquiring a deflection of 11½ in. during loading. The author of the paper directed attention to the backward state of the facilities in Great Britain for handling and transporting ore, and showed how some of the leading features of the Great Lake ore-carriers may be adapted with advantage for ocean-going ore-carriers.

Mr. J. Montgomerie read a paper on the scantlings of light superstructures, by which is meant the light steel deckhouse erections now commonly fitted above the strength deck in passenger steamers. Two alternatives present themselves to the designer:—(1) The structure may be made so flexible that it cannot take any share in the straining action to which the vessel is exposed as a whole; (2) it may be made strong and rigid enough to share that general straining action without damage. The first method of design is impracticable, since the superstructures have to carry heavy weights such as boats, casings, and funnels, and the structure has to be substantial enough to support these when the ship is moving in a seaway. Partial flexibility may be obtained by cutting the superstructure at several places and fitting expansion joints. The whole efficiency of such joints, in respect of the relief from stress which they afford to a long house, depends on the distance between them, and that in turn states a problem in shipbuilding which has never been solved satisfactorily, viz., the determination of the distribution of stress in way of an abrupt discontinuity, such as a bridge, or other erection. In the absence of any theory to which complete assent can be given, we must turn to the record of experience. The author then proceeds to give descriptions and illustrative sketches showing typical cases of damage to existing ships at places of discontinuity. These examples are of particular value to engineers and others interested in the strength of materials, and will well repay careful study.

An analysis of the damage observed supports certain conclusions which can be drawn from a consideration of the whole question of superstructures:—(1) That in way of a discontinuity in the structure of a ship, stresses outside the erection will be transmitted to the material of the deeper girder much more rapidly than has been thought to be the case; (2) that the fitting of expansion joints, spaced as in the present practice, does not appreciably relieve the superstructures of stress, or obviate damage; (3) the best method of providing against damage in deckhouse superstructures is to dispose the material so as to make these capable of taking part in the straining action of the hull, following as far as possible the general law that all discontinuity of longitudinal material should be minimised. The author then proceeds to take certain typical cases, and gives methods of working out the scantlings required to comply with (3), above noted.

Mr. F. W. Lanchester gave a contribution to the theory of propulsion and the screw propeller. The author made reference to the controversy in which Dr. Froude's work was attacked violently by Prof. Henderson. Without entering, or taking part, in the dispute, Mr. Lanchester reviews the theory from its foundation, in order to make sure of his own ground. In the past there appears to have been insufficient attention to the initial definition of the problem, with corresponding uncertainty as to the ultimate interpretation of results. In discussing Dr. Froude's theory, and speaking academically, Mr. Lanchester says that the weak point of the whole conception is that there is no proof offered that either the work done (*i.e.* the energy expended), or the momentum communicated, is confined strictly to the column of fluid passing through the actuator, and there is, in fact, nothing to restrict, or confine, the fluid as in the case of the efflux theory, by which the problem is rendered really definite. It is understood that the *régime* contemplated by Dr. Froude is not capable of exact expression. This, however, is no obstacle to the application of any theory in real hydrodynamics; if it were necessary for the engineer to await the work of the pure mathematician in these matters, the subject would have made scarcely perceptible progress since the time of Noah. In such a case as the present, if the method of treatment contains 80 or 90 per cent. of truth, it may demand acceptance.

Further work at the William Froude National Tank on the resistance of mercantile ship forms was presented by Mr. J. L. Kent, and Mr. Stromeyer contributed an interesting paper on the law of fatigue applied to crankshaft failures.

EAR PROTECTION AGAINST ARTILLERY SOUNDS.

THOSE who have associated with our gunners must have noticed how often they suffer from deafness. The sudden access of pressure in the neighbourhood of a gun at the moment of firing imposes so great a strain on the drum of the ear that deafness is a usual result. The increase in pressure in the modern gun, and the high pressure still remaining when the shot reaches the muzzle, make the conditions more serious than they used to be comparatively recently. Not only those who are near the gun when fired, but those also in the neighbourhood of bursting shells, bombs, or explosives, are liable to suffer in a similar way even if they are not otherwise damaged.

Mr. A. Mallock, F.R.S., who has for many years conducted investigations in connection with artillery, has invented an "ear defender," the object of which is to protect the drum of the ear from very sudden and violent access of pressure, while still allowing the minute variations produced by ordinary sounds to be received with but little loss. The defender consists of a containing piece made of ebonite and shaped like the pieces used in the game of Halma, and of about the same size. The ball end is very finely milled, and it is made to fit the passage of the ear, there being five sizes, differing very slightly in size in this part, to suit different people. The piece is pierced centrally by a hole 5 mm. in diameter at the small end, and gradually enlarging towards the other end, where it opens into a recess 1 cm. in diameter. Into this are fitted in order a flat ring washer, a disc of fine wire gauze, a very thin, flat ring washer, a delicate diaphragm, a very thin, flat ring washer, a disc of fine wire gauze, and a flat ring washer. When a pair of defenders are placed in the ears, the thin diaphragms, untouched except near their edges, where they are held, are free to take up aerial vibration and to transmit it to the ear passage, and so the wearer hears ordinary sounds with but little loss; when, however, the violent impact due to gun fire or explosion in the neighbourhood occurs, the diaphragm is brought up against the wire gauze, by which it is prevented from further movement, thus limiting the increase of pressure in the air passage and defending the ear.

The defenders are neatly packed in a small tin matchbox with a rubber fitting, which prevents them from falling out, but which allows them to be removed at once. A small cleaning tool is similarly held elastically so that it cannot fall out by accident. The price of the set is three shillings, and at the present time there is great scope for its use. The instrument is called the Mallock-Armstrong ear defender, and the address of the proprietors is 86 York Street, Westminster.

C. V. B.

SOME SCIENTIFIC ASPECTS OF PIANO-PLAYERS.[1]

THERE are few modern inventions which have not been employed in the present war for the destruction of property and of human life. The pneumatic piano-player is an exception. It is also exceptional in that it possesses but a scanty literature outside the catalogues of the manufacturers. It has never been associated with any inventor of distinction, and the general public knows nothing about its history. The aeroplane, on the other hand, is closely linked in popular thought, not only with such modern names as Wright, Langley, and Blériot, but also with the names of early designers and projectors of flying machines, such as Dante of Perugia and Leonardo da Vinci. Yet, considered merely from an engineering point of view, the modern piano-player is a marvel of human ingenuity.

The feature which distinguishes it from its early predecessors is the element of controllability, which leaves the interpretation of the music largely to the

[1] Abridged from a discourse delivered at the Royal Institution on Friday, March 19, by Prof. G. H. Bryan, F.R.S.

choice of the performer. Of recent years, however, personal control has been supplemented by accent devices, automatically operated, the construction of which is essentially an engineering problem. The separation of the scale into two independently controlled halves was certainly to be found in the old mechanical pianotist in 1902, and it may date from still earlier. I consider this last feature unnecessary, and its use open to serious objections.

The object of my experiments has been to apply dynamical and physical principles to the control of what I will call the striking action in piano-players, as it very soon appeared to me probable that by so doing it would be possible to obtain differences of effect that could not be produced by purely mechanical methods.

The ordinary practical man asserts that in striking a note or chord on the piano you can increase or decrease the force of the blow, but that the only effect will be to play the whole chord louder or softer, so that you cannot bring the bass or treble parts into prominence unless you connect the pneumatics with different degrees of vacuum. I have been told that it is mathematically impossible to produce effects without which I now regard no piano-player as worth playing.

But any mathematical physicist will understand that what engineers call the "force of the blow" is in reality a very complex phenomenon. In my piano I find that a fairly soft note is produced *in the middle of the scale* when the hammer strikes the strings with a velocity of 30 cm. per second, and that the hammers themselves rise through a height of about 5 cm. This means that *if the acceleration were uniform* the operation of depressing the key and releasing the hammer would occupy one-third of a second. But during the operation the pressure applied to the key may be increased or decreased in an infinite number of ways. It may be made very large at the commencement of the blow, sinking to zero at the end, as when a finger-pianist strikes the note from a height; or it may be very small at first and gradually increased, an action which some describe as a "caressing" touch. These differences would be represented by differences in the shape of the graph connecting the pressure on the key with the time measured from the instant it is first touched to the instant that the note is sounded. We might call them differences in the "shape of the blow." But the check action greatly influences the character of the accelerating force impressed on the hammer when regarded as a function of the time. The operation of playing a note is usually divided into two periods. At the end of the first period a support is withdrawn from the palet which raises the hammer, and the latter becomes disconnected. In the second period either the hammer may fly up freely and strike the note, or the palet may again overtake it and drive it forwards. To produce these different actions the variable forces applied to the key of a piano must evidently be similar in character to the "screw-back" and "following" strokes in billiards. It is, of course, theoretically possible that the hammer may rebound and strike the string a second time. But it is very difficult to test this point.

Another important point is that, as the driving force is applied close to the base of the hammer, considerable flexural vibrations are liable to be set up in the shaft. These may probably differ in amplitude and phase, according to how the note is struck. A difference in this respect may affect the tone-quality.

Now the bass and treble hammers differ considerably in weight, and therefore also in inertia, and the intermediate hammers vary continuously from one end of the scale to the other. It follows that a short sharp blow will produce its greatest effect in the higher parts of the scale, while a longer sustained blow, or an increasing blow, will drive the bass notes forward with increased velocity even after the treble notes have been released.

In the case of a repeated treble note with bass accompaniment the second time it is struck, accentuation is more difficult, and there is considerable danger of the note failing to sound owing to the bridge between the two notes buckling, thus continuously admitting air to the primary valves. The best plan is to keep the tension low until the chord containing the repeated note has passed the tracker board, and then force the notes down hard. On account of the additional difficulty thus incurred in reading the music, I believe that it would be justifiable to cut the troublesome note a little after the accompanying chord.

The apparatus originally used in these experiments was figured and described in NATURE of May 8, 1913 (vol. xci., p. 246), but the principle has now been embodied in a patented device which the Moto Music Company, of 42 Eyre Place, Edinburgh, have undertaken to fit to any make of internal or detachable player, and which in the case of a player-piano does not interfere with the appearance of the instrument or its use when required for hand playing. In addition to the suction bellows which generates the vacuum, all pneumatic players have a large reservoir bellows, which acts as an accumulator or condenser of considerable capacity, but between this and the playing pneumatics two channels of communication usually exist. One is through an accent valve controlled by a lever, the other connection is through a smallish regulating bellows, controlled usually by a spring, and through an air valve which opens or closes with it according to the degree of vacuum. This arrangement is sometimes called a "choker," and its statical action tends to equalise the pressure of the air from the playing pneumatics.

Now it will be found that in playing the regulating bellows is in a continual state of vibration, and that this vibration has a very marked effect upon the tone quality and expression. The character of the variable force applied in projecting the pianoforte hammer is determined very largely by the elasticity of the controlling spring, and the fact that this remains constant is found to account for the dulness and want of variety which is noticed even in the best players when they have been in use for a certain time. In my device the spring is replaced by a weight the leverage of which can be varied, thus enabling the tension on the bellows to be varied from time to time in playing different passages, and introducing, further, a variable element of inertia. It is convenient to describe such changes as "sub-permanent." Further, the bellows can be controlled by a hand lever for the purpose of accentuating individual notes, such changes being describable as "temporary." The usual expression marks, F F, F, M F, P, and P P, are indicated.

The experiments lead to the following conclusions:—

(1) A light sub-permanent tension with fairly strong pedalling will give bright treble effects with light bass. A heavy sub-permanent tension with light pedalling produces a strong bass and a soft treble.

(2) Corresponding to every note of the scale, there is an action which produces the maximum effect, this action varying continuously from one end of the scale to the other.

(3) The brightest effects are obtained by keeping the accent valve open, or partly so, as in this case the closing of the regulating bellows is affected by the pedalling. The effect of closing the accent valve is very similar to the use of the soft pedal.

(4) In playing solo passages, light and heavy sub-

permanent tensions produce different effects even when it is sought to maintain the corresponding degree of loudness by suitable variations in the strength and method of pedalling. This observation leads us to believe in the existence of a relation between tone-quality and touch. While it is easy for an inexperienced person to produce the necessary differences of touch with a pneumatic player fitted with this controlling device, I find it very difficult to obtain the same effects by striking the keys of an ordinary piano with my fingers.

(5) There appear to be two different ways of accenting particular parts of chords by hand pressure applied to the control lever. With a slight sub-permanent tension, treble notes are usually best accented by depressing the lever before the note has reached the tracker board, and subsequently allowing it to fly up smartly. With a heavy sub-permanent tension, it is necessary to jerk the lever upwards from below just after the note has reached the tracker board. For a bass note with light tension, the lever is firmly pressed down after the note has reached the tracker. With heavy tension the lever is previously raised, and then allowed to drop down with the note. In either case the action is supplemented by a corresponding action in pedalling.

(6) With a heavy sub-permanent tension and the lever supported from below, it is possible to obtain very soft effects in which the treble parts ring out clearly and are not drowned by the bass. With a light sub-permanent tension and the lever pressed down the results are more brilliant. I attribute these differences to the inertia of the controlling weight.

(7) There is a great satisfaction in being able to slam down a vigorous chord, hand and foot working in unison.

(8) In the earlier experiments the connection between the lever and the bellows was made first with strings and tapes, and afterwards with wires passing over pulleys. It was found, however, that the stretching of these connections greatly interfered with the effects and led to the production of harsh results, and the connections frequently broke.

(9) The best accentuation of particular notes in chords is obtainable when the notes reach the openings in the tracker board at exactly the same instant. When they are cut unevenly it is often very difficult to accentuate at will either the upper or lower notes of a chord.

(10) With experience it is possible to learn the exact kind of effort required to accentuate a note in any part of the scale, and thus to obtain marked differences between the treble and bass parts of a comparatively short chord.

(11) Where a note or chord is repeated a number of times in rapid succession it is advantageous to hold the controlling lever firmly. This obviates all the strain on the ankles in pedalling, which under ordinary conditions is considerable.

(12) In every case the exertion of pedalling is greatly reduced, not improbably by about 50 per cent.

(13) Some players have separate regulating bellows for the bass and treble parts, but this does not interfere with the working of the device.

(14) A very small effort often produces a considerable difference in the effect. It is possible to emphasise a particular note or chord by a suitable stroke of the pedals alone, but the lightest possible touch of a finger applied to the lever will often produce a conspicuous improvement in the effect.

(15) Experiments with pianos of different makes, both upright and horizontal, operated by either detachable or interior players, lead to practically identical results.

Although I have been trying for a long time past to account theoretically for the observed effects, the results are still far short of finality. It is clear that neither Helmholtz's nor Kaufmann's mathematical investigations fully suffice for the purpose. There are, however, other difficulties. One is that, although it is easy to observe differences of effect which are, as a rule, quite conspicuous, it is not as easy to define exactly in what these differences consist. Again, the success of a piano-player as a musical instrument largely arises from the fact that the manipulation of the various controls, both for tempo and expression, soon becomes intuitive. A great deal evidently depends on the elasticity of the muscles of the hands and feet. It would be very difficult to ascertain precisely the effect of differences in this elasticity on the tension in the playing pneumatics while a note is being sounded. In short, it appears probable that a complete dynamical theory of the observed effects will involve investigations of no small degree of difficulty. The mere engineering of this control device into a form in which it can easily be adapted to any internally fitted player without interfering with its use for hand playing, has given Mr. Ireland a great deal of trouble. It is now important that the experiments should be repeated by a number of different independent observers, and their experiences compared; until this is done it would be futile to proceed much further in seeking a theoretical explanation.

Educational Problems.

The average children of player owners will not wish to spend much time in acquiring manual dexterity with scales and five-finger exercises. In place of the present "practising," they will practise exercises in player manipulation, and begin by learning the meaning of the expression marks on the roll. The exercises will be mainly devoted to:—

(1) The control of the speed regulator and the acquisition of the subconscious or instinctive faculty of playing every note or chord at the desired instant. Practice in accompanying.

(2) The production of differences of expression and touch, including those described in this lecture, and the acquisition of the power of accenting parts of chords in any part of the scale. The pupil must not be satisfied until he has learned the exact action corresponding to every note on the keyboard. For school practice automatic accent perforations and separation of bass and treble halves must be forbidden. A school prize should be given for the best rendering of some composition.

The pupils will, however, require some familiarity with the structure of music, and musical notation. For this purpose there will be needed a scale to be placed in front of the tracker showing the black and white notes, and in addition special rolls marked in such a way as to illustrate:—

(1) The rulings of the treble and bass clef in the ordinary staff notation.

(2) The relative value of semibreves, minims, crotchets, quavers, etc., and the corresponding rests.

(3) The distribution of the sharps and flats in different keys.

(4) The meaning of such terms as staccato, legato, arpeggio, trills, etc.

(5) The lengths of the various musical intervals, such as major third and minor fifth.

Finally, in order to acquire practice in reading music, the pupils may learn to cut their own music rolls. Appliances for this purpose are already obtainable, and will doubtless become common in the future. A school class in roll cutting should prove an efficient form of manual training, and prizes could be given for the best cut roll.

NOTE 1.—Owing to the war, I have dropped an application for a German patent, which was made several months previously to its outbreak. Still, I think it desirable that readers of NATURE should see the following criticism by the examiner of the Patent Office at Berlin.

"Owing to the replacement (which is very obvious) of the customary springs by weights, the action of the regulating bellows cannot be improved, but only made worse, since the action will not take place more rapidly but more slowly."

This objection shows the absurdity of placing important decisions regarding the validity of patents, and equally important other matters in the hands of officials who are not in touch with the actual facts of the case. In this case the patent examiner's decision is not backed up either by experimental evidence or by exact mathematical investigations, and his decision is just what might be expected in the circumstances, but is, none the less, hopelessly in error. As a matter of fact—

(1) My experiments prove conclusively that the action of the regulating bellows, instead of being "*made worse*," is greatly "*improved by the replacement of springs by weights.*" That this effect is not "*very obvious*" is shown by the fact that the examiner has conspicuously failed to realise its advantages.

(2) My experiments can only be explained on the hypothesis that "*on account of the necessary accelerations of the weights, the action will not take place more rapidly but more slowly,*" and that this retardation is proved experimentally to give greatly improved results, even though this conclusion is contrary to our preconceived opinions.

No doubt arguments similar to those raised by the German Patent Office would naturally be raised by anyone who had not tested the question by actual experience. But if these objections give any clue to the extent to which the modern piano-player has been perfected up to the present time by German inventions accepted by the Berlin Patent Office, the results must be regarded as hopeless failures.

NOTE 2.—The differences of tone quality produced by differences of touch in my experiments would appear to be identical with those obtained by finger playing which are largely responsible for the success of Prof. Tobias Mathay's pianoforte school. It would, however, appear that some pianos are incapable of exhibiting these differences, and Prof. Mathay unfortunately found when it was too late that the piano kindly lent for the lecture was defective in this respect. I have since tested another player-piano and found an absolute constancy of tone quality, whether played manually or pneumatically.

SCIENTIFIC WORK OF THE SMITHSONIAN INSTITUTION.[1]

Researches and Explorations.

DURING the year the institution continued to carry on investigations in various lines throughout the world by means of small allotments from its funds. It also accomplished a great deal in the way of exploration and research through the generosity of friends of the institution, who contributed funds for special work or provided opportunities for participation in explorations which they had undertaken personally or through the aid of others. Each year, however, the institution is obliged to forgo opportunities for important investigations through lack of sufficient funds.

The Langley Aerodynamical Laboratory.

On May 1, 1913, the secretary was authorised to re-open the Smithsonian Institution laboratory for the study of aerodynamics, and in future it was to be known as the Langley Aerodynamical Laboratory. The functions of the laboratory were defined to be the study of the problems of aerodromics, particularly those of aerodynamics, with such research and experimentation as may be necessary to increase the safety and effectiveness of aerial locomotion for the purposes of commerce, national defence, and the welfare of man.

The first year's work of the laboratory was to arrange a comprehensive programme of operations, devise ways and means of carrying on investigations and publishing reports, conduct such active experiments as were possible with the means immediately available, and to secure and arrange in the library the best aeronautical literature.

The first technical publication sets forth the results of experiments made at the model tank at the Washington Navy Yard. Another report describes the organisation and equipment of the leading aeronautical laboratories of England, France, and Germany. Some of the reports of the committee are as yet confidential or incomplete. The library has been furnished with the chief aeronautic periodicals and the best books thus far published.

The rehabilitation and successful launching of the Langley aeroplane (called "aerodrome" by Prof. Langley), constructed more than a decade ago, was accomplished in May, 1914. The machine was shipped from the Langley Laboratory to the Curtiss aeroplane factory in April. It was re-canvassed and provided with hydroaeroplane floats, and was launched on Lake Keuka on May 28. With Mr. Glenn H. Curtiss as pilot it ran easily over the water, rose on level wing, and flew in steady poise 150 ft. Subsequent short flights were made in order to secure photographs of the craft in the air. Then Mr. Curtiss was authorised, in order to make prolonged flights without overtaxing the bearings of the Langley propulsion fixtures, to instal in its place a standard Curtiss motor and propeller. At the close of the fiscal year the experiments were still making satisfactory progress.

The tests thus far made have shown that the late Secretary Langley had succeeded in building the first aeroplane capable of sustained free flight with a man. It is hoped that further trials will disclose the advantages of the Langley type of machine. It may be recalled that this man-carrying aeroplane was begun in 1898 for the War Department, and in the interest of the national defence. It was built on the design of the model machine which, on May 6, 1896, first demonstrated to the world that an aeroplane heavier than air could be propelled through the air by its own power. The large machine was completed in 1903, but its actual flight was at that time hindered by injuries sustained through defects in the launching apparatus.

Geological Explorations in the Canadian Rockies.

In continuation of his previous geological researches in the Canadian Rockies, Dr. C. A. Walcott, the secretary of the institution, revisited during the field season of 1913 the Robson Peak district, in British Columbia and Alberta, and the region about Field, British Columbia.

On this trip Robson Peak was approached from the west side in order to study the local geological section, one of the finest in the world. Owing to exceptionally good climatic conditions the season of 1913

[1] Abridged from the Report of the Secretary of the Smithsonian Institution for the year ending June 30, 1914.

proved unusually favourable for studying Robson Peak. Frequently in the early morning the details of the snow slopes and bedded rocks on the summit of the peak were beautifully outlined, but toward evening the mists, driven in from the warm currents of the Pacific, 300 miles away, shrouded the mountain from view.

From the west slopes of Titkana Peak, east of the great Hunga Glacier, a wonderful view is obtained of the snow fields and falling glaciers east and north of Robson Peak. The glacial streams come tumbling down the slopes and often disappear beneath the glacier to reappear at its foot with the volume of a river.

At Field, British Columbia, work was continued at the great Middle Cambrian fossil quarry, where a large collection of specimens was secured. It was necessary to do much heavy blasting to reach the finest fossils which occur in the lower layers of rock.

FIG. 1.—Langley man-carrying aerodrome (built 1898-1903) equipped with floats, in flight over Lake Keuka, Hammondsport, N.Y., June 2, 1914.

The collection of 1913 contains a number of very important additions to this ancient fauna and many fine specimens of species found in 1912. A report on these collections is now in preparation.

Geologic History of the Appalachian Valley in Maryland.

Dr. R. S. Bassler, of the National Museum, spent a month during the summer of 1913 in the Appalachian Valley of Maryland and the adjoining States, studying the post-Palæozoic geologic history of the region, as indicated by the present surface features. Since Carboniferous times western Maryland has been above the sea, and its rocks have accordingly been subjected to a long period of aerial erosion. During Jurassic time the area remained stationary for so long a period that the surface of the land in the Appalachian province was reduced to a rolling plain. Later uplift raised this plain still higher above sea-level, and in Maryland only remnants of the old surface are preserved in the flat sky line of the highest mountains. This ancient plain, or Schooley peneplain, as it is termed, is well preserved on the top of the Blue Ridge.

A second great period of erosion occurred in early Tertiary times, the effects of which were chiefly in the Appalachian Valley proper, where the erosion is indicated by a pronounced plain at an elevation of about 750 ft. This plain was formed only on the softer Palæozoic rocks, and, because of its prominence near Harrisburg, Pa., is known as the Harrisburg peneplain. Conococheague Creek traverses the Harrisburg peneplain in Maryland, and has dissected it considerably, but even the sky line of the ancient plain is still clearly evident.

Other factors in the geologic history of Maryland are recorded in the well-defined gravel terraces along the major streams of the area and in great alluvial fans of large and small boulders, spreading out at the foot of the larger mountains and sometimes reaching a depth of 150 ft.

Pleistocene Cave Deposit in Maryland.

As the results of a further examination of the Pleistocene cave deposit near Cumberland, Md., by Mr. J. W. Gidley, of the National Museum, many new forms were added to the collection, and much better material obtained of several species represented only by fragments of jaws in the first collection. The series now includes more than 300 specimens, representing at least forty distinct species of mammals, many of which are extinct. Among the better preserved specimens are several nearly complete skulls and lower jaws. The more important animals represented are two species of bears, two species of a large extinct peccary, a wolverine, a badger, a martin, two porcupines, a woodchuck, and the American eland-like antelope. Other species represented by more fragmentary material include the mastodon, tapir, horse, and beaver, besides several species of the smaller rodents, shrews, bats, and others. This strange assemblage of fossil remains occurs hopelessly intermingled and comparatively thickly scattered through a more or less unevenly hardened mass of cave clays and breccias, which completely filled one or more small chambers of a limestone cave, the material, together with the bones, evidently having come to their final resting place through an ancient opening at the surface of a hundred feet or more above their present location

Geological Survey of Panama.

Last year an allotment was made from the institution's funds toward the expenses of an investigation of the geology of Panama. The general plan includes a systematic study of the physiography, stratigraphy, and structural geology, geologic history, geologic correlation, mineral resources (including coal, oil, and other fields), petrography and palæontology of the Canal Zone, and of as much of the adjacent areas of the Isthmian region as is feasible.

Upon the completion of the work the institution will print a general account of the results, and later there will be published a detailed report of the geological data of the Isthmus and adjoining regions.

Vertebrate Fossil Remains in Montana.

During the summer of 1913 Mr. Charles W. Gilmore, of the National Museum, headed an expedition for the purpose of obtaining a representative collection from north-western Montana. Between 500 and 600 separate fossil bones were obtained, many of them of large size. The most notable discovery was a new Ceratopsian or horned dinosaur, the smallest of its kind known. There were portions of five individuals of this animal recovered, representing nearly all parts of the skeleton, making it possible to mount a composite skeleton for exhibition. Although Ceratopsian fossils were first discovered in the Rocky Mountain region in 1855, and portions of a hundred or more skeletons have been collected, this is the first individual to be found having a complete articulated tail and hind foot. It thus contributes greatly to our knowledge of the skeletal anatomy of this interesting group of extinct reptiles. Another find was a partial skeleton of one of the Trachodont or duck-billed dinosaurs recently described from specimens obtained in Canada, and its discovery in Montana greatly extends its known geographical and geological range. Less perfect skeletons of carnivorous and armoured dinosaurs, turtles, crocodiles, and ganoid fishes were also obtained.

FIG. 2.—Langley man-carrying aerodrome (built 1898–1903) equipped with floats, in flight over Lake Keuka, Hammondsport, N.Y., June 2, 1914.

Life Zones in the Alps.

Dr. Stejneger, head curator of biology in the National Museum, visited the eastern Alps towards the close of the last fiscal year, to make further observations toward a determination of the limits of the life zones, which in that part of Europe might correspond to those established in North America. That a system of such life zones exists in Europe has long been more or less vaguely stated by authors, but although a definite correlation was established by Dr. Stejneger and Mr. Miller in 1904, certain points, especially the interrelation of the zones corresponding to the so-called Canadian and Hudsonian life zones in America, were greatly obscured by the long-continued interference of man and animals with nature, such as the grazing of cattle in the high Alps, deforestation, and, more recently, artificial reafforestation. It was thought that the eastern Alps might show more primitive conditions. Dr. Stejneger visited the mountain region between Switzerland and the head of the Adriatic. Arrived at the town of Bassano, at the foot of the Venetian Alps, he began to study the life zones of the Val Sugana and the plateau of the Sette Comuni from that point. He made a series of excursions from Bassano, Levico, and Trento as successive headquarters. He was able to trace the boundaries of the Austral life zones in considerable detail, as well as to gather data which connect with the previous correlation of these zones in the western Alps and with the corresponding zones in North America. It was found that the bottom of the entire Val Sugana belongs to the upper Austral zone.

Researches under Harriman Trust Fund.

Dr. C. Hart Merriam continued during the year to carry on certain natural history and ethnological investigations provided for by a special trust fund established by Mrs. E. H. Harriman for that purpose. His principal work during the year was on the big bears of America. In furtherance of this study, specimens have been placed at his disposal by numerous sportsmen and hunters and by the larger museums of the United States and Canada. In the course of his investigations a transcontinental line was run across the country to the coast of California by which the easternmost limits of range were determined for a number of species of mammals, birds, reptiles, and plants. And while traversing Utah and Nevada several remote tribes of Indians were visited, particularly the Gosinte, from whom a long-needed vocabulary was obtained.

Anthropological Research in Eastern Asia.

For the extension of researches in eastern Asia, in continuation of anthropological investigations carried on in Siberia and Mongolia under the direction of the institution in 1912, an allotment has been made from the Smithsonian fund for work during the next fiscal year and for a limited period thereafter. The plan of operations includes a thorough study of the peoples of the eastern coast of Asia, Manchuria, Mongolia, Tibet, and Siberia, among whom it is believed lies the secret of the origin of the American Indian. Investigations thus far made by Dr. Hrdlička on behalf of the institution indicate, he says, "that there exist to-day over large parts of eastern Siberia and in Mongolia, Tibet, and other regions in that part of the world numerous remains which now form constituent parts of more modern tribes or nations, of a more ancient population (related in origin, perhaps, with the latest Palæolithic European), which were physically identical with, and in all probability gave rise to, the American Indian."

Researches under the Hodgkins Fund.

The Hodgkins fund was established in 1891 by a gift of 40,000*l.* from Mr. T. G. Hodgkins. By subsequent gifts the fund has increased to about 50,000*l.* It was stipulated by the donor that the income of 20,000*l.* of his gift should be devoted to the increase and diffusion of more exact knowledge in regard to the nature and properties of atmospheric air in connection with the welfare of man He indicated his desire that researches be not limited to sanitary science, but that the atmosphere be considered in its widest relationship to all branches of science, referring to the experiments of Franklin in atmospheric electricity and the discovery of Paul Bert in regard to the influence of oxygen on the phenomena of vitality as germane to his foundation. To stimulate researches in these directions the institution offered a prize of 2000*l.* for a paper embodying some new and important discovery in regard to the nature and properties of atmospheric air, which was awarded in 1895 to Lord Rayleigh and Sir William Ramsay, of London, for the discovery of argon, a new element in the atmosphere. Another prize of 200*l.* for the best popular treatise on atmospheric air was awarded to Dr. H. de Varigny, of Paris. Numerous investigations on the "composition of expired air and its effects upon animal life," in "atmospheric actinometry," the "air of towns," "animal resistance to disease," "experiments with ionised air," "the ratio of specific heats," and kindred topics have been carried on with the aid of grants from the Hodgkins fund. Researches have likewise been aided in connection with the temperature, pressure, radiation, and other features of the atmosphere at very high altitudes, extending during the past year to more than 45,000 feet, and many other lines of investigation have been carried on, through all of which it is believed that valuable knowledge has been acquired by which the welfare of man has been advanced.

Under a grant from the Hodgkins fund Mr. A. K. Ångström carried on some observations in California during the year for the purpose of measuring nocturnal radiations at different altitudes ranging from below sea-level to the summit of Mount Whitney, 4420 metres (14,502 ft.).

A grant was also made to Mr. Ångström to enable him to measure the "nocturnal radiation"—that is, loss of heat to space during the total eclipse of the sun, August 21, 1914, in the north of Sweden.

In connection with the International Congress on Tuberculosis held in the National Museum in 1908, the institution offered a Hodgkins fund prize of 300*l.* for the best treatise on "the relation of atmospheric air to tuberculosis." The prize was divided equally between Dr. Guy Hinsdale, of Hot Springs, Va., and Dr. S. Adolphus Knopf, of New York, for their essays.

Research Corporation.

In February, 1912, the Research Corporation was organised under the laws of New York as a means for furthering scientific and technical research. Its principal object is—to acquire inventions and patents and to make them more available in the arts and industries, while using them as a source of income, and, second, to apply all profits derived from such use to the advance of technical and scientific investigation and experimentation through the agency of the Smithsonian Institution and such other scientific and educational institutions and societies as may be selected by the directors.

The Smithsonian Institution is interested in the management of this corporation through the membership of the secretary in its board of directors. The chief assets of the corporation at present are the Cottrell patents relating to the precipitation of dust, smoke, and chemical fumes by the use of electrical currents. A number of other patents in various fields of industry have been offered by officers of the Government and scientific institutions, as well as by manufacturing corporations holding patents not available for their own purposes, and undoubtedly there are many others, both in this country and abroad, who will be glad to have their inventions utilised for the benefit of scientific research.

National Museum.

The growth of the museum during recent years has been greater than during any prior period of its history. The natural history collections are now given adequate room in the spacious halls of the new building. Increase in every division of the three principal departments of the museum—anthropology, biology, and geology—is now welcomed both for purposes of exhibition and in the study series.

Bureau of American Ethnology.

The work of the Bureau of American Ethnology during the year has brought together much new material relating to the habits and customs and the languages of the American Indians. One of special interest was a reconnaissance by Mr. F. W. Hodge, ethnologist-in-charge, of a group of prehistoric ruins on a mesa in Cebollita Valley, N. Mex. These ruins consist of a number of house groups forming a compound built on an almost impregnable height, and designed for defence; not only the groups but the individual houses have the form of fortifications, while the vulnerable point of the mesa rim is protected by means of a rude breastwork of stones. Among the special features of interest which Mr. Hodge discovered were a burial cist in which skeletons, pottery, and the remains of a mat were found; three small cliff lodges situated in the sides of the cliffs; several ceremonial rooms or kivas associated with the ruined houses; and the remains of the early reservoirs of the inhabitants.

National Zoological Park.

The collection in the park is the outgrowth of a small number of living animals which for several years had been assembled in very crowded quarters near the Smithsonian building, mainly for the purposes of scientific study. Chiefly through gifts and exchanges the size of the park collection has gradually increased, until it now numbers 340 species of mammals, birds, and reptiles, represented by 1362 individuals.

Astrophysical Observatory.

The work of the Astrophysical Observatory has comprised observations and computations at Washington and in the field relating to the quantity of solar radiation, its variability from day to day, and the effect of the atmospheric water vapour in absorbing the radiations of great wave-length such as are emitted toward space by the earth. Much attention has been given to the design, construction, and testing of new apparatus for these researches, including apparatus for measuring the sky radiation, special recording pyrheliometers to be attached to free balloons for the purpose of measuring solar radiation at great altitudes, and a tower telescope at the Mount Wilson Station.

The principal results of the year include: a new determination of the number of molecules per cubic centimetre of gas, depending on measurements at Mount Wilson of the transparency of the atmosphere; successful measurements by balloon pyrheliometers of the intensity of solar radiation up to nearly 45,000 ft. elevation above sea-level. The results tend to confirm the adopted value of the solar constant of radiation. Most important of all, the investigation by the tower telescope at Mount Wilson shows that the distribution of radiation along the diameter of the sun's disc varies from day to day and from year to year. These variations are closely correlated with the variations of the total amount of the sun's radiation. Thus the work of the year yields an independent proof of the variability of the sun and tends to elucidate its nature.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Birmingham.—Dr. Douglas Stanley has been appointed to the chair of therapeutics.

Dr. L. G. Parsons has been appointed to the newly created lectureship in infant hygiene and diseases peculiar to children.

Dr. C. K. Tinkler is resigning his post as lecturer in chemistry on his appointment to the London University readership in chemistry in the department of home science at King's College.

Cambridge.—An exhibition of 50*l.* a year tenable for two years is offered each year by the governing body of Emmanuel College to a research student commencing residence at Cambridge as a member of Emmanuel College in October. The governing body may award additional exhibitions of smaller value should properly qualified applicants present themselves. The exhibitions will be awarded at the beginning of October. Applications, accompanied by two certificates of good character, should be sent to the Master of Emmanuel not later than September 24.

It is stated in the issue of *Science* for March 12 that the Massachusetts Committee on Education voted unanimously on February 25 in favour of "taking initial steps toward the establishment of a State university."

Dr. F. J. Goodnow will be formally inaugurated president of the Johns Hopkins University on or about May 20. According to *Science* it has been arranged to give the occasion a double significance, for, in addition to the inauguration of the third president of the University, the new site at Homewood is to be dedicated formally.

The scientific advisory committee of the University of Sheffield has recently held, on March 18, 19, and 20, an exhibition of British-made laboratory apparatus and material, with the double object of acquainting consumers with sources of supply, and of obtaining support for the new industries so as to enable them to become permanently established. The exhibits included glass and porcelain ware of different kinds and different sources of manufacture, glass wool, transparent and opaque silica ware, acid-resisting metals, filter papers, and a variety of clay goods. The exhibition aroused considerable interest in Sheffield and the neighbourhood, and great satisfaction was expressed by visitors at the progress which the manufacture of laboratory ware has made in this country in the period since the war began.

The Board of Education has published a "Memorandum on the Teaching of Engineering in Evening Technical Schools" (Circular 894, price 6*d.*). Its object is to furnish suggestions to teachers and organisers of schools which provide evening classes in mechanical and electrical engineering, and not to lay down a scheme of instruction suitable for universal application. The need for a great variety both in methods and organisation, to meet the needs of students working in different areas under special industrial conditions, is borne in mind throughout. Part-time courses only are considered in the memorandum, and such subjects are dealt with as the classification of the courses, suitable curricula, and the outlines of laboratory and class work. The detailed outlines of work for courses in mechanical and electrical engineering to suit students of different grades will provide teachers with practical help in modifying and improving their own syllabuses of instruction.

The annual report of the University College, London, Committee shows that the total number of students for the session 1913–14 was 2206, including in the faculty of science 148 men and 50 women; in the faculty of medical sciences, 138 men; in the faculty of engineering, 134 men; post-graduate and research students, 313 men, 128 women. Of evening students there were in the faculty of science 22 men, 29 women. For the current session, 1914–15, owing to the war, there has been a decline in the total number of 335, the decline in full-time students up to the present date being 462. The fall in numbers will involve a decrease in fees of not less than 10,000*l*. The "Pro Patria" list already issued contains 665 names, distributed as follows:—Army, 523; Navy, 30; Officers Training Corps, 69; Red Cross work, already abroad, 17; voluntary aid detachment, ready for service, 26. A large number of refugee students has been received, each student paying a nominal fee. The number admitted since the beginning of the session has been 116; at the opening of the second term, the number actually at work was 81. The college staff, with the help of its friends, has provided hospitality for about forty-eight persons, and has raised a sum of nearly 300*l*. to aid the students. The revenue of the college in 1913–14 was 71,567*l*., the expenditure 71,260*l*. Members of the college have already indicated their willingness to assist in helping towards the deficit created by the war. The completion of the new buildings has been delayed by the war. A special effort on the part of the Equipment and Endowment Fund Committee is to be made to raise the remainder of the sum necessary for the completion of the chemical laboratories. The sum still needed for this purpose is 13,650*l*., the greater part of which (10,000*l*) is required for the special equipment of a physical and electrical chemistry laboratory. The national need of improved facilities for chemical education emphasises the desirability of completing the equipment of these new laboratories.

SOCIETIES AND ACADEMIES.

London.

Mineralogical Society, March 16.—Dr. A. E. H. Tutton, president, in the chair.—Prof. G. **Cesàro**: Orpiment from Balia, Asia Minor. Results of a crystallographic examination were given.—Prof. G. **Cesàro**: Stereographic projection of a cone touching the sphere of projection along a small circle.—Dr. S. **Kôzu**: The dispersion of adularia from St. Gothard, felspar from Madagascar, and moonstone from Ceylon. A second communication giving the results of careful measurements.—Dr. G. T. **Prior**: The meteoric stone of Launton, Oxfordshire. The stone, which was seen to fall on February 15, 1830, was acquired by Dr. Lee and placed in his natural history collection at Hartwell House, near Aylesbury. After his death it was, through confusion with another meteorite, lost sight of until 1895, when it was found by Dr. Fletcher wrongly labelled in the Lee collection, and was secured for the British Museum. The stone belongs to the white-veined chondrite group, and in chemical and mineral composition agrees with other members of that group.

Linnean Society, March 18.—Prof. E. B. Poulton, president, in the chair.—J. A. **Wheldon** and W. G. **Travis**: The lichens of South Lancashire. In the introductory part of their paper, the authors, after referring to the enormous industrial development and increase of population which took place in South Lancashire during the last century, point out the deterioration of the flora which ensued, and then proceed to detail the results of their study of the effects of air-pollution by coal-smoke on the cryptogamic vegetation, and more particularly on lichen-growth. They are of opinion that South Lancashire exhibits the deleterious effects of smoke on vegetation to a higher degree over a larger area than is, perhaps, the case in any other part of Great Britain. They think, however, that these adverse conditions have now reached their maximum. It has, therefore, been considered of importance exactly to describe the state of the lichen-flora as it at present exists, so that data may be afforded for purposes of comparison at some future time when a regenerated lichen-flora has developed under purer atmospheric conditions. The authors show the extent to which the various classes of lichens, more especially those of corticolous and rupestral habitats, have suffered; and in this connection the marked influence of a calcareous substratum in neutralising the deleterious effects of smoke on lichen-growth is discussed. Particular attention has been paid by the authors to the lichens of the coast sand-dunes, the lichens of the Sand-dune Plant Formation in Britain not having hitherto been specially investigated. The characteristic lichens of these dunes and their ecological relations are described. A systematic list of all species of lichens found in the vice-county is given; and four new species and two new varieties are described.

Manchester.

Literary and Philosophical Society, February 23.—Mr. F. Nicholson, president, in the chair.—Prof. W. W. Haldane **Gee**: A projection screen invented by the late Mr. Thomas Thorp. The screen is made by producing a special type of matt surface on glass, on which is then deposited silver. This forms the opaque back of the screen, the front being of transparent glass. The screen gives a well-illuminated picture when employed for ordinary lantern work, and is especially good for use with the projecting microscope. By its means the Brownian motion of colloidal particles, which requires high magnification and great loss of light, can be demonstrated. The screen is most effective when viewed at an angle nearly perpendicular to its surface. A microscopic examination of the surface shows that it is made up of minute convex discs.—Prof. G. Elliot **Smith**: The significance of the geographical distribution of the practice of mummification. Mummification is the most distinctive element of a complexly-interwoven series of peculiar customs, including the practice of building megalithic monuments, sun- and serpent-worship, circumcision, tattooing, etc. The art of embalming certainly originated in Egypt, and, as the practice is of a nature extremely repulsive to mankind, the circumstances must have been of quite an exceptional nature to have driven any people to adopt such a custom. It is altogether unlikely that such a complex combination of special circumstances as we know to have called the practice into existence in Egypt should have arisen in more than one place. The details of the technique, in whatever part of the world the custom is found, emphasise an Egyptian origin. The practice spread from Egypt to the Mediterranean littoral, Europe, and the Canary Islands; to East Africa, Upper Congo, Southern Nigeria; to the Persian Gulf, India, Ceylon, Burma, Indonesia, New Guinea, the islands of the Torres Straits, and thence to Australia. Emigrants from Indonesia carried it to Tonga, New Zealand, Tahiti, and eventually to the Peruvian coast of South America.

THE COMPLETE WORKS OF TYCHO BRAHE.

Tychonis Brahe Dani Opera Omnia. Edidit I. L. E. Dreyer. Tomus I. Pp. lix+320. (Copenhagen: Gyldendalske Boghandel Nordisk Forlag, 1913.)

PERHAPS one's first sensation on handling this beautiful volume is one of surprise that three centuries have been allowed to pass after Tycho's death before his writings were given to the world in a collected form; for he took a notable part in building the structure of modern astronomy. He was the first to realise the imperfections of the existing solar and planetary tables, and the fact that their improvement needed prolonged observations with larger and more carefully designed instruments than any that had yet been employed; he fortunately had the skill to design these, and the means to purchase them. Thanks to the bounty of Frederick II., he was enabled to found Uraniborg Observatory, where sun, moon, planets, and stars were observed assiduously for twenty years.

The planetary observations led Kepler to the enunciation of his three laws, those of the moon led Tycho himself to detect the variation and annual equation, also the oscillatory changes of the node and inclination; those of the sun led to the detection of atmospheric refraction, and an approximate measure of its amount. Those of comets showed, by the minuteness of their diurnal parallax, that they were much more remote than the moon, and hence that they were not vapours in our own atmosphere, as many had supposed, but belonged to the planetary sphere. His observations of the fixed stars were far more precise than any previous ones, so that according to Dr. Dreyer the probable error of his standard right ascensions is only 24″; thus we may reasonably conjecture that if Tycho had lived a few years later, and known of the telescopic method, his results might be of utility even in our day.

The present reprint is under the auspices of "Det Danske Spreg og Litteratur Selskab," which has been fortunate in securing the services of Dr. Dreyer as editor. The task is evidently a labour of love with him, as he has made a special study of Tycho's life, having written his biography in 1890; he has written a Latin preface of fifty-nine pages in the present work, giving a biographical outline and a summary of the astronomical achievements; the fuller biography should however, be read by all serious students of his life.

Mr. G. A. Hagemann is generously bearing the cost of the publication of the collected works, which must be considerable, as it is being carried out in a sumptuous manner, with very large, clear type on thick, strong paper, and will run into several volumes.

The heavens themselves signalised in a brilliant manner the advent of Tycho by the outburst of Nova Cassiopeiae in 1572. The memoir, "De Nova Stella," was the first of his published writings, and appropriately begins the collection. "Last year, on the evening of November 11, while contemplating the stars, according to my custom, I observed a new, remarkably bright one nearly overhead. And since from my boyhood all the stars were perfectly familiar to me (such knowledge is not difficult to acquire) it was certain that there had not been even a faint one in that position, much less one of surpassing splendour." Mistrusting his own eyes, he quickly got his neighbours to verify the discovery, which appeared more startling to him than to us, since he knew of no parallel except the star of Hipparchus.

He diligently observed the position of the Nova at various hour-angles, and after some months' observation satisfied himself that it had neither proper motion nor diurnal parallax (on his geocentric hypothesis annual parallax was not to be expected), so he rightly concluded that it belonged to the sphere of the fixed stars; the fact that it scintillated confirmed this view. He estimated its bulk as many hundred times that of the earth, no doubt thinking himself very daring.

His notes on the magnitude and colour are interesting, to compare with those on modern Novæ. In November, 1572, the Nova was much brighter than Venus, so that many people saw it in full daylight; at that time its colour was compared to that of Jupiter. The brightness in December was equal to Jupiter, in February and March to a star of the first magnitude, in May to one of the second. The colour became red like Mars or Aldebaran; later still it became livid like Saturn.

The astrological significance of the Nova is fully discussed; Tycho made some lucky hits; in the next century many people saw in the career of Gustavus Adolphus a striking fulfilment of the horoscope based on the Nova.

The volume before us also contains the horoscopes of the three sons of Frederick II.: Christian, Ulrich, and Hans. Dr. Dreyer notes that astrology cannot be omitted if we desire to enter fully into the thought of that age, and that Tycho could not refuse to draw up these horoscopes when the king, his patron, requested him to do so. Also, belief in planetary influence seems less unreasonable in the case of those who accept the geocentric hypothesis. Tycho seems to have had some faith in his predictions, but he regarded them rather as warnings of evil tendencies to be resisted, or good ones to be encouraged, than as hard and fast determinations of inevitable destiny. It is rather pathetic to remember that when the eldest prince ascended the throne as Christian IV., he withdrew all Tycho's emoluments, and treated him with such marked coldness that Tycho was glad to leave Denmark altogether, and end his days in exile in Bohemia.

The remaining matter in the volume is an oration on the teaching of mathematics, and a short treatise on practical trigonometry. Tycho had access to seven-figure tables of the natural functions, and made use of the formulæ transforming products of sines and cosines into sums of the same, to save multiplication, logarithms not having been invented.

It is one of the advantages of a verbatim reprint that it satisfies our curiosity on such small matters of procedure, and helps us to realise the everyday life and thought of astronomers of distant ages.

THE RISE AND GROWTH OF BOTANY IN THE UNITED KINGDOM.

A History of Botany in the United Kingdom from the Earliest Times to the End of the Nineteenth Century. By Dr. J. Reynolds Green. Pp. xii + 648. (London: J. M. Dent and Sons, Ltd., 1914.) Price 10*s*. 6*d*. net.

MANY British and Irish botanists have been anticipating the appearance of Prof. Reynolds Green's history of the development of their science within the United Kingdom, but its reception cannot but be accompanied with feelings of sincere regret that the author is no longer with us. Indeed, he was seriously ill during much of its preparation, and one should not lose sight of this while perusing its pages. His friend, Prof. Harvey-Gibson, undertook the duty of seeing the work through the press, though, as he states in an appendix to the preface, he has refrained from editing it in any way.

As anyone who is familiar with Green's writings would be led to expect, the book is well arranged, lucid, and clearly written, and it provides an excellent general description of the rise and development of the science of botany amongst us. Opening with a summary of the work of the old writers of herbals, the book goes on to trace the varied phases of the newer advances, the use of botanic gardens, and the recognition and growth of the subject at the universities; it also discusses the more recent ramifications of botany and its points of contact with kindred sciences. A considerable portion of the volume is devoted to an account of the activities of modern and still living botanists. It is full of generous appreciation of the work of his contemporaries, but Green, with characteristic modesty, is almost silent on his own important contributions to vegetable physiology.

We could wish to give a measure of praise to the book more full than mature reflection enables us to do. It is admirable up to a point, and one must remember the disadvantages under which its author laboured, failing health and severe family bereavement, during its production. Without doubt, had Green been spared to see the whole work through its final stages and up to publication, he would have corrected many of the errors one meets with in its pages. It would be ungracious to dwell on these overmuch, but truth to tell the book stands in some need of revision on the score of historical accuracy, and sometimes also in the matter of names of the writers who are quoted. It is, furthermore, not improbable that there may be some difference of opinion as to the correctness of the general perspective, and as to the insight into the relative importance of the work and powers of more recent botanists.

But when this has been said, we may recognise that Green has left us a book of permanent value —a lively impression of the services to science, as well as of the personalities of a number of his contemporaries. The way in which he has treated this part of his subject shows him as a genial friend; perhaps somewhat apt to overvalue those for whom he entertained feelings of personal affection, but to no one is he either mean or unkind.

J. B. F.

OBJECTIVE PSYCHOLOGY—PURE AND APPLIED.

Objektive Psychologie oder Psychoreflexologie; die Lehre von den Assoziationsreflexen. By Prof. W. von Bechterew. Autorisierte Uebersetzung aus dem Russischen. Pp. viii + 468. (Leipzig and Berlin: B. G. Teubner, 1913.) Price 16 marks.

Psychology and Industrial Efficiency. By Hugo Münsterberg. Pp. xviii + 322. (London: Constable and Co., Ltd., 1913.) Price 6*s*. net.

THESE two books, though widely different in origin and aim, agree in exemplifying a single method of psychological investigation: namely, the method which American writers describe by the ungainly term "behaviourism." It is a psychology in which (to quote Prof. von Bechterew) questions of subjective processes, or processes of consciousness, find no place. The science defined by this exclusion obviously differs widely from the psychology based upon introspection; it may be regarded as an extension into the human field of the methods developed by Lloyd Morgan in his experiments on the instinctive behaviour of chickens, and by other workers who have followed his highly important lead.

(1) The point of view is explained and defended by von Bechterew in the first fifty pages of his volume. As he conceives it, objective psychology is the science of "psycho-reflexes," that is, of the neural mechanisms the activities of which are either known or supposed to be accompanied by psychoses, whether the subject is conscious of them or not. The remainder of the work is a systematic exposition of the results hitherto obtained by the objective methods, from the analysis of the simpler primary and secondary reflexes to that of the complicated forms of behaviour covered by such terms as will. Many of the researches described have been carried out in von Bechterew's own laboratory in Petrograd; those of other workers are summarised with much ability and with copious references to the original sources. The whole argument is, in fact, developed so clearly and is so elaborately documented that even students who do not accept the author's methodological postulates will find in his book a very valuable collection of material, admirably organised.

(2) Prof. Münsterberg's book is directed less to the student than to the educated layman—particularly to the business man who has heard of the remarkable achievements (and still more remarkable claims) of the pioneers in the "scientific management" of industrial processes and desires to know what a competent psychologist has to say upon the subject.

The author shows by a number of interesting examples, largely from his own laboratory, that the psychologist can help the leader of industry in two specific and important ways. In the first place, by submitting candidates for employment to laboratory tests, he can differentiate with confidence between those whose psychophysical outfit is suitable for the work to be done and those who are unlikely ever to become efficient. Among his illustrations Münsterberg describes, in this connection, the ingenious devices he uses to test the capacity of a man to drive an electric car through busy city streets. In the second place, the psychologist can determine the conditions of rapid and effective training in the performance of skilled acts (*e.g.*, typewriting), and the conditions which will secure the most economical use of the trained worker's skill while minimising the deleterious influences of fatigue and monotony.

In both these departments the "psychology of industry" leads directly to social efficiency in both the narrower and the wider sense; for it tends to the increase both of the productivity and of the happiness of the worker. It is difficult to view with equal approval the investigations into the effects of advertisements and the psychology of the shop-counter, though Prof. Münsterberg's studies of these topics have undoubted interest as explorations of human frailty. T. P. N.

ZOOLOGICAL MONOGRAPHS.

(1) *Reptiles and Batrachians.* By E. G. Boulenger. Pp. xiv + 278. (London: J. M. Dent and Sons, Ltd., n.d.) Price 16*s*. net.

(2) *Some South Indian Insects and Other Animals of Importance, considered especially from an economic point of view.* By T. Bainbridge Fletcher. Pp. xxii + 565. (Madras: Government Press, 1914.) Price 9*s*.

(1) THE prominent features of this convenient volume are the notes on habits, and the illustrations—mostly prints of photographs from life taken by Mr. W. S. Berridge in the Zoological Society's Gardens. Comparative anatomy and the general principles of vertebrate zoology do not come within its scope; but a knowledge of these things being taken for granted, the two classes of reptilia and amphibia are surveyed as detached assemblages. Much after the fashion of the best type of museum catalogue, the distinctive characters of every subordinate group of each class are defined, and the geographical distribution of the minor groups determined; and, much after the fashion of the best type of guide-book, the notable species are succinctly characterised and carefully considered as objects of living interest. A vast amount of well-arranged and easily assimilated information is thus presented to the intelligent reader, not only in respect of structural features, taxonomic relations, life-history, habits, range, and mode of life, but also with regard to popular beliefs and native superstitions, economic bearings, and numerous other matters of interest. Beyond this the author, as one of the curators of the Zoological Society's Gardens, has taken every opportunity of recording interesting facts concerning the behaviour, adaptability, and treatment of reptiles and batrachians in captivity, and of noting their peculiarities, preferences, and other interesting phenomena of their growth and being.

Snakes occupy exactly one-third of the book, and the author has done justice to the subject. With regard to venomous snakes, however, he has scarcely made it clear that in order to inject its venom in lethal amount a snake must not only strike but must also grip, so as to drive its poison-fangs home and wring out its glands. And with regard to the treatment of snake-bite, he has failed to impress sufficiently upon his readers the important facts (*a*) that the most efficient ligatures and the most powerful local antidotes are perfectly useless if applied after a lethal dose of venom has been absorbed—the available interval, according to the ample and carefully controlled experiments of Captains H. W. Acton and R. Knowles, being from ten to twenty minutes; and (*b*) that after the venom has been absorbed in lethal quantity the *only* hopeful remedy is a suitable anti-venom.

Good and useful as this book is, it is to be regretted that, like so many modern things, it recks so little of the priceless past. Without going back to Herodotus and his entertaining account of the crocodile, the author might have said something about the great pioneers of herpetology.

(2) This is a book that, notwithstanding the limitations of its title, is of much more than local service. Its contents are disposed in three progressive stages, the first dealing with insects generally from a biological viewpoint, the second treating more particularly of insects in their economic range, while the third is at once an exact survey and an illustrated epitome of the specific local forms that affect man and his works for good and ill, but chiefly for ill.

As is natural in a work sponsored by a director of agriculture and a board of revenue, the main end is economic—namely, to place on record what is known about the insect pests of agriculture in southern India, to facilitate their identification, and to explain approved methods of limiting their ravages. Order by order, and family by family, the specific pests are marshalled and individually figured on a lavish scale, referred to their local habitation, characterised in their life-history and economic *rôle*, and relegated to the code of criminal procedure. Beyond this certain forms concerned in the transmission of disease are treated in a practical manner, and many insects of approved utility or potential service to man are individually noticed and portrayed.

The earlier pages that deal with insects as a class in their broad economic incidence are also well done. Among other things they include good chapters on pests as a whole, the general causes that favour their increase, the various means by which they may spread, and the methods adopted for their control. These last, both direct and indirect, are discussed with insight and discrimination, and insecticides of divers kinds, and all the ingenious apparatus of their application, are fully described and criticised; while at the same time the author is careful to emphasise the rational factor underlying all remedial treatment—namely, exact knowledge not only of the life-history of the particular pest, but also of all the local conditions, natural and otherwise, of its particular occurrence. The series of chapters on economic insects brigaded according to *rôle* or circuit—*e.g.* as caterpillar pests, beneficial insects, pests of stores, and so on—are also extremely useful, such collective unities being easy to follow and to tackle.

The preliminary chapters on insect biology, though rather promiscuous and sketchy, are good in intention and are suggestive. In the chapter on "tropisms," however, the author gives his reader no hint that the subject-matter of his definitions and classification lies on the very boundary-line of legitimate inference and beyond the bounds of exact knowledge, and that these "tropisms" are mere imposing words which not only do not explain any process of nature, but are not even generalised expressions of the results of any analysis of natural processes.

The price of the volume, with its fifty beautiful coloured plates and many hundreds of illustrations in the text, is absurdly low, but its weight (5 lb. 6 oz.) is prodigious.

OUR BOOKSHELF.

Memoirs of the Colombo Museum. Series A., No. 1. *Bronzes from Ceylon, Chiefly in the Colombo Museum.* By Dr. A. K. Coomaraswamy. Pp. 31+xxviii plates. (Ceylon: Colombo Museum, 1914.) n.p.

This is the first issue of a series of monographs intended to describe the art treasures of the Colombo Museum, among which the bronzes are of special importance. Some of the finest examples have been published in Mr. Vincent Smith's "History of Fine Art in India and Ceylon," but a more complete description of these beautiful objects is welcome. Dr. A. K. Coomaraswamy has contributed a useful introduction. It is not easy to fix the exact date of the bronzes, but they seem to cover the period beween the ninth and fourteenth centuries, A.D. They fall into two groups: Buddhist and Saiva Hindu. The discovery in Ceylon of many images of Bodhasattvas and female Mahāyāna deities is important because it proves that the latter cult existed in the island, and that it is now more than ever inaccurate to speak of Northern and Southern Buddhism as if these geographical terms connoted a distinction between the Hīnayāna and Mahāyāna schools. In this connection the images of Brahmanical deities absorbed into Buddhism are of special value.

The Saiva Hindu bronzes, like those from Polonnāruva, differ widely from the Buddhist group: they may have been cast in Ceylon, but as a group they are allied to the school of South India. Their existence may represent a Tamil occupation of the island, but it is possible that both Buddhist and Hindu cults may have been contemporaneous. Siva here is found performing his orgiastic dance, and he is accompanied by his Sakti, or female energy, the Mother of the Universe, source of power and fertility. Finally come the local deities, like Pattini, patron of chastity and guardian of disease, who was a deified woman executed on a false charge of stealing the anklet of the Queen of Madura. The bronzes thus represent a complex of cults: Buddhism, Brahmanical Hinduism, and the worship of local deities, all combined by the eclectic tendencies of modern Hinduism. Those who are interested in Ceylon will welcome the promised publication in this series of monographs on the local archæology, ethnology, and botany.

A Text-book of Practical Assaying, for the use of Mining Schools, Miners, and Metallurgists. By Prof. J. Park. Pp. xii+342. (London: C. Griffin and Co., Ltd., 1914.) Price 7*s.* 6*d.* net.

This capital little book is a welcome addition to the lengthening list of treatises on assaying which are available in this country. It has already appeared in New Zealand, where it has been used for the last ten years as a text-book in many class-rooms. It is arranged as a course of instruction for students, intended to be spread over two years, beginning with the easier operations and gradually leading up to more difficult ones.

The book contains a comprehensive course, and in his zeal for completeness the author towards the end so far diverges from his own definition of assaying as to include the analysis of soils, manures, sugar, and milk. Nevertheless, it must not be assumed that everything is fair game which comes into the net of this well-known professor of mining. There is little which could be omitted with advantage. It will readily be believed, however, that one of the merits of the book is conciseness, and in some sections strength would be gained by expansion and the addition of a few more details, as, for example, in the assay of copper by electrolysis.

The book is also commendable in its accuracy, and it will be prized by students who are familiar with it after they have passed out into the works laboratory.

The directions for arithmetical computation of results are perhaps unnecessarily full and explicit for university students, and such a remark as the following might be omitted:—"Suppose one gramme of copper ore yielded 0·46 gramme of copper, then the percentage is equal to 46." Some other directions in the book are similarly elementary, but teachers of classes in secondary and technical schools will not object to it on that account. For these classes it is an eminently suitable book. A few more illustrations of apparatus would not be amiss.

T. K. R.

New "Acribo" Sectional Pads. Fifty sheets in a pad with cover. (London: W. H. Harling.) Price of each pad, 2*s.* 6*d.*

Mr. Harling's new pads of squared paper are printed in grey with a view to obviate eye strain and to ensure prominence for the curves plotted. Three rulings are available: inches and eighths, inches and tenths, and centimetres and millimetres. The size of the ruled portion of each pad is 10 in. by 8 in. or 26 cm. by 20 cm. The paper is excellent, the ruling is accurate, the pad is convenient, and the production is British throughout.

The Counties of Clackmannan and Kinross. By J. P. Day. Pp. viii+145. (Cambridge: At the University Press, 1915.) Price 1*s.* 6*d.* net.

The Counties of Moray and Nairn. By Charles Matheson. Pp. x+139. (Cambridge: At the University Press, 1915.) Price 1*s.* 6*d.* net.

These recent additions to the series of Cambridge County Geographies maintain the high standard of attractiveness and utility to which attention has been directed in the case of many previous volumes. The books should become popular guides for tourists, who will appreciate the interesting style in which they are written.

MODERN SUBSTITUTES FOR BUTTER.

Until the last few years the word margarine was usually associated, in the mind of the British public, with poverty; but now, under the new name of "Nuts and milk," with which advertising enterprise has made us familiar, it is becoming freely used in the kitchen, and is even found on the breakfast table in many households. On the continent, where the general standard of luxury is not so high as here, butter substitutes are used far more generally; and the demand for the raw materials from which they are made has increased to such an extent as to cause a noteworthy increase in their cost. In most cases the legislation affecting butter substitutes has been influenced by vested interests, so that, whilst only partially effective in preventing fraud, it has checked the development of the industry. Taking into account also the universal prejudice against margarine which prevailed formerly, it is very remarkable that the industry should have made such advances. It is of interest, therefore, to examine its development in some detail, more particularly from the scientific point of view; for it is desirable at the outset to emphasise that the margarine industry is essentially scientific in character, and that considerable technical skill is demanded in its manufacture.

The finished margarine must be satisfactory in taste, odour, and texture; this necessitates that the fats composing it shall be entirely free from fatty acids, and show no tendency to become rancid. Much depends on the texture of the fat, which the user expects to be the same as that of butter. The margarine maker so blends his raw materials that the mixture has the same melting point as butter, and he is able, further, to vary the melting point to suit the climate, an advantage which will be more fully appreciated in the future when margarine has found its way to tropical countries.

The present success of the margarine manufacturer is to a large extent due to the great variety of raw materials which are now available. In the early days of the industry soft beef fat was the sole basis obtainable; this was known as oleo oil or oleomargarine, and the conditions of its manufacture were not always above suspicion. This has now been entirely changed; the factories are models of cleanliness; they are officially inspected, and above all, animal fats have become of secondary importance to vegetable oils.

The process of manufacture is briefly as follows:—The carefully purified oils are blended at a suitable temperature, churned and pulverised with new or separated milk in suitable machines, cooled, washed, salted if required, and worked in exactly the same way as butter. The product is a butter substitute, and has the same composition, viz., about 84 per cent. of fat. Therefore on the accepted standards it has the same nutritive value.

A certain amount of butter fat is usually contained in the mixture, but by law this is not allowed to exceed 10 per cent. In Germany, Austria, and Denmark the presence of 10 per cent. of Sesame oil is obligatory for the purpose of earmarking the substitute. Sesame oil gives a colour reaction with certain reagents, which enables its presence to be very readily detected; for the British palate this addition of Sesame oil is unwelcome. In Belgium the addition of 0·2 per cent. of potato starch, as well as of 5 per cent. of Sesame oil to margarine is obligatory. It may be remarked that the analytical discrimination between butter and margarine is a lengthy process, and that the detection of 10 or 15 per cent. of added fat to butter is a matter of considerable difficulty. All fats are very much of the same composition, and with one or two exceptions they lack individual characteristics. The analyst depends, therefore, on small differences in physical characteristics, or on the proportion of fatty acids of low molecular weight, for their identification when in admixture.

It is an increasing practice in factories and for culinary operations in restaurants or in the kitchen to use the pure or blended fats themselves without churning them with milk. The advantages of this procedure are obvious, and it will be followed more generally by the housewife in the future. Thus in the United States, and in the poorer districts of our large towns, enormous quantities of refined cotton seed oil are sold for frying purposes, and the use of nut and blended butters containing 100 per cent. of fat for the same purpose is largely on the increase amongst the upper classes.

With the exception of olive oil the edible vegetable oils require very special refining before their characteristic flavours or impurities can be removed; in consequence it is only since these difficulties have been overcome in practice that they have been so largely used for margarine. It is certain that as the knowledge of refining processes increases, the development of the industry will be still greater. The methods of refining vary according to the oil; they are mostly jealously guarded as valuable secrets.

In Britain, and particularly in the United States, very large quantities of cotton seed oil are used either in margarine or for culinary purposes, both as a substitute for olive oil and as a cooking fat. About three-fourths of the world's production comes from the United States, about half of this oil being refined for edible purposes. The crude oil obtained by pressing the seed is first treated with caustic soda, then with fuller's earth, and finally made as nearly as possible free from taste and odour. From the point of view of the margarine maker, cotton seed oil is too liquid to be used in any large proportion, though its relatively low cost makes it a very desirable ingredient.

Far more important as butter substitutes are the nut oils—coco-nut, and palm kernel. The former is obtained by pressing copra—the flesh of the coco-nut, which is exported in a dried condition from its place of origin. In the past the copra-pressing industry has been localised at Marseilles, though in later years an almost equal quantity of material has been dealt with at Hamburg.

Palm kernels are the seeds of the palm fruit, of which the fleshy part is utilised for the manufacture of palm oil. The natives on the West Coast of Africa collect the kernels, crack and remove the shell before the nuts are exported to Europe. It is stated that kernels were first brought to Marseilles as ships' ballast and thrown into the sea on arrival until their value was recognised. Originally the chief receiving port was Marseilles, but latterly the industry has been almost entirely carried on at Hamburg, where in 1911 93 per cent. of the total quantity was dealt with, the remainder going to Liverpool.

The palm kernel oil made in North Europe last year is estimated at 125,000 tons, of which about 40,000 was refined for edible purposes. The kernels contain about 50 per cent. of oil, which is extracted by pressing in hydraulic presses similar to those used for copra. The residue, palm kernel cake or meal, has found a very wide use in Germany as an ingredient of compound cake for cattle feeding, and in this form has been largely exported to England. The commercial success of the pressing industry largely depends on the price obtained for this meal, and no pains have been spared on the Continent to demonstrate its value to the farmers by means of scientifically conducted feeding trials. There is at present much talk of developing the industry in Britain, in which case the disposal of the cake here will be an important consideration. It is of interest that the decline of the industry in Marseilles is largely due to the cake failing to find a ready sale as cattle food in the South of France. If the new industry is to succeed here it will have to be supported by the agricultural interests.

Some idea of the magnitude of the nut-oil industry is gained from the following figures:—The world's production of coco-nut and copra oil 1913-1914 is estimated at 377,000 tons, of which 300,000 tons were used in Europe. The total supply of hard vegetable fats (coco-nut and palm kernel oil) available for margarine is said to have been 240,000 tons in 1913, and perhaps 300,000 tons in 1914. Out of 347,000 tons of hard fat stated to be used for margarine in 1913, 204,000 tons were vegetable, and the quantity of vegetable fat used in 1914 may have amounted to 300,000 tons, *i.e.*, the total visible supply. There is little wonder that there has been a great increase in the price of these oils, and that the tropical sources of palm tree oils are being widely exploited. Nearly all tropical countries report an increase in the area under coco-nuts, or an improvement in the methods of dealing with the existing trees, and in the machinery for making copra or extracting the oil, which is still very primitive and inadequate.

The nut oils resemble butter and differ from all other fats in containing a large proportion of fatty acids of low molecular weight. Butter contains acids from butyric acid upwards in the homologous acetic acid series; the chief constituent of nut oils is lauric acid. Few of the remaining oils of commerce contain acids lower in the series than palmitic acid.

In preparing vegetable fats for the market the all-important consideration is the careful selection of the raw materials. The oil is worked as fresh as possible, so that the best results are obtained when the seed is pressed in this country. It should be understood that the refining process involves no treatment with chemicals except the agitation with weak alkali to remove the fatty acids present.

The importance of fats in the dietary requires no emphasis; on the other hand, it is questionable whether all fats have the same value as food materials. Fats, being glycerides, are decomposed in their passage through the alimentary system into glycerol and fatty acids. The decomposition is effected through the agency of an enzyme, lipase, so that the digestibility of the fat depends on the rate at which it is attacked by the enzyme. The fat has to be brought into a suitable state of emulsification before the enzyme can act on it; and though the factors controlling this state are still somewhat obscure, it is above all important that the fat should melt readily at the temperature of the body. Hence the comparative digestibility of a fat is in the first place based on its melting-point. Stearine is badly digested, liquid oleine is readily digested. The addition of sufficient oleine to stearine so as to reduce the melting-point of the mixture renders the stearine also digestible. Consequently the all-important point which margarine makers keep in view is the melting-point of their product in relation to the body temperature; if this is correct the material may contain some ingredients of a considerably higher melting-point.

It is of interest to note in this connection that vegetable fats are composed to a great extent of mixed tri-glycerides—that is, the glyceride contains more than one fatty acid in its molecule, whereas normally one molecule of glycerol is coupled with three molecules of the same fatty acid. Experience teaches that the melting-point of the fat will be greatest when these are all the same. The melting-point of the fat is further influenced by the fact that it consists of a number of different glycerides, both simple and mixed. Since mixing of fats has the result of altering the relative proportions of these it is evident that the final melting-point of a mixture cannot be predicted on theoretical grounds, and it is agreed that butter substitutes of suitable melting-point are as digestible as butter.

It is customary to measure approximately the nutritive function of a food by its energy value in calories per pound, but modern research has shown this method to be inaccurate in two respects. In the first place it ignores the quality of the food; secondly, it neglects the presence in traces of the vitamines.

It has been found by experimenting with isolated food substances that diets otherwise sufficient in energy value fail to maintain growth and health unless they contain certain substances hitherto unrecognised, but which have been named vitamines. The work in this field is of recent date, and is vitiated by the usual errors accompanying premature publication—indeed, much of it has been recalled already, but it would appear that the vitamines are of lipoid nature. They are present in butter, but not in the refined fats which are used for butter substitutes. How far this difference is of importance it is difficult to say; probably sufficient vitamines are present in the rest of the dietary to enable them to be dispensed with in the fat.

The question of quality is of more importance, though it has hitherto largely escaped attention. The individual fatty acids probably differ in their value in somewhat the same way as the different amino-acid constituents of the proteins have been shown to do, though to a less extent. The lower fatty acids in butter are perhaps specially important in making it of more value than olive oil, which is composed mainly of oleic acid, or than fats composed entirely of palmitic and stearic acids. Nut oils, however, resemble butter in containing a proportion of the lower acids, and hence their use in butter substitutes is entirely rational from the point of view of nutritive value.

In the foregoing the nature and preparation of materials available for use as butter substitutes have been indicated and their food value discussed. When it is remembered that the new industry is under rigid scientific control and conducted with a cleanliness mostly unknown in the butter industry, and, moreover, that it has made edible fats available for the masses at half the price of butter, it must be proclaimed as yet another of the achievements of science in the service of man.

THROUGH THE INTERIOR OF BRAZIL.[1]

IT is an instance of rare good fortune for a man who delights in the life of a field-naturalist to be offered the honorary leadership of a scientific expedition, by a Government not his own, through a large stretch of unexplored tropical country, to embark upon an unknown river, piecing it together with others but hazily known, and to have the now complete large river called after himself. However unique such a stroke of luck, the necessary premises are equally rare in their combination of an ardent naturalist, keen sportsman, vigorous experienced traveller, leader of men as a former president of the great American Republic, and attractive, versatile writer!

The idea of a journey through the interior of Brazil had been suggested to Colonel Roosevelt by Father Zahm, a missionary. It took shape when he was invited, through the Governments of Argentina and Brazil, to deliver addresses to their various learned societies, and he decided to combine this visit with a collecting tour for the American Museum of Natural History. When at Rio, the Government offered him the conjoint leadership of a scientific expedition which the Telegraph Commission was going to make through the very heart of the continent, down the now famous Rio Duvida. The geographical problem may be illustrated as follows. Let my right arm represent the lower Amazon river, the thumb the Tapajoz, the middle finger the Madeira, the index its most eastern and last tributary. The first joint of the index finger was known as the lower Aripuanan, composed of the upper Aripuanan and the Castanho river; this, the second joint, was known to rubber men only. The third joint represents the Duvida. A few miles of this river had been discovered by the Telegraph Commission in 1909, and there was a long gap between it and the Castanho of unknown extent. Moreover, it was not unlikely that the Duvida was, after all, but a tributary of the Gyparana, an affluent of the Madeira, already well known; and it was just possible that the river of Doubt turned sharp to the east and fell into the Tapajoz. However, the authorities ordered a party to ascend the Aripuanan up to the mouth of the Castanho and there to wait for the explorers.

The American party consisted of the Colonel and his son, Messrs. Miller and Cherrie as experienced zoological collectors, Fiala, of Arctic experience, as the handy man, and Father Zahm. Well found and equipped they left Asuncion on December 9, 1913, and ascended the Paraguay up to the headquarters of the Telegraph Commission, about 15° S. There is, extending towards north-west, the Serra Geral, the divide between the La Plata basin and that of the Amazon, but recently explored, with its numerous streams, by the Commission. Here the collections hitherto made were sent back, with Father Zahm. Fiala, with a few companions, was sent down a tributary of the Tapajoz. They got through, down this river, having lost everything but their lives. On February 3, 1914, the main party continued the journey with mule packs and ox carts, still following the telegraph and crossing many streams. Miller, with a small party, went on, to descend the Gyparana, etc., for Manaos, which turned out a most successful collecting trip. The main party combined with the Brazilian members: Colonel Rondon, chief of the Commission, Lieut. Lyra, and Dr. Oliveira.

FIG. 1.—One of the canoes. From "Through the Brazilian Wilderness."

They embarked upon the Duvida on February 27 in seven dug-outs, with sixteen paddlers, twenty-two men all told, with provisions for fifty days, hoping to reach the Madeira within six weeks. The starting point was at 12° 1′ S.; 60° 15′ W. All went well until March 3, when at 11° 44′ S. the first rapids were encountered. Then began the misery of portaging, carrying the loads and dragging the clumsy dug-outs through or past rapid after rapid, amidst dense forest, in the rainy season, with a plague of biting ants, flies, and termites which devoured their outfit. Nevertheless, the Colonel was "reading poetry in head-net and gauntlets." On one occasion it took them three full days to negotiate one mile of rapids. By March 25 they had descended only 160 kilometres of the winding river, had lost four canoes,

[1] "Through the Brazilian Wilderness." By Theodore Roosevelt. Pp. xiv+374. (London: John Murray, 1914.) Price 18s net.

including a new one made on the way, with provisions, ropes and pulleys, and one of the crew. A dog was killed by unseen Indians, the outfit had to be cut down to the utmost, and the sadly shrunk provisions had to be supplemented by palm-tops, fish, nuts, and an occasional monkey or wood-fowl. Illness, and a case of murder amongst the crew added to the depression.

Things were at their worst, when the river became more manageable, and when, on April 15, they came to the first house of rubber men, who informed them that they were on the Castanho river, about fifteen days from its confluence with the Aripuanan. This happened at 10° 24′. Henceforth, they enjoyed every help, and on April 26 they made the mouth of the Castanho, at 7° 34′, where Lieut. Lyra was encamped, waiting for the explorers. On the last of the month all the parties met at Manaos. By discovery and piecing together they had put on the map a new river; allowing for unknown headwaters and the windings of its whole, rather straight course, amounting to a total length of 1000 kilometres, not miles. This river enjoys now an abundance of names. Duvida + Castanho + Lower Aripuanan = Rio Roosevelt, as proclaimed officially by Colonel Rondon, but in one of the two maps of the book it is called Rio Teodoro. It was a very successful expedition, its object having been obtained in the way it had been planned.

Fig. 2.—Rapids of the Duvida From "Through the Brazilian Wilderness."

The various collections amounted to the great number of 3000 birds and mammals. Concerning the description of the country, its people, fauna, and flora, the narrative divides itself naturally into two parts. Soon after reaching the Duvida the pleasant occupation of collecting and observing had to give way to dangerous toil, the ways and means of getting through at all. Up to the divide Colonel Roosevelt had a glorious opportunity of indulging in the study of nature in her most varied aspects. He kept his eyes open, and, with a pleasant style, shows his delight whenever he comes across some creature he had not seen before. At the outset, at a visit to the serum-therapeutic institute at São Paulo, we get a lecture on snakes and their poison, and he assisted in experimenting with the mussurana, a snake-eating, harmless, immune snake. But we are not told its scientific name (*Rhachidelus brazili*, Blgr.) one of many similar regrettable instances in his book. The technical names are, of course, the bane of the vast majority of readers. Vernacular names are preferable, but there is a limit, and two words in brackets would satisfy everybody.

He speculates whether the white-tailed deer is an immigrant from the Northern Continent, arguing from the season of the shedding of its antlers. The marsh-deer, with its advertising red coloration, is just as successful as the black- and the white-tailed deer, which are found in the same neighbourhood. "Evidently it is of no survival consequence whether the running deer displays a white or a black flag." Pumas, ocelots, jaguars, spotted or quite black, were killed in the same locality. "In many cases coloration is of no consequence whatever; instead of being a survival factor, it becomes negligible through the other factors of overwhelming importance, as habits, cleverness, etc." Thus speaks the experienced sportsman on one of his favourite subjects. On another occasion he is puzzled why the jaguar should climb trees to escape dogs, "for ages have passed since there were in its habitat any natural foes from which it needed to seek safety in trees." Such and similar arguments usually do not come to much, but they are samples of scores that he did not go out merely to bag his jaguar. Birds, beasts, coral snakes, and piranha fishes, toads and ants, and primitive natives, he has something to say about, not always new, but to the point.

Every naturalist will agree with him that the mere collecting for museums is all very well, to a certain extent, a necessary evil, but what is now wanted are observations of the economy of the creatures, as parts of their environment. To secure such information, send out educated men who can give a readable account of their experiences. With exception of the two very sketchy maps most of the fifty illustrations are beautiful and characteristic.

H. G.

THE "ORIGINAL" SPECIFIC GRAVITY OF BEER.

THE December (1914) issue of the Journal of the Institute of Brewing is an important number of this publication, and of more than merely technical interest. It contains a series of reports and memoranda upon the subject of the determination of the "original" specific gravity of beer, and the results of the work described have now, by the Finance Act of 1914, been legalised as the basis for checking or determining the charge of duty upon this beverage. The main reports are contributed jointly by Sir Edward Thorpe and Dr. H. T. Brown, and the latter author supplements them by interesting studies of both the historical and the scientific aspect of the question.

Beer is taxed as being an alcoholic beverage, and it is popularly supposed to pay duty according to the amount of alcohol it contains. This, however, is not strictly the case. The basis of taxation is not the actual quantity of alcohol in the beer, but the specific gravity of the unfermented wort, which may be regarded as a measure of the quantity of alcohol potentially producible. Essentially, the wort of beer is a solution of various sugars—maltose, dextrose, cane sugar, and invert sugar—either arising from the malt and grain used, or directly added as such. The proportion of sugars varies considerably, according to the kind of product desired. In wort for producing strong ale, for instance, there may be twice as much sugar as in that destined for ordinary table beer. But, in the main, the proportion of sugar determines the specific gravity of the unfermented wort, and the specific gravity is therefore made the basis of the charge of duty levied on the beer. A brewer is thus left at liberty to ferment his wort as much or as little as he likes, and to produce a stronger or a weaker, a heavier or a lighter beverage, as his fancy dictates or his customers prefer.

As soon as fermentation commences, the specific gravity of the wort begins to alter, and in general to decrease. This is so for two reasons. First, the destruction of sugar by fermentation removes solid matter from solution; and secondly, the alcohol produced is specifically lighter than the wort. Hence, unless the specific gravity is determined before fermentation has commenced it is useless as the basis for the correct assessment of duty. It is impracticable, however, to have a revenue officer in attendance in all cases to take the specific gravity of the wort before fermentation begins; moreover, it often happens that the "collection" of the wort extends over several hours, during which time the first portions may have been in contact with yeast, and fermented to an appreciable degree, before the last portions have been added. Even were this not so, other difficulties arise. A large quantity of beer is exported, and the exporter is entitled to a "drawback" or rebate equivalent to the duty originally charged upon the unfermented wort from which the beer was made. Hence it is necessary to devise a method whereby the original specific gravity of the unfermented wort can be ascertained by the analysis either of the partly-fermented wort or of the finished beer, as the case may be.

As a first approximation, such a method may be based upon the well-known equations of Gay-Lussac denoting the conversion of sugar into alcohol. With maltose, for example, it is readily calculable from the equation:—

$$\underset{\text{Maltose}}{C_{12}H_{22}O_{11}} + H_2O = 4\underset{\text{Alcohol}}{C_2H_6O} + 4CO_2,$$

that 100 parts of this sugar yield theoretically 53·8 parts of alcohol. Hence by determining the quantity of alcohol in a given specimen of wort or beer, we find the equivalent amount of sugar destroyed; and from the known density of solutions of maltose we can thus deduce the corresponding loss of specific gravity. Adding the number denoting this loss to the specific gravity of the residual wort or beer freed from alcohol, we can, theoretically, obtain the "original" specific gravity of the wort, *i.e.*, the gravity before fermentation had commenced.

In practice, however, this calculation is not sufficiently accurate. As Pasteur long ago showed in his studies of fermentation, a part of the sugar destroyed is not converted into alcohol. Moreover, different classes of sugars yield different percentages of alcohol. Again, the introduction of yeast complicates the matter, since part of the solid matter of the wort is used up in sustaining the growth of the yeast, and a sensible quantity of alcohol may be added as such with the yeast itself. These and other disturbing factors, small individually, together affect the result sufficiently to render the figures given by the simple theoretical method, as outlined above, only an approximation to what obtains in actual brewery operations.

We have, in fact, to fall back upon an empirical basis for the calculation of results sufficiently accurate to be used in practice. Starting with worts of known specific gravity, fermentations may be carried out, and from the examination of samples drawn as the process continues, it can be ascertained experimentally what is the actual loss of specific gravity consequent upon the production of known quantities of alcohol. Such experiments, in fact, have been made, and the results have been embodied in statutory tables for use in assessing the duty on beer.

Manifestly it is of much importance that these tables should be true and just. If inaccurate in one direction they are unfair to the public by reason of the loss of revenue entailed; if erroneous in the opposite sense they are unfair to the brewer.

The first original gravity tables were constructed in the year 1847 by Messrs. Dobson and Phillips, of the Inland Revenue Department. They were drawn up with considerable care; but some discussion having arisen, the whole matter was referred a few years later to Profs. Graham, Hofmann, and Redwood, whose report was presented to the authorities in 1852, and published the same year in the Journal of the Chemical Society. For some time past it has been known that the table supplied with this report is less accurate than is desirable—not, it appears, from any inherent errors, but from having been based upon fermentations which differed in some respects from those obtaining in ordinary brewery practice. About six years ago, therefore, the Commissioners of Customs and Excise gave instructions for a revision of the table to be made. This was undertaken by Sir Edward Thorpe, who was at that time principal chemist of the Government Laboratory, conjointly with Dr. H. T. Brown, nominated on behalf of the brewing trade by the Council of the Institute of Brewing. The necessary experiments, which altogether extended over a period of about two years, comprised not only brewings made under laboratory conditions, but an extensive series of observations at representative breweries, in order to obtain data which should correspond fairly with the actual working conditions met with in modern brewing practice. In the result a table has been constructed which there is every reason to believe is trustworthy, and which has now been legally established for use in place of the former statutory table of Profs. Graham, Hofmann, and Redwood. As compared with the older table, its general effect is somewhat to increase the amount of duty chargeable.

Dr. Brown's special contribution is a valuable study of the scientific principles underlying the empirical method of determining original specific gravity. He shows that a reasoned or "theoretical" process is quite possible—though not necessarily preferable—if the data have been properly established. C. Simmonds.

ROLL-CALL OF BRITISH BIRDS.[1]

We have received from the British Ornithologists' Union the second and revised edition of its "List of British Birds." It is an authoritative compilation which does credit to the zeal and carefulness of the editorial committee. While the task was only accomplished by division of labour, the whole has been revised by the entire committee, who consider themselves jointly responsible, although many disputed points have been decided by the votes of the majority. The first edition, published in 1883, included 376 birds; the present edition has 475, quite apart from a long list of species the presence of which has been recorded, but not satisfactorily proved.

It is interesting to look into the composition of the list of 475 birds. In the first place, 188 are regular breeding birds, and 286 are non-breeding, and one (the great auk) is extinct. The list may be further sub-divided. Thus, there are 141 residents, including, of course, many that are partially migratory. In this category are included three introduced birds—the little owl, the pheasant, and the red-legged partridge, besides the capercaillie, which was indigenous, but became extinct about 1760–70, and was re-introduced from Sweden in 1837–8. A second set is made up of 47 summer visitors, including a few which occasionally leave representatives with us in winter. The third set consists of 46 winter visitors; the fourth of 30 birds of passage; the fifth of 61 occasional visitors which have occurred on more than twenty occasions.

The largest category in the classification is that of rare visitors, which have been recorded on fewer than twenty occasions. This group numbers 149, which shows how diligent the search for the occurrence of rare birds has been in the British Islands. Under each bird we find a few references, the etymology of the name, the distribution in the British Islands, and the general distribution. A long appendix is devoted to the birds which have been excluded because the evidence of their occurrence is not regarded by the committee as entirely satisfactory. Two others deal with questions of nomenclature. The members of the committee deserve the thanks of all ornithologists for the effectiveness with which they have done their work, which must have made heavy demands on their time and afforded abundant exercise for their judgment.

NOTES.

We learn with much regret of the sudden death on March 23, through heart-failure, of Prof. Otto N. Witt, professor of chemical technology in the Technical High School at Charlottenburg.

Dr. F. Taylor, consulting physician to Guy's Hospital, has been elected president of the Royal College of Physicians in succession to Sir Thomas Barlow.

The fifth annual award of the Willard Gibbs Medal, founded by Mr. W. A. Converse, of Chicago, has been made, says *Science*, to Prof. A. A. Noyes, director of the research laboratory of physical chemistry, Massachusetts Institute of Technology.

A strong after-shock of the Avezzano earthquake of January 13 was felt in Rome on April 5, at 7.20 a.m. (6.20 G.M.T.). According to a report issued by the geodynamic observatory at Rome, the epicentre of the after-shock appears to have been close to Avezzano.

The American Philosophical Society will meet at Philadelphia on April 22–24 for the reading and discussion of papers. The programme includes papers on many subjects of recent research in physical and natural science, and also a symposium on the earth: its figure, dimensions, and the constitution of its interior.

Dr. J. Scott Keltie, who has been secretary of the Royal Geographical Society since 1892, vacated that office at the end of last month, and has been succeeded by Mr. A. R. Hinks, who has been assistant secretary of the society since 1913. Dr. Keltie will not, however, entirely sever his official connection with the society, for he has undertaken to act with Mr. Hinks as joint-editor of the *Geographical Journal* for the next two years.

It is announced in the issue of *Science* for March 12 that Col. George W. Goethals has been promoted to be a major-general of the line in recognition of his services in the construction of the Panama Canal. Brig.-Gen. William C. Gorgas, surgeon-general, has been promoted to be major-general in the medical department. Col. H. F. Hodges and Lieut.-Col. W. L. Sibert, U.S. Corps of Engineers, have been promoted to be brigadier-generals. The Bill authorising these promotions extends the thanks of Congress to the officers mentioned.

We regret to see the announcement of the death on Sunday, April 4, at fifty-eight years of age, of Dr. H. Lewis Jones, medical officer in charge of the electrical department at St. Bartholomew's Hospital, and a leading authority upon electro-therapeutics. Dr. Jones was president in 1903–4 of the British Electro-Therapeutic Society, and acted as official delegate for the British Government to the International Congress of Physiotherapy at Liège in 1905, and also at Paris in 1910. He was the author of "Medical Electricity," and of numerous papers on the principles of ionic medication and related subjects.

The desirability of excluding cotton from Germany and Austria has been urged upon the Government by a number of men of science. At a conference on March 10 a letter was drawn up and sent to Lord Moulton at the High Explosives Department of the War Office, pointing out that Germany is entirely dependent on her imports of unspun cotton for the manufacture of propulsive explosives, and asking whether a complete embargo on cotton destined to Germany and Austria by any channel had been declared and would be exercised. Among the signatories to the letter were Sir William Ramsay, Prof. Clowes, Sir Alex. R. Binnie, Prof. H. Jackson, Mr. B. Blount, Prof. Meldola, and Prof. W. J. Pope. Lord Moulton replied on March 19 to the effect that the Order in Council of March 11 would, he thought, satisfy the signatories, who, however, on March 22 pointed out that the Order in Council would become effective only if cotton were made contraband of war. Further correspondence has taken place, and the signatories have had an interview with the Board of Trade, but they appear to have been unable to obtain the assurance they desire for the prevention of the importation of cotton by Germany.

The present shortage in this country of synthetic yellow dyes has put difficulties in the way of manufacturers of khaki cloth. A temporary way out of the difficulty was found, however, by the increased use of fustic, a natural yellow dye-stuff, consisting of the wood of a tree (*Chlorophora tinctoria*) which grows freely in Jamaica and also in British Honduras. When the shortage of yellow dye-stuffs first became apparent the Imperial Institute took steps to place British dye firms in touch with exporters of fustic in Jamaica. Only a moderate amount of cut fustic wood was, as it happened, then available in the island, but, as a result of the institute's action the Government of Jamaica has offered to purchase from the growers further supplies, and carry these at Government cost to Kingston, the port of shipment. Negotiations are accordingly now pending for the purchase and shipment of considerable quantities of Jamaica fustic by dyers in this country. The Government of British Honduras is also taking action in this matter, and a further supply of the wood may possibly be forthcoming from that Colony. Further information may be obtained on application to the Imperial Institute, South Kensington, London, S.W.

By the death of Mr. J. J. Beringer on March 28, Cornwall has lost an indefatigable worker whose investigations in the science of mining and metallurgy made him one of her most prominent and interesting personalities. A personal friend, W. H. T.-J., sends us the following particulars of his career and work. Born at Penzance, Cornwall, in 1857, Mr. Beringer was educated at Redruth. In 1877 he won a Royal Exhibition, and took the course of the Royal School of Mines in London. In 1880 he passed his examinations with distinction, and secured his diploma A.R.S.M. In 1881 he became assistant in the chemistry and assaying department to Prof. Huntingdon at King's College, where his work was very highly appreciated. From 1882 to 1891 he was lecturer to the Miners' Association, also public analyst for the county of Cornwall. From 1882 down to the date of his death, he was principal of the County School of Metalliferous Mining, Camborne, of which he also was made a governor, and it is mainly in that position that he distinguished himself as a lecturer of remarkable ability on mining and metallurgical subjects, not only by his erudition, but also by his sympathetic hold on his students. He was the author of a text-book on assaying, which has gone through some ten or more editions, and remains to-day the standard text-book in Great Britain, and may be said to be used in nearly all schools of mines throughout the world. The Institution of Mining and Metallurgy, in recognition of the distinguished services he had rendered to the science and industry of metallurgy, bestowed upon him the honorary membership of the institution. His death was partly due to weakness induced by severe and continuous overwork, and especially by the loss of vision in one eye due to his close application to microscopic and ultra-microscopic work. His loss will long be keenly felt, especially in Cornwall, by a large circle of personal friends, including the many students who passed through his hands.

In the University of Pennsylvania's Anthropological Publications, vol. iv., No. 2, Mr. M. R. Harrington describes a remarkable collection of the sacred bundles of the Sac and Fox Indians collected by the expedition maintained by Mr. G. G. Heye. These bundles, containing many heterogeneous articles, are held in the highest veneration, and in many cases the religious observances of the tribe centre round them. The concepts underlying their use are often obscure, but the idea at the basis is that they are endowed with some supernatural power or *mana,* which directly influences the phenomena of life in the interest of their owner. The bundles are supposed to possess a consciousness of their own, to understand what is said to them, and to enjoy offerings presented to them. Some are used in religion, some in war, while others are of a private nature, and bring success in hunting or in love, heal the sick, promote health, bring luck in sports, gambling, or are used in witchcraft. Some belong to shamans, others are in private hands. A full catalogue with photographs fully illustrates this interesting collection.

IT is generally held that the presence of *B. coli* in pasteurised milk indicates either that the milk has not been properly heated, or that it has been subsequently reinfected by careless handling. In the *Journal of Agricultural Research* for February, S. H. Ayres and W. T. Johnson, jr., describe experiments which suggest that this conclusion may not always be justified. From an examination of pasteurised milk supplied by twenty-four dairies in Amsterdam, Ringeling declared that nearly half of them did not pasteurise or handle the milk properly, since he found *B. coli* in the samples received from ten of the dairies. In recent years many investigators have found that cultures of *B. coli* were easily destroyed at temperatures below 60° C., which is the lowest pasteurising temperature, but certain strains required heating for 30 mins. at 70° in order to destroy them. The authors have studied the thermal death-point of 174 cultures of typical colon bacilli, isolated chiefly from cow fæces, as well as from milk, cream, flies, human fæces, and cheese. These cultures were heated in milk at temperatures ranging from 52° C. to 68° C. for 30 mins. At 63° C., the usual temperature of pasteurisation, 6·9 per cent. of the cultures survived, but only one culture (0·6 per cent.) survived heating to 66° C. Repeated heatings of the cultures that survived the normal pasteurising process showed that 63° C. is a critical temperature for the comparatively few resistant strains, which are able to survive the original heating by the resistance of a few organisms only. If milk is pasteurised at 66° C. or above for 30 mins., the authors expect from their results that no colon bacillus would survive. Consequently under such conditions the *B. coli* test for the efficiency of pasteurisation may be of value. It is, however, possible that a study of a larger number of cultures would show that some strains may survive even higher temperatures.

VOL. xi., part 1, of Records of the Indian Museum contains articles on boring-sponges of the family Clionidæ, by Dr. N. Annandale, on hermit-crabs from the Chilka Lake, by Mr. J. R. Henderson, and on some South Indian frogs, by Mr. C. R. N. Rao, as well as two others. Of five species of hermit-crabs only one is described as new.

THE beauty and delicacy of execution of the two plates (reproduced from photographs) form a striking feature of a memoir by Mr. S. Yehara on Cretaceous trigonias from Miyako and Hokkaido, published as vol. ii., No. 2, of Science Reports of Tohoku Imperial University, Sendai, Japan, series 2 (Geology). The beautiful preservation of the specimens themselves is likewise noteworthy.

IN the *American Naturalist* for March Mr. R. R. Hyde describes a fly of the species *Drosophila confusa*, reared by himself, which differed from the normal form by the curvature of the wings. In the new form the wings curve upwards at an angle of about 45° from the end of the abdomen, and thus somewhat resemble rose-petals, instead of projecting horizontally over and above the abdomen, as in the wild form. Unfortunately, all the members of the new stock died during the hot weather of the summer of 1914.

THE problem of utilising museum collections for the use of children seems to have been satisfactorily solved by the authorities of the Museums of the Brooklyn Institute of Arts and Sciences, whose report for 1913, unusually belated, has just reached us. The museum for children has been brought into close relation with the city schools, the majority of visitors being under fourteen years of age. Well-arranged series are adapted for purposes of instruction, and the library serves the threefold purpose of supplying children with books and magazines relating to their studies, their clubs, and their hobbies. The total attendance was nearly 48,000, and about 2300 parents and other adults attended, some with their children, others desiring help in choosing children's books, while others who began coming in their early days continue their visits. Teachers are encouraged to inspect the collections under the guidance of experienced instructors. The scheme seems to be well organised, and an examination of it may be useful to school authorities in this country.

THE uncertainty that prevails with regard to the correct zoological names of many of the commonest or most familiar animals is a source of great confusion, especially to those who make use of such names without being themselves experts in the study of the particular class of animals dealt with. It is, for instance, extraordinarily perplexing for a medical practitioner or student to see common human parasites appearing under different names in different books, or the same name applied to quite distinct species by different authorities. The efforts, therefore, that are being made by the International Commission on Zoological Nomenclature to fix the names of animals in cases where the matter is in dispute, will be welcomed by all who require to make use of the names. The latest "Opinion" (No. 66) issued by the Commission deals with certain genera of Nematodes and Gordiacea, including the round-worms parasitic in man, namely, *Ancylostoma* (type *duodenale*), *Ascaris* (type *lumbricoides*), *Dracunculus* (type *medinensis*), *Gnathostoma* (type *spinigerum*), *Necator* (type *americanus*), *Strongyloides* (type *intestinalis = stercoralis*), *Trichostrongylus* (type *retortaeformis*), *Gordius* (type *aquaticus*), and *Paragordius* (type *varius*). The first of these genera, of which the type is the "Old World Hook-worm," notorious as the cause of miner's anæmia, has hitherto appeared under about a dozen different spellings, including even such barbarous forms as "Agchylostoma"; it is to be hoped that in the future uniformity in this respect will be maintained.

IN Records of the Botanical Survey of India, vol. vi., No. 5, an account is given by Mr. M. S. Ramaswami of a botanical tour in the Tinnevelley Hills.

A good map is included showing the author's route. Of the 470 species collected, thirty-three, or about 7 per cent. of the whole, are endemic to the region, 2 per cent. are purely Ceylon species, and 10 per cent. are peculiar to the South Indian peninsula. Leguminosæ, with fifty-five species, and Rubiaceæ, with thirty-eight, are the most extensively represented natural orders. One new species, *Senecio calcadensis*—a composite—is described and figured.

The Missouri Botanical Garden completes its first volume with several interesting papers. Mr. E. A. Burt contributes a third paper on the Thelephoraceæ of North America, and details twenty-one species of Cyphella. Mr. R. R. Gates publishes an account on some Œnotheras from Cheshire and Lancashire, with three well-executed plates. The work represents the results of cultivation and hybridisation both at the Missouri Botanical Garden and the John Innes Institution at Merton, and details of the new forms, both mutants and hybrids, are given. In the same part Messrs. Greenman and Thompson describe and illustrate new species of flowering plants from the south-western United States and Mexico.

The first number of the *Kew Bulletin* for 1915 is mainly occupied by a paper on the semi-parasitic genus Thesium in South Africa, which is illustrated by two plates showing the different types of floral morphology. The genus which exhibits its maximum development in South Africa has been studied in connection with the preparation of the "Flora Capensis." Some 128 species are found to be represented at the Cape, belonging to four well-marked floral types or sections. Two of these, the sections Penicillata, in which the tuft of hairs behind the anther remains free and not attached to the anther, and Annulata, where a ring of hairs at the throat of the perianth replaces the tufts of hairs behind the anthers, are peculiar to the Cape region. A fresh description of the genus is given, a key to all the South African species, and fifty-two diagnoses of new species are published by Mr. A. W. Hill. The distribution of the genus is remarkable. The majority of species are African, but several are spread over Europe and temperate Asia, while two occur in Brazil and one in Australia.

The permanence of the aroma of hops of a particular variety when grown in another locality has long been a vexed question. Mr. Johs. Schmidt has been carrying out investigations at Carlsberg, and has satisfactorily proved that if pure lines of hops with the "Saaz" aroma from Bohemia, or Oregon cluster hops, with the distinctive and peculiar "American" aroma, are grown in Denmark, they do not lose their characteristic qualities. The experiment of cross-fertilising these varieties with pollen of wild Danish hops has also been made, and it was found that a proportion of $\frac{3}{4}$–$\frac{1}{2}$ the offspring exhibited the characteristic aromas of the female parents, though the plants carrying the aroma did not necessarily retain the external appearance peculiar to the mother plant. These latter results are similar to those recently published by Mr. E. S. Salmon from crossing female Oregon cluster by English male plants. The series of experiments suggest an interesting line of Mendelian research. Mr. Schmidt's paper appears in *Comptes rendus des travaux du Laboratoire de Carlsberg* (11me volume, 3me livraison, 1915).

Prof. A. P. Brigham's presidential address to the Association of American Geographers, delivered at the meeting in Chicago at the end of last year, is published in *Science* of February 19. Broadly speaking, his theme was that the geographer's "goal is broad generalisation. But the formulation of general laws is difficult and the results insecure until we have a body of concrete and detailed observations." Prof. Brigham's geographical keynote is environment, and certainly in this study the generalisations which have hitherto preceded detailed observations have presented many pitfalls. Prof. Brigham's address was full of suggestions for detailed research in various fields. In an early paragraph he referred to the symposium on the trend of modern geography conducted by G. B. Roorbach, and published in the Bulletin of the American Geographical Society for November, 1914. This marshalling of the views of some thirty geographers, mainly American, but some British, pointed to the same conclusion. It perhaps gave unfair weight to a particular aspect of geographical opinion, inasmuch as fully two-thirds of those whose views were given were professors or other teachers, and the mathematical and cartographical department of the subject received rather scanty treatment. This apart, however, most of them expressed their ideas of the functions of geography in a variety of carefully worded formulæ all of much the same meaning. In indicating fields of research, they were less successful than Prof. Brigham, and some suggestions (in the direction of climatology, for instance) travelled well outside the geographical scope.

Dr. Bruce and Dr. Rudmose Brown gave an account to the Royal Geographical Society on March 22 of Dr. Bruce's expedition to Spitsbergen in 1914. Its object was to investigate Stor Fiord, the great bay to the south-east of Spitsbergen. Difficulties due to the war seriously interfered with their plans, and most of the time was spent in geological work on Prince Charles Foreland, the island off the western coast of Spitsbergen. Most of the paper was devoted to a discussion of the ownership of Spitsbergen. The authors of the papers claimed that the archipelago should be British in virtue of prior claim. After the abandonment of the whaling fishery, the country was long left derelict, but during the last forty years claims for its possession have been advanced by Russia, Norway, and Sweden. In 1909 the United States suggested the establishment of an American protectorate. In 1912 a conference between Norway, Sweden, and Russia agreed that Spitsbergen should remain neutral territory and be jointly administered by those three Powers. Drs. Bruce and Brown maintain that this agreement would deprive Britain of any voice in the future of Spitsbergen, despite her right of ownership due to annexation, exploration, and preponderating commercial interests They represent this agreement as a practical surrender of Spitsbergen to Russia, which they insist has practically no claim to the country. In the development of the coal-mining the American interests are important though localised, and are of less value than the British. The authors urge that in consequence of the growing commercial development of Spitsbergen some definite government must be established, and they claim that many of those interested in the country consider its interests would be best served by the establishment of a British protectorate.

A Society of Vulcanology has recently been founded in connection with the University of Catania. The objects of the society are to collect accounts and photographs of the volcanic phenomena of Etna and Sicily and specimens of the materials ejected, and to encourage generally the study of vulcanology. We have received the first four numbers of the *Pubblicazioni* issued by the society. They include papers by Prof. G. Platania on the recent eruptions of Etna and on a proposal for the international organisation for the study of volcanoes.

The well-known Vesuvian Observatory was built in 1841. Its first director, the physicist Melloni, was removed shortly after taking office, on account of his action in political movements. The observatory then remained closed until 1852, when Palmieri obtained permission to make use of it for his own investigations. Four years later he was appointed director by the Neapolitan Government, though regular observations only became possible when he was provided with an assistant at the close of 1863. Four of the six papers which appear in the last five numbers of the *Bollettino* of the Italian Seismological Society relate to Vesuvian phenomena and to work done in the observatory since the latter date (vol. xviii., pp. 87–338). Mr. A. Malladra studies the rainfall of Vesuvius during the fifty years 1863–1913, and the effects of volcanic gases on vegetation. He also describes the seismographs and seismoscopes in the observatory and various chambers in the neighbourhood. Some of these are of modern Italian construction and are capable of recording strong earthquakes in all parts of the world. An important paper is that by Mr. C. Cappello on the variations in the altitude of Vesuvius from 1631 to 1906, and in the outline of the mountain in the years 1911 to 1914. After the eruption of 1906, the greatest height of the crater rim was 4013 ft. on the west-south-west side, the least 3619 ft. on the opposite side, and the greatest diameter of the crater about 2395 ft.

A plot of ground covering seventy-five acres, which includes the remarkable Green Lake near Jamesville, N.Y., with its series of abandoned cataracts, rock channels, and dry plunge-basins, has been given to the New York State Museum by Mrs. Mary Clark Thompson, of New York, and presented in the name of her father, Myron H. Clark, a former governor of that State, and by her desire it is to be known as the "Clark Reservation." The significance of the conformation of the new reservation has, says Dr. J. M. Clarke, in *Science*, been worked out by Prof. Fairchild and Mr. E. C. Quereau. In the course of Prof. Fairchild's work upon the Pleistocene geology of New York State, he demonstrated the accuracy of Mr. Quereau's suggestion that in the retreat of the ice mantle the outflow of the glacial waters was by way of great rivers moving eastward into the Mohawk-Hudson drainage, and in the Green Lake one of these streams cut its rock gorge in the limestones of the Helderberg escarpment and left a series of plunge-basins beneath great cataracts which surpassed the dimensions, as they must have equalled the dignity and grandeur, of Niagara. The lake is surrounded on all but its eastern side by an amphitheatre of sheer limestone cliffs rising to a height of nearly 200 ft., and the depth of the lake is stated to be not less than 100 ft. Water of a deep emerald hue still fills this ancient plunge-basin, without visible outlet or inlet.

A valuable investigation of the "Absorption, Reflection, and Dispersion Constants of Quartz" has been carried out by Mr. W. W. Coblentz, and published as Bulletin No. 237 of the Washington Bureau of Standards. Unlike fluorite, quartz shows a marked absorption in the infra-red at 2μ, and becomes practically opaque beyond 3μ; but from $0{\cdot}25\mu$ in the ultra-violet to $1{\cdot}7\mu$ in the infra-red it is almost perfectly transparent in thicknesses up to 3 cm. Thus, after allowing for losses by reflection at the interface between quartz and air, the transmission is actually found to be 100 per cent., if an allowance of 2 parts per 1000 is made for experimental error. The absorption does not appear to be affected by the direction in which the radiations pass relatively to the optic axis of the quartz.

In the Annals of the Association of American Geographers, vol. iv., Prof. de Courcy Ward gives an excellent account of the general features of American weather regarded from the point of view of climate. Although climate is usually defined as the average of weather, the irregularities of weather, the variations from day to day, are in some respects more significant than averages: in addition to averages, we require frequencies and rates of change to get even an approximately true representation of climate. Prof. Ward shows how in winter the controlling factor in America is the non-periodic variation arising from the passage of cyclones and anti-cyclones: the storm control, he calls it expressively. In summer, on the other hand, the non-periodic variations are less dominant than the regular diurnal changes: storm-control is subordinate to solar-control. The paper is illustrated by diagrams showing the different paths of cyclones and anticyclones and the changes in the weather as the cyclones and anticyclones cross the country. The distribution about the cyclonic centres is illustrated for different seasons, and the changes which take place at a fixed spot as the cyclones pass over it are shown by reproducing curves from self-recording instruments.

The February number of the Journal of the Royal Microscopical Society contains a paper which Mr. J. E. Barnard read before the society in December last on the possibility of utilising Röntgen rays in microscopic work. In his experiments the author has used the soft rays from a tube provided with a lithium glass window. The rays can only pass out of the lead chamber in which the tube is enclosed through a series of fine holes in lead screens in line with each other, and in consequence they strike the photographic plate as a parallel beam. The object to be photographed is placed in contact with the plate, which is enclosed in a light tight box. Plates with thin gelatine films and very fine grain must be used. The time of exposure depends on the thickness and opacity of the object, and the author prefers to use the harder rays from the tube as the opacity increases. The resulting photographs are the same size as the object, and must be enlarged by the usual photographic method. Six reproductions of photographs showing the internal structure of microscopic objects are given in the paper.

The *Rendiconti* of the Italian Chemical Society (vol. vii., pp. 173–222) has an interesting discussion of the relationship existing between Mendel's principles of heredity and the atomic theory by Prof. C. Vulpiani. A brief survey is given of the recent developments of our views as to the atomic and molecular state, and an attempt is made to show that the natural basis of the hereditary elements which are transmitted according to Mendelian laws is to be found in the molecular or atomic groupings present within the cells, and of which the chromosomes are only the outward visible manifestation. The author very justly emphasises how the Mendelian laws of heredity have led to a more general recognition of the complexity of cell protoplasm. The view that each hereditary element corresponds with some material factor in the ultramicroscopic or molecular structure of the contents of the reproductive cells will undoubtedly lead to more correct conceptions being formed as to the nature of cell protoplasm than those which have in the past been current among biologists.

A paper on the processes of manufacture of wrought iron and steel tubes was read by Mr. J. G. Stewart at the Institution of Engineers and Shipbuilders in Scotland on February 16. The author states that it is very rarely that potable waters are found to have any appreciable corrosive effect on steel pipes, and quotes several instances of pipes which have been in service many years with very little deterioration. The principal fear is for the outside of the pipes. Most natural ground, especially clay, is not only innocuous, but is actually a permanent protection to steel pipes from corrosion. In some cases where the pipes are laid through artificially made, or alluvial ground, external protection is desirable. The want has been met by dipping the pipes in a hot bath of Dr. Angus Smith's or other bituminous solution, and in cases where the ground contains an excessive amount of salts and acids which cause corrosion, the additional precaution is taken of wrapping the pipes in coarse jute Hessian cloth saturated with the hot solution, winding it spirally on the already coated pipe.

The March number of the Journal of the Franklin Institute contains a paper on paints to prevent electrolysis in concrete structures, by Mr. H. A. Gardner, assistant director of the Washington Institute of Industrial Research. An extensive series of experiments on iron rods of 1/2 or 3/4 in. diameter embedded in concrete cylinders 1 ft. long has been carried out by the author to determine what type of paint was most effective. The rods were thoroughly cleaned, and two coats of the paint applied, each being allowed a week to dry. They were then embedded in the concrete, which was aged for a month before the test was commenced. Each cylinder was then immersed in water, and a potential difference of 30 to 100 volts applied for 10 days between two rods in each cylinder, or between one rod and an outside electrode, the current transmitted being observed. In all cases in which an appreciable current passed, the concrete cracked round the anode. The uncracked cylinders were tested for the strength of the bonding between the iron and the concrete. The author concludes that the paint should be prepared from boiled or bodied oils which dry by polymerisation rather than oxidation, that the pigments should be insulators and should give a rough surface, and that the paint should have fine sand scattered over it before it is quite dry.

We are asked by the proprietors of the Mallock-Armstrong ear defender described in last week's Nature (p. 131) to say that since January 1 of this year all the defenders sold have been of an improved pattern, furnished with gold-plated gauze wire to resist corrosive effects—such as those of sea air—and generally are more expensive to make than those first put on the market. Accordingly the price is now 4*s.* the pair, instead of 3*s.*, as stated in our notice.

OUR ASTRONOMICAL COLUMN.

Comet 1915*a* (Mellish).—The following is a continuation of the ephemeris given last week:—

	R.A. (true) h. m. s.	Dec. (true) ° ′	Mag.
April 10	18 14 8	−3 6·8	8·1
12	16 21	3 32·3	
14	18 32	3 59·7	8·0
16	20 42	4 29·3	
18	18 22 51	−5 1·3	7·8

The comet is situated a little to the east of η Serpentis.

Measures of Saturn.—From December, 1913, to March, 1914, Prof. Percival Lowell made a series of measures of the ball, rings, and satellites of Saturn with the 24-in. of the Lowell Observatory. They were taken, as he states, "with an eye to the irradiation," and the measures have been deduced to what is commonly taken as the mean distance. These are now presented by the author in a communication to the Lowell Observatory Bulletin No. 66 (vol. ii., No. 16). The diameter of the ball as determined from direct measures, measures of satellites, and measures of B ring is first given, followed by measures of the radius of the ball, breadths of B and A rings, and width of Cassini's division. All these are summed up in a table giving the means of the measures for mean distance, followed by a table of the direct measures of the diameter of Titan.

Stars with Variable Radial Velocities.—Several communications are contained in No. 267 of the Lick Observatory Bulletin. The first, by Mr. R. E. Wilson, gives the details of fourteen stars which have recently been found to have variable radial velocities, from plates taken by the D. O. Mills expedition to the southern hemisphere. The same author deduces the orbit of the spectroscopic binary ν Centauri, giving the period as 137·939 days. This star is one of a group of Class B binaries, which have periods of about 130 days. Mr. R. F. Sanford describes his investigation of the orbit of the spectroscopic binary ϵ Volantis, a star of magnitude 4·5 and of Class B5. The new elements show a period of 14·16833 days. A note by the same author on two spectrograms of the interesting irregular variable η Carinæ indicates that the observations of 1913 and 1914 show no evidence of variation in radial velocity.

SOLAR RADIATION MEASURES IN EGYPT.—Bulletin No. 14 of the Helwân Observatory contains an account of some observations of solar radiation which have been carried out at the Helwân Observatory by Mr. Eckersley. It has been shown by Prof. Abbot that values of the "solar constant" vary from day to day, and that even at two stations as far apart as Mount Wilson (California) and Bassour (Algeria) there is a very well-marked correspondence between the values derived at these stations, so that the action of local atmospheric effects is not the cause of the fluctuations. Prof. Abbot considers the outstanding variation to be due to a real fluctuation of the solar constant. In order to investigate this question further, it was decided to make an extended series of observations at Helwân, and this was commenced at the beginning of last year. The account of these measures is given in this paper. For the statistical purpose of comparing the results obtained with those at Mount Wilson, the highest precision of individual observations is not required, but an extended series of measurements uniformly treated is of the greatest value. For this reason pyrheliometer measures of the total energy alone were made. The communication describes the method employed, the reduction of observations, and the results secured. While the value of the radiation derived from the Smithsonian Institution observations at Mount Wilson is 1·932 (mean value of 696 observations taken at Washington, Mount Wilson, and Bassour during the period 1902–1912), the Helwân mean value derived is 1·782. The latter value is considerably less than the Smithsonian mean value, and the cause of the difference is dealt with by the author in subsequent paragraphs. Finally, evidence for the fluctuation during the period of observation is dealt with, and it is concluded that while some of the deviations are probably due to real fluctuation, no conclusive decision can be reached until the Mount Wilson results can be compared.

THE BRILLIANT FIREBALL OF SUNDAY, MARCH 28.

BETWEEN March 21 and 29 eight large meteors were observed, but by far the most brilliant object among them was that of March 28, 7.47½ p.m. Its flight was witnessed by many hundreds of persons from the southern parts of England, as well as from the English Channel, France, and Belgium.

As viewed from London, the meteor sailed slowly along a few degrees under the stars Sirius and Rigel, and further westwards to possibly beyond γ Eridani. Mr. H. P. Hollis saw the meteor from a place about three miles due east of the Royal Observatory, and estimated its duration of flight as between five and six seconds. He did not see the beginning, and it was difficult to trace the exact point of extinction owing to trees behind which the object passed.

Mr. G. P. B. Hallowes was in his observatory at East Howes, Bournemouth, with an astronomical friend, Mr. C. Gregory, when the meteor burst out in the southern sky. It moved from the region of α Hydræ to near Rigel at about the place of ν Leporis. It passed a little above Sirius. Brilliancy far exceeded Venus, and its duration was from three to four seconds. A trail 5° or 6° long followed the nucleus, and the latter burst into fragments at the end. The front of the head was yellow, the rear part red. Diameter, about 15′, or half that of the moon.

Mr. A. King saw the meteor from Scunthrope, Lincolnshire, and from this northerly position its apparent path was very low, being from about $117° - 31°$ to $98° - 32°$. The brightness was estimated equal to Sirius, the colour yellow-green, and duration 7½ seconds.

Mr. H. Rollason, of Montgomery, Wales, states that the meteor flamed out on the western sky, moving from S.E. to N.W., bursting twice, and enduring altogether five to six seconds. Many other observations have been received or published in the daily papers. As usual, there are discordances, but it is not difficult to derive a real path fairly consistent with the data.

The radiant point is indicated at $192° + 4°$, or possibly $220° + 14°$, low in the eastern region of the sky. The height of the object was from about 71 to 23 miles along a path of 175 miles from over the neighbourhood of Vire in France to the English Channel, about 60 miles south of Eddystone. Velocity, 24 miles per second. The meteor seems to have been directed from a radiant comparatively unknown in March, but in April, contemporary with the Lyrids, there is a rich shower of slow and brilliant meteors from $200° + 8°$ near *o* Virginis.

The recent fireball must have passed almost vertically over Jersey, and from the Channel Islands and western parts of France it created a splendidly luminous effect. As viewed from Bournemouth the apparent size of the pear-shaped head of the meteor was considered to equal half the moon's diameter, which, from the distance of the object, would imply a magnitude of nearly two-thirds of a mile. This must have enormously exceeded the actual dimensions of the stony, or metallic, material composing the meteor. When undergoing combustion, the flame and expanding gaseous vapours from meteors give a vastly exaggerated idea of their real size. It must be very rare that a fireball exceeds one or two feet in the diameter of its material.

I have ascribed a flight of 175 miles to the recent fireball, but it may have been much longer than that. Many of the observers did not detect the object until it had developed considerable brilliancy. The moon was nearing the full at the time of its appearance, but the meteoric visitor startled some of the spectators with its astonishing lustre. W. F. DENNING.

THE INSTITUTE OF METALS.

VOLUME XII. of the Journal of the Institute of Metals, representing the work of the Institute during the second half of 1914, has just appeared. This is one of the first volumes of proceedings to appear since the outbreak of the war, and it indicates that the Institute of Metals has been able to pursue its activities, except for the fact that the autumn meeting which was to have taken place at Portsmouth early in September had to be abandoned. An interesting series of papers, however, are fully discussed by correspondence in the Journal. One of the most interesting from the scientific point of view is the paper by Mr. O. F. Hudson on the critical point at 460° C. in zinc-copper alloys. Mr.

Hudson brings forward evidence, which appears to be quite conclusive, that the interpretation of this point as marking the decomposition of the β phase of brass into $\alpha+\gamma$, which has been elaborated by Prof. Carpenter in a series of papers, is erroneous, and that the β phase merely undergoes a polymorphic change from β to β_1. A striking method of proof adopted by Mr. Hudson is that of preparing a series of alloys in a single piece of metal by the method of superposition. By superposing molten zinc on a layer of solid copper, the alloys can be formed at a temperature below 460° C., and yet a phase which corresponds to β makes its appearance. If what Carpenter has called "apparent β" were really unstable below 460° C., it could never be produced synthetically below that temperature.

Equally interesting from another point of view is the paper, and resulting discussion, by Mr. Arnold Philip dealing with the causes of corrosion in condenser tubes. In the recent Report to the Corrosion Committee of the Institute of Metals, Dr. Bengough and Mr. Jones had been led to reject entirely the view that particles of foreign matter, such as coke, which might set up local electrolytic effects, could thereby accelerate local corrosion and produce "pitting." Mr. Philip traverses this conclusion, and suggests that it was reached on insufficient evidence, while he adduces positive evidence to show that particles of coke can cause local pitting. While such divergence of views among those studying these matters is somewhat unfortunate from the point of view of the practical man seeking guidance for his practice, it serves to show the great need which exists for the further exhaustive investigation of such fundamental questions, and at the same time demonstrates the useful work of the Institute of Metals in encouraging such work and providing a meeting ground for full and—fortunately—dispassionate discussion.

Further papers of special scientific interest are those by Mr. S. W. Smith on the surface tension of molten metals, by Mr. Phelps on the effect of hydrogen on the annealing of gold, and by Messrs. Bengough and Hanson on the tensile properties of copper at high temperatures. In a "Note" Prof. Huntington also deals with the tensile properties of metals at high temperatures, but while Bengough and Hanson find in their results strong support for the theory that the crystals of a metal are held together by something of the nature of an amorphous cement, Huntington urges somewhat vague objections to that view.

Another "Note," contributed by Prof. Carpenter, deals with "The Extraction of Native Cooper at Calumet, Lake Superior"; while in itself not uninteresting, it is difficult to understand why this note has been included in the Journal of the Institute of Metals, since it deals with a subject outside the scope of its work and coming well within that of the Institution of Mining and Metallurgy. Although unimportant in itself, such a departure from accepted limitations causes confusion when references have to be looked up.

RECENT WORK ON INVERTEBRATES.

THE journal of a college of agriculture is about the last kind of periodical in which we should expect to find descriptions of deep-sea cephalopods. Nevertheless, three out of the four articles constituting the contents of the seventh number of vol. iv. of the Journal of the College of Agriculture, Imperial University of Tokyo, are devoted to new and rare species of squids, the remaining communication dealing with the eels of the Japanese, Corean, and Formosan seas. In the first of the three articles on squids, all of which are very fully illustrated, Mr. C. Ishikawa describes a new species of the genus Enoploteuthis from the Japan Sea, while in the second Messrs. Ishikawa and Wakiya treat of a number of fragments of a gigantic species taken from the stomach of a sperm-whale. The latter is identified with *Moroteuthis robusta,* of which it forms the fifth known example; in the third article the last-named writers describe a new species of the same genus under the name of *M. loennbergi.*

In an article, illustrated by one coloured and four black-and-white plates, in the February number of the *Entomologist's Monthly Magazine,* Dr. T. A. Chapman describes the larva of the butterfly *Everes argiades,* with figures, not only of the entire caterpillar, but also magnified representations of the shed skins at various stages of development. In the same issue Dr. D. Sharp continues his account of the beetles of the group Holophorini, dealing in this instance with the structure in the genital tube known as the ædeagus, which, as exemplified in *Meghelophorus aquaticus,* is described in great detail.

Aberrant modes of reproduction in certain well-known insects, such as the blue oil-beetle, the parasitic genus Stylops, and the vine-phylloxera, form the subject of an illustrated article by Mr. W. M. Scheyen in the January number of *Naturen.* A continuation is promised.

Writing in the January number of the *Zoologist* of non-sexual reproduction in sea-anemones, as observed at the Millport Marine Biological Station, Mr. R. Elmhirst remarks that although division is usually completed in a few days or weeks, especially among the members of the genus Anthea, yet that he has seen instances in which "double" individuals of Actinoloba showed no change during a period of several months. He also records a case in which an Actinia with two complete discs, mouths, and rings of tentacles retained the same form for close on four years in an aquarium. Possibly, of course, the somewhat unnatural conditions in such an environment may be a factor in these cases.

In *Spolia Zeylanica,* vol. x., part 36, Mr. A. Rutherford mentions that the females of a "glow-worm" (*Dioptoma adamsi*), in addition to the usual terminal light, have a number of other luminous points, apparently arranged in ten transverse rows. Somewhat similarly situated points of light also occur in the smaller males.

In the February number of the *Irish Naturalist* Mr. A. W. Stelfox gives a list of land and fresh-water molluscs from the Dingle Promontory, Kerry. Seventy-four indigenous species are recognised.

R. L.

MINERAL STATISTICS.[1]

PROBABLY the first point that will strike the student of mineral statistics when he sees the report now before us is the extreme dilatoriness of our Home Office. This report, which covers the mineral statistics of the world up to the end of 1912, was not published until the end of 1914; the Chief Inspector endeavours to excuse this delay by a reference to the lateness of the publication of official foreign statistics, but it is a significant fact that a private firm in the United States of America issued a large volume covering the world's mineral statistics for 1913 in July last, so that our own official production is no fewer than eighteen months behindhand. Statistics of mineral production are practically valueless unless they are published promptly, and all the

1 "Mines and Quarries. General Report with Statistics for 1912." By the Chief Inspector of Mines. Part iv., Colonial and Foreign Statistics.

information under this head afforded by the present publication has been common knowledge amongst all those interested for so long that it no longer presents any features capable of attracting attention.

The most interesting portion of the present report is accordingly that portion that deals with the labour employed in the world's mineral industry. It is shown that the number of persons engaged in this industry exceeded 6½ millions, more than one-third of whom were employed in the British Empire. It is interesting to note that more than one-half of this number was employed in coal mining, and as coal mining in different countries is more readily comparable than any other class of mining, because the conditions under which it is carried on present closer points of agreement, it may be profitable to compare briefly the labour statistics. Out of a total production of 1,250,000,000 metric tons of coal in the whole world, Great Britain alone produces 264,600,000 tons and the whole British Empire 314,500,000 tons, or about a quarter of the whole output. The other large producers are the United States with 484,900,000 metric tons; the German Empire, 255,800,000; Austria-Hungary, 51,700,000; France, 41,100,000; Russia, 31,300,000; Belgium, 23,000,000; and Japan, 19,700,000. It is curious to note that, with the exception of the United States, this list includes all the important nations engaged in the present war. The producing capacity of the miners engaged in this industry in metric tons per worker per annum is shown in the following table :—

Great Britain	230	United States	671
Australia	535	German Empire	272
Canada	486	Austria	307
India	129	France	307
New Zealand	511	Russia	142
South Africa	347	Belgium	157
		Japan	129

It will be seen that with the exception of India, where the labour is almost exclusively native, no part of the British Empire can show so low an output per head as does Great Britain itself, whilst of foreign countries it is only the smaller producers that rank worse than ourselves. In part, this small production is no doubt due to the fact that so many of our thicker and more easily wrought seams are to a large extent worked out, and that we are therefore compelled to work the thinner seams, from which a smaller output per man is necessarily produced. This drawback should, however, have been largely offset by the use of mechanical means for cutting and transporting coal, and it is difficult to avoid the conclusion that the low output is due to the restrictive policy covertly, it not overtly, encouraged by the Trades Unions.

It is some satisfaction to find that British coal mining is conducted with a great regard for the safety of the men engaged in this occupation. The death-rate per thousand workers employed is given as follows :—

Great Britain	1·17	France	1·49
British Empire	1·24	Russia	4·27
United States	3·26	Belgium	1·00
German Empire	2·44	Japan	5·64
Austria	1·48		

If the death-rate be compared, not per worker but per million tons of output, Great Britain will not appear in quite so highly favourable a light as compared with the United States, for example, that of the former being 4·66 deaths per million metric tons, and of the latter 5·44. Nevertheless, from every point of view our standard of safety may be looked upon as high.

It ought to be added that the above statements are calculated from the data tabulated in the report in question, which gives the figures for the various countries as though they were obtained in the same way, and therefore strictly comparable, which is far from actually being the case. Different countries use different methods of determining their mineral production, the number of men engaged in the industry and the number of deaths due to it, and the figures given are not therefore strictly comparable, though they may be expected to give a rough standard of comparison. One of the objects aimed at for many years by statisticians interested in mineral production was to get an international understanding as to the basis on which all these figures were to be determined, but now that Germany has in a few months destroyed the work of many years of European civilisation, and by her own relapse into barbarism has dragged all other nations down with her, any prospect of agreement on such minor international questions appears to be quite hopeless. H. L.

REPRODUCTION AND HEREDITY.

PROF. J. A. DETLEFSEN (University of Illinois) has made an important contribution to our knowledge of "Mendelian" inheritance by his "Genetic Studies on a Cavy Species Cross" (Carnegie Institution, Publication No. 205, 1914). The research —begun by Prof. W. E. Castle—is of interest as affording information from the crossing of two distinct species, for the wild Brazilian cavy (*Cavia rufescens*) is apparently sharply distinct from the common domestic guinea-pig (*C. porcellus*). The sterility of hybrid animals is known to be a rule admitting of many exceptions. In the experiments with cavies here described, crosses between *C. rufescens* males and *C. porcellus* females gave completely sterile male and fertile female hybrids. By mating the female hybrids with *porcellus* males, quarter-wild hybrids were obtained, again sterile males and fertile females; but by repeated back-crosses of female hybrids to *porcellus* males, individuals with increasing fertility were obtained. "Fertility seemed to act like a very complex recessive character; for the results obtained were what one would expect if a number of dominant factors for sterility were involved, the elimination of which would give a recessive fertile type." The paper is noteworthy because skeletal characters of the parents and hybrids are figured and compared, in addition to the usual external features, such as coat-colour.

A case of sex-limited inheritance in plants is discussed by Mr. G. H. Shull, who has made crosses between the typical *Lychnis dioica* and its variety *angustifolia* (*Zeitschr f. indukt. Abstammungs u. Vererbungslehre*, xii., 5, 1914). The narrow-leafed form is a recessive which reappears in half the males of the F_2 generation. All the F_2 broad-leafed males are heterozygous for the broad-leaf factor, while of the females half are heterozygous, half homozygous for this factor. As regards sex, the female Lychnis is a homozygote and the male a heterozygote.

Dr. Raymond Pearl continues his observations on the reproductive organs of domestic fowls. In a paper on the effects of "Ligation, Section, or Removal of the Oviduct" (*Journ. Exper. Zoo.*, xvii., 3, 1914), he states that these operations have no injurious effect on the growth of the ovary, and that after removal or closing of the oviducal funnel, eggs are passed into the body-cavity, where, if not absorbed at the peritoneal surface, they may cause "serious metabolic disturbances." In the *Journ. Biol. Chemistry* (xix., 2, 1914) Dr. Pearl informs us that injection of the desiccated fat-free substances of a cow's corpus luteum into a laying fowl at once inhibits ovulation. The possible practical importance of studies in heredity is shown by a short pamphlet from the annual report of the Maine Agricultural Experiment Station for 1914 on improving egg-production by breeding, and by a Bulletin (No. 110) of the U.S. Department of Agriculture (Bureau of Animal Industry), in which Dr. Pearl, with Dr. F. M. Surface, gives "A Biometrical Study of Egg-Production in the Domestic Fowl."

BACK TO LISTER.[1]

When Sir James Crichton-Browne, amongst whose many charms is a singular felicity of phraseology, invited me to undertake this task, he kindly supplied the title. It sounded rather startling, but as I could not think of a better, I humbly accepted it. It shows that I have no great discovery to announce, no new theory to propound, but only to take you back over old, well-trodden ground, to try to interest you in very technical matters, and to suggest that, in this particular case, reaction has overstepped the bounds of moderation, and that, as in many other fields, the most modern ideas are not always the best.

I will not trace the various steps by which Lister was led to his conclusions about the causes of suppuration and hospital diseases, nor draw a lurid picture of the deplorable mortality from these diseases before the introduction of the antiseptic system of treatment. I must, however, give you a short account of his first antiseptic method, which was founded on the discoveries of Pasteur, and explain in what way and for what reasons he afterwards modified it. If I succeed in making this clear it will be easy to understand how the relinquishment of much that he at first considered essential, but which later discoveries proved to be superfluous, led others to give up still more —much more than he ever considered it prudent to do. It will then be maintained that what he feared has come true: that the results obtained to-day, good though they are, are not so good as they would be if we were to return, perhaps not altogether, but almost, to those simpler and safer methods which Lister employed at the end of his active career.

Let us begin by trying to place ourselves in Lister's position during the years preceding 1865, when the writings of Pasteur were first brought to his notice. It was that of every thoughtful surgeon in those days. Of all the dealings of Providence with men—remember I am speaking of sixty years ago—not the least mysterious appeared to be the ordinance that the life-giving air, heaven's blessed breeze, without which life cannot be maintained for more than a few minutes, and on the purity of which man's vigour depends, should carry in some unexplained way the seeds of death and disease, being one day the doctor's greatest friend and the next his deadliest foe.

Physicians were quite sure that the acute specific fevers, such as scarlet fever and measles, were carried on the wings of the wind, and few had any doubt that cholera was borne by the same vehicle. Surgeons were equally certain that erysipelas should be placed in the same class as the acute specific fevers and that the suppuration of wounds depended upon the same agency. It seemed quite obvious, to anyone who thought about the difference in the behaviour of simple and compound fractures, that is, fractures with unbroken skin and those which are complicated by the presence of a wound. Except for this complication the fractures might be identical, but, in pre-antiseptic days, the presence of a wound was almost certain to lead to suppuration of a serious, if not a dangerous nature.

Old Glasgow students speak of Lister contemplating a simple fracture of the leg; the muscles torn and pulped, the limb swollen and shiny, black and blue, and pointing out to them that all this destruction of tissue and extravasation of blood would be surely and safely dealt with by the kindly influences of nature; but that the admission of the air through the smallest wound in the skin would completely change the prospect; the extravasated blood would soon stink, the injured tissues—bone and muscle—would die, and suppuration would take place, which might possibly infect the whole system. It did not enter into the mind of anyone, therefore, to doubt the morbific influence of the air. It was one of those things which appear so obvious that for a time they form the very foundations of belief, such as that the earth is flat and that the sun rises, matters which in more barbarous times laid sceptics open to the rigours of the Inquisition.

This was still the universal belief when Pasteur's discoveries were made known. Pasteur put the finishing touch to the work of many observers, who, during the first half of the last century, had been striving to find out what there was in the atmosphere which gave rise to fermentations of all sorts, and amongst others to that form of fermentation known as putrefaction. So long as fermentation and putrefaction were looked upon as chemical processes it was natural to suppose that one of the gaseous constituents of the air was the cause. But clear thinkers, like John Hunter, saw that this could not be the case.

There are two surgical conditions that prove this:—

(1) If a rib be broken and a sharp fragment injures the lung, large quantities of air may pass from the lung into the pleural cavity, but if the lung be healthy, decomposition never occurs in the putrescible fluid that is always present in the pleura in small quantity.

(2) If air passes into the cellular tissue of the body, as it sometimes does after the same accident, or some other injury of the air passages, large portions of the body may be distended by it to an extent that appears alarming. But again, as the air is effectually filtered on the way, decomposition does not occur and the evil result is only a temporary mechanical one.

Investigators, therefore, began to think that the cause of fermentation must be something solid and possibly living; something so small that it eluded their highest magnifying glasses, and so they adopted different lines of attack.

Some calcined the air, some filtered it, some passed it through causic fluids. There was an old French confectioner named Appert—Citoyen Appert, in the time of the Republic, who anticipated by many years the work of our modern fruit preservers. He succeeded in preserving all sorts of food in well-corked bottles by boiling them for various lengths of time according to the particular article he was dealing with; and his results were so nearly uniform and so remarkable, from an economic as well as from a scientific point of view, that they attracted the attention of the French Minister of the Interior in 1810, and also of the Académie Française.

Unscientific as these observations were, they gave an impetus to the work of chemists and biologists who carried out an enormous number of really scientific investigations in consequence. These were repeated by Pasteur, who made countless others of his own, of marvellous ingenuity. The results of his labours in this particular field before 1865 may be given in a tabular form. He showed that:—

(1) Putrefaction is a species of fermentation.

[1] Discourse delivered at the Royal Institution on Friday, March 12, by Sir R. J. Godlee, Bart., K.C.V.O.

(2) It is caused by the growth of micro-organisms and does not occur independently of them.

(3) The micro-organisms that produce fermentation and putrefaction are conveyed by the air on the dust that floats in it.

(4) These micro-organisms can be destroyed by heat and other agencies, or separated by filtration.

(5) Certain recognisable organisms produce definite and distinct fermentative processes.

(6) All of these organisms require oxygen. Some of them flourish only in the presence of free oxygen (aerobic), others only in its absence (anaerobic). The latter acquire their oxygen from the bodies which, by their growth, they are causing to ferment or putrefy.

(7) Many natural animal and vegetable products have no tendency to ferment or putrefy even in the presence of oxygen, if collected with proper precautions and kept in sterilised vessels.

(8) Spontaneous generation has never been observed to occur, and thus may be regarded as a chimera.

Now it will be observed that Pasteur's work presented Lister with two great fundamental facts.

(1) That putrefaction is caused by germs which can be destroyed by heat and chemicals and separated by filtration.

(2) That germs are carried by the dust in the air.

It is true that both Pasteur and Lister did not fail to recognise that if the air carried the germs it must deposit them upon the surface of everything, and that therefore the surface of every solid and the whole of every liquid must be, or might be, infectious. It is also true that Lister bore this in mind, and acted on the assumption that it was true from the very first. But still it was the air to which he paid and directed most attention—more attention, as we shall see, than it deserved. He probably did not recognise, he certainly did not say, that his precautions with regard to other sources of infection were far more important than those which he took with regard to infection from the air.

The sceptics and cavillers, the believers in spontaneous generation, kept saying, "Show us your germs in the air." They did not doubt that organisms were found in putrefying substances, they could not do that; but they said that they might be accidental, the result of putrefaction, not the cause of it, and asked for proof that germs existed in the air. Pasteur had tried to meet this objection by filtering the air through gun-cotton, which he afterwards dissolved and submitted the solution to the microscope. There were certainly objects which he was satisfied were germs, but the doubters were still unconvinced.

A few years later, about 1869, John Tyndall, whose eloquent addresses on "Dust and Disease" were listened to with breathless attention in this hall, succeeded in showing to the naked eye of untrained amateurs, the existence of, and the amount of, floating dust in any given sample of air, by passing through it a concentrated beam of light. Next he showed that, if the air was left undisturbed, say in a glass flask, the dust settled, and there was nothing for the beam to illuminate. Then he produced the same result by filtering the air, or by raising to a great heat a piece of platinum wire passing through the flask which burned up the dust. Finally, he proved, by a series of charmingly simple experiments, that what he called optically pure air was incapable of setting up decomposition in putrescible fluids, whereas optically impure air invariably caused them to decompose.

Most of these facts were known to Lister in 1865. All the evidence pointed in the same direction; and therefore, stated in the simplest way, the problem seemed to be to kill the germs which might have gained access to the wound before it came under treatment, and to prevent the air from carrying in others afterwards.

He first applied what he now called the antiseptic principle to compound fractures, injuries which, above all others, were liable to be followed by those hospital plagues—pyæmia, erysipelas, and hospital gangrene.

He had to choose between the three recognised methods of excluding the germs—filtration, calcining, and chemical antiseptics—and he naturally selected the last as the most convenient. The first antiseptic he tried was carbolic acid, and as the crude sample he first worked with was insoluble in water he used it undiluted.

His plan for treating compound fractures was, after cleansing the wound, to sponge the whole of the raw surface with this undiluted crude German creosote in order to destroy the germs introduced by dirt or other foreign material at the time of the accident, or that, as he supposed, had been carried to it by the air. The carbolic acid mixed with the blood, caused an antiseptic crust, which he fortified by covering it with a thin piece of block-tin, and this crust effectually prevented the access of unpurified air to the wound; for he left it undisturbed for days or weeks and painted the outside with more of the undiluted acid from time to time.

I wish to impress upon you that in the earliest dressings he used a very strong antiseptic and did his best absolutely to exclude the air, and it is important to note that his results were strikingly good, in spite of the fact that the undiluted acid did actually cause a certain amount of superficial sloughing—or death of the tissues—in the parts to which it was applied. As time went on a purer carbolic acid was obtained which dissolved in water, so he abandoned the caustic undiluted acid in favour of a saturated watery solution: 1 part to 20.

He soon extended the treatment, first to abscesses and then to ordinary operation wounds. The old antiseptic crust was soon given up, and various dressings containing carbolic acid or other antiseptics were employed instead. But for a long time he was so anxious about the air that he irrigated the wound with a solution of carbolic acid in water throughout an operation, and took the most elaborate precautions against allowing any air that had not been submitted to the influence of carbolic acid to reach the wound at the changing of the dressings. He used to say that merely taking out a drainage tube without antiseptic precautions involved a serious risk, because the air which rushed in to take its place might carry some speck of dust and a germ along with it.

In his most palmy days, when he was professor of clinical surgery at Edinburgh (1869–77), and Edinburgh was for the time the surgeon's Mecca, he introduced the spray in order to deal still more effectually with the air. In its most highly developed form the steam spray-producer threw a copious vapour, which was supposed to contain one part of carbolic acid in forty of water, that surrounded the whole region of the operation, and, if the room were small, might even fill the whole apartment with a pungent vapour, to the great discomfort of all concerned. He thought at the time that the momentary contact of the dust with the particles of carbolised water in the spray, or the carbolised atmosphere between the drops would be enough to destroy the germs; but in after years he owned that such a result was impossible.

At this period, though he was still using strong antiseptic lotions very freely, his results were yet more remarkable; and in the meantime, relying on the antiseptic principle, he was doing new operations which, without it, he would have considered to be altogether unjustifiable.

In spite of this, as you know, Lister's treatment, though hailed with acclamation abroad, met with a very ungenerous reception in this country. His compatriots could not understand the great principle that underlay it. They said that there was nothing new in it, or, if there was, it was bad. They said that their results were quite as good as his, or, if they were not, it was only because he paid so much personal attention to his cases. They gave the treatment silly names, showing that they had not grasped the meaning of it; at first it was the "carbolic treatment," now it was the "spray and gauze treatment." This last name was even adopted by Lister's disciples, and thus the spray came to be regarded as a fetish to such an extent that anything which cast a doubt upon its infallibility sorely tried the tender faith of the converted.

But increasing knowledge forced Lister to alter his own beliefs and greatly to modify his practice in the two particulars to which I have especially directed your attention. Thus he more and more diminished the strength of and the amount of his antiseptics; and, having become gradually convinced that infection from the air, far from being the greatest source of danger, was a negligible quantity, he gave up the use of the spray for good and all.

We must now inquire how this came about. Lister always looked upon an antiseptic as a necessary evil, because he saw that anything strong enough to kill germs must damage the living tissues. Therefore in quite early days he tried to do without antiseptics altogether, or at all events to admit nothing of the sort to the wound after the operation was finished. He also recognised from the first that healthy-living tissues had the mysterious power of preventing the growth of micro-organisms; and that this protective power was diminished by anything that lowered their vitality. He further pointed out that the vitality of the tissues varies in different individuals and in different parts of the body, as is illustrated by the well-known fact that healing takes place more readily in infancy than in old age, and in the face than in one of the limbs. The true meaning of this power was not then known. The explanation was given by the marvellous discoveries of Metchnikoff which Lister's own work prepared him to receive, when they were made known to the world.

Everyone now is familiar with the word "phagocytosis," but have you, ladies and gentlemen, really grasped its meaning? It is a sufficiently appalling thought that each one of us, who looks upon himself as a single individual, is only a huge joint stock company. We carry about with us millions and millions of other individual organisms—micro-organisms indeed—but each one endowed at least with life and definite individual functions. Some of them are apparently essential to the success of our bodies as a going concern. Many, even of these, are only waiting for some interference with the vitality of a part, or the whole, of our body, to afflict us with local or general disease, and finally to dissolve us into our elements.

Metchnikoff showed how these malignant organisms are kept at bay. Our very own body is made up of cells, each of which has, so to say, its individual existence and its special functions—almost its special intelligence—a fact which Lister was one of the first to demonstrate. Hosts of these cells—Metchnikoff's phagocytes—form, some of them, our main mobile army of defence. They are not like other defensive cells, such as those of the spleen and bone marrow, confined to their fortresses, though as a rule, they keep their allotted positions. But they can move along strategic railways to any special point of attack, and when they have reached it, there ensues a battle royal with the invading army of pathogenic organisms, which they try to swallow, and, if possible, to destroy. If they are successful, health is restored. It may mean the aborting of a cold in the head, the subsidence of a pneumonia, or the rapid healing of a cut. If, on the other hand, they are overpowered by the invaders, the catarrh may extend to the smallest bronchi, the pneumonia may end fatally, or the wound may suppurate with disastrous results.

These illuminating facts turned the attention of surgeons into another direction; and seeing that everyone knew that the vitality of the phagocytes must be impaired by any mechanical or chemical injury, the tendency was to reduce the strength of the antiseptics and to trust more and more to the phagocytes. Lister himself used weaker and weaker antiseptic lotions, but he never thought it wise to dispense with them altogether. Others, however, being chiefly obsessed with the notion that chemical antiseptics diminish the power of the phagocytes, maintained that their use should be altogether discontinued, and have adopted, or say they have adopted, a treatment which, though having the same object as Lister's, is supposed to be founded upon a different principle. How far this is actually the case it will presently be our business to inquire.

This was one of the reasons why it began to be said that Lister's teaching, like the Old Testament, was obsolete, and must be replaced by a newer and more perfect gospel.

We must now further consider how far the air is really a source of infection. In the early days it was said that the number of germs in the air was enormous. As a matter of fact, such a statement is still true, as is easily shown by exposing a plate of cultivating medium in any room, say in the most up-to-date modern operating theatre.

It was also taken for granted that the large majority of germs were pathogenic—that is, disease producing. But very little was known, in 1865, of the varieties of micro-organisms. It is true that Pasteur had isolated various yeasts or ferments, and had shown that some organisms were aerobic and some anaerobic, and that the words vibrio and bacterium were beginning to be used. But as time went on two very important facts were made out. *First*, that only a small proportion of the flora of the air are pathogenic; and, secondly (and this was one of Lister's own discoveries), that great dilution of a septic fluid very much diminished its chance of infecting a putrescible medium. Thus typhoid pollution of the Nile in a few miles ceases to be a source of danger, and one or two septic organisms introduced into a vessel of blood serum will fail to grow. It is really masses of particulate dirt which are dangerous, because they contain colonies of organisms adequately protected from attack. And, if this applies to attempts at infection of vessels containing blood serum, still more does it apply to the dropping of isolated staphylococci and streptococci on to a wound where the greedy phagocytes are lying in wait to devour them. At every operation scores of germs fall upon a wound—hundreds if it be prolonged—but most of them are those of moulds and other innocuous vegetables which have no chance of growing there; and although there is a possibility of an occasional pathogenic organism being among the number, the risk of its developing is so small, that it is now generally considered to be negligible, and that if one or two should escape into the lymph channel, they will never elude the phagocytes in spleen or bone marrow or elsewhere.

I must now explain how the spray helped to prepare Lister for the acceptance of Metchnikoff's discoveries.

I said it was unpleasant for all. There were some surgeons to whom it was positively poisonous. Amongst these was a friend of Lister's, Thomas Keith, the ovariotomist, whose field of operation was, of course, the peritoneal cavity. In pre-antiseptic days he had obtained results that had astonished the world, by dint of great dexterity, devoted personal attention, and scrupulous regard to cleanliness. His success tried the faith of some, but not of Lister, who was aware of the specially high vitality of the peritoneum, and of other anatomical and physiological peculiarities which diminish the chance of survival of germs, but which are too technical for discussion here.

Keith's success was so great that he hesitated to adopt rigorous antiseptic methods, and Lister at first dissuaded him from doing so, fearing that carbolic acid might dangerously interfere with the vitality of the peritoneum. Besides, at that time he did not fully trust the efficacy of the spray. Keith did, however, for a time use all Lister's methods, including the spray; but this seriously interfered with his health, so he abandoned it, and yet, when he gave it up, his results continued to be as good as when he was using it.

The germicidal powers of the peritoneum are great, but they are only in degree greater than those of muscle, fat, and other tissues. And when it was found that other surgeons, some of them keen disciples, were absolutely forced to give up the spray, or give up surgery, and that, when they chose the former alternative, their results were no worse than before, Lister at last came to the conclusion that the spray was unnecessary, even if it had really made an antiseptic atmosphere, but, as I said before, he now saw that this was impossible. The spray was really only a convenient, unconscious, automatic irrigator. It killed germs on the wound, not in the air, and as such had been very useful during the time when the lesson was being gradually learned that every surgical operation, every surgical dressing, is, in fact, a complicated bacteriological experiment.

The mitigation of the strength of the lotion and the abandonment of the spray seemed to some like lowering the standard. But it was not so. It was not so because the principle remained unshaken, namely, that as organisms are the cause of putrefaction they must be excluded from a wound, or if they had gained access to it they must be destroyed or prevented from growing. Two changes of method had indeed been introduced:—weaker antiseptics were employed because greater respect was paid to the defensive powers of the body, and the spray was given up because opinion had altered with regard to the importance of aerial attacks. Aircraft came to be disregarded, while it was seen that what may be compared to land and water attacks were far more dangerous. The germs on the skin of the patient, the dirt on the hands of the surgeon, the unpurified sponge, the dried clot on a badly cleaned instrument; these were the dreadnoughts and submarines; these were the sappers and miners, the howitzers, and hand-grenades that really decided the fate of the campaign. Thus it became obvious that the precautions taken against such sources of danger, which, though they were adopted from the first, had been overshadowed by the attention devoted to the air-raids, were really of far more vital importance; and much ingenuity was thenceforward devoted to devising means for purifying the skin by mechanical or chemical means, to inventing gloves which would not impair the sense of touch, and also to proving that there was a radical difference between aseptic and antiseptic surgery.

We now come to the question of what is meant by aseptic as opposed to antiseptic surgery. Aseptic is no new word. Lister employed it quite early in his writings, and, though it is plain to see why he called his system antiseptic, it is almost to be regretted that he did not call it aseptic. It would have prevented the confusing suggestion that, as Hunter and others had spoken of and used antiseptics, his system was nothing new, and perhaps it might have saved us from the still more confusing suggestion that there is some fundamental antagonism between aseptic and antiseptic treatment, though they are really the same.

Those who call themselves aseptic surgeons maintain that they do not employ chemical antiseptic agencies. The idea started amongst the gynæcologists who, as has been shown, were working under peculiarly favourable conditions as regards asepsis. They were supposed to use only mechanical means in striving after cleanliness—washings and scrubbings and so forth, which do, of course, remove the deadliest form of danger, particulate dirt. But even these surgeons, or some of them, used to employ freely the most potent of all antiseptics, heat. They boiled their instruments and boiled the water with which they washed out the peritoneal cavity, and some were in the habit of using a pretty powerful antiseptic, sulphurous acid for purifying those most dangerous things, sponges.

Let us now watch an aseptic surgeon at work. Somewhere in the background there must be a very large steriliser for superheating overalls, caps, veils, towels, dressings, and bandages; also a boiler for boiling instruments, and an unlimited supply of boiled (he calls it sterilised) water and normal salt solution.

He spends a long time in scrubbing his hands in soap and water, and probably in spirit of wine, which is an antiseptic; he then puts on his sterilised overall, cap, veil, and india-rubber gloves. Thus, converted from a dangerous into a harmless character, he ought never to touch any contaminated object. But it is to be feared that he sometimes forgets the meaning of his vestures: that he wrongly looks upon them as armour, and, inspired by this confidence, he touches the unclean thing, and then puts his fingers into the wound.

One may be forgiven a passing smile at the unreasoning way in which these details are followed out. Surgeons dress themselves up like white-robed priests to examine the external ear, or to explore those parts of the body that no process on earth can render even approximately aseptic.

But to return to our aseptic operation. The instruments, having been boiled, are commonly placed in a tray containing boiled water. Why I have never been able to discover. They would be equally safe if used dry. Probably it is only an imitation of Lister's plan of sterilising his instruments in a tray of carbolic acid lotion.

The patient's skin is almost always purified by a chemical antiseptic, sometimes alcohol, but now usually tincture of iodine. The part to be operated on is then surrounded by superheated dry towels, and the operation proceeds. Superheated swabs have replaced marine sponges. No antiseptic is applied to the wound. Plain boiled water or boiled saline solution is used for washing away clots; preferably saline solution, because it does not interfere with the living cells by osmosis as plain water does.

When the operation is over, a dressing of superheated gauze and wool is fixed by a superheated bandage or by plaister. This, of course, only acts as a mechanical filter of dust, but it is now looked upon with reverence, as if it had some other special virtue, and you may see it applied with extraordinary precautions to septic suppurating wounds and kept on for twenty-four hours, regardless of the fact that it becomes a septic dressing immediately after application; that it is, in fact, nothing but a beautifully whitened sepulchre full, if not of dead men's bones, at all events of all uncleanness.

Some aseptic surgeons apply their principle to compound fractures and rely solely on mechanical means for removing dirt from the recesses of the wounds; but most, I believe, continue to employ powerful antiseptics for this purpose, and in this class of injury follow Lister's instructions.

I am not so ignorant or bigoted as to suggest that so-called aseptic surgery is a bad way of treating wounds. I know that first-rate results are constantly obtained by means of it. But, I maintain, and here I am repeating what Lister often said to me:—

(1) That it is a troublesome and difficult process, involving for successfully carrying it out an amount of paraphernalia and an amount of training that puts it almost beyond the reach of all except hospital surgeons.

(2) That it is misleading to set it up in opposition to the antiseptic system, because most of its advocates use chemical antiseptics for one purpose or another, and all employ heat with great freedom.

(3) That infections of the skin and consequent later suppuration is more likely to occur than if Lister's methods are followed.

I will now describe one of Lister's operations in his last years at King's College. He did not require a huge autoclave for sterilising. He did not wear gloves, but he purified his own hands and the skin of the patient by a most potent antiseptic, which was called the strong mixture. It consisted of 1 to 20 carbolic acid in 1 to 500 corrosive sublimate. Lister, fortunately or unfortunately, had a very resisting skin; his hands, however, were usually rough, but he did not seem to mind. This was not the case with many of his followers, who could not, or would not, stand the discomfort strong lotions produced. This has undoubtedly been one cause of secession. The instruments and the sponges (he used marine sponges) had been long steeped in strong carbolic acid lotion, but during the operation they were wrung out of a very weak antiseptic solution. The towels placed round the field of operation were also carbolised. No irrigation was carried out. When the operation was complete, a dressing containing an antiseptic substance was applied.

His treatment of compound fractures was never modified after the first few years.

The differences you see are these:—

(1) Lister trusted to a potent chemical antiseptic, instead of to mechanical cleansing and heat, for sterilising the skin, instruments, and the objects likely to be brought into contact with the wound.

(2) He applied a very weak antiseptic in small amount to the wound itself, instead of boiled water or normal saline solution.

(3) Instead of plain gauze he used an antiseptic dressing, which has the great advantage of acting upon any organisms that, after the operation may reach the surface from the sweat and sebaceous glands of the patient.

These differences between the two systems, as thus stated, do not appear to be great, but they are important. "The little more, and how much it is! and the little less and how far away!" For in one there is simplicity and safety, in the other complication and risk. Thus in the first place sterilising by a chemical antiseptic involves no special apparatus. It can be carried out in the humblest cottage. Secondly, the use of an antiseptic during the operation does away with the necessity of the surgeon and his assistants, young dressers, or busy country doctors, or nurses being constantly on the *qui vive* lest their simply aseptic garments should touch some unpurified thing and then convey defilement to the wound. Thirdly, security is provided for against secondary infection from the skin; or secondary infection through the dressing, if the discharges should soak through to the surface and thus supply a neutral track for the germs to travel along.

When I come to speak of results I must necessarily be vague. I have, however, formed the opinion, from much observation and long experience, that the standard as regards suppuration amongst aseptic surgeons is lower than Lister's used to be. If a case "goes wrong," as the common but mischievous expression is, it is looked upon as an unavoidable accident, not as a disgrace. In recent years the term, "stitch abscess," has sprung into use. Lister said he never had stitch abscesses. Forgive me for dwelling on them for a moment. The name is applied to suppurations occurring about stitches, and they arise in this way. Our skin is full of small glands for supplying greasy material to the hairs. Organisms are present in these glands, and any weakening of the tissues gives them a chance of doing mischief, the commonest illustration of which is the ordinary boil that starts from the fretting of a cuff or a collar. A tight stitch, or a not very tight one, may do the same. But the risk is very much diminished by thorough purification of the skin, which is much more effectually obtained by following Lister's instructions than by "aseptic" methods. It may be granted that stitch abscesses do not often lead to serious mischief, but they often cause troublesome suppuration in the wound itself and involve delay, and the removal of important deep stitches, which were intended to be permanent. This risk is also lessened by using an antiseptic as opposed to an aseptic dressing. I confess I have never been able to understand the objection to an antiseptic gauze dressing. If the wound heals by first intention the antiseptic substance cannot possibly act upon the raw surface of the wound. Antiseptic gauze has all the advantages of sterilised gauze except that it is slightly more expensive and has none of its disadvantages; in fact, I am confident that it has only been discarded on purely theoretical grounds.

To what extent, then, should we return? I would not urge the use of marine sponges, because they are difficult to clean and expensive, and because cotton swabs are equally efficient. Nor would I recommend the giving up of india-rubber gloves, although I know that they have their dangers, and although I know that they may safely be dispensed with by an antiseptic surgeon. Boiling instruments, I think, should be continued. Otherwise I say that it is only fair to students to tell them, and show them, that by carrying out Lister's technique, it is more easy to obtain the very best results and less likely to fail.

I have only spoken of civil practice, but I would not have ventured to offer you a surgical address, and I could not have hoped to attract your attention if it had had no bearing upon the war which is now raging.

Lister's faithful followers had not only watched with regret what they considered to be a retrograde step in civil practice, but they feared that a war would bring out in relief its weak points.

Wars have occurred of late in distant parts of the world, but we paid little heed to the details. It required a war in our midst, with our own flesh and blood in the trenches exposed to the bullets of the foe, and to the pestilence that walketh in darkness, to bring the matter really home to Englishmen. And when it came, the reports from the front of almost universal sepsis made us fear that our prognostication had come true, and that the abandonment of antiseptics was, at least in part, accountable. It appears, however, that antiseptics are being very largely used, though with most disappointing results.

The fact must not be overlooked that military surgery is exceptional, and that this particular war is being fought in most exceptional circumstances—trenches dug and monster shells exploding in the highly-cultivated soil of a noted tetanus area like the valley of the Aisne. It is almost impossible for us at home to appreciate what is going on. Listen, therefore, to this graphic extract from a letter I received last week from Sir Anthony Bowlby:—"In this trench warfare you must remember that, if a man is hit, he often falls into filthy mud and water, which may be 3 ft. deep or more. Remember also that the trench is only $2\frac{1}{2}$ ft. wide. *If it is night,* you can only grope about in the dark and can do no dressing of any kind, for you can't even get any clothes off in the dark, and in so cramped a space, and you must try to get the man away to a 'dressing station' half a mile distant, and thence to a field ambulance. *If it is daylight,* you can't get the man out of the trench at all, and he may have to be kept there for many hours, because he would certainly be killed if he was got out of the trench. And the water in the trenches is hopelessly polluted, and soaks his clothes and his wound. It is only too evident that large lacerated wounds, and especially bad bone smashes, are so contaminated that it can never be possible to render them aseptic."

This is a dreadful picture; but all fighting is not trench fighting, and we might have hoped not to be told that all wounds, except bullet wounds, are septic, seeing that a few, at least, come under treatment within a reasonable period, say twelve hours, after infliction.

I have been helping Sir Watson Cheyne to lead a crusade in favour of applying to these dirt-infected wounds Lister's original method of purification by means of undiluted carbolic acid. Not that I advocate it for civil practice, but because I think that the only chance of destroying the organisms of tetanus and gas gangrene, and the best way of dealing with streptococci, is to use the most potent and safest antiseptic which is at the disposal of the surgeon for the purpose.

The suggestion met with the cordial approval of those who, like myself, have employed this agent extensively. But it excited a certain amount of loud criticism from others, who were chiefly impressed by the fact that undiluted carbolic acid produces a certain amount of sloughing. This criticism is easily met, because, if employed with the discretion that may be expected of reasonable people, the slough is unimportant, superficial, and antiseptic—incomparably less suited for the growth of micro-organisms than the extensive and spreading sloughs which they themselves produce. Moreover, these antiseptic sloughs do no harm, but are quickly absorbed if the wound heals antiseptically.

That is not the weak point in the argument. There is, however, another, more difficult to answer, of which our opponents did not make so much. Unfortunately, it cannot be denied that the spores of the bacilli of tetanus resist the action of even undiluted carbolic acid for a very considerable time. Moreover, my colleague, Dr. Thiele, has shown that, if easily recognisable micro-organisms are injected into the subcutaneous tissue, they enter the lymph channels, and may pass into the circulation in the course of a few minutes, long before there is a chance, if the same thing happens in contused wounds, of getting at them with our antiseptics.

Are we, then, to abandon this line of treatment, to fold our hands in despair and say that it is useless to attempt to disinfect any wound in civil or military practice to which spore-bearing or other organisms may have gained access? By no means. All Lister's work cries out against such a conclusion. We must clear our minds of the delusion that carefully planned experiments on guinea-pigs in the laboratory are on all fours with unrehearsed experiments in factories, or on wounded soldiers in the battlefield. Lister did undoubtedly succeed in stopping sepsis in compound fractures and in banishing tetanus and hospital gangrene from his wards, and the experience of generations of surgeons working with a saturated watery solution of carbolic acid has confirmed his conclusions. Surely, then, it may be possible to find a practical way of applying the principle to military practice.

It will not, however, do to brush the argument aside in this way without examining it and answering it. I therefore submit for your consideration a suggestion as to what happens in a case successfully treated antiseptically, that is, one that heals without suppuration.

We do not know for certain in what form the anaerobic spore-bearing organisms are introduced into a wound. I, at all events, do not know of scientifically conducted observations upon the subject. But it is clear that they must be either in the form of bacteria, or spores, or both, probably embedded in decaying organic matter in the soil. If the antiseptic reaches them it destroys the bacteria, together with the other septic organisms. But possibly, or, let us say, probably, it has not sufficient time before becoming too diluted to kill the spores, though it may for a while inhibit their power of development. There, then, these spores lie dormant between a thin layer of carbolised slough and a mass of more or less carbolised blood clot. If sepsis is avoided, the phagocytes at last invade both the slough and the clot, and healing takes place without suppuration. What is the fate of the spores?

We must suppose that, when the carbolic acid has disappeared, as they are embedded in a warm, airless nidus, they germinate, but only to find themselves surrounded by active phagocytes which, if they form a suitable pabulum, destroy them. And so the matter ends so far as the wound is concerned.

This, I maintain, is a reasonable hypothesis and a sufficient answer, and fortunately it is rare indeed, if it ever happens, for tetanus to occur *after* a wound has healed without any suppuration at all; and, moreover, the abolition of tetanus in civil practice has coincided with the reduction in the number of suppurating wounds.

As a further support of the argument, let us now consider the case of the bacteria and spores of tetanus or gas gangrene lying together in an untreated wound, or in one to which less powerful antiseptics are applied, antiseptics not strong enough to destroy the pus-producing organisms. They find themselves, therefore, amongst extensive septic sloughs and decomposing blood-clots in which the phagocytes, if they can penetrate at all, have their time fully occupied with myriads of other organisms, which first weaken and then overpower them. Is it to be wondered at that lockjaw and gas gangrene affect a certain proportion of such cases? On the contrary, the marvel is that these complications are not more frequent.

For, after all, though tetanus and gas gangrene are ghastly things, and make a great impression because the laity knows about them, these diseases are not by any means the most deadly or the most frequent. Probably 40 per cent. of the wounds at one part of the campaign were infected with tetanus, but, up to date, there have been reported only 207 cases, of which only 2 have occurred since January 20. And it must be remembered that there are effectual ways of dealing with both diseases—tetanus by the prophylactic administration of antitetanic serum, and gas gangrene by very free incisions.

No, the deadliest enemy is the ubiquitous streptococcus, the foe that kills more than shells and bullets. But as it is certainly killed by undiluted carbolic acid or by a 5 per cent. solution in water, there is at least a chance that, so far as streptococci are concerned, wounds may be disinfected even in war, and if these and the other pyogenic organisms are destroyed, there is, as I have shown, great reason to suppose that sporing anaerobes like *Bacillus tetani* would have no chance of growing.[2]

But it may be said: "What about the organisms that have entered the lymph channel and the blood current? What is the good of trying to purify the wound if they have already given us the slip?"

Let us see precisely what Dr. Thiele says, and remember that his experiments are conducted by injecting cultivations of micro-organisms subcutaneously. He maintains:—

(1) That they travel quickly to the nearest lymphatic glands, where they are retarded, perhaps killed.

(2) If not, they make their way along the thoracic duct to the jugular vein and enter the blood stream, and by that channel are conveyed, a few at a time, not in sufficient numbers to be detected by the microscope, to the bone marrow, the spleen, and other parts where groups of cells of the phagocyte class are ready to deal with them.

(3) If the enemy overpowers all these means of resistance they may invade the blood in large numbers and cause general blood-poisoning.

(4) That some are quickly taken up by the blood without passing through the lymphatics.

I must again point out that, in spite of all these alarming facts, general septicæmia probably never occurs if the wound heals without suppuration. To take another simile from the war, the germs that escape into the circulation are like enemy aliens, prisoners of war, or the struggling Turks who crossed the Suez Canal. It is not they, but the main body on the fighting line—that is, the wound—who are engaged in manufacturing the deadly toxins. If they can be annihilated, there is not much fear of mischief from the enemy in our midst. It has never been suggested that germs which have entered the circulation from the wound go back with their ill-begotten progeny to make it suppurate. The argument, therefore, that it is useless to try to make wounds aseptic because some germs have already escaped into the circulation is no stronger than that founded on the resisting powers of spores to the action of antiseptics. Both are the arguments of the bacteriologist rather than of the practical surgeon, and, whilst being treated with all respect, they must not be estimated above their true value.

I cannot hope that your patience is not exhausted. But I trust that you are now convinced of the real danger that may result from neglecting Lister's teaching both in civil and military practice.

As to the latter, which for the moment occupies almost all our thoughts, I should be the last to say that there is only one way of salvation—that, for example, corrosive sublimate is dangerous, or iodine untrustworthy, or peroxide of hydrogen of little value. Still less would I say that military and civil surgery should be run on the same lines. But I still think that undiluted carbolic acid is, according to our present lights, the antiseptic most likely to be practically useful in the rough-and-tumble practice of the battlefield.

And whether or not this may turn out to be the conclusion of our gallant brethren at the front, I would add that the experience of the present war is one of the strongest arguments for rallying to Sir James Crichton-Browne's battle-cry, "Back to Lister."

Long ago it was prophesied that science would stop war by making it too horrible. Are we nearing that blessed result? One fact stands out in spite of the faint hopes I have expressed—that nothing can stop sepsis in war except stopping war altogether.

[2] In using the word anaerobe I desire to own that I do not completely understand its meaning. It certainly has been used in more than one sense, and to-day bacteriologists are not agreed about the effect of oxygen on anaerobes, their need for it, the sources from which they obtain it, and other points. We cannot divide micro-organisms by a clear cut line into aerobes and anaerobes.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—Mr. W. L. Mollison has been elected master of Clare College, in succession to the late Dr. E. Atkinson. He was Second Wrangler in the Mathematical Tripos of 1876, and Second Smith's Prizeman, and was elected a fellow of Clare in that year. Afterwards he became successively junior tutor and senior tutor, and was at one time moderator and examiner in the Mathematical Tripos. He was made an Honorary LL.D. of the University of Aberdeen in 1897.

London.—Mr. L. W. King, assistant keeper of the Egyptian and Assyrian department of the British Museum, has been elected professor of Assyrian and Babylonian archæology at King's College. Mr. King's professorship will be a part-time post, and he will retain his position at the museum.

Dr. F. Wood-Jones, lecturer and head of the department of anatomy at the London (Royal Free Hospital) School of Medicine for Women, has been granted the title of professor of anatomy in the University.

We learn from *Science* that Robert Flersheim has left a bequest of a million marks to the University of Frankfurt.

The Rockefeller Foundation has, says *Science*, made comprehensive plans for improving medical and hospital conditions in China. The plans are based on the report of the special commission sent by the foundation to China. To carry out this work the foundation has established a special organisation to be called the China Medical Board of the Rockefeller Foundation, of which Mr. J. D. Rockefeller, jun., is chairman. The plan outlined by the commission provides for the development of medical education in China as the first step. With the view of building up a body of Chinese medical men able to teach medical science, the foundation has decided to establish six fellowships, each of 200*l.* a year and travelling expenses, to enable Chinese graduates to study abroad. Six fellows have been appointed, one of whom is already studying in the United States.

The new buildings of the Mellon Institute of Industrial Research and School of Specific Industries of the University of Pittsburgh were formally opened on February 26 last. The institute, which cost 75,000*l.*, was the gift of Messrs. A. W. and R. B. Mellon, of Pittsburgh; it is provided with complete facilities for the investigation of manufacturing problems and for conducting industrial research in accordance with the system of co-operation between science and industry, founded by the late director of the institute, Dr. R. K. Duncan. By this system, a manufacturer having a problem requiring solution may give a fellowship to provide the salary of a researcher selected to carry out the investigation desired, the institute supplying every facility for the work. At present twenty-three fellowships are in operation and forty research chemists are at work. At the opening ceremony fifteen honorary degrees were conferred on distinguished Americans. Though the institute possesses its own endowment and has its own board of trustees, it is an integral part of the University of Pittsburgh.

SOCIETIES AND ACADEMIES.

London.

Zoological Society, March 23.—Mr. R. H. Burne, vice-president, in the chair.—R. **Lydekker**: The true coracoid. The element in birds and post-Triassic reptiles universally known as the coracoid is the homologue of the human coracoid process, and its equivalent the true coracoid of the monotremes and mammal-like reptiles.—Dr. F. E. **Beddard**: Certain points in the anatomy of the Cestode genera Amabilia and Dasyurotænia.—B. F. **Cummings**: New species of Polyplax (Anoplura) from Egypt. This paper contained a systematic description of two new species of louse based on a large supply of material in spirit collected on *Acomys cahirinus*, Des., and forwarded by the Department of Public Health in Egypt to the Lister Institute, by whom they were subsequently presented to the British Museum. Both the new species were fortunately collected in large numbers in all stages of development, and an account of the larvæ consequently has been prepared.—J. T. **Cunningham**: The resemblance in form and markings of the plates of paraffin-wax originally obtained by Prof. Kappers, of Amsterdam, to the shells of Molluscs. Examples of these structures had been exhibited at a previous meeting by Mr. R. H. Burne. Mr. Cunningham found that the forms were produced by pouring molten paraffin-wax on to the surface of cold water, and he had no doubt that Prof. Kappers's specimens were produced in the same way by the molten wax running over on to a vessel filled with water. The author concluded that the form and markings were not in either case in any way due to effects of crystallisation as Prof. Kappers supposed.

Geological Society, March 24.—Dr. A. Smith Woodward, president, in the chair.—P. G. H. **Boswell**: The stratigraphy and petrology of the Lower Eocene deposits of the north-eastern part of the London basin. The following divisions of the Lower Eocene occur in the area:—London Clay—basement-bed only; the Pebble-Beds and accompanying sands; Reading Beds; Thanet Beds. The unconformity of the Eocene upon the Chalk is discussed, and reasons are given for regarding the layer of green-coated flints at the bottom of the Thanet Beds in the area as a true basal conglomerate. Evidence is adduced to show that the London Clay overlaps the Lower London Tertiaries, and rests directly upon the Chalk in Norfolk. The Reading Beds also overlap the Thanet Beds in the western part of the area. A hypsometrical map of the Chalk-surface in the London Basin is presented, and a minimum estimate of the unconformity, in terms of thickness of Chalk removed, is given for the northern part of the basin. Stratigraphical details of the various divisions and descriptions of new sections are given. The variations in lithology of the Reading Beds are described, and it is shown that the Pebble-Beds belong lithologically and petrologically to the Reading Beds, but that their scanty fauna is a London Clay one. The distribution of the sarsens in the area is plotted out on a map, and their petrology is considered; it is concluded that, in this district, they are derived from the sands of the Reading Beds. The mineral constitution of the various divisions of the Eocene Beds is discussed in detail.

Manchester.

Literary and Philosophical Society, March 9.—Mr. F. Nicholson, president, in the chair.—Sir Ernest **Rutherford**: Origin of the spectra given by β and γ rays of radium. An account of recent experiments by Sir Ernest Rutherford and Dr. Andrade to determine the wave-length of the very penetrating γ rays emitted from radium. The spectrum of the γ rays was obtained by a photographic method by reflecting the rays from a thin slip of rock-salt. The radio-active source consisted of a fine glass tube containing a large quantity of radium emanation. Special precautions were taken to get rid of the effect of the β rays emitted with the γ rays. A large number of lines were observed in the spectrum over a wide range of wave-length. Two well-marked lines are reflected from rock-salt at 10° and 12°, and correspond to some soft γ rays. There were other strong lines of 1° and $1{\cdot}7^\circ$, corresponding to the very penetrating rays. The shortest wave-length observed was 0·7 Angström unit, which is about 1/50,000 of the wave-length of visible light. This radiation has much the shortest wave-length at present known. An account was also given of the methods for determining the magnetic spectrum of the β rays. The rays from a fine source, passing normally in a strong magnetic field, describe a circular path and fall on a photographic plate. A number of well-marked lines are observed on the plate, which correspond to groups of rays of definite velocity. The speed and energy of the β particle comprising each of those groups of rays from radium products have been accurately determined by Rutherford and Robinson. The general evidence indicates a very close connection between the emission of β and γ rays from radio-active bodies, and that the energy of the groups of β rays are intimately related with the frequency of the γ radiation from which they arise. The author outlined a general theory to explain the connection between the β and γ rays.

Paris.

Academy of Sciences, March 29.—M. Ed. Perrier in the chair.—Edmond **Delorme**: Artificial limbs for the use of the amputated. Medical treatment is required by the amputated for some time after the wound has healed, if the full benefit of artificial limbs is to be obtained.—J. Comas **Solá**: Certain rapid displacements of short duration registered by photography. In photographs of the sky taken for the purpose of detecting minor planets, a certain number of stars showed changes of position from hour to hour, which could not be attributed to contractions or deformations of the gelatine of the plate.—J. Comas **Solá**: The discovery of a new minor planet.—E. **Keraval**: A family of triply orthogonal systems.—Gaetano **Scorza**: Singular Abelian functions.—M. **Dussaud**: New experiments on sources of light of small surface.—O. **Bailly**: The constitution of glycerophosphoric acid and of lecithin. Egg lecithin is a mixture of two isomers from which a mixture of α- and β-glycerophosphoric acids is obtained, the latter predominating.—G. **Tizzoni**: The infectious nature of pellagra. Results of researches made in Italy and in Bessarabia. Further studies on the micro-organism previously described by the author under the name of *Streptobacillus pellagrae*.—M. **Guépin**: The destruction by suppuration and ablation of a considerable part of the brain resulting in no appreciable trouble.—Pierre **Delbet**: Extra-pericardic cardio-thoracic symphysis.—H. **Busquet**: The comparative pharmacodynamical action of gold in the colloidal and soluble states. So far as gold is concerned, the qualitative reactions on the heart are quite different in the colloidal and dissolved conditions.—B. **Collin**: *Chromidina elegans*.—E. **Kayser**: Contributions to the study of the ferments of rum.

COLOUR VISION.

An Introduction to the Study of Colour Vision. By Dr. J. H. Parsons. Pp. viii + 308. (Cambridge: At the University Press, 1915.) Price 12*s.* 6*d.* net.

THE whole subject of colour vision is admittedly very difficult, as the knowledge of it involves familiarity with the experimental results of a physical as well as of a physiological laboratory, with the minute anatomy of the retina, and with the latest results of psychological research. Hitherto, all that is known, and the various suppositions that have been made about the subject, could only be learnt by a prolonged search through innumerable scattered papers on physics, physiology, medicine, and psychology in various languages, chiefly English and German; so that it is with most cordial thanks to the author that this *résumé* of the subject in its present state is welcomed.

The book is divided into three parts: part i. (pp. 1–157) devoted to "The Chief Facts of Normal Colour Vision"; part ii. (pp. 158–192), "The Chief Facts of Colour Blindness"; and part iii. "The Chief Theories of Colour Vision." The arrangement is admirable, the facts are well described with very few omissions, and no one after reading the first 191 pages will be surprised that so far no theory has been suggested that will account for all the facts. Perhaps a few of the difficulties of the subject may be indicated.

A given colour may be determined as is well known by its hue, its luminosity, and by its degree of saturation. It is not always remembered that:—

"Great increase of intensity of light not only alters its hue, but also alters its saturation, so that eventually it produces only the sensation of white light. It would seem, therefore, that luminosity is in some recondite sense an inherent 'whiteness' in the colour itself, differing in degrees in different spectral colours and varying with the intensity of these colours. Clearly we are here at the outset face to face with a *physiological* fact of immense importance, and much of the difficulty of colour vision is connected with this fact" (p. 29).

There is the obvious difficulty in comparing the luminosity of two different coloured lights, arising from the fact that they give rise to two different impressions, and we are surprised to find that, according to the note in the preface, there is no discrepancy when the luminosity is measured by the equality of brightness method or by the flicker photometer. The curious coloured phenomena of rapid, intermittent stimulation of the retina (*e.g.* Benham's top) lead us to expect that there would be a marked discrepancy. However, the author's statements are fully borne out by Ives's results with the flicker photometer.

On p. 3 a sentence that refers to the diffraction spectrum has missed correction when the proofs were read:—

"It suffers, however, from the disadvantage that the spectrum is less bright and less extended than the prismatic spectrum, and from the still greater objection that the interference spectrum is never free from scattered light."

Surely the extent of the spectrum depends entirely upon the fineness of the grating, and its brightness may be increased by increasing the size of the grating; and if by the term "interference spectrum" is meant a diffraction spectrum, any impurity in it is due to the faultiness of the grating.

We are glad to notice Mr. Parsons's criticism of v. Helmholtz's spectro-photometer and similar instruments in which the intensity of light is reduced by means of Nicol prisms; much of the German work on the subject is inaccurate owing to the polarising methods used.

With regard to Weber's law, the important point mentioned on p. 20 that "it does not hold good for very low or very high intensities of stimuli" is to be borne in mind. Fechner's law is true within the limits that Weber's law holds. Schirmer found that it was true between 1 and 1000 candle-power illuminations (*i.e.* the function is continuous between these limits), but that at first his minimum difference was $\frac{1}{128}$, while after eight days' practice he could recognise a change of $\frac{1}{217}$ or even less (see *Ophth. Rev.*, vol. x., p. 179). Possibly the failure of the law at the lower limit might be explained by Fechner's later addition of a term s_0 to represent the "intrinsic light of the retina." If E denote the sensation, and S the stimulus, Fechner's law then takes the form

$$E = C \log(S + s_0) + C'$$

where C and C′ are constants. Mr. Parsons makes no reference to this suggested emendation. The failure of the law at the upper limit may be due to changes in the mechanism verging on the pathological. The variation of the minimum distinguishable difference not only in each individual, but also according to his practice (as in the case of Schirmer), necessitates great precautions being used in the application of Fechner's law.

When the eye has been kept in the dark for

 H

twenty minutes or so, the condition of scotopia or twilight vision is developed, in which the retinal sensibility is enormously increased; it will now be found that if the illumination be very low the eye is absolutely colour blind. The curve of luminosity in such an achromatic scotopic eye is practically identical with the luminosity curve of the spectrum in any colour-blind person (p. 53), the brightest part of the spectrum being near the E line (530 $\mu\mu$) instead of near the D line (580 $\mu\mu$) as in the normal eye.

The phenomena of simultaneous and successive contrast and fatigue are dealt with in pp. 100–129, and then there follows an interesting account of the researches on the discrimination of colour by various animals and by primitive races. Conclusions about both of these must necessarily be indefinite. With regard to the latter, the mural decorations of ancient Egypt show that the sense of colour for red, yellow, green, and blue was well developed five or six thousand years ago.

Limits of space forbid a review of Part iii. on the various theories of colour vision: the duplicity theory—that the cones are the seat of impulses that lead to colour perception, while the rods are only influenced by light stimuli; the three components theory (Young, Helmholtz); the three opponents theory (Hering); and seven other theories are described and criticised with justice and judgment. The author is to be congratulated on producing a work that contains an immense amount of information with a good bibliography on the subject. He has given us an excellent general and unbiassed view of the facts and theories of colour vision.

THE EXPERIMENTAL METHOD IN MEDICINE AND SURGERY.

Animal Experimentation and Medical Progress. By Prof. W. W. Keen. With an introduction by Dr. Charles W. Eliot. Pp. xxvi+312. (Boston and New York: Houghton Mifflin Company, 1914.) Price 7*s.* 6*d.* net.

IN America there are very few surgeons more eminent, more beneficent, or more widely beloved than Prof. Keen. He fulfils and represents the very highest traditions of American surgery. He has done great things in practice, and in teaching, and in writing; and his name is held in reverence by doctors and surgeons over here. So, when he writes a book for general reading on a medical subject, the general reader had better read it: especially as it has an introduction from Dr. Charles W. Eliot, sometime president of Harvard University. Besides, the book is admirably written, full of learning, full of sympathy, full of a thousand facts touching man's daily welfare.

It is a justification, and more than justification, of experiments on animals for the advancement of the science and art of medicine and surgery. Prof. Keen is one of those leaders of his profession who are very sensitive to the brutal abuse and false witness of the "anti-vivisectionists." Whether it is wise to care so much what they say, each man must settle for himself. Anyhow, Prof. Keen does care very much indeed. He takes it to heart that these wild people are set to insult the medical profession, to give the lie to plain facts, and to attack with virulent language the very methods which they themselves take advantage of when they are ill. These people seem to be just as unkind and untruthful in America as they are here. Indeed, we are having a rest from them here, since the war began; except that some of them are trying to stop our soldiers from being protected against typhoid fever. It will be a grand thing, after the war, if we can keep anti-vivisection down, and give ourselves to worthier pursuits.

The book is a collection of essays, from 1885 to 1913, on the debt which mankind and the animal world owe to experiments on animals; and on the character and the attitude of anti-vivisection. The essays are complete, final, authoritative; they are the work of a master of surgery, a leader among surgeons. Where all are good it is hard to prefer one before another. Among those essays which review the benefits gained from experiments on animals, nothing could be better than "Recent Progress in Surgery," "Vivisection and Brain-Surgery," and "What Vivisection has done for Humanity." Among those essays which review the moral obliquity of anti-vivisection, nothing could be better than "The Influence of Anti-vivisection on Character," and "The Anti-vivisection Exhibition in Philadelphia in 1914." These two essays are masterpieces; they are gentle, quiet, courteous; but they expose a state of mind, in some American women, which is not pleasant to contemplate. Things were bad enough here, up to last August; but they seem even worse in New York.

Indeed, that is one of the strongest arguments against anti-vivisection—that it tends, unless it be held under self-control, to such amazing dishonesty, such greedy willingness to believe evil of other men, such loss of the sense of responsibility and of restraint.

But these faults, after all, are not the main theme of the book: and the work of nailing lies to counters is less important to us than the work of setting forth the great discoveries of medical and surgical science and art, especially those discoveries which have been made within the last half-century. These chapters of history are as good as good can be, and here is a book full of good reading, written by one of the chief of living surgeons.

Stephen Paget.

PURE MATHEMATICS.

(1) *A Treatise on the Analytic Geometry of Three Dimensions.* Fifth Edition. Vol. xi. By Dr. G. Salmon. Pp. xvi+334. (London: Longmans, Green and Co., 1915.) Price 7*s.* 6*d.* net.

(2) *A Course of Pure Mathematics.* By G. H. Hardy. Second Edition. Pp. xii+442. (Cambridge: At the University Press, 1914.) Price 12*s.* net.

(3) *Proceedings of the London Mathematical Society.* Second Series. Volume xiii. Pp. liii+500. (London: Francis Hodgson, 1914.) Price 25*s.*

(1) It cannot have been an easy task to prepare the new edition of Salmon's classical treatise; the result may be considered quite satisfactory, although, no doubt, different readers will form different opinions about the choice of additions that has been made. In this volume, the principal ones are as follows:—First of all, a considerable addition has been made to the section on line-geometry. So far as we can judge, this has been very well done; it includes Ribaucour's theory of isotropic congruences, a good deal about normal congruences, and other interesting matter. Next, and partly connected with the foregoing, we have an account of curvilinear co-ordinates, triply orthogonal systems, and cyclides; also other theorems due to Ribaucour.

In the part dealing with cubic and quartic surfaces, there is a sketch of Segre's analysis of the singularities of cubics; Geiser's correspondence of lines on a cubic with bitangents of a plane quartic; and some very good articles on cyclides, and the special quartics of Steiner and Kummer. Towards the end of the book, we have eight pages or so on birational transformations, with some useful references, and a revised table of singularities, mainly based on Zeuthen's memoir of 1876 (*Math. Ann.*, x.). This last does not seem to be quite up to date; for instance, no reference has been made to the work of Enriques and Castelnuovo, and their discussion of the deficiency of a surface, which has yielded a new fundamental characteristic, besides that called the deficiency in this book.

Reference is made (Art. 527*a*) to some recent work on the reduction of a cubic to the canonical form $\sum_{1}^{5} x_i = 0$, and the proof that this is unique. One way of doing this is to obtain the equation $\Pi x_i = 0$, by a combination of invariants and covariants; this the present writer succeeded in doing a good while ago, with the help of Salmon's list of invariants, but the result was unpleasantly long.

Perhaps the most striking omission in the revised work is that of the theory of minimal surfaces. It would not have taken very many pages to give a fair account of this elegant theory, now that Lie and Weierstrass have reduced it to its simplest form. However, it may fairly be said that a student who has this work, and Prof. Forsyth's "Differential Geometry," will be able to make acquaintance with all the most important divisions of the subject, and be able to follow up any one in which he is specially interested.

(2) It is gratifying to see that Mr. Hardy's excellent treatise has so soon reached a second edition; and it helps to justify the statement in the preface that "it is no longer necessary to apologise for treating mathematical analysis as a serious subject worthy of study for its own sake." The author combines, in a remarkable way, strictness of method with an agreeable style; and his choice of topics seem to us to be eminently judicious. The principal additions in this re-issue are an account of Dedekind's theory of irrational numbers; a proof of Weierstrass's theorem about points of condensation, of the Heine-Borel theorem, and of Heine's theorem about uniform convergence; the notions of "limits of indetermination" and "implicit function" are also discussed. To save space, some analytical geometry and trigonometry has been deleted. The examples are well chosen, and hints towards solution are frequently given. This book, and Mr. Bromwich's "Infinite Series," to which Mr. Hardy refers in his preface, ought to do a great deal towards making school and college mathematics more rigorous, without making it repulsive; on the contrary, the apparent paradoxes explained, and the latent fallacies exposed, ought to provide a certain amount of fun, even for an undergraduate.

There are one or two very trifling points that may be noticed. On page 231, $D^{-1}(x^{-1})$, when x is negative, is defined as $\log(-x)$. This is very artificial, especially as the figure, page 359, implies that $\log x$ is undefined when x is negative. The same complaint of artificiality applies to the treatment of differentials (page 280). A rather more important point is on the proof (page 313) that the sum of a series of positive terms is the same "in whatever order the terms are taken."

This certainly requires more explanation than is given. The words "of course no terms must be omitted" begs the whole question; the sum is a *limit*, and we cannot take all the terms. Perhaps the following might be suggested. Let $\sum_1^\infty u_m$ be convergent as it stands, so that $\mathrm{Lt}(m\rightarrow\infty)u_m = 0$. Let $\sum_1^\infty v_n$ be so related to Σu_m that there is a one-one correspondence of terms, so that we can write

$$u_m = v_{m'}, \quad v_n = u_{n'},$$

where m', n' are determined by m, n respectively. Suppose *further* that when $m\rightarrow\infty$, then $m'\rightarrow\infty$, and that when $n\rightarrow\infty$, then $n'\rightarrow\infty$; in these circumstances we can infer that $\Sigma u_m = \Sigma v_n$. So far as Mr. Hardy's proof goes, we might infer that—

$$u_1 + u_2 + u_4 + \ . \ . \ . \ = u_2 + u_3 + u_4 + \ . \ . \ .$$

but this is not true, unless u_1 occurs at a finite place on the right.

(3) The contents of the last volume of the London Mathematical Society's proceedings are, as usual, very varied, and only a very gifted or very conceited reviewer would venture to express an opinion on the absolute or relative value of the different papers. As specimens, we note Mr. Bromwich's on Foucault's pendulum, Mr. Burnside's on prime-power groups, Mr. Carslaw's on Green's function for $\Delta^2 u + k^2 u = 0$, Mr. Hobson's on the linear integral equation, and Sir J. Larmor's on the electromagnetic force on a moving charge. There is also an interesting paper by Mr. Mordell on the diophantine equation $y^2 - k = x^3$. Altogether, the volume gives an encouraging view of the state of English mathematics, except for the lack of geometry, especially pure geometry. This is becoming really a serious symptom; not only is there an element of culture in geometry which analysis does not possess, but there is a risk of our studying the whole science from a one-sided point of view, even if (as is probable) strict mathematical geometry is reduced to formal logic applied to a few indefinable axioms.

G. B. M.

PSYCHOLOGY AND PHILOSOPHY.

(1) *The Foundations of Character, Being a Study of the Tendencies of the Emotions and Sentiments.* By A. F. Shand. Pp. xxxi+532. (London: Macmillan and Co., Ltd., 1914) Price 12s. net.

(2) *Perception, Physics, and Reality: An Enquiry into the Information that Physical Science can Supply about the Real.* By C. D. Broad. Pp. xii+388. (Cambridge: At the University Press, 1914.) Price 10s. net.

(3) *Philosophy: What is it?* By Prof. F. B. Jevons. Pp. vii+135. (Cambridge: At the University Press, 1914.) Price 1s. 6d. net.

(4) *Know Your Own Mind. A Little Book of Practical Psychology.* By W. Glover. Pp. ix+204. (Cambridge: At the University Press, 1914.) Price 2s. net.

(1) PSYCHOLOGISTS have been slow to meet the popular demand for a science of character. Under the name ethology, it was planned by John Stuart Mill. But Mill failed to accomplish his plan. The 'laws of psychology,' upon which he proposed to base his new science, were, in his day, inadequate and unsuitable for the task. In Mr. Shand's eagerly awaited book the attempt has been renewed. Will the new attempt meet with a greater success?

Judged by Mr. Shand's criterion, it undoubtedly will. Mr. Shand no longer claims to deduce the laws of character from certain fundamental conceptions, initially established as true. He seeks rather to formulate provisional hypotheses, and to test them by their fruitfulness. His method is thus concrete and synthetic. It gives him the viewpoint of the novelist and dramatist, of the biographer and historian; and enables him to utilise their material. In place of Mill's 'laws of association' he propounds the 'principle of organisation': all mental activity tends to produce and sustain system; and, in sharp distinction from the school of Mill, and in common with others who have more recently approached his field, he seeks the springs of conduct on the instinctive and emotional side of man's original nature, rather than on its intellectual side.

In his conception of character the chief place is given to those lower systems called emotions, and those higher systems, which he has already taught us to call 'sentiments.' The influence of intelligence and will is somewhat briefly dismissed. He treats more fully the influence of temperament; and, most suggestively, that of temper.

The present volume deals in detail with each of the primary emotions. Together with fear, anger, wonder, and disgust, he includes repugnance, surprise, sorrow, and joy. Tenderness, self-assertion, and self-submission are omitted. His list thus differs a little from that suggested by Mr. McDougall. A yet deeper difference is revealed in his treatment of instinct. In Mr. McDougall's view, to each principal instinct there corresponds innately some one specific emotion. According to Mr. Shand, an emotion may include within its system several instincts, and the same instinct may be found organised in several different emotions. The difference is partly a question of fact, which future investigation may well set itself to solve; but it is partly a question of what we are to term instincts. Emotion itself is defined so as to include a cognitive and a conative attitude, as well as one of feeling. But the part played by the former aspects is not quite as clear in the book as it obviously is in Mr. Shand's own mind; this perhaps is due to a postponement of a full treatment of knowledge, intelligence, and will to the later volume dealing with the sentiments.

Perhaps the least convincing feature of the book is the source from which Mr. Shand has collected his facts. To observational and experimental data he makes scarcely any appeal. In support of his one hundred and forty-four provisional laws he goes almost entirely to literature. To illustrate the association of qualities in various character-types he turns to Balzac and La Bruyère rather than to the correlations of Heymans and Wiersma, or the records of the followers of Binet, Stern, and Freud. In the present stage of knowledge he is perhaps justified. Doubtless, field-workers will soon come forward to collect observations, make experiments, and apply statistics. And for preliminary conceptions, problems, and hypotheses they can go to no more inspiring source than Mr. Shand.

(2) Mr. Broad's book attempts to discover how much natural science can actually tell us about the nature of the real. But, unlike recent authors who have approached this question, he deals with physical science rather than with biological. His chief philosophical concerns are perception and causation. His problems are thus those of Mach or Lotze rather than those of Bergson or Driesch. And his point of view owes much to Mr. G. E. Moore and Mr. Bertrand Russell. His treatment, however, is none the less suggestive. And his book provides an excellent refutation of Kant's dictum that, in dealing with the traditional problems, philosophy is concerned only with certainty and not with probability.

(3) The minds of most English people (so Mr. H. G. Wells has declared) will only be reached, under present conditions, by thoughts that can be expressed in the meanest commonplace. In "Know Your Own Mind" and "Philosophy: What is it?" we have two deliberate endeavours to falsify this pessimistic prophecy. Mr. Glover and Prof. Jevons have set themselves to interest the average man in two of the most abstruse and technical branches of human knowledge—philosophy and psychology. Unfortunately, philosophers and psychologists themselves may be inclined to think that the point of view represented in both is not indeed commonplace, but perhaps a trifle old-fashioned.

Philosophy and science, materialism and idealism, scepticism and philosophy, personality and the whole—these are the time-honoured themes that Prof. Jevons discusses in a masterly but time-honoured manner. They were chosen for lectures delivered at the request of a branch of the Workers' Educational Association. In the debates that followed, the burning controversies of the day, and the actual contributions of contemporary philosophers, were doubtless freely discussed; and so, perhaps, it was best that the main impression left was the enduring character of the old enduring questions. Often and ably as these have already been treated in brief, cheap, popular manuals, Prof. Jevons's little book will rank among the best.

(4) Mr. Glover's volume belongs to the same pleasantly printed and pleasantly bound series. In his endeavour to be up-to-date, he tells us, he has tried to catch something of the 'cinema spirit.' His metaphors, his similes, and his allegories are both vivid and picturesque. But his matter is not quite as up-to-date as his style. He gives us a revised and racy epitome of the traditional Herbartian psychology. But the methods and marvels of the psychological laboratory he dismisses as of little practical utility and no popular interest. Nor does he give any reference which would help his reader to realise that the knowledge of our own minds, like most other knowledge, has been largely extended by careful observation and experiment. His main purpose, however—to present the subject-matter of psychology in a light which will be intelligible and interesting to the man in the street—this he has brilliantly fulfilled.

OUR BOOKSHELF.

The Next Generation: a Study in the Physiology of Inheritance. By F. G. Jewett. Pp. xi+235. (Boston and London: Ginn and Co., 1914.) Price 3s. 6d.

The author of this skilful little book is persuaded that the improvement of the human breed would be accelerated if people knew more biology. They perish for lack of knowledge. "Science says human beings will be safer when people know the facts, and are influenced by them. Teachers say 'Give us the facts, and we will pass them on to the boys and girls whom we teach.' Both man of science and teacher agree that the human race will be better able to escape certain kinds of peril if we let young people know what the perils are, and how to avoid them. Such is the purpose of this book."

The general facts of evolution, heredity, and development are stated with simplicity and vividness, and on this foundation the author bases her instruction in regard to the culture of adolescence, the use of alcohol, the raising of the standard of parental fitness, and similar problems. In a detached appendix the dangers of venereal diseases are frankly pointed out. The author's general position is that much is to be attained by greater cleanliness, increased control of the hours and conditions of labour, and improved environment for children, but that there must also be some way of preventing the decisively unfit from becoming parents. The book is competent and wise, but some of the statements seem to us to require safeguarding. The citations as to child labour "in the greatest canning factory" in America are so terrible that we hope there is some mistake. The date should have been given. The book is dedicated to "Boys and Girls, the Guardians of the Next Generation," but we hope we are right in understanding that it is meant only for the teacher's use.

Principles of Physical Geography. By G. C. Fry. Pp. x+151. (London: W. B. Clive, 1915.) Price 1s. 6d.

THIS little book contains that part of the author's text-book of geography which deals with physical geography, with some additions on such subjects as map drawing, climate, and the crust of the earth, as well as a new chapter on man and his work. It contains no definite instructions for practical exercises to be worked by the pupil, but the descriptive treatment will prove suitable for students preparing for the examinations mentioned in the author's preface.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Thermionic Current.

IF a carbon filament lamp is silvered inside, and a platinum wire through the side of the glass makes electric connection with the belt of silver, it is easy to experiment with the thermionic current, using a telephone receiver with one terminal to the platinum wire and the other to the water mains.

With an alternating current at 110 volts, a loud note is heard, depending on the frequency of alternation. With a direct current from a dynamo there is sufficient variation in the voltage to obtain a sound just audible at 100, loud at 110, very loud at 130, and it might be described as an uproar at 140 volts. It might be expected that the intensity would increase until the lamp burnt out. Nothing of the sort. At 142 volts the uproar is replaced by dead silence, which continues up to 165 volts, as high as the lamp would stand.

The explanation may be gathered from Langmuir's paper (*Physical Review*, December, 1913). The thermionic current does not increase with the temperature, according to Richardson's law, unless the vacuum is of a high order. With a moderate vacuum the volume charge between the filament and silver causes the thermionic current to remain at a value nearly constant, as the temperature is raised above a certain value. The thermionic current begins by obeying Richardson's law ($i=a\sqrt{T}e^{-\frac{b}{T}}$), and then later approximates to a steady value.

Thus at low voltages variations of voltage cause variations of temperature and consequent fluctuations of thermionic current, heard through the telephone.

Above 140 volts, however, for the particular lamp in question, a change of voltage and of temperature produces no change of current, and hence no sound can be heard in the telephone.

It is possible that this method may prove very convenient for testing the electron emission from various substances in different gases, and it suggests a method of measuring a high vacuum. A. S. EVE.

McGill University, Montreal, March 31.

A Mistaken Butterfly.

WHILE waiting for a car at Pacific Grove, Monterey County, California, on February 12 (Lincoln's birthday) of the present year, I noticed that a man standing near me had the brightly-coloured "eye" of a peacock's feather in the band at the back of his hat. While looking at this I saw a butterfly floating above the man's head. It suddenly lighted on the "eye" and apparently began trying to extract food from it. I directed the man's attention to it; he removed his hat, and we watched the insect for several minutes as it tried to secure food from the feather. It then flew away, as if satisfied that it had made a mistake. I do not know the name of the butterfly, but it was one of many of a light brown colour that seem to be plentiful at Pacific Grove at that season. I was told that these butterflies at a certain time regularly alight in thousands upon a special pine tree (one of a great many) in the western edge of the town, and from this fact they have called it the "Butterfly Tree." I do not know whether these insects seek their food from flowers by the sense of smell or that of sight, but it was evident in the present case that this one was guided entirely by sight.

E. E. BARNARD.

Yerkes Observatory, Wisconsin, U.S.A March 29.

BRITISH SUPPLY OF DRUGS AND FINE CHEMICALS.

AT a British Association meeting about twenty years ago an eminent physicist received some rough handling from his chemical colleagues on account of the impurities which were manifestly present in the materials he had used in his experiments. He replied, in effect, that chemists should employ themselves in purifying chemicals for physicists to use. Nowadays chemicals such as he would have desired are made by the ton, chiefly by three firms in Germany. For ordinary chemical, and even physical, research such fine materials are turned out that it may be doubted in many cases if the work done with them is worthy of such refinement. Frequently the chemicals used are better than the chemist who works with them could have produced for himself. For work of the highest degree of refinement, such as the determination of atomic weights, the chemicals which can be purchased cannot be used without much further purification, but even in these cases much time is saved by the previous elimination of the grosser forms of impurity. To those who were in their early days limited to chemicals produced in this country, the standard of purity attained by the German manufacturer came as a revelation, and the study of prices made it clear that the enormous advantage gained by the use of the German materials was obtained at no unreasonable cost. The standard set by the German makers has not even been aimed at by our own countrymen, and the words "pure," "puriss," and "absolutely pure, for examination purposes" on the labels, are ludicrously misused. Want of method, want of care, and the employment of workmen instead of chemists in the preparation are at the bottom of the failure.

With regard to drugs, it has been stated that some eight hundred different medicinal preparations have been patented within recent years by German chemists, and although this is probably an exaggeration, it is certain that a very large number of such substances have been prepared, and that many of them have been found of sufficient value from the physiological point of view to warrant their retention as commercial products.

In these days when the relationship between chemical constitution and physiological action is fairly well understood, it is clear that the discovery of an organic structure which has valuable physiological action will lead to the preparation of large numbers of others differing but slightly in composition, and that these will find their way into patent literature mainly in the hope of their being useful, and, incidentally, to retain the field for further investigation. Such was the case of salvarsan, and since the discovery of that substance by Ehrlich, the patent literature has teemed with specifications dealing with the preparation of organo-metallic derivatives of almost every conceivable description. The antipyretics, again, of which phenacetin and aspirin may be quoted as types, belong to definite groups of organic compounds, the other members of which possess more or less important properties, depending on a slight change of structure the nature of which is not definitely understood.

There is another class of drugs of which the Germans have made a special study, those which are obtained from vegetable sources. In looking through their descriptive catalogues (in English) which are largely circulated among medical men in this country, one is struck by their far-reaching enterprise in this direction. Their travellers have gone to the ends of the earth to investigate native diseases and the local remedies which are used for their treatment. So long ago as 1850, Schweinfurth, in his journeys in central Africa, compiled a list of such remedies and brought home specimens of plants from which they were made. In Germany a large trade is now done in the extracts from vegetable sources collected from the remotest corners of the globe, many of them British possessions. The medicines are sold in elegant and even attractive form, and those whose memories go back to the pre-tabloid days may well envy the younger generation. It would not be just to underestimate the work done by certain firms in this country in the same direction, but in the number of the drugs and the enterprise shown in collecting new ones, we are, without doubt, behind our enemies.

In these matters of fine chemicals and drugs, both synthetic and natural, it is an arguable question whether the trade should be left as it is. On one hand it might be said that the work is admirably done by the German manufacturers in both branches; they have large and capable staffs and works excellently fitted for the purposes for which they were built; should not these particular manufactures be left in their hands? On the other hand, we have a sense of humiliation that we should be, in any conceivable juncture, dependent on those who are at present our enemies. Certain allied manufactures, *e.g.*, heavy chemicals, are still left largely in our hands, but if we yield in the smaller trades, is it not likely that they will succeed in wresting from us the larger source of profit? There can be no convention or agreement in these matters; each country will make what profit it can in the most convenient direction. "Capturing the Enemy's Trade" makes a good newspaper heading, but it is painful to read the many impracticable suggestions which have been made on the subject since the beginning of the war. Many people seem to have the idea that all that is wanted is that a works shall be built, or even a derelict factory be adapted, and then the thing is done. No thought is given to the years of patient research, the long training of the workers, and the period which must elapse before even the raw materials could be collected.

In the particular directions with which this article is concerned there is no doubt that the thing can be accomplished in time. In one laboratory of university rank the manufacture of three synthetic drugs in large quantities has been carried on since the opening of the war, and the resulting products have been handed over to the naval hospitals which were in urgent need of them. The preliminary investigation in this piece of work occupied a staff of seven experienced workers, under the direction of the professor, two whole months before the details of the processes could be mastered. The results not only gave to the naval service what was wanted at the moment, but they enabled the details of the processes to be handed over, through a committee of the Royal Society, to three manufacturers who will produce the drugs on a large scale. In a similar way the laboratory of another institution has succeeded in working out the process of making a natural drug from its plant sources. These instances illustrate the magnitude of the task which is before us, and the amount of highly specialised labour which must be employed on the problems. It is only courting failure if the conditions necessary are not realised before a start is made.

In the matter of highly purified chemicals another point must be noticed. The reputation of the German makers is high, and deservedly so, and it follows that it will be a long time before possible rivals, even if they produced materials of an equal degree of purity, could obtain the same degree of confidence in the minds of their customers. In order to give this confidence it has been suggested that the object might be most quickly attained by the establishment of a National Chemical Laboratory analogous in constitution and management to the National Physical Laboratory, in which the products of the manufacturers could be tested and the standard of purity guaranteed. The scheme would undoubtedly serve to hasten matters. The guarantee of the National Physical Laboratory is accepted as impartial and accurate throughout the world, and there is no reason why a chemical institution of the same kind should not command equal confidence. Into the question of cost there is perhaps no need to enter, but the fact must be faced that the average man would not expect to pay a much higher price than he has paid heretofore because the substances were made in England. H. B. Baker.

HOME FORESTRY AND THE WAR.

In an article in Nature of December 10, 1914, p. 393, it was shown how dependent we were upon foreign countries for our supplies of pitwood, without which coal-mining could not be carried on. About half the total amount of pitwood exported in normal times into the United Kingdom comes from Baltic ports; and as a result of the action of Germany in declaring pitwood contraband, the supplies from this source have practically ceased, what now arrives from Scandinavia being merely small cargoes from Gottenburg, Christiania, and other ports outside the Baltic. The important supply of pitwood from France, Spain, and Portugal still continues, though at enhanced prices; and in case of need, large quantities can be obtained from Nova Scotia, Newfoundland, etc. Nevertheless, it became necessary to ascertain the available amount of home-grown timber suitable for use in mining; and an inquiry into the subject was undertaken by the forestry branch of the Board of Agriculture, the report of which has been issued with great promptitude. From this it appears that the total area of woodlands in England, 1,884,000 acres, is capable of yielding 380,000 tons of pitwood annually by normal fellings; and that by anticipating the fellings of the next five years almost 3,400,000 tons of pitwood are available in England and Wales alone. Scotland by similar extraordinary fellings could supply about 2,500,000 tons; so that with the aid of a small quantity from Ireland, about 6,000,000 tons of pitwood could be felled, enough to keep the collieries going for eighteen months, as their average annual consumption of pitwood is approximately 4,500,000 tons.

In the *Quarterly Journal of Forestry*, January, 1915, pp. 1–7, Sir W. Schlich, criticising the preceding report, asks what will be the position if the war should last for more than two years; and considers that in this case our coal mines would be obliged to shut down for want of pitwood. As labour in Canada is very expensive, he believes that supplies of mining timber from Nova Scotia, etc., may prove unavailable on account of the prohibitive cost. He urges upon the Government the necessity of taking early steps to increase the area under trees in these islands, and reiterates well-known arguments that, however sound, appear to have little effect upon our rulers. He sums up as follows:—

> Forest schools have been set up for instruction in forestry; a forestry branch has been established in connection with the Board of Agriculture and another in Ireland; an officer has been appointed to convert the Dean and High Meadow Woods into a demonstration area. All this is in the right direction, but *very little has as yet been done to increase the area under forest.* Too much talking and too little action —that is the long and short of it. Let us hope that the new situation will lead without further loss of time to action. Of course, I should not advocate the taking of a single acre out of cultivation, because the production of food goes before everything else; but there are large stretches of land unfit for cultivation and yet quite fit to produce forest crops. Nor should I advocate the formation of large blocks of woodland, all in a ring fence as it were. No, what I look forward to are moderate sized areas scattered over the country. As long as the area is sufficiently large to justify placing a woodman in charge and also sufficient to be placed under systematic management, say a minimum of 500 acres, we snall have all that is required. In that case agricultural labourers and tenants of small areas will in time come forward and do the bulk of the forest work during the winter months, when agricultural work is practically at a standstill, thus improving their resources. Such a scheme will not be perfection all at once, but it will come by degrees. Only let the Government, with funds allotted by the Development Commissioners, start actual work, even on a small scale; it is sure to grow.

Another article in this journal deals also with the subject of pit-timber, and reviews the result of an independent inquiry by the English Forestry Association. Further articles treat of the preparation of yield tables, which are necessary in the estimation of the financial returns that are probable, when waste lands are afforested. Mr. Hiley writes a preliminary report on an investigation at Oxford into larch canker, and advocates a means of treatment which is scarcely advisable on account of the expense, not to mention the fact that the mode of infection on which the treatment is based is not yet clearly demonstrated to be the actual one.

In the *Transactions of the Royal Scottish Arboricultural Society*, xxix., part i. (January, 1915), the production of pitwood on wooded estates in Scotland is investigated by Mr. J. H. Milne Home, both as regards the present crisis and also with a view to a permanent increase in the supplies of mining timber in the future. Mr. Home considers that one-fourth of the normal amount required by British collieries could be readily supplied from Scotland, if railway rates of freight could be reduced by 25 per cent. An admirably illustrated paper by Mr. P. Leslie deals with the afforestation of the coastal sand dunes at Culbin, between the rivers Nairn and Findhorn. The Culbin sands have a remarkable history, as they conceal an estate of 3600 acres, which was once the richest agricultural district in Morayshire. The incursion of the sand took place suddenly in 1694, leaving a wilderness until 1865, when Major Chadwick began plantations, which have been continued by his son. The species mainly used has been been Scots pine, but Corsican pine wherever planted has given the best results, producing tall, clean poles of valuable timber. The operations, which include the prior fixing of the moving sands (Fig. 1) by maram grass, are carefully described, and are similar to those used by the French in the Landes.

Photo] [*Geological Survey.*

Fig. 1.—Culbin Sand-hills, Elginshire: near the Binsness Plantations. The background shows a travelling dune of advancing sand. The steep bank with cornice atop and slipping sand on slope, the tails of sand behind the tufts of bent, and the wind ripples in the foreground, indicate that the sand-drift is from left to right, *i.e.*, from west to east.

Wood-charcoal and its uses is the subject of an article by Mr. W. D. Ashton Bost, who states that the only firm in Britain which reduces iron-ore by charcoal is that of Messrs. Harrison Ainslie. Their charcoal furnace at Backbarrow on the river Leven in Cumberland produces annually about 2400 tons of so-called "Lorn" charcoal pig-iron, which is the dearest iron in the market, and is exported for special uses to all parts of the world.

The production of potash salts from woodlands and wastelands is the subject of a timely article by Mr. G. P. Gordon. It is probable that the material obtained by burning lop-and-top and brushwood in plantations and bracken fern on wild hill-sides, together with the ash of furnaces, using sawdust as a fuel, can compete successfully with kainit, which has been for many years the main source of the potash salts that enter into the composition of artificial manures. There is an account of a peculiar witches'-broom infesting willow trees at Hampstead and in parts of Essex near London, which appears to be hitherto undescribed. Prof. A. Henry gives an account, from Japanese sources, of the distribution of *Larix leptolepis* in its native home.

Many useful notes from continental sources are given, of which the following may be cited, taken from the Norwegian *Manual of Silviculture* by Barth:—The limit of the existence of forest trees in Norway is fixed by the mean temperature of the four months of vegetation, June to September. Birch is content with a mean summer temperature of 45° F.; aspen and grey alder with one just under 46° F.; Scots pine and spruce, 47° F.; *Alnus glutinosa*, 54° F.; oak, 55° F.; and beech, 56° F. It would be interesting to obtain similar figures regarding the limit of these species and larch in Britain.

THE CARNEGIE TRUST.[1]

THE Carnegie Trust for the Universities of Scotland has steadily pursued the policy of making quinquennial distributions of the funds at its disposal; and the present year finds the third of these schemes in operation. The total sum to be expended during the current five years was 203,250*l*. Of this, 21,250*l*. is to be applied towards providing books, etc., for the libraries of the universities; 160,750*l*. goes to supply new buildings and permanent equipment; while 21,250*l*. is to be spent on endowing lectureships and upon other general purposes.

With regard to that portion of the scheme which concerns itself with assisting students by paying their class fees, a sum of 41,789*l*. was paid on behalf of 3,900 beneficiaries in 1913–14. It is gratifying to note that in the same period 605*l*. has been repaid to the trustees by beneficiaries who had been assisted under the scheme.

The expenditure on research for the current twelve months is divided as usual under the heads of scholarships, fellowships, and grants, with the additional expenditure necessary to support the laboratory of the Royal College of Physicians in Edinburgh. 1392*l*. has been spent upon the laboratory, while the fellowships, etc., have necessitated an outlay of 7652*l*.

These sums have not been expended without good return, as the present report shows. Special mention is made of the long and conspicuously successful investigations of Dr. Margaret B. Moir on the effect of temperature upon the magnetic properties of steel; while the executive committee point to the work of Dr. Dougall on elasticity as a proof that their fellows do not relinquish research with the termination of their fellowships, but continue to bring forward investigations of first-class importance.

The scholars in the branches of chemistry and physics have published no fewer than thirteen papers during the session, and much unpublished work is still in process of completion. The research grants have aided in the production of twelve papers during the present year; and in this connection stress is laid upon the collaboration between the permanent staffs of the universities and other beneficiaries of the trust, the cases of Profs. G. G. Henderson, J. C. Irvine, and Dr. T. S. Patterson being singled out as examples of success in this respect.

In more than one direction, the war has had an effect upon the progress of the research scheme. Naturally, as far as materials go, the chemical field is the one most affected, owing to the difficulty of obtaining substances for some classes of work; but all branches have suffered owing to the enlistment of fellows and scholars in the army. No fewer than nine of the fellows and scholars have interrupted their scientific careers for this object; and it is satisfactory to learn that their positions are being kept open for them should they wish to resume research work after the war. A similar state of affairs is found in the Royal College of Physicians' laboratory, from which no fewer than nine of the workers are absent on military duty; so that this institution has been heavily handicapped during the current year.

Bearing these factors in mind, the results obtained in the operation of the trustees' scheme during the period covered by the report cannot be said to fall below the high standard attained in previous years; and it must also be recalled that many of the beneficiaries of the trust have resigned their fellowships or scholarships in order to take up permanent positions either in the universities or in other lines of professional work.

During the academic year 1914–15, twenty fellows and forty-seven scholars have been at work, while grants have been given to seventy-eight applicants. The investigations of these beneficiaries are extended over so wide a field of knowledge that it is impossible even to mention the branches of science, medicine, history, and languages in which work is being carried out; but a perusal of the report leaves the impression that the operations of the trust are steadily opening out wider and wider fields. The success of the trust's methods has never been in doubt, and the interest of observers becomes concentrated upon the developments which seem likely to flow from this vast machinery for enabling competent investigators to acquire a grasp of the methods of research, and to put the knowledge thus obtained into practice on a bigger scale than would otherwise be possible to them.

[1] Thirteenth Annual Report of the Carnegie Trust for the Universities of Scotland, 1913–14.

INEXACT ANALOGIES IN BIOLOGY.[1]

THE philosopher of the forum is notorious for the looseness of his analogical arguments from biology, and biologists themselves deserve castigation for their lax terminology. Even a Galton can write: "Parents are very indirectly and only partially related to their own children." Every word has its halo, and may be regarded according to one's point of view as either a potted poem or a tabloid theory. When the theory has been overturned, the use of the word in serious argument is dangerous. Then comes the critic to set us straight again, and so here is Dr. Johannsen putting such blessed words as "evolution," "affinity," "tradition," and "inheritance" in their proper places. So far as he condemns the use of inexact analogy, especially as a method of proof, we shall all agree with him—at least theoretically. But an analogy, strict in its application, may be falsified by its premisses. Many such are rejected by Dr. Johannsen as incorrect presentations of the facts of organic life and history. But here he often seems a little too certain that his interpretation of nature is the only right one. Belonging to the strictest sect of the Mendelians, he believes that, though the organism may respond variously to external

[1] Falske Analogier med Henblik paa Lighed, Slaegtskab, Arv, Tradition og Udvikling. By W. Johannsen. 8vo, pp. 114. (København, 1914).

conditions, the constitution of the germ is unaffected thereby, and that any change in it is necessarily discontinuous. Hence, though individual growth is inevitably continuous, organic evolution must be discontinuous; and any analogy between race-history and individual history must be false. The idea that the latter recapitulates the former "cannot be applied to concrete instances."

That likeness does not necessarily imply relationship is true enough; but there is more than "likeness" when we find the last of an ascending series of fossils repeating in its life-history the adult stages of the successive species immediately preceding it, all those stages having been linked by gentle gradations. The semblance of continuous evolution may conceivably be explained by an appeal to the mongrel (heterozygote) constitution of the germ, and by allowing wide limits of modification to the soma, in successive species. But why is the trend of germinal saltation so often the same as that of somatic modification, and why should individual growth repeat and follow this trend? These are questions not of analogy, but of fact, and are not to be dismissed with a bare denial.

Biologists may differ on these matters, but all might read with pleasure Dr. Johannsen's criticism of Prof. Bergson's "Élan vital."

F. A. Bather.

PROF. OTTO N. WITT.

By the sudden death, through heart-failure, on March 23, of Otto Nikolaus Witt, Geheimer Regierungsrat and professor in the Technical High School of Charlottenburg, at the comparatively early age of sixty-three, and in the full maturity of his intellectual power, Germany loses one of the most distinguished of her teachers of chemical technology, and one of the most successful of her pioneers in the application of organic chemistry to industrial pursuits. Of Russian extraction, Witt had intimate associations with all the countries now warring against Germany. Like Hofmann, Griess, Caro, Martius, and others who could be named—the founders of Germany's unrivalled supremacy in the manufacture of the so-called coal-tar dyes—upwards of thirty years ago Witt spent some time in England as a member of the now defunct firm of Williams, Thomas and Dyer, then engaged in the industrial production of this class of colouring matters. He took kindly to English life, moved freely in scientific and literary circles in London, joined the Savile Club, which had then its home in Savile Row, had his boat on the river, and enjoyed to the full the hospitality which his many social gifts, the range of his knowledge, his admirable conversational powers and charm of manner readily secured for him.

Witt spoke and wrote our language with ease and fluency. *Habitués* of the Royal Institution well remember the brilliant Friday evening discourse he gave on the development of the synthetic indigo industry, illustrated with a wealth of material and a mass of detail which his close connection with the great firms which have combined to exploit that industry had enabled him to accumulate. Among the many fruits of his scientific activity in England at that time may be mentioned his paper in collaboration with Thomas, on the induline group, published in the Transactions of the Chemical Society for 1883. At another period of his career he was associated with Nölting and Grandmougin, at Mulhouse, in developing the chemistry of the indazole derivatives, and his Alsatian connections brought him into contact with the leading manufacturers of synthetic colouring matters in France, and he learned to know Paris and to appreciate its scientific interests as fully as he knew and valued those of London.

The most fruitful period of Witt's scientific activity was comprised between the years 1876 and 1892. During the earlier years of his connection with the Charlottenburg institution, he was hampered by the want of adequate laboratory accommodation, and in spite of his acknowledged position as an authority on that particular section of applied organic chemistry with which his name and fame are indissolubly associated, and notwithstanding his generally recognised powers as a teacher, his success in creating a school fell short of his hopes, and neither the number of his students nor the character of their output, as determined by the quality and number of their communications to chemical literature, were commensurate with his aspirations.

Witt was one of the earliest to attempt to explain the properties and colour of dyes in terms of chemical constitution, and his memoir of 1876, published in the *Berichte* of the German Chemical Society, attracted considerable attention by the originality and boldness of its views, and the ingenuity with which they were supported. The terms "chromophor" and "chromogen" which he introduced in order to denote the special groups and molecules which he conceived to be concerned with the production of colour are still current in the literature. Although Witt's hypotheses have not wholly stood the test of time, the paper will always have its place in the history of the subject. It is at least noteworthy as the production of a young man of twenty-four.

Witt's name is associated with the discovery of certain typical classes of synthetic dye-stuffs. His published work includes papers on the indulines and indophenols; on the nitroso-derivatives of aromatic amines, eurhodines, eurhodols, safranines, etc., and he contributed the monographs on azines, indamines and indophenols, artificial indigo and indigoid dyestuffs, and triphenylmethane colouring matters to the "Dictionary of Applied Chemistry," published by Messrs. Longmans, Green and Co. They are amongst the most valuable articles in that work, and are characterised by Witt's excellent literary qualities, his grasp of principles, his power of co-ordination, his sense of proportion, and felicity of expression—qualities exhibited in no less degree in his frequent contributions to *Prometheus*, with which he was associated as editor for many years, a periodical which played much the same part in Germany as Nature does among English-speaking communities.

Witt was a singularly gifted man, of great attainments, artistic and literary, of large sympathies and wide interests, far removed indeed in mental habit and outlook from what is usually regarded as the typical German professor. He had an extensive knowledge of what is best in the literature of nearly every European nation, to which his remarkable linguistic attainments gave him ready access. In early life he was attracted to biological problems, was an excellent microscopist, and rivalled Cleve in studying and delineating the lower forms of organic life. In his later years he was devoted to the culture of orchids, and was an occasional visitor to the Temple show of our Royal Horticultural Society, and a frequent purchaser at the plant auctions in London. Of his power of initiative and capacity for organisation and direction, and of his merits as a host, those who attended the International Congress of Applied Chemistry at its meeting in Berlin, of which he was president, have a pleasurable and grateful recollection. T. E. Thorpe.

NOTES.

We regret to announce the death, on April 10, in his eightieth year, of Dr. W. Grylls Adams, F.R.S., Emeritus Professor of Natural Philosophy and Astronomy in King's College, London.

The death is announced, at nearly sixty-two years of age, of Dr. Louis Waldstein, author of "The Subconscious Self," and of many articles on pathological subjects.

On Monday, April 12, at a meeting of the Council of the Royal Society of Arts, the society's Albert Medal was presented to Senator Guglielmo Marconi "for his services in the development and practical application of wireless telegraphy." The medal, which was instituted in 1863 to commemorate the Prince Consort's presidency of the society, is awarded annually as a reward for "distinguished merit in promoting arts, manufactures, and commerce."

According to a message to the *Morning Post* from its Stockholm correspondent, the projected Anglo-Swedish Antarctic Expedition, under the leadership of Prof. Otto Nordenskjöld, has been postponed until the war has been brought to a conclusion. It will be remembered that the expedition was to sail in August next.

The death is announced of M. Edmond Rigaux, of Boulogne, in his seventy-seventh year. M. Rigaux was a well-known authority on the geology of the Boulonnais, and contributed especially to our knowledge of the Jurassic rocks and fossils of that region of France. He was a foreign correspondent of the Geological Society of London, and in 1883 received the Lyell Fund of the Society in recognition of the value of his researches.

The Jacksonian prize of the Royal College of Surgeons for 1914 has been awarded to Mr. Jonathan Hutchinson for his essay on the pathology, diagnosis, and treatment of trigeminal neuralgia, and the John Tomes prize to Mr. J. F. Colyer for his work on comparative dental anatomy and pathology. The subject of the Jacksonian prize for 1916 will be "Methods and Results of Transplantation of Bone in the Repair of Defects caused by Injury and Disease."

Protozoologists and marine biologists will be interested to learn that the whole of the collections and library of the late Fortescue W. Millett, of Marazion and Brixham, have been acquired by Mr. Heron-Allen, and will be incorporated as a special section of the Heron-Allen and Earland collection, to which the collection of the late J. D. Siddall, of Chester, was also added recently. It is hoped that this entire collection, numbering some 10,000 slides, and the library which accompanies them, will ultimately be incorporated with the Museum of Oceanography and Marine Biology, which it was the ambition of the late Sir John Murray to found. Broadly, his object was to form his collections of material and soundings into a department of the Natural History Museum in conjunction with the H. B. Brady and W. B. Carpenter collections, which are already there. The co-ordination of the Brady, Carpenter, Murray, Millett, Siddall, and Heron-Allen and Earland collections would form a reference museum of oceanic deposits and type specimens without an equal in the world.

The death is announced at the age of sixty-three of the well-known bacteriologist, Friedrich Loeffler, director of the Institute of Infectious Diseases, Berlin, and formerly Professor of Hygiene and Director of the Hygienic Institute, University of Greifswald. Loeffler's name is best known as the co-discoverer with Klebs of the diphtheria bacillus; this was in 1884. A year or two previously the presence of peculiar bacilli in the diphtheritic membrane was noted by Klebs, but it was Loeffler who afterwards isolated and cultivated this organism. With Koch and Gaffky, Loeffler carried out investigations on disinfection with steam at the Imperial Institute of Hygiene, Berlin, and he showed the keenest interest in the comparative study of the infectious diseases of animals, such as the diphtheria of calves and of pigeons. He was with Schütz the discoverer of the nature of the causative organism of foot-and-mouth disease, which he proved to belong to the group of micro-organisms known as "filter-passers," which owing to their minuteness are invisible with the highest powers of the microscope, and are capable of passing through the pores of a porcelain filter. To Loeffler also belongs the credit of achieving some of the early work associated with the application of aniline dyes to the staining of bacteria, "Loeffler's Methylene Blue" being used to this day as a routine laboratory stain. Loeffler's name will ever rank with those of Pasteur, Koch, and Ehrlich as a pioneer in the domain of bacteriological research.

The death of Major Samuel Flood-Page removes from the electrical world an interesting personality who played no small part in two important developments—electric lighting and wireless telegraphy. His first notable achievement after leaving the army was the organisation of the Electrical Exhibition at the Crystal Palace in 1882, when he was acting as manager of that institution. About this time the problem of the subdivision of the electric light had been solved by the introduction of the carbon incandescent lamp, and Major Flood-Page devoted his energies to promoting the commercial utilisation of the new illuminant. He was instrumental in introducing the first incandescent electric light into Australia, and then became secretary and manager of the Edison and Swan United Electric Light Co., Ltd. In the later years of his life he was interested in wireless telegraphy, and his faith in the ultimate success of this enterprise guided him through the many trials and difficulties which beset its path in the early days. Major Flood-Page first became actively engaged in wireless telegraphy in 1899, when he joined the Marconi Company in the capacity of managing director. In that year wireless telegraphy had advanced to a stage which permitted the establishment of communication across the Straits of Dover, between the Chalet d'Artois, Wimereux, near Boulogne, and the South Foreland lighthouse. He was one of a small party which waited at the wireless station at the Needles, Isle of Wight, in November, 1899, for the first wireless signals ever sent from a liner at sea to the British shores, and he was ever proud to recall the delight and satisfaction which he enjoyed as the liner's message was being received over a distance of sixty-five miles. After resigning the managing directorship, he remained a member of the board of the parent Marconi company and many of its leading subsidiaries. He died on April 7, in his eighty-second year.

Sir Rupert Clarke, who in the summer of last year led an expedition up the Fly River in British New Guinea, recently arrived in London to take up an appointment in the Army Service Corps. In 1890 Sir W. Macgregor reached a point 610 miles from the mouth of the river. Sir Rupert Clarke's expedition went 20 miles further. He also made the first ascent of Mount Donaldson, close to the German boundary. In a communication to the *Times* of April 10, he reports that the natives, a fine-looking, tall race, were at first inclined to be hostile, but later became friendly. They are divided into communes ranging in numbers from five or ten families to a thousand persons. No one is supposed to die a natural death, which is caused by suggestion through their magic men. After a man's death his relations must get a head so that his spirit may rest in peace. These heads are usually those of the women and children of hostile tribes. They are in constant fear of attack from their enemies, and live on scaffolds raised on high trees. Their bows are exceedingly formidable, beyond the strength of a white man to draw. They protect themselves from arrows by a kind of bamboo cuirass. They wear no other clothing. The height of Mount Donaldson was provisionally fixed at about 2000 ft. The return journey was effected in safety, without firing a shot, on rafts down the Fly River. Some signs of gold were discovered, but not rich enough to make working worth the trouble.

The Royal Geographical Society has received news of Sir Aurel Stein's explorations in Central Asia from April to November, 1914. The expedition started in April from Tunhuang, where it had halted to recruit after the trying campaign in the Lop-nor desert between Turfan and the northern boundary of Tibet. The cave temples of the Thousand Buddhas near Tunhuang were re-visited, and further interesting collections were made. The explorer followed the ancient wall for 250 miles, and found that it was constructed of fascines of reeds or brushwood, admirably adapted to check the wind erosion of the desert sands. Coins, pottery, and metal fragments found near the surface made it possible to define the Chinese frontier posts with accuracy. Beyond the So-lu Hu valley further remains of the same kind were found. While Sir Aurel Stein was hunting for remains of the Great Yuechi on Indo-Hun culture to the north, his surveyor, Lal Singh, examined the ruined town of Khara Khoto, and proved that this could be no other than Marco Polo's "City of Etzina," where in ancient times travellers bound for Karakoram, the old Mongol capital, used to lay in supplies for the march across the great desert. Here many Buddhist remains were found, and it was ascertained that the ruin of the city was due to failure to maintain the irrigation system. When he despatched his report Sir Aurel Stein had planned to examine Buddhist ruins round Turfan, while his surveyor was to undertake the exploration of the little-known desert ranges of the Kuruk-tagh between Turfan and the Lop-nor depressions.

A systematic paper on Termites from the East Indian Archipelago, by Masamitsu Oshima, has been published in *Annotationes Zoologicae Japonenses* (vol. viii., part 5). Of the twenty-four species enumerated, nineteen are described as new to science. The author imitates many modern American entomologists by illustrating his new species with photographic figures, most of which are valueless for the purpose of identification.

In the April number of the *Entomologists' Monthly Magazine* Mr. J. T. Wadsworth records the occurrence at Northenden, Cheshire, at the roots of cabbages, of the larvæ of an anthomyid fly (*Phaonia trimaculata*) new to the British fauna. Several of the grubs pupated, and eventually developed into the perfect insect, which measures 16 mm. across the extended wings—a fact rendering it somewhat remarkable that such a comparatively conspicuous species had not previously been observed in this country.

Many English-speaking naturalists who attended the meetings of the International Entomological Congress at Brussels and Oxford remember with pleasure conversations with a courteous and enthusiastic Spanish priest, the Rev. P. Longihos Navas, S.J., whose good knowledge of French made him a valuable interpreter to his compatriots. We have received a little "Manual del Entomologo," written by Father Navas, and published last year by the Catholic Press of Barcelona. It contains concise directions to the beginner for collecting, preserving, and classifying insects. Neither old nor new methods have been overlooked, for a well-worn figure of a collector "beating" into a venerable type of umbrella faces a sectional drawing of the modern "Berlese funnel."

Dr. Rolf Witting continues to contribute a great deal of most valuable hydrographical information on the sea-waters in the neighbourhood of Finland. In addition to the *Jahrbuch*, 1913, of the *Finländische Hydrographisch-Biologische Untersuchungen*, No. 13, which contains the details of salinity, temperature, and current measurements obtained on the seasonal cruises and at particular stations, we have received special papers by him on the optical and chemical examination of the water samples and on the methods of determining traces of ammonia in sea-water, as well as a paper by Prof. K. M Levander on the plankton of the Tavastfjärd. The oceanographers of Finland are to be congratulated on the regularity and persistence with which this work has been maintained for a number of years upon a uniform plan, a persistence which has obtained for them a place in the forefront of the European countries which have been engaged in marine researches in recent years.

We have received from the British Museum (Natural History) a report by Dr. S. F. Harmer on Cetacea stranded on the British coasts during 1914. The arrangements made by the Board of Trade for reporting such strandings a couple of years or so ago have been continued, and in some respects amplified, a notable innovation being the dispatch of the lower jaws of the smaller species, and of a plate of whalebone in the case of the baleen-whales. Up to the outbreak of the war returns were received regularly, but afterwards, when coastguards had their hands full of other duties, there was a great falling-off in the returns, this being particularly the case during the period from August to mid-October, when the items should have been at their maximum. The whole annual record of strandings amounted only to fifty-seven, as compared with seventy-six in the previous year. It may now be regarded as definitely established that the porpoise is by far the most abundant of the smaller cetaceans visiting the British coasts, and it may be added that the series of lower jaws of this species received at the museum has enabled Dr. Harmer to make some valuable observations with regard to the rate of growth, wear, and variation of the teeth—such observations indicating that a so-called species founded on such differences is invalid. Four records of the dolphin and the same number of the white-beaked dolphin are included in the list, which also comprises a Sowerby's beaked whale taken alive in September on the Wexford coast.

A recently published number of the *Indian Journal of Medical Research* (vol. ii., No. 3) begins with a memoir by Mrs. Helen Adie on the sporogony of *Haemoproteus columbae*, the "halteridium" parasite of the blood of the pigeon. The development was studied in *Lynchia maura*, the hippoboscid fly which is a common parasite of pigeons, and well known to be the invertebrate host of the Hæmoproteus. Whereas, however, previous investigators had not been able to find any stage of the parasite more advanced than the "ookinete" or "vermicule" in the Lynchia, and were of opinion that the parasite was inoculated into the pigeon by the fly in this phase of its development, Mrs. Adie has found that the ookinete-stage is succeeded by a process of sporogony exactly similar to that of the malarial parasites, with oocyst and sporozoite stages, ending with vast numbers of sporozoites in the salivary glands of the fly. The author states that no blood-parasites other than the Hæmoproteus were to be found in the pigeons; this statement, if correct, disposes of the obvious criticism, that the sporogony seen might be that of some Proteosoma parasite of the birds. Mrs. Adie is much to be congratulated on having filled an important gap in the knowledge of the development of these parasites, and on having discovered a series of stages which had escaped the notice of such competent observers as the Sergent brothers and Aragao. It is to be regretted that all recent writers on the development of malarial parasites use the term "zygote" in an entirely incorrect manner; the term should be used to mean the body formed by the union of the two gametes, and should therefore be applied, in the present case, to the rounded stage preceding the ookinete, and not to the oocyst-stages following the ookinete-stage.

Attention may usefully be directed to a paper on the care of old trees, illustrated by plates, in the *Kew Bulletin* (No. 2, 1915), since this is a subject often sadly neglected by those in charge of our parks and gardens which contain historic or interesting trees. The questions of breakages by wind, injuries by fungi, proper watering, feeding, and mulching, and the proper treatment of wounds are dealt with fully.

Mr. T. Petch contributes to the Annals of the Royal Botanic Gardens, Peradeniya (No. vii., vol. v.), a useful preliminary note on the genera Hypocrella and Aschersonia, fungi parasitic on scale insects which he has studied in connection with the type specimens preserved in the principal European herbaria. As a result of his investigations Mr. Petch has been able to clear the ground for his full paper, to be illustrated, we hope, with the drawings, by setting out the synonymy of the species examined. The species of the western hemisphere, with the one exception of *Hypocrella camerunensis*, found in Brazil and Africa, are distinct from those of the eastern hemisphere.

The description of new species of plants from China occupies the greater part of No. xxxviii. of vol. viii. of the Notes of the Royal Botanic Garden, Edinburgh, and are largely the result of Forrest's and Ward's collecting in western China. Among them are six new Rhododendrons to swell the long list of this important Chinese genus, and one of them, *R. Wardii*, W. W. Smith, with its large flowers, "slightly fleshy bright yellow with the faintest touch of crimson on interior at base," fills the heart of the cultivator with an eager desire to introduce the species. Messrs. Lace and Smith also describe three Rhododendrons from Indo-Burma, two of which were previously but very imperfectly known; all three species are figured.

The *Kew Bulletin*, No. 2, 1915, contains several papers dealing with systematic botany and matters of general botanical interest. *Diospyros ebenaster*, a widely cultivated tree in the tropics, often considered to be a native of the Philippine islands, is almost certainly indigenous in the West Indies, whence it has been introduced to other countries at a very early date. Mr. Sprague enumerates the sections of the South African species of Loranthus, the outcome of his work on the genus for the "Flora Capensis," and there are descriptions of twenty new plants, ten from Africa and ten from Australia, India, Malaya, etc. Of more general interest is a paper on the germination of coco-nuts, with reference particularly to the age of the trees from which seed nuts should be taken. There appears to be no reason, especially in the light of recent experiments in the island of Nevis, why nuts from good trees in their third year of bearing should not be used despite the prevalent beliefs usually held on the subject that to use such nuts is to court disaster. The doubts entertained recall the words of Sir Thomas Browne: "So these Traditions how low and ridiculous soever, will find suspition in some, doubt in others, and serve as tests or trials of Melancholy and superstitious tempers for ever."

There are few better Transactions than those of the Norfolk and Norwich Naturalists' Society, and their high place in science is well maintained by their latest publication, vol. ix., part v., 1913–14. The work in this goodly volume of some 200 pages is admirable: and we think that the members of the society receive a full return, or more than full, for their subscriptions. We would also congratulate the hon. secretary, Dr. Sydney Long, on the care which he has given to the editing of the volume. The president of the society, Miss Alice Geldart, in her address to the annual meeting, announced that the society has published the "Flora of Norfolk," edited by Mr. W. A. Nicholson. The subject of her address was the lives of some of the earlier Norfolk botanists; and it is a model of careful and sympathetic biography. Next comes Mr. Wormald's paper, well illustrated, on the courtship of ducks; then the valuable reports on that sanctuary of birds and of wild plants, Blakeney Point. Other monographs, of no less value, are contributed by Dr. Brenchley, Mr. Burrell and Mr. W. G. Clarke, and Mr. Rivière; and there is a wealth of shorter papers. Altogether, the volume deserves the highest praise as the publication of a county scientific society.

Mr. E. Mancini contributes an account of the Italian earthquake of January 13 to the *Revue générale des Sciences*, etc. (March 15, pp. 146–48). Most of the details contained in it have already appeared in our columns (vol. xciv., p. 565; vol. xcv., pp. 76–7). Mr. Mancini remarks that the exact position of the epicentre is still undetermined, but that, according to Dr. Agamennone, there may have been two separate foci in action at, or nearly at, the same time (see Nature, vol. xciv., p. 565). He estimates the total number of lives lost at more than 25,000. The number of persons saved at Avezzano was 2300 out of 13,000, so that the death-rate in that town must be reduced to 82 per cent.

A biographical notice of the late Prof. Adolfo Venturi appears in a recent number of the *Rendiconti della R. Accademia dei Lincei* (vol. xxiv., 1915, pp. 277–83). Born at Florence on September 22, 1852, he studied mathematics in the University of Pisa, obtaining his diploma in 1875. Shortly afterwards, he became mathematical teacher in the lyceum of Como, and in 1888 was appointed to the chair of geodesy in the University of Palermo. His work while at Como dealt mainly with the motion of the earth about its centre of gravity and the perturbations of comets and minor planets. At Palermo, he naturally turned his attention to geodetic problems, and afterwards to terrestrial refraction. Prof. Riccò in 1896 had begun a gravimetric survey of eastern Sicily, and this was extended by Venturi to the western half of the island. After a brief illness, Prof. Venturi died at Palermo on December 28, 1914.

Messrs. Edward Stanford, Ltd., have issued Nos. 11 and 12 of their series of war maps. No. 11 shows the eastern theatre of operations, and includes Hungary, Galicia, Bukowina, Poland, and parts of the neighbouring areas. The map is on a scale of eighteen miles to the inch, and shows contours coloured on the layer system, which demonstrate clearly the Carpathian heights between the northern plain in Poland and the plain of Hungary. Railways, roads, rivers, and numerous towns and villages tend to facilitate reference in connection with the official *communiqués*. This very useful publication is 33×45 in. in size, and the price ranges from 7*s.* 6*d.* to 17*s.* 6*d.*, according to style of mounting. No. 12 is devoted to the Dardanelles area of conflict; the sheet includes seven separate maps. There are plans of Constantinople, Smyrna, and Skutari; large-scale maps of the Dardanelles from Kum Kaleh to Gallipoli, and of the Bosphorus; a map of the Sea of Marmora and its entrances, and a map of Turkey-in-Europe and the western portion of Asia Minor. The two latter maps show contour at intervals of 1000 ft., and indicate relief by colour shading.

Scientific Paper No. 239 from the Bureau of Standards contains a description of a vibration electrometer by Mr. H. L. Curtis, of the bureau. The needle of the instrument consists of a light aluminium vane, 2 cm. square, supported with its plane vertical by a bifilar suspension, which extends both above and below the vane. Two fixed plates, 1×2 cm., are placed on each side of the vane, with their planes also vertical. The distances of the plates from the vane can be varied from 0·5 to 1·0 mm. To obtain complete control of the damping the whole instrument is enclosed in a bell jar which can be exhausted. The vane is connected to a battery giving 240 volts, and the alternating electromotive force to be detected is applied to the plates, which are cross connected, as in the quadrant electrometer. Resonance is secured by adjusting the tension or length of the suspension, and the deflections are read by the telescope and scale method. With the air pressure reduced to 0·005 mm. of mercury the deflection per volt at 50 cycles per second is 6 cm. on a scale at a metre distance, and the least current the instrument will detect is 10^{-11} ampere. The behaviour of the electrometer agrees very closely with the theory developed by the author.

Technologic Paper No. 41 of the Bureau of Standards, Washington, by R. S. McBride and J. D. Edwards, deals with the lead acetate test for hydrogen sulphide in illuminating gas, and is of interest here, as sulphuretted hydrogen is now the only impurity in coal gas officially controlled. It is pointed out that the various modes of testing in use are not all directed to the same end, since some of the tests are designed to detect as small traces of hydrogen sulphide as possible, while others aim to give a negative test when a permissible amount is not exceeded. The previous work of W. J. Dibdin and R. G. Grimwood, R. Forbes Carpenter, and C. J. Ramsburg, is described and criticised, and details of a new set of experiments are given in which some of the errors ascribed to the earlier work are avoided. The variations due to the kind of paper, concentration of lead acetate solution, preparation and condition of the paper, humidity of the gas, rate of flow and time of exposure, and the various forms of testing apparatus have been studied separately. Based on these results a method is recommended for use which is claimed to be quick and convenient, and gives reproducible results.

A recent publication among the Oxford pamphlets is by Prof. J. O. Arnold, the professor of metallurgy in the University of Sheffield, entitled "British and German Steel Metallurgy." It was inspired, as the opening sentences show, by an article by Prof. Rein, of the University of Vienna, on "Civilisation and 'Kultur.'" The pamphlet attempts to show (1) that German steel metallurgy owes far more to British inventors than British steel metallurgy owes to German inventors, and (2) that the steel department of the University of Sheffield has done work greatly superior to that of the corresponding department at Charlottenburg. The following claim bearing on the latter thesis may be quoted from the pamphlet as typical of the style:—"There are about twenty-nine constituents or sub-constituents of steel and iron. Of these, twenty-six have been discovered in Sheffield, the steelopolis of Great Britain; three in Middlesbrough, its ironopolis; and the record of Charlottenburg in this branch of research is absolutely blank." We confess to regretting that the author has by this publication placed himself in the category of those who desire to minimise the debt that British science owes to German science. It would have been better if the task had not been attempted.

The *Engineer* for April 9 directs attention to some absurd British methods of dealing with drawings received from consulting and other engineers on the Continent. In a recent instance, detail drawings received from abroad showed particulars all dimensioned metrically. The British drawing office, with much care, translated these dimensions into feet, inches, and fractions. Some typical examples of the results are noted: A bolt circle diameter of 418 mm. was translated to $16\frac{7}{16}$ in. + $\frac{1}{64}$ in.; 21 mm. clearance holes for black bolts became $\frac{13}{16}$ in. + $\frac{1}{64}$ in. The chances of mistake in this method are considerable, and include translation errors, errors in ordering drills to such odd sizes, and errors in marking off and making jigs and templates. In addition, trained mechanics have an ingrained fear of dimensions in sixty-fourths, and will spend much more time over these figures than over even numbers. The commonsense method is to give the workmen the drawings in metric system and supply them with metric rules. In view of the continually increasing demand from the Continent for material manufactured in this country, it is probable that we are on the eve of a very considerable extension of the use of the metric system in our workshops and factories.

The ninth report of the Royal Commission on Sewage Disposal has now been issued. Part ii. consists of a brief statement relating to the disposal of sewage in rural areas where sewers are not available. The question as to whether a rural committee should adopt some dry method of disposal, or provide sewers and purification works, depends upon whether a water supply is laid on to the houses or not. If it is, a sewerage system is almost inevitable; but if not, then dry closets may be used satisfactorily under proper supervision. In a minority report on this subject Sir William Ramsay appears to favour the extension of dry systems, even when a water supply is laid on to houses, mainly on the ground that the valuable nitrogen of domestic sewage ought to be returned to the soil. *Engineering* for April 9, commenting on the report, sympathises with Sir William Ramsay's desire to put some check on such a waste; but points out that epidemic disease amongst the people involves a greater waste, and there is no denying the beneficial effects on health which follow the acquisition of a pure and abundant water-supply, or the evils which, literally, lie at the door of ill-managed "dry" systems.

OUR ASTRONOMICAL COLUMN.

Comet 1915*a* (Mellish).—The following ephemeris of Comet Mellish is a continuation of that calculated by Messrs. Braae and Fisher-Petersen, and printed in a circular issued by Prof. Elis Strömgren:—

	R.A. (true) h. m. s.	Decl. (true)	Mag.
April 20 ...	18 24 59 ...	−5 36·0	
22 ...	27 6 ...	6 13·6 ...	7·6
24 ...	29 12 ...	6 54·4	
26 ...	18 31 18 ...	−7 38·8 ...	7·4

The comet is moving in the constellation of Aquila, and lies to the west of λ Aquilæ and is about equidistant from η Serpentis, which star is further to the westward.

The Chromospheric Spectrum without an Eclipse.—In the March number of the Proceedings of the U.S. National Academy of Sciences, W. S. Adams and Cora G. Burwell describe briefly the results of an investigation of the flash spectrum without an eclipse in the region λ 4800 and λ 6600. The full paper will soon be published as No. 95 of the *Contributions from the Mount Wilson Observatory*. In the first place, it is interesting to record that the total number of lines measured upon the negatives taken without an eclipse is greater than that obtained from eclipse negatives. Thus Mitchell's beautiful chromospheric spectrum of 1905 showed 901 lines, while those here measured number 1027 lines. It is further pointed out that in the photographs taken without an eclipse the wave-lengths of the bright lines have been determined with reference to the dark lines at the limb. A comparison of 512 lines shows that the difference between the wave-lengths of the bright lines and the dark lines at the limb gives a value −0·002 Angstrom. The preponderance of the negative sign in the case of the individual elements makes it fairly probable that this quantity may be regarded as real. Reference is made also to the marked gain in accuracy for the Mount Wilson results, attributed notably to the greater linear scale of the photographs. Some peculiar characteristics of the dark line spectrum of the sun's limb as seen on the photographs of the flash spectrum are briefly decribed, and the identification of the elements to which these lines belong is suggested as a research of decided interest.

The Rotation of Nebulæ.—Prof. Percival Lowell has forwarded two very interesting photographs of the spectra of nebulæ taken by Dr. V. M. Slipher, both of which are briefly described by the latter. The first is the spectrum of Virgo nebula, N.G.C. 4594, taken in April, 1913, with an exposure of 30 hours, together with comparison spectra of vanadium and iron. It was from this photograph and two others, also taken in the same year, all of which showed the nebula lines inclined, that the first direct evidence that nebulæ rotate was secured. In the photograph sent the slit was placed east and west, and the rotation in the sense that brings the west side of the nebula towards the earth. In addition to their inclination the lines have a large displacement, which makes the solar band G nearly coincident with the iron line λ 4326, thus indicating a velocity of recession of 1100 kilometres. Dr. Slipher remarks that this was far the highest velocity then known, but "further observations of nebulæ here have revealed others as high." The second photograph is of the spectrum of the Crab nebula, N.G.C. 1952, taken in February of the present year, with 18 hours' exposure, and similar comparison spectra. This is described as "the most remarkable nebula spectrum known." Upon a rather strong continuous background are found bright lines typical of gaseous nebulæ lines. Thus the lines $\lambda\lambda$ 5007, 4959, 4861 ($H\beta$), 4686, 4341 ($H\gamma$), seem to be present. The strange appearance of these bright lines is described as follows:—"They seem to be split into doubles, best seen in λ 5007 and λ 4861 (the inside components of λ 4959 and λ 5007 would be blended). The distance between the components changes with the position in the nebula. It reminds one of the Zeeman effects in a non-uniform magnetic field and implies the origin to be within the atom. However, the maximum separation is quite enormous—40 tenthmetres. A plausible explanation of the spectrum as velocity effects has not occurred to me as yet."

The "Scientific American" and Astronomy.—The Paris Observatory and its work is the subject of an interesting article to the *Scientific American* (March 13) by Prof. G. A. Hill, of the United States Naval Observatory. The author accompanies his text with two excellent reproductions showing the large transit circle and the eye end of the equatorial Coudé. The history of this famous institution is briefly sketched, and special reference made to the lunar photographs taken by MM. Loewy and Puiseux. In the issue of the same journal for March 20, Abbé Th. Moreux describes the planet Saturn, its ring system, and the satellites, and accompanies his remarks with a large number of reproductions from early and late drawings. Such articles popularly written and finely illustrated render a great service in disseminating astronomical knowledge, and we hope to direct attention to similar contributions in future issues.

EXPERIMENTAL STUDY OF THE MECHANISM OF WRITING.

Of recent years considerable advances have been made in the experimental study of the complex processes of reading and writing, mainly in the interests of a new experimental science, which is at present calling itself "experimental pedagogy," and at recent meetings of the British Association the Educational Science Section has devoted a good deal of attention to such work. In the Proceedings of the Royal Society of Edinburgh a further contribution to the experimental analysis of the writing process is made in a paper by Mr. James Drever, on the analytical study of the mechanism of writing.

Looked at from the outside, and regarded purely as a mechanical process, the writing act consists of certain movements and co-ordinations of movement of the fingers, hand, forearm, and shoulder. Of these the hand movements and the work of the fingers are the most important. By employing various pieces of comparatively simple apparatus it is possible to separate hand and finger movements, as well as to isolate for observation and study both the pressure of the fingers in holding the writing instrument and also the pressure placed upon the writing point.

To Prof. C. H. Judd, of Yale, we owe the original idea of a simple piece of apparatus which enables the experimenter to separate hand and finger movements. This apparatus consists essentially of an attachment for the fifth metacarpal, which carries a pencil or style for recording the movement of the hand. The original form of the apparatus was defective in several respects, but a modified form described in the above-mentioned paper seems to eliminate most of these defects. By comparing the record of the hand movement with the actual writing we can determine the part played by finger movement. It should be noted, however, that there is one movement of the hand in writing which cannot be recorded in this way. That is the movement known as pronation—the movement round the axis of the wrist.

Records taken with Judd's apparatus yield several interesting results. Some writers use little, if any, finger movements, and most writers, when writing at maximum speed, and especially with the pencil, approximate to this type. Ordinarily, however, in careful adult writing in this country, all the finer work in the formation of the letters is due to finger movement, and this to a greater extent in pen writing than in pencil writing. As a rule the writers themselves are quite unconscious of such finger movements. In the writing of the child, who is merely at the learning stage, there is little finger movement, but finger movements develop as facility is acquired.

The isolation of grip pressure in writing is secured

FIG. 1.

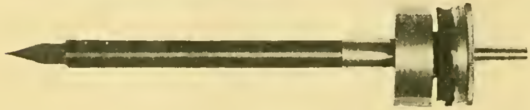

FIG. 2.

by an apparatus consisting essentially of a double-walled rubber capsule, inserted into the pen or pencil holder to take the grip (Fig. 1). The space between the walls, and also the inner space, are filled with mercury. A capillary glass tube passes into the inner space, and its top is connected by means of rubber tubing in the usual way with a recording tambour. Any variations in pressure on the outer wall of the capsule are in this way transmitted to the tambour and graphically recorded by the marking lever on a smoked drum.

Very little work has hitherto been done in the study of grip pressure. The most striking feature in the grip pressure curve obtained is its rhythmical character (Fig. 3, VI.). With the adult this rhythm is extremely regular, but it is absent in the earliest writing of children, first appearing about the age of eleven, and then with marked irregularities (Fig. 3, VII.). In writing with the pencil the grip pressure is considerably greater than in writing with the pen, and the difference between maxima and minima in the rhythm also greater. Finally, there are in adult writing definite indications that a word or even phrase is written with one total impulse.

Several different forms of apparatus have been employed for obtaining a record of point pressure in writing. Continental investigators have employed a writing plate, either connected directly with a lever for marking on a smoked surface, or resting on an air cushion pneumatically connected to a recording tambour. In Mr. Drever's apparatus the pen or pencil is attached to a receiving tambour, which forms the top of the pen or pencil holder (Fig. 2). This last form of apparatus is exceedingly simple and convenient for use with children.

The study of the point pressure curve has already yielded some interesting results, which bear not only upon education but also on the study of mental defects. In normal adult writing two types of pressure curve were early and easily distinguished, and it is possible to distinguish three. The first, which is known as the masculine type, shows a single definite maximum of pressure for each word, and increased pressure with increased speed of writing (Fig. 3, IV.). The second, known as the feminine type, shows several maxima of pressure in each word, and diminished pressure with increased speed of writing. The third, which might be called the clerical or mechanical type, shows great uniformity of pressure in each word, and practically no change of pressure with increased speed of writing; further, there is comparatively little increase of speed beyond the ordinary rate, and in some cases the speed actually

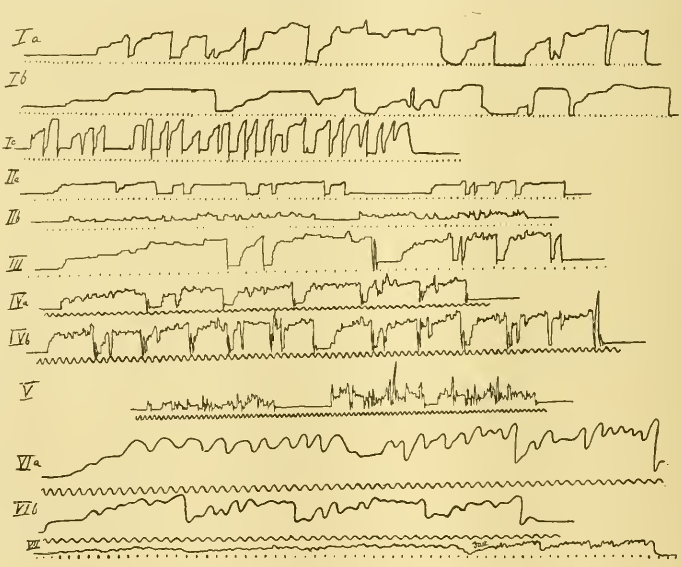

FIG. 3.

I. to III. Point pressure tracings from children. Time record in seconds by Jacquet Chronograph.
I*a*. Child of six. Words "The cow gives us milk."
I*b*. Child of six (first attempt at script). Words "A man can."
I*c*. Child of six (printing). Words "A man can run"
II*a*. Pencil writing, and II*b*. Pen writing of child of eight. Words "Moray House School," written twice in each case.
III. Child of eleven. Pencil writing. Words "Moray House School," written twice.
IV. and V. Point pressure tracings from adults. Time record in $\frac{1}{5}$ secs. by vibrating spring.
IV*a*. Pencil writing, ordinary rate. Words "Moray House School," written twice.
IV*b*. Pencil writing by same subject, maximum rate. Words "Moray House School," written four times.
V. Pen writing, slow and fast. Words "Moray House School," written once slow and twice fast.
VI. and VII. Grip pressure tracings from adults and child of eleven. Time records for adults in $\frac{1}{5}$ secs. and for child in secs.
VI*a*. Adult pencil writing. Words "Moray House School."
VI*b*. Adult pen writing. Words "Moray House School Moray."
VII Child's pencil writing. Words "Moray House School" twice, slow and fast.

diminishes, while the subject thinks he is writing faster.

The pressure curves obtained from children differ from all the adult types. A flat-topped curve had been considered until recently the characteristic child's curve (Fig. 3, II a). This curve does not, however, represent the first stage in the acquiring of writing. The first curves obtained are more or less characteristically drawing curves (Fig. 3, I.). Such curves are best seen where the child begins with printed letters rather than script (Fig. 3, I.c). In this case each stroke requires a definite and separate impulse, and this is well marked in the pressure curve. In the earliest script the curve seems merely irregular, but this is due to variations in the drawing unit with which the child is dealing, which may be a single stroke, a letter, or a group of letters. The second stage in learning to write is marked by what was formerly called the child type of pressure curve, a curve with a strikingly regular, flat top, which is still a drawing curve, though the child is now drawing the whole word. This curve passes gradually into the curve with rippled top of adult writing, the time when the transition can really be said to take place being about the age of ten or eleven (Fig. 3, III.). The transition seems to mean two things. In the first place the necessary co-ordinations are established to such an extent that the mechanism of writing works without attention to the individual strokes and forms which the hand is making. In the second place, and partly because of this, writing has ceased to be drawing and has become language, the rhythmical variations in point pressure corresponding to the rhythmical variations in grip pressure, and being analogous to a certain extent to the rhythm of speech. When this stage is reached the impulse under the direction of which writing takes place is distinctly a word impulse, and sometimes even a phrase or sentence impulse.

It has also been found that the writing of defectives fails to show this characteristic rhythm of adult writing, while drugs like alcohol tend to impair the rhythm and ultimately to break it down altogether, apparently because of their effect on co-ordination. It is also somewhat interesting to find that the pressure curve is almost as characteristic of an individual as his signature, and persists even in left-hand writing without previous practice. There is evidently a wide field for investigation in this direction, and perhaps we may yet see the development of a real science of graphology based upon such investigation.

FLORA OF ADEN.[1]

PROF. BLATTER has brought together an interesting account of the vegetation of the Aden peninsula, in which, after summarising the history of botanical exploration of this region from the earliest times, he gives data regarding physiography, climate, soils, tabulated lists of the plants, and brief notes on their distribution, origin, means of dispersal, etc. No references are made to work on plant ecology, but a comparison of the characters of the Aden vegetation with that of other arid regions, as investigated particularly by the Carnegie Institution botanical staff in North American and North African deserts, brings out some points of considerable ecological interest.

The first botanical description of Aden was given by Ibn Batuta in about 1330, and it consisted of the brief statement that "there are neither seeds nor trees nor water." Though Aden is not so entirely destitute of vegetation as this famous traveller supposed, the impression it produced upon much more recent botanical visitors was scarcely more favourable. Sir J. D. Hooker, in 1847, described Aden as being "upon the whole the ugliest, blackest, most desolate, and most dislocated piece of land, of its size, that ever I set eyes upon, and I have seen a good many ugly places"; but he mentioned the comparatively fertile lower valleys, thickly studded with beautiful-flowered shrubs and small trees. Prof. Blatter's compilation is based largely upon the scattered reports and collections made by residents and visitors, and shows that Aden, despite the fact that it consists largely of "bare naked rocks which cannot find their equal in any part of the world as regards dryness, infernal heat, and barrenness," possesses an interesting and surprisingly varied vegetation.

The volcanic rocks forming the greater part of the Aden peninsula, which is about fifteen miles in circumference, are practically devoid of plant life; even lichens are scarce on the sun-baked and disintegrating rock-surfaces. These lofty and jagged rocks, rising in places to 1700 ft. altitude, are scored by steep gulleys and mostly run straight down to the shore, but here and there the lower slopes are gentle or almost flat, and in such places the clayey soil retains rain-wash, which elsewhere quickly runs off or percolates through the loose soil, and the vegetation in these parts is fairly rich. Apart from such habitats, the rigorous character of the conditions with which the Aden plants have to contend may be realised from the facts that there are no permanent streams or springs or marshes or ponds; the annual rainfall rarely exceeds six or seven inches in the wettest years; no rain may fall for two years at a time, and when it does fall it usually comes down in a torrent lasting for a day or two, changing the dry gulleys into turbulent streams which quickly dry up again.

The Aden flora consists of 250 species of flowering plants, including ten trees, fifty-eight shrubs, forty-six undershrubs, and 136 herbs. The work of the Carnegie Institution botanists has shown that in the most arid regions of the earth, where the rainfall is extremely scanty, infrequent and irregular, what were formerly regarded as the typical desert-plants, namely, species with fleshy water-storing leaves and stems (cacti, etc.), are almost or entirely absent, and that the desert type *par excellence* is not succulent, but sclerophyllous. This term is applied to plants which do not store up water but contend with the extreme aridity of their environment by various adaptations for reducing water-loss to a minimum—reduced leaf surface, dense hair-covering, waxy cuticle, gummy epidermis, development of leaves or branches or both as spines, etc. From Prof. Blatter's list such plants appear to be dominant in the vegetation of Aden; fleshy species are practically confined to the sea-coast. A further point of interest is that about half of the herbaceous plants listed for Aden are short-lived annuals, which grow in the clayey soil of the flats and gentle slopes where water can be retained in the surface layers long enough for these plants to complete their brief life-cycle whenever rain comes. This, again, is a characteristic feature of the typical desert flora with clayey oases.

The records of the Botanical Survey of India contain so much that is, at any rate potentially, of general interest to students of plant ecology, that while the material they contain is welcome and useful, it is much to be hoped that the survey workers will make themselves acquainted with what has been and is being done on modern ecological lines, so that they may

[1] "The Flora of Aden." By Ethelbert Blatter, Professor of Botany at St. Xavier's College, Bombay. Records of the Botanical Survey of India. Vol. vii, No. 1. Calcutta, 1914. Pp. ii+79; 5 plates; 1 map.

correlate their results with those obtained in other regions by the application of methods which alone can make a botanical survey what it is now generally expected to be—a correlated study of the plant communities and the plant habitats of the area surveyed.

F. C.

ORNITHOLOGICAL NOTES.

At the annual meeting of the Royal Society for the Protection of Birds, held at the Middlesex Guildhall, on March 11, when the Ranee of Sarawak presided, an optimistic tone prevailed in the first portion of the report for 1914, as several of the schemes and objects for which the Society had long been labouring were apparently on the point of realisation. Then came the war, when all these fair prospects—particularly the expected passing of the Government Plumage Bill—were dissipated, to be renewed, it may be hoped, at the conclusion of the war. In other respects the work of the Society was, on the whole, satisfactory; but finance is a matter on which there is serious ground for anxiety, as a falling-off in subscriptions during the current year is almost inevitable.

The condor forms the subject of the first article in the March number of the *Children's Museum News*, where particular reference is made to the long period taken by these birds to attain the adult plumage. Hatched during the height of the southern summer, the young exchange their white nestling dress for a uniformly brown garb, which is not finally discarded until the seventh year, in February or the early part of March. Although able to fly when a year old, young condors do not leave their parents until the completion of their third year.

In the course of a wonderfully illustrated article on a breeding-colony of buff-backed herons, published in the March issue of *Wild Life*, Mr. B. Beetham directs attention to the small size of the nests of these birds, which alone renders it possible for so many to be crowded into a single bush. So heavily weighted, indeed, are some of the boughs that they hang almost vertically; and it is little short of marvellous how the eggs and young are retained in the shallow, cup-like nests, generally overhanging a lagoon, into which the hapless offspring may be precipitated by a gust of greater strength than usual. The nests are devoid of lining, and in some cases so flimsy in structure that the pale blue eggs are visible from below.

The nesting-habits of fulmar-petrels on a precipitous cliff in the Orkneys form the subject of an article by Mr. O. G. Pike in *British Birds* for March. The author arrived on the scene in the second week in July, when most of the young were hatched; but he was able to secure a couple of photographs of sitting birds, as well as one of a downy nestling. Each female lays but a single egg, and at a very early stage the young bird is capable of indulging in the distinctly petrel-trait of discharging a forceful jet of evil-smelling green oil from its mouth in the face of a real or supposed enemy.

To the Journal of the Straits Branch of the Royal Asiatic Society for December, 1914, Mr. J. C. Moulton, curator of the Sarawak Museum, contributes a list of Bornean birds. In an appendix to Hugh Low's "Sarawak," published in 1848, the number of species then recognised was fifty-nine; this was raised in 1889 in a list drawn up by the late Mr. A. H. Everett to 536 (exclusive of thirty-four from Palawan), while in the present list the number is again augmented to 555; and this, too, despite the fact that several birds formerly regarded as distinct species have been relegated to the rank of local races.

According to the report in the January number of the *Emu*, the fourteenth annual session of the Royal Australasian Ornithologists' Union, held in Melbourne in November, 1914, was a thorough success, a number of interesting excursions being taken and several papers read. In the same issue Mr. A. J. Campbell directs attention to the apparent extermination of three beautifully coloured species of parrots—namely, the scarlet-shouldered *Psephotus pulcherrimus*, the chestnut-shouldered grass-parrot (*Euphema pulchella*), and the night-parrot (*Geopsittacus occidentalis*), all of which were to be met with a few years ago in Queensland or the neighbouring districts. Their disappearance is attributed to domesticated cats run wild, aided by bush-fires and the spread of cultivation.

In the *Zoologist* for March, Prof. J. C. Patten describes an immature aquatic warbler picked up at Tuskar light-station, County Wexford, on August 9, 1913. The paper is illustrated by a plate showing how the plumage of this species differs from that of the sedge-warbler at the same age. In the aquatic warbler the back is marked by streaks of black and buff, which are but slightly developed in the sedge-warbler; both webs of the middle pair of tail-feathers are also margined with buff, and all the tail-feathers are likewise longer, narrower, and more pointed than those of the sedge-warbler. The Tuskar bird is the second of its kind taken in Ireland; the number of specimens recorded from Great Britain (England) is seventeen.

MOUNTAIN GEOLOGY.

In the *Mémoires de la Société de Physique et d'Histoire Naturelle de Genève* (vol. xxxviii., pages 69–168) M. Louis Duparc and Mme. M. Tikanowitch continue their work on the Ural Chain by an account of its rocks to the east of the main watershed and in the upper basin of the rivers Kakwa and Wagran. This, the fourth of their contributions to the geology of that chain, is prefaced by a sketch of the physical features of the district, the illustrations to which show that it consists of huge hills rather than of rugged mountains. The rocks are partly sedimentary, arenaceous, or slaty argillaceous, with some quartzose crystalline schists; partly igneous. Of the latter a very complete petrographical study has been made, including chemical analyses of the principal types, several of which are very interesting. Among those of deep-seated origin are the following: quartz-bearing micaceous diorites (evidently allied to tonalites) and gabbro-diorites (in which probably the hornblende is secondary), olivine-gabbros, and massive dunites. Besides these and serpentines, are tilaite (a variety of eucrite) and pyroxenites. This association is interesting, for it often exists, more or less completely, in other regions, and suggests certain modes of magmatic differentiation. The dyke-rocks include hornblendic berbachites and various dioritic porphyrites, besides amphibolites, in some at least of which the hornblende appears to be secondary. The article ends with a description of the crystalline schists which, however, do not appear to be of any unusual interest. The memoir, illustrated by twelve photographic figures of the microscopic structure of the more interesting rocks, forms a most welcome addition to petrology, the more remarkable when we learn the difficulties with which the authors had to contend in their three visits to this region, in consequence of the sparse population, the want of roads, and the absence of maps.

In the next fascicule (pp. 169–98) M. Jules Favre describes the relation of the plant-life to the geology of the Salève. This mountain, which rises about 3000 ft. above Geneva, consists of limestones and shales (Upper Jurassic and Neocomian), with Middle Tertiary sandstones, chiefly molasse, and glacial deposits. Apart from the effects of altitude, the flora is much affected by the nature of the rock on which it grows, and besides this, a small colony of special plants generally accompanies any local physical peculiarity. Of this association the large erratics of Alpine granite and schists afford a remarkable instance. *Asplenium septentrionale* is the only phanerogamous plant found on them to which rocks, in the High Alps, it is practically restricted.

BLOOD-PARASITES AND FLEAS.

FOR the past five years Prof. E. A. Minchin and Dr. J. D. Thomson have been engaged upon the investigation of the rat trypanosome, *Trypanosoma lewisi*, with special reference to its relation to the rat flea, *Ceratophyllus fasciatus*. The results of this laborious and painstaking research are now published in the *Quarterly Journal of Microscopical Science*. They form a comprehensive monograph which occupies the whole of the last part of this journal (vol. lx., part 4) and will undoubtedly be a standard work of reference for students of these very important blood-parasites. The fact that the authors have dissected and examined more than 1600 fleas in the course of their investigations shows the thoroughness with which the work has been carried out, while the artistic treatment and accuracy of detail contributed by the illustrations, for which due acknowledgment is made to Miss Rhodes, leave nothing to be desired. *T. lewisi* is fortunately a non-pathogenic parasite, at any rate so far as the rat is concerned, and it cannot live at all in human blood. It therefore forms a much more suitable type for general study than such deadly species as those which are conveyed by the tsetse-fly in Africa, and are responsible for fly-disease amongst horses and cattle, and for sleeping sickness in human beings. The authors give a very useful account of the technique employed in their investigations, and, incidentally, throw a good deal of light upon details of the anatomy and histology of the flea.

The flea, of course, receives the parasite with the blood which it extracts from the rat, but apparently it cannot infect the rat by inoculating trypanosomes into it through the proboscis. The rat is supposed to become infected through the mouth; in the process of licking its fur it takes in trypanosomes with fæcal matter deposited by the flea; or it may become infected by eating infected fleas.

While in the flea the trypanosome is confined throughout its whole development to the digestive tract, where it undergoes extensive asexual multiplication and passes through a number of more or less distinct phases, some of which are intracellular in the epithelium of the stomach. No sexual phenomena have been detected, and the authors agree with Miss Robertson that such phenomena have not as yet been satisfactorily demonstrated in the case of any trypanosome.

CHANGES OF RELATIVE LEVELS OF LAND AND SEA.

AMONG the different kinds of evidence showing that changes in the relative levels of sea and land are going on all over the globe, the forms assumed by coast-lines are now recognised by geologists as being the most convincing and satisfactory. Sea-erosion, acting only along shore-lines, and sub-aerial denudation, operating over the whole land-surfaces, result in features of such clearly differentiated character that no unbiassed observer can fail to recognise their great significance and value. When we find long, narrow, deep, and winding inlets from the sea into the land ("fiords," etc.), it is obvious that such features could not result from the cutting back of the coast-line by the sea, but that they are old river-channels that have been drowned by the sinking of the land. On the other hand, sea-beaches, with caves, fan-taluses, and other signs of shore work, occurring at various heights above the present sea-level, speak, quite as unmistakably, of elevation having taken place.

The illustrious American geologist, James Dwight Dana, when accompanying the United States Exploring Expedition under Wilkes, had the opportunity of visiting many coral-reef islands, and we are indebted to him for first showing, in 1849, the value of the evidence afforded by coast-lines, where bounded by "encircling" or "barrier" reefs, of subsidence having taken place. These valuable observations of Dana seem to have been almost completely overlooked until quite recent years, and it is only fitting that to a fellow-countryman of his should fall the task of recalling and developing this pioneer work.

Where a coral-reef encircles a land-mass it is evident that the presence of "fiords" or their equivalents in the central island supplies clear evidence of submergence having taken place, though possibly this may not be the latest of the movements that have occurred. On the other hand, the existence of islands composed of upraised coral-rock, with sea-caves and shore deposits at different stages, up to more than 1000 ft. above the present sea-level, supplies equally clear evidence of movements in an opposite direction having taken place. The late Prof. Alexander Agassiz published a very valuable series of reports, abundantly illustrated, concerning these upraised Pacific reefs, and we now have the promise of equally important descriptions by Prof. W. M. Davis, also of Harvard, of the cases in which the proofs of subsidences can be no less satisfactorily made out.

The general result to which these various observations appear to point is that, over the whole area of the Pacific, areas of elevation and others of subsidence can be clearly traced, though the movements were often interrupted and sometimes reversed; nevertheless, it must be admitted that in some cases the evidence seems puzzling and contradictory—islands with clear evidence of elevation lying in close proximity to others which have clearly subsided. Geologists will not, however, be unprepared for the occurrence of such seeming anomalies; they will only recognise that, eventually, actual fault-lines may be traced by such means in the oceanic areas. At the same time it may be well to bear in mind the caution suggested by Darwin in his correspondence with Semper that, however clear may be the evidence in favour of any special theory of coral-reef formation, we must be always prepared for the occurrence of special cases which can only be accounted for by the operation of exceptional causes. The full and complete account—which will no doubt be sufficiently illustrated—of Prof. W. M. Davis's important series of explorations will be looked forward to with special interest, and in the meantime the subjoined general summary of his results will be welcomed by all naturalists.

J. W. J.

Preliminary Report on a Shaler Memorial Study of Coral Reefs.

A liberal grant from the Shaler Memorial Fund of Harvard University, supplemented by a generous subsidy from the British Association for the Advancement of Science, with an invitation to attend its meeting in Australia last August as a foreign guest, enabled me to spend the greater part of the year 1914 in visiting a number of islands in the Pacific Ocean with the object of testing various theories that have been invented to account for coral reefs. Thirty-five islands, namely, Oahu in Hawaii, eighteen of the Fiji group, New Caledonia, of which the entire coast-line was traced, the three Loyalty islands, five of the New Hebrides, Raratonga in the Cook group, and six of the Society islands, as well as a long stretch of the Queensland coast inside of the Great Barrier reef, of north-eastern Australia, were examined in greater or less detail. A brief statement of my results has been published in the Proceedings of the National Academy of Sciences for March, 1915. A full report upon my observations will appear later, probably in the Bulletin of the Museum of Comparative Zoology at Harvard College. The general conclusions reached are here briefly summarised.

Any one of the eight or nine theories of coral reefs will satisfactorily account for the visible features of sea-level reefs themselves, provided the postulated conditions and processes of the invisible past are accepted; hence a study of the visible features of the reefs alone cannot lead to any valid conclusions. Some independent witnesses must be interrogated, in the hope of detecting the true theory of their origin. The only witnesses, apart from sections obtained by deep and expensive borings, available for sea-level reefs are the central islands within oceanic barrier reefs, or the mainland coast within a continental barrier reef. The testimony of these witnesses has been too largely neglected, apparently because most investigators of coral reefs have been zoologists, little trained in the physiography of shore lines. Elevated reefs afford additional testimony in their structure and in the relation of their mass to its foundation; but this testimony also has been insufficiently considered, perhaps because most investigators of reefs have as zoologists been little trained in structural geology; hence it seemed desirable to give as much time as possible on the Pacific Islands to questioning the independent witnesses above designated.

The testimony of the first group of witnesses—the central islands of barrier reefs—convinced me that Darwin's theory of subsidence is the only theory competent to explain not only the development of barrier reefs from fringing reefs, but also the shore-line features of the central islands within such reefs; for the embayments of the central islands testify emphatically to subsidence, as Dana long ago pointed out; thus my results in the study of this old problem of the Pacific agree with those of several other recent students, especially Andrews, Hedley, and Taylor of Australia, and Marshall of New Zealand. Darwin's theory of subsidence also gives by far the most probable explanation of atolls; for it is unreasonable to suppose that a subsidence of the ocean bottom should occur only in regions where the central islands of barrier reefs are present to attest it, and not in neighbouring regions where reefs of identical appearance, but without a central island, are given another name.

The testimony of the second group of witnesses—massive elevated reefs such as occur on certain Fiji islands—convinced me that Darwin's theory of subsidence gives the only satisfactory explanation of the origin of such reefs also; for their limestones rest unconformably on the normally eroded surface of a pre-existent foundation. The erosion of the foundation surface shows that it stood above sea-level before the reef was deposited upon it; and the occurrence of the reef shows that the eroded foundation subsided to receive its marine cover. Only after this subsidence was the compound mass uplifted. The mere occurrence of elevated reefs above sea-level does not for a moment prove that they were formed during the emergence of their foundation.

All the still-stand theories of barrier reefs—that is, all the theories which involve a fixed relation of the reef foundation to the sea-level during the formation of the reef mass—are excluded by evidence of submergence found in the embayed shore lines of the central islands within barrier reefs. It may seem over-bold thus at a stroke to set aside several well-known theories, accepted by experienced observers; and so indeed it would be if these observers had discussed the features of the embayed central islands, and had explicitly shown that their embayments are not due to submergence but to some other cause. It is, however, a regrettable fact that the observers who adopted one or another of the still-stand theories took, like Darwin himself, practically no account of the embayed central islands, essential as the testimony of these islands is in the solution of the coral-reef problem. Such neglect is all the more remarkable in view of the clear statement, long ago published by Dana, regarding the pertinence and the value of the testimony afforded by the central islands of barrier reefs.

The glacial-control theory of coral reefs, recently elaborated by Daly with special reference to the lagoons of atolls, will not hold for barrier reefs. This theory assumes that no subsidence of the reef-foundations took place, and explains the lagoon floors of atolls as platforms abraded across pre-glacial sea-level reef-masses by the lowered and chilled sea of the glacial period after the corals were killed; the pre-glacial reef-masses having been formed by upward or outward growth on still-standing foundations. It then explains the encircling reefs which now surround the lagoons as having been built up while the sea was rising and warming in post-glacial time. But if the broad lagoons of large atolls twenty or thirty miles in diameter were thus formed, the central islands within narrow-lagoon barrier reefs should be cliffed all around their shore line, and they are not. Furthermore, this theory explains the embayments of central islands within barrier reefs as occupying new-cut valleys that were eroded during the glacial period of lowered sea-level; but if this were the case, the new-cut valleys should be prolonged upstream from the embayment heads as incisions in the floors of pre-glacial valleys, thus producing a "valley-in-valley" landscape; and this is not true in any one of the hundreds of embayments seen during the past year. Furthermore, many of the embayments are so wide that, if they were opened by slow subaerial processes, the spur-ends ought to have been well cliffed by the sea; yet, as above stated, they are not cliffed. Finally, many of the embayments are too wide to have been eroded during the last glacial epoch, or even during all the glacial epochs of the entire glacial period, if the valleys of the formerly glaciated volcanoes in central France are taken as standards of the amount of erosion that could be accomplished on such masses during such intervals of time. The glacial control theory thus proves incompetent to explain barrier reefs, and it is therefore held to be generally incompetent to explain atolls also; it may have more importance on the borders of the coral zone, where the corals would most likely have been killed during the glacial period: the Marquesas islands promise interesting results in this connection. The glacial-control theory has its greatest importance in conjunction with Darwin's theory of subsidence; for submergence during subsidence may have been almost neutralised by the lowering of the sea-level during the oncoming of a glacial epoch, and under such conditions coral reefs would broaden and lagoons would become shallow; but with the passing of a glacial epoch the return of ice-sheet water to the ocean would accelerate the submergence due to subsidence, and at such a time, coral reefs might be more or less completely drowned; thus the discontinuity of certain reefs on so-called "platforms" may be explained.

All the phenomena which testify to the formation of coral reefs on subsiding foundations can be equally well explained by the assumption of a rise of the ocean surface around or over fixed foundations; but a rise of the ocean surface in any coral-reef region demands a rise of the whole ocean surface; and if the coral-reef foundations are to stand still, a rise of the whole ocean surface can be explained only as the diminished result of a greater rise of the ocean floor in some non-coral-reef region. The conditions involved in this alternative for the simple theory of local subsidence are so extravagantly improbable that, as soon as they are explicitly defined, they must be rejected.

No absolute demonstration of the origin of coral reefs, or, for that matter, of any other geological structure, is possible; the most that can be hoped for is a highly probable conclusion. The conclusions announced above in favour of Darwin's theory are believed to have about the same order of probability as that usually accepted as "proof" in geological discussions.

A number of local conclusions may be briefly announced as follows:—

The elevated reef along the south coast of Oahu, Hawaii, was formed during or after a sub-recent period of subsidence, for its limestones enter well-defined valleys that must have been eroded when the island stood higher than now, and before the reef-limestones were deposited in them.

The Fiji group has suffered various movements of subsidence and elevation by which its many islands were affected in unlike ways. Elevation has taken place at different times in different islands, for some of the elevated reefs are elaborately dissected, others are very little dissected, and still others remain at sea-level. The embayments due to the latest submergence of the larger islands, Viti Levu and Vanua Levu, are now largely filled with delta plains. All the reefs, those now elevated as well as those at sea-level, appear to have been formed during periods of subsidence; the evidence afforded by the elevated reefs of Vanua Mbalavu, Mango, and Thithia is specially significant on this point. The medium-sized island of Taviuni has few visible reefs, because its flanks and shores are flooded by sheets of recent lava. The small island of Wakaya seems to be a tilted block of lava beds, not a dissected volcano.

The extensive barrier reef of New Caledonia has grown up during a recent subsidence by which that long and maturely dissected island has been much reduced in size and elaborately embayed; but unlike most encircled islands, this one was strongly cliffed around its south-eastern end, and along much of its north-eastern side before the recent subsidence took place.

The two south-eastern members of the Loyalty group, Maré and Lifu, are former atolls, evenly uplifted about 300 ft.; Maré shows a small hill of volcanic rock in the centre of its limestone plateau or elevated lagoon floor. Uvea, the north-western of the three Loyalty islands, is a slightly tilted atoll; its eastern side shows an uplifted reef in rudely crescentic form, which reaches a height of 100 or 200 ft. at the middle of its crescent, and slowly descends to sea-level at its horns; a bight in its convex front may be the result of a landslide; the tilted lagoon floor slowly deepens westward and is enclosed by disconnected, upbuilt reef-islands.

The New Hebrides show signs of uplift in their elevated reefs, and of depression in their embayments. There is some evidence that certain uplifted fringing reefs on the island of Efaté, near the centre of the group, were formed during pauses in a subsidence that preceded their uplift, and not during pauses in their uplift as inferred by Mawson. The narrowness of the lagoons enclosed by the barrier reefs that encircle certain strongly embayed islands in this group may be explained by supposing alternations of slow and rapid subsidence; thus the earlier-formed reefs, which began to grow when the subsidence was slowly initiated, were drowned when it was later accelerated; and new reefs, thereupon begun on the shore line of that time, now, after a second period of slow subsidence, stand near the present shore line, though the shore line is strongly embayed, because the total subsidence has been large. The absence of reefs around the island of Ambrym is due to its abundant eruptions in recent time, the latest one being in December, 1913; scattered corals were seen growing on one of its sea-cliffed lava-streams, thus illustrating the initial stage of a fringing reef.

The Great Barrier reef of Australia, the greatest reef in the world, with a length of some 1200 miles and a lagoon from 15 to 70 or more miles wide, has grown upward during the recent subsidence by which the Queensland coast has, after a long period of still-stand, been elaborately embayed, as was pointed out by Andrews in 1902. A very recent uplift of some 10 ft. has occurred, as was long ago noted by Jukes. There is much reason for believing that a broadened reef-plain, with extensive land-fed deltas along the continental margin, had been formed before the recent subsidence took place; and it is this broadened reef, now submerged, that is thought to form the "platform" on which the Great Barrier reef has grown up. Guppy's suggestion that the platform or "submarine ledge" is due to marine abrasion, before coral reefs were established here, and that no subsidence has taken place, cannot be accepted. It is highly probable that the well-attested recent subsidence was due to a gentle flexure, by which the offshore sea-bottom was bent down; and, if so, the coastal submergence will give too small a measure of the thickness of the distant barrier reef. In this respect the Great Barrier reef along the shore of a continent differs significantly from smaller barrier reefs around oceanic islands, in which the subsidence of the island and its reefs are essentially uniform.

A few hours on shore at Raratonga, the southernmost member of the Cook group, sufficed to show that extensive embayments formerly entering its elaborately carved mass are now occupied by delta plains and perhaps in part by slightly elevated reef-and lagoon-limestone.

Five islands of the Society group exhibit signs of recent subsidence in their intricately embayed shore lines, as has lately been announced by Marshall. A sixth, the cliff-rimmed island of Tahiti, the largest and youngest of the group, suffered moderate subsidence after its cliffs were cut, but the resulting bays are now nearly all filled with delta plains, which often advance into the narrow lagoon; hence a pause or still-stand has followed its latest subsidence. All the barrier reefs of this group appear to have been formed during the recent subsidence that embayed their central islands.

W. M. Davis.

FORMULAS FOR GLASS MANUFACTURE.

THE Institute of Chemistry has sent us an account of the work of the Glass Research Committee appointed by the council of the institute in October last to conduct investigations with the view of arriving at suitable formulas for laboratory glassware, miners' lamp-glasses, combustion tubing, resistant glass for pharmaceutical products, glass for X-ray bulbs, etc. The main part of the report is here reprinted, and is of particular interest at the present time. Copies of the formulas can be obtained from the secretary, Institute of Chemistry, 30 Russell Square, W.C.

Since October, 1914, the research has been continued uninterruptedly, the chief aims being:—(i) to produce working formulas for all glasses used in laboratory work, and (ii) to ascertain the influence of various ingredients on the physical and chemical properties of glasses. The work was extended to include glass for miners' lamp-glasses, at the suggestion of the Home Office; and also glass for ampoules, to meet the needs of wholesale pharmaceutical chemists engaged in the production of army medical requirements. The committee also examined and reported on samples of British and French laboratory glassware, produced since the beginning of the war, a number of the specimens being made from formulas similar to, and in some cases almost identical with, those recommended by the committee.

The committee has had before it many specimens of glasses used for various purposes, of which analyses have been made by Mr. Bertram Blount, Mr. W. C. Hancock, and Mr. Otto Hehner. It has been found, however, that mixtures prepared in accordance with the analytical results were not always satisfactory; but the analyses were helpful in suggesting synthetic experiments, and during recent investigations some intricate analyses made by Mr. G. J. Alderton under the supervision of Mr. Blount have proved especially valuable. Apart from the analyses, the work has been almost entirely carried on at King's College by Prof. Herbert Jackson and Mr. T. R. Merton, and by the former at his own house. The work has involved a careful study of the chemistry of silicates, aluminates, borates, etc., in their relation to the manufacture of glasses.

Up to the present time, the research committee has reported eleven formulas for glasses for various purposes based on the results of about 400 experimental melts on a scale large enough for drawing rods and blowing small vessels. In addition, a very great number of experiments have been made in order to study the influence of the various constituents employed. No formula has been issued without submitting the specimens made to rigorous tests to prove their suitability for the purposes for which they are intended. Moreover, by varying the experimental working conditions, it can be said with reasonable confidence that the mixtures will prove equally satisfactory under the actual working conditions of a glass furnace. The question of workable temperatures has been carefully considered, and, so far as it is possible to judge, the melts on a small scale indicate that even better results will be obtained on the industrial scale. This view has been justified by the samples already received from manufacturers who have tried some of the formulas.

In deciding the formulas it has been found necessary to direct special attention to the proportions of basic and acidic substances in respect of the action of glass mixtures on clay crucibles during fusion, and it has been shown by careful investigation that the formulas proposed give melts in which the influence of the ingredients of the crucibles is very slight and in some cases practically inappreciable.

The following formulas have been communicated to a number of manufacturers who have expressed their interest in the progress of the investigation and to scientific workers who are conducting similar experiments.

Soft glasses, suitable for ordinary chemical laboratory ware.

	Parts		Parts
(1) Sand	67·0	Calcium carbonate	11·6
Sodium carbonate (Na_2CO_3) ...	34·2	Alumina (Al_2O_3)	6·5

A soft glass which does not give up alkali readily to water, works well in the blowpipe, and does not devitrify readily.

	Parts		Parts
(2) Sand	67·0	Calcium fluoride	1·6
Sodium carbonate (Na_2CO_3) ...	29·0	Alumina (Al_2O_3)	8·3
Calcium carbonate	9·6	Boric anhydride (B_2O_3) ...	2·0

A soft glass of higher quality. Does not give up alkali under severe tests. A kindly working glass before the blowpipe, and very difficult to devitrify.

A resistant glass suitable for pharmaceutical purposes, ampoules, etc.

	Parts		Parts
(3) Sand	67·0	Potassium nitrate	1·0
Alumina (Al_2O_3)	10·0	Sodium carbonate (Na_2CO_3) ...	17·0
Calcium carbonate	12·5	Boric anhydride (B_2O_3) ...	8·0
Magnesia ...	0·5		

This glass is intermediate in hardness between soft glass and combustion tubing, is highly resistant to chemical action, withstands changes of temperature well, and should be a very suitable glass for high-class beakers, flasks, etc.

Glasses for combustion tubing.

	Parts		Parts
(4) Sand	68·2	Sodium carbonate (Na_2CO_3) ...	5·5
Alumina (Al_2O_3)	6·2	Boric anhydride (B_2O_3) ...	5·5
Barium carbonate	8·8	Calcium fluoride	1·0
Calcium carbonate	13·0		
Potassium nitrate	4·3		

This glass resembles Jena combustion tubing very closely indeed. It has practically the same fusing point. It fuses on to Jena glass perfectly, and is indistinguishable from it before the blowpipe and in its behaviour on prolonged heating below its fusing point. The presence of the small quantity of calcium fluoride facilitates the incorporation of the ingredients. The sodium carbonate can be reduced to 1·34 parts provided 7·93 parts of anhydrous borax be used in the place of boric anhydride.

	Parts		Parts
(5) Sand	68·2	Sodium carbonate (Na_2CO_3) ...	5·5
Alumina (Al_2O_3)	6·2	Boric anhydride (B_2O_3) ...	5·5
Barium carbonate	8·8		
Calcium carbonate	14·2		
Potassium nitrate	4·3		

This glass is practically of the same composition as (4). It is not so easy to make or to work, but it does not become so opaque as Jena combustion tubing on prolonged heating. As in No. (4), the proportions given for sodium carbonate and anhydrous borax can be substituted for the figures for sodium carbonate and boric anhydride.

Miners' lamp glasses.

	Parts		Parts
(6) Sand	65·0	Potassium nitrate	3·0
Alumina (Al_2O_3)	1·0	Sodium carbonate (Na_2CO_3) ...	14·0
Calcium carbonate	0·6	Boric anhydride (B_2O_3) ...	24·0
Arsenious oxide (As_2O_3) ...	2·0		
Antimony oxide (Sb_2O_3) ...	1·0		

A colourless and fusible glass withstanding rapid changes of temperature exceptionally well.

	Parts		Parts
(7) Sand	65·0	Potassium nitrate	3·0
Alumina (Al_2O_3)	1·0	Anhydrous borax ($Na_2B_4O_7$) ...	26·68
Calcium carbonate	0·6	Boric anhydride (B_2O_3) ...	5·5
Arsenious oxide (As_2O_3) ...	2·0		
Antimony oxide (Sb_2O_3) ...	1·0		

The same glass as (6), but the ingredients have been varied to avoid the use of so much boric anhydride, which is at present apparently difficult to obtain on a commercial scale.

Resistance-glass.

	Parts		Parts
(8) Sand	65·5	Sodium carbonate (Na_2CO_3) ...	10·2
Alumina (Al_2O_3)	2·5	Borax anhydrous ($Na_2B_4O_7$) ...	13·0
Magnesia (MgO)	5·0		
Zinc oxide (ZnO)	8·0		

A glass almost identical in its general behaviour with Jena resistance glass; withstands changes of temperature well, but, like Jena, is not suitable for working before the blowpipe. It darkens and tends to devitrify; operations—such, for instance, as sealing side tubes into flasks—are difficult, if permanent and neat joints are required.

Formula No. 3, recommended for pharmaceutical purposes, ampoules, etc., may be substituted for the resistance glass with advantage, as the ampoule glass lends itself very well to blowpipe work, and is also especially resistant chemically.

Alternative for combustion tubing.

	Parts		Parts
(9) Sand	72·0	Potassium nitrate (KNO_3) ...	3·0
Alumina (Al_2O_3)	10·0	Sodium carbonate (Na_2CO_3) ...	11·2
Calcium carbonate	11·0	Borax anhydrous ($Na_2B_4O_7$) ...	7·2
Magnesia (MgO)	0·5		

This glass is capable of withstanding high temperatures and rapid changes of temperature; works well before the blowpipe, and is free from the chief defect of Jena glass—namely, the readiness with which it becomes cloudy, and finally quite opaque after prolonged use.

By slight modifications of this formula, almost any degree of hardness can be obtained.

In formulas (8) and (9) substances such as magnesia (MgO) and zinc oxide (ZnO) can be added in the form of carbonates if the actual percentages of MgO and ZnO respectively present in the carbonates are known.

Soft soda-glasses suitable for tubing and for X-ray bulbs.

	Parts		Parts
(10) Sand	68·0	Potassium nitrate (KNO_3) ...	14·5
Alumina (Al_2O_3)	4·0	Sodium carbonate (Na_2CO_3) ...	26·0
Calcium carbonate ($CaCO_3$)	12·8		

	Parts		Parts
(11) Sand	68·0	Potassium carbonate (K_2CO_3)	10·0
Alumina (Al_2O_3)	4·0	Sodium carbonate (Na_2CO_3)	26·0
Calcium carbonate	12·8		

These glasses do not lose their easy-working qualities after repeated heating and blowing, and are plastic over a long range of temperature. They require a temperature of at least 1400–1500° C. for complete incorporation of the ingredients in order to obtain that homogeneity which is necessary for resistance to rapid changes of temperature and ease of working before the blowpipe.

No. (10), containing potassium nitrate, is considered the better of the two, and is more easily incorporated.

The committee considers that the formulas obtained and the work done on the various glasses justify it in the opinion that there is now information available for the manufacture of all the important glasses used in the laboratory and for industrial purposes, which have hitherto been mainly obtained from abroad.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

LONDON.—Prof. T. G. Brodie, professor of physiology in the University of Toronto, will deliver a course of four lectures on "The Gases of the Blood" at King's College, London, on May 31, June 2, 7, and 9. These lectures take the place of those previously announced; they are free to medical students, to internal students of the University, and to medical men on presentation of their cards.

MR. A. G. R. FOULERTON has been appointed lecturer in public health at the London (Royal Free Hospital) School of Medicine for Women, in succession to Prof. W. J. Simpson, resigned.

THE Education Committee of the County Council of the West Riding of Yorkshire has arranged a summer vacation course for teachers, which is to be held at Bingley Training College from August 4 to 18 next. Four evening lectures will be given during the course, including one by Mr. Mackinder on how much geography and history can be taught within the limits of the elementary school. The general course makes provision among numerous other subjects for lectures on the teaching of informal domestic work in schools, and the special courses include lectures on animal and plant life. The primary object of the courses is to increase the educational spirit and efficiency of persons teaching in the West Riding, and to enable them to supplement their knowledge of the various subjects, and of the most approved methods of teaching them. All particulars of the course, including time-tables, are given in the "Bingley Vacation Course Syllabus," copies of which may be obtained on application to the Education Department, County Hall, Wakefield.

ON March 6, Lord Hardinge, Viceroy of India, presided over the annual convocation of Calcutta University, and delivered an address in his capacity of Chancellor of the University. The address is printed in the issue of the *Pioneer Mail* for March 12. The Chancellor referred to the increased interest which has arisen in Indian universities in the teaching of science subjects. University inspection combined with an ordered procedure in affiliation has considerably raised the standard of instruction in the colleges. Some of the laboratories attached to these institutions can now compare favourably with any in the world. The teaching staffs have been strengthened. The advanced students produce papers dealing with subjects of research which are accepted by leading scientific journals in Europe. In the past years the Government of India has contributed generously to the capital requirement of the University of Calcutta, which also draws an annual sum, the capitalised value of which is 36½ lakhs, and generous gifts have been received recently from the late Sir Taraknath Palit and Dr. Rashbehari Ghosh. In Bombay the contributions of few public-minded citizens to the proposed Royal Institute of Science have totalled nearly 25 lakhs, while Sir Chinubhai Madhav Lal has endowed the Institute of Science of Ahmedabad with six lakhs, giving a further two lakhs to the Gujerat College, with which it is associated. Lord Hardinge also dealt with the question of university buildings and libraries The universities of India have recently made laudable efforts, which have been substantially aided by the Government, to provide for themselves local habitations in the shape of buildings befitting their dignity, and libraries where their alumni may learn the use of books and the methods of investigation and research which collections of books alone make possible. Calcutta has not been behindhand. Thanks to the generosity of the Maharaja of Darbhanga, the University is now possessed of a handsome library. The students of the Law College are accommodated in a hostel towards which the Government contributed three lakhs. The Government has also made a grant of eight lakhs for the purchase of a valuable site which abuts on the University buildings, and the acquisition of which should permit of further extension.

SOCIETIES AND ACADEMIES.

London.

Physical Society, March 26.—Dr. A. Russell, vice-president, in the chair.—Prof. A. W. **Porter** and F. **Simeon**: The change of thermal conductivity with fusion. The change in question was determined for mercury and for sodium by finding the temperatures at different points of a cylinder of the metal contained in a glass tube. The ends of the cylinder were maintained at such temperatures that the metal was liquid half-way down its length, the remaining part being solid. The temperatures were taken by means of thermo-electric junctions inserted in narrow tubular depressions which had been formed in the glass tube by forcing a knitting needle down into the locally heated glass. The ratio of the thermal conductivity for solid and liquid was estimated from the slope of tangents drawn to the temperature-curve on each side of the melting point. The values of these ratios are of the same order as the ratio of the corresponding values of the electrical conductivities. The mean value for mercury is 3·91, and for sodium 1·31.—Dr. J. A. **Fleming**: An instrument for the optical delineation and projection of physical curves such as hysteresis, resonance, and characteristic curves. This instrument is designed for projecting on to a screen or photographing on a plate such curves as magnetic hysteresis, resonance, or characteristic curves which can be performed slowly, or are non-periodic or non-repetitive.—Dr. P. **Phillips** and J. Rose **Innes**: The stability of some liquid films. The authors give a simple method of calculating the equilibrium form of a thin film which is a surface of revolution. They then consider the stability for certain kinds of displacement of three classes of such films, viz., the sphere, the cylinder and the catenoid. The mathematics used is quite elementary throughout and the treatment is rigorous.—Prof. A. W. **Porter** and E. Talbot **Paris**: A demonstration of the green-flash of the setting of an artificial sun. A large disc of card mounted so that it can be slowly rotated has a hole, 1 in. in diameter, cut in it about 2 in. from the periphery. This is covered with red gelatine films, and is illuminated from behind so as to form an artificial sun. The front of the disc is covered with white Bristol board and is moderately illuminated by a lamp in front. This sun is viewed through a rectangular aperture (4 in. wide) in a blackened board, the lower edge of the aperture serving as the horion. When the disc is rotated the artificial sun sets and green after-images are obtained of characters varying according to the amount that the eye has been exposed to the bright sun. If the sun is not viewed until immediately before the complete setting the after-image represents simply the disappearing segment to which it is due. The authors claim that this phenomenon is what is often described as the green-flash at sunset, though they are ready to admit that other (but probably rarer) phenomena also go under the same name.

Manchester.

Literary and Philosophical Society, March 23.—Mr. F. Nicholson, president, in the chair.—T. A. **Coward**: A note on the behaviour of a blackbird—a problem in mental development. The author referred to the habit of certain birds—individual, not specific—which when stirred by spring rivalry will fight with their own reflections as seen in windows, and spoke, in particular, of a male blackbird which for more than a month has been daily assaulting its own image in a particular window. A blackbird, presumably the same, behaved in a similar way at the same window all through last spring. Attention was directed to the psychological problem presented by a bird with an excellent memory but without any apparent power of learning by experience. The recollection of this visionary antagonist was stimulated by the seasonal sexual activity and died down with the normal waning of this force.—A. W. Rymer **Roberts**: Two cases of parallelism in the Aphidæ. Parallel series of aphids may co-exist on the same or on different plants, having the same ancestry but differing in habits and sometimes also in form. The phenomenon was first brought in prominence by Cholodkovsky's recent researches on Chermes. Though there exists some doubt, in the light of more recent research, whether the instances principally relied upon are not those of distinct biological species, other instances have been discovered of as many as four parallel forms being descended from the winter-form on the secondary host-plant in certain species of Chermes. Parallelism exists also in other groups, as in the Pemphiginæ, two instances observed being (1) *Thecabius affinis*, a species migrating between poplars and Ranunculus, and (2) *Hamamelistes tullgreni*, so far only found on birch. *T. affinis* has been found continuing to live over the winter on Ranunculus after the migrating individuals have returned to the poplar. *H. tullgreni* has been observed in England for the first time during the past year. Certain of its forms resemble scale insects. It has so far only been found upon birch, but winged individuals fly from that to some other plant, leaving wingless individuals to continue the race on the birch, both being descended from a single ancestress by parthenogenesis.

Edinburgh.

Royal Society, March 1.—Prof. Hudson Beare, vice-president, in the chair.—H. **Levy**: The resistance of a fluid to a body moving through it. In this paper it was shown that trails of vortices following in the wake of a body moving through a fluid did not form a stable system, so that the theory recently advanced by Karman, which was based upon a suggestion made originally by Kelvin, did not seem to be tenable. The paper also contained an interesting development of the method of finding the stream lines with certain definable forms of boundary.—F. D. **Miles**: The electrical conductivity of aqueous hydrochloric acid, saturated with sodium chloride; and on a new form of conductivity cell. Within the range of concentration (15 to 27 per cent. of hydrogen chloride) the specific conductivity is lowered by saturation with salt. The salt-saturated acid of maximum conductivity was prepared by adding salt to a solution containing 21·9 per cent. of hydrogen chloride, whereas the best conducting solution of hydrogen chloride alone contains only 19·1 per cent. of that substance. The conductivity cell described was specially suitable for solutions which are saturated or contain volatile constituents.—F. D. **Miles**: The reaction between sodamide and hydrogen. At temperatures near to 250° C. these substances react according to the formula, $NaNH_2 + H_2 = NaH + NH_3$.

March 15.—Prof. Bower, vice-president, in the chair.—Dr. J. H. **Ashworth**: The larvæ of Lingula and Pelagodiscus. Sixteen larvæ of *Lingula anatina* were taken by him last year in the surface waters of the southern part of the Red Sea, and one in the Indian Ocean about 4° south of Colombo. The latter is noteworthy because of the depth of water (2200 fathoms) in the locality where the larva was taken. The larvæ varied from 0·5 to 1·6 mm. in length. Descriptions were given of the alimentary canal, calomoducts (nephridia), and statocysts, and of the changes in shape of the shell valves as growth proceeds. An account was also given of the anatomy of the larva of *Pelagodiscus* (*Discinisca*) *atlanticus*, based on six specimens, about 0·4 mm. in length, which were taken in October last a few miles west of Cape Cormorin in water of 40 fathoms. Adult specimens of this Brachiopod have almost entirely been recorded from deep water. Blochmann has denied the presence of statocysts in both Lingula and Pelagodiscus, but these organs were certainly present in both genera.—C. **Cochrane**: The reflective power of pigments in the ultra-violet. The diffuse reflection from the prepared strip of pigment, which was illuminated by a complete iron-arc spectrum, was photographed, a similar photograph of the reflection from a contiguous strip of white cardboard being simultaneously taken as a standard of comparison. More than thirty different pigments were experimented with, and of these the greater number showed selective reflection in the higher ultra-violet. There were, however, marked exceptions, such as Chinese white, the reflective power of which rapidly diminished as the wave-lengths became shorter.—Dr. W. T. **Gordon**: Archæocyathinæ collected by the Scottish National Antarctic Expedition. The specimens were obtained in a block of limestone dredged in the Weddell Sea, and associated with them were remains of calcareous algæ and sponges. The Archæocyathinæ can be grouped under the genera Archæocyathus, Spirocyathus, Coscinocyathus, Syringocnema, and Protopharetra. The fauna shows striking similarity with that described by Taylor from the Cambrian rocks of South Australia.

Paris.

Academy of Sciences, April 6.—M. Ed. Perrier in the chair.—G. **Bigourdan**: The instrumental undulations of images; their daily and annual variation and their relation with the general state of the atmosphere. A discussion of the causes and means of elimination of the irregular movements of the focal images of stars.—Paul **Appell**: The approximate inversion of certain real integrals, and on the extension of Kepler's equation and Bessel's functions.—L. E. **Bertin**: Calculation of the increase of velocity or of range of submarines resulting from increase of their dimensions. Data furnished by ordinary vessels are not directly applicable to submarines. It would appear that the maximum speed and range will be reached for a submarine having a displacement at the surface of 1000 tons.—Maurice **Hamy**: Radiography in the hospital at the Institute. Radiographs of all the wounded are made as they enter the hospital in the same attitude on two distinct plates, the bulb being moved a distance of 7 cm. The negatives, examined in a specially constructed stereoscope, show the position of the metallic fragment or damaged bone in relief, by means of which the operation is much simplified.—M. **Guignard**: The formation of pollen.—J. **Bosler**: The rotation of the solar corona. Measurements of the red line of wavelength 6374·4 on the east and west borders gave by the application of the Doppler-Fizeau principle a tangential velocity of 3·7 kilometres per second, with a possible error of 25 to 30 per cent. This agrees well with the determination of W. W. Campbell, who by applying the same method to the green line 5303 obtained a velocity of 3·1 kilometres per second. Hence the corona moves in the same sense as the direction of movement of the sun, and apparently with a higher velocity.—H. **Deslandres**: Remarks on the preceding communication and on problems connected with the rotation of the solar corona. The study of the corona throws light on the important question of a corpuscular radiation emitted by the sun and received by the earth, but increase of knowledge in this direction must necessarily be slow, since the corona is only observable during eclipses.—Daniel **Berthelot**: The temperature-coefficient of photochemical reactions. For the changes studied, the decomposition of lævulose and the decomposition of a mixture of oxalic acid and ferric chloride the rate of photochemical change is increased by a rise of temperature, but the coefficient is very much smaller than that of an ordinary chemical change.—Henri **Coupin**: The resistance of marine bacteria to the action of salt. Marine bacteria have tolerance for a considerable range in the proportion of salt in the water in which they develop, as they can support 8 per cent., and are content with as little as 0·3 to 0·2 per cent. They adapt themselves better to proportions lower than the normal sea-water salt-content than to more concentrated solutions.—C. **Sauvageau**: The development and the biology of *Saccorhiza bulbosa*.—J. **Bergonié**: The detection and localisation of magnetic projectiles by an electromagnet actuated by an alternating current. The vibration of the flesh immediately over the metallic fragment gives an accurate indication of its position. Details are appended of several operations successfully carried out by this means.—MM. **Belot** and Maxime **Ménard**: The use of the Coolidge tube in the medico-surgical applications of the X-rays. The Coolidge tube is based on the discharge of independent electrons and details are given of a pattern made in France by Pilon. The advantages obtained, as compared with the ordinary tube, are the regularity in working, the long period of regular working, the possibility of regulating the tube without modifying the vacuum, the fixed point of impact on the kathode, and the homogeneity of the bundle of X-rays.—Miramond **de Laroquette** and Gaston **Lemaire**: Tables of the coefficients of magnification of radiographic images utilisable for the localisation of projectiles in the tissues.—Pierre Delbet and H. Vaquez: Chondrectomy in certain irreducible dilatations of the right heart.

THE BIOLOGICAL PROBLEM OF SEX.

The Determination of Sex. By Dr. L. Doncaster. Pp. x + 172. (Cambridge: At the University Press, 1914.) Price 7s. 6d. net.

DR. DONCASTER deals in a masterly way with a problem as difficult as it is fascinating, and his book is a fine illustration of scientific method. He states a theory and presents the evidence, and when the reader has just begun to enjoy a sense of satisfaction, more facts are brought forward which show that the theory breaks down, and that we have still much to learn regarding the determination of sex. It is a pleasure to follow a discussion which is so keenly critical and at the same time open-minded. Those who know Mr. Doncaster's book on heredity will expect lucidity in his treatment of a cognate subject, and they will not be disappointed. He goes deeply into things, but it is all clear, including the glossary. The illustrations are interesting and instructive. An indication of the scope of the book may be given in the chapter-headings: The problem; the nature and function of sex; the stage of development at which sex is determined; sex-limited inheritance; the material basis of sex-determination; the sex-ratio; secondary sexual characters; the hereditary transmission of secondary sexual characters; hermaphroditism and gynandromorphism; general conclusions on the causes which determine sex; the determination of sex in man. The author does not deal with the subject in its entirety, the case of plants, for instance, being deliberately left out, but selects for illustration and discussion the lines which seem to him most promising.

Dr. Doncaster's general position may be stated. In some cases sex appears to be determined already in the unfertilised ovum, for male-producing and female-producing ova are formed. In other cases sex seems to depend on the spermatozoon, and to be fixed at fertilisation; thus, to take a simple case, the unfertilised ova of the hive bee develop into males, and there are many instances now known of two kinds of spermatozoa differing in respect of their chromosomes. In a few cases there is evidence that sex may be modified during embryonic development or even later. Many facts point to the conclusion that a sex-determining factor sometimes resides in special sex chromosomes, and is inherited like a Mendelian character (as was first suggested by Bateson and by Castle). Individuals which receive it from both parents would be of one sex; those to which it is transmitted by one parent only would be of the other sex.

But the author goes on to point out that there are many facts which do not fit in with this theory. There is evidence that the ovum may influence the sex in cases in which observations on the chromosomes indicate that the sex should be determined by the spermatozoon; and there is evidence that the sex may in some cases be modified after fertilisation by influences acting on the embryo or some later stage. Therefore the author is inclined to give up the simple hypothesis of an unchangeable hereditary entity, the presence of which always causes one sex and its absence the other. He supposes that sex is dependent on a physiological condition of the organism, depending on the interaction of certain chromosomes with the protoplasm of the cells, and therefore determined, in the absence of other disturbing factors, by the presence or absence of these particular chromosomes. But where the determination expressed by the chromosome difference is not decisive, other conditions may have their influence. "Put in different words, every germ-cell would bear a sex-determining factor, but when this factor has relatively small intensity of action, its effect may be counterbalanced by other causes which alter the physiological relation on which sex-determination depends."

As to Man, the evidence from the study of chromosomes is at present unsatisfactory, but it is maintained by some that Man is one of those species in which the male has one chromosome less than the female; all the ova contain an X-chromosome (supposed to have a sex-determining function), while half of the spermatozoa have it and half have not. When two X-chromosomes are present in a fertilised ovum it develops into a female; when only one, into a male. But apart from the chromosomes, there are some other facts which point to the conclusion indicated. The most important of these is the sex-limited transmission by the male, as seen in the inheritance of colour-blindness, night-blindness, and hæmophilia. "If a man transmits certain characters always or nearly always to his daughters, the conclusion can hardly be avoided that he produces two kinds of germ-cells, female-producing which bear the factor for these characters, and male-producing which do not." If sex in man is determined solely by the spermatozoon, "there is no hope either of influencing or of predicting it in special cases." But if the ovum has some share in the effect, as some other facts suggest, if there are two kinds of ova, or if the physiological condition of the ova is alterable, the possibility of influencing the sex of the offspring through the mother is not excluded. The author regards "the control of sex in Man as an achievement not entirely impossible of realisation."

As regards the differences between the sexes, with which the author is not specially concerned in this volume, the view is entertained that "the physiology of the female is relatively anabolic, that of the male catabolic in character. That this should be so is perhaps a necessary consequence of the difference in function between the sexes. . . . It is interesting to speculate, however, whether the active, vigorous habits of the male and the restless movement of the spermatozoon on the one hand, and the quieter habit of the female and the passivity of the egg on the other, may not each be due to fundamental catabolic and anabolic tendencies, characteristic of maleness and femaleness, quite apart from the exigencies of reproduction."

This speculation is luminous and interesting, but we should have liked it better if reference had been made to the fact that it was advanced more than a quarter of a century ago by Prof. Patrick Geddes. It may be, however, that this is just another illustration of great minds thinking alike.

X-RAYS AND CRYSTALS.

X-Rays and Crystal Structure. By Prof. W. H. Bragg and W. L. Bragg. Pp. vii + 229. (London: G. Bell and Sons, Ltd., 1915.) Price 7*s.* 6*d.* net.

A BOOK in which are gathered together the results so far obtained in the new field of research concerning X-rays and crystals is particularly welcome at the present time, and especially from Prof. Bragg and his son. For not only have they carried the subject very much further than its initiators, Drs. Laue, Friedrich, and Knipping, but they have also given us an entirely new mode of experimenting. Indeed, in the hands of the English observers the investigation has already borne surprisingly important results, both as regards experimental confirmations of the views of crystallographers based on crystal measurement and as regards the nature of the X-rays themselves. The book will be gladly received by all who desire to explore the possibilities of the new method of attack, as it affords much-needed detailed descriptions of the apparatus employed, and instructions for its use.

The photographic diffraction method of Laue only receives a relatively small amount of attention, as the Bragg method, which involves the use of the X-ray spectrometer, is shown to be much more capable of affording indications of the internal structure of the crystal in the more complicated cases. It is clearly shown, however, that the two methods are mutually complementary, and lead to essentially the same result, with the advantage of detail on the side of the spectrometer, and permanence of record on the side of the photographic radiogram.

The whole subject is still so fresh that it might have been considered premature that a book should yet be written concerning it. But the results obtained already are so clear, and the stage reached may so truly be said to be one at which the initial difficulties have been overcome in the simpler cases tackled, that this book is in reality fully justified, and should prove of great use in attacking the immense difficulties which are presented by the more complicated crystalline chemical compounds. It may be that our first transports over the opening-up of so remarkable a new field of research may have to be modified, as it appears to be only capable of yielding unmistakably intelligible indications in the very simple cases, those of the chemical elements and their binary and ternary compounds, and not to be generally capable of indicating hemihedrism. For Friedel has shown that only eleven different types of radiogram are afforded by the thirty-two classes of crystals. It was hoped that it might throw a clear light on the much-discussed Pope-Barlow conception of valency, as dependent on the relative volumes of the spheres of influence of the various elementary atoms in a crystalline compound. But so far the indications are not favourable to that theory, and have led its propounders to doubt the value of the X-ray results. The chief substance studied which has afforded indications is the diamond, the analysis of which with the aid of the X-ray spectrometer is perhaps the most brilliant piece of work carried out by the Braggs. Whatever its indications may be as to the nature of the packing of the atoms and the sizes of their spheres of influence, there can be no doubt that the structure arrived at in the case of this, the most interesting, form of carbon is one which must commend itself both to the crystallographer and to the organic chemist as bearing the impress of truth.

The book will be found to afford much information concerning the properties of X-rays, as revealed by the Bragg spectrometer, and details of the investigations of all the simple crystalline substances which they have studied by its aid. The main work of the authors has been to show that the different orders (first, second, and third) of reflection, at the specific angles for maximum effect experimentally found for certain "monochromatic" X-radiations, correspond to reflections from different sets of planes among the whole parallel series of planes of atoms present in the part of the crystal penetrated by the rays, that is, to consecutive planes, alternate planes, and sets composed of every third plane; and from the intensity (if present) or absence of the different orders of reflection most important conclusions have been derived as to the constitution of these several planes of atoms, that is, as to the distribution in them of the atoms of the different chemical elements present in the crystallised substance. Moreover, the actual distances apart of the planes, and therefore of the contiguous atoms, have been calculated.

As regards the crystallographic bearing of the work described in this book, it may be unhesitatingly affirmed to afford ample confirmation of the structure of crystals which has been accepted during the last decade, as being indicated by the combined results of the work of experimental crystallographers and theoretical geometricians; this is certainly true so far as that structure has been authoritatively stated in such works as the latest edition of von Groth's "Physikalische Krystallographie," Miers' "Mineralogy," or the "Crystallography and Practical Crystal Measurement" of the writer of this review. It thus proves up to the hilt the solid ground-work on which the science of crystallography is now built, while throwing little light upon, and giving as yet no countenance to, the more speculative theories which are the matter of current discussion. It reveals crystallography more than ever as the handmaid of chemistry, and enhances a hundredfold the necessity for a much more universal study of crystals than has hitherto been recognised. Crystallographers are deeply grateful to Prof. and Mr. Bragg for their highly interesting and timely book.

A. E. H. Tutton.

SIR HIRAM MAXIM.

My Life. By Sir Hiram S. Maxim. Pp. ix + 322. (London: Methuen and Co., Ltd., 1915.) Price 16*s.* net.

To write in the first person singular is not according to the English temperament; even the best autobiographies annoy us, and the more we admire a man the sorrier do we feel when reading his life. Therefore it is thought to be better "form" to let a friend write one's life. But if we are to know Sir Hiram Maxim, we must listen to him telling his own story in his own way; we must not only bear with him when he shows pride in his performances, we must try to sympathise with him. He is a naturalised British subject; he was knighted; he is known in good society; he has received many orders and honours and hospitality from our own and foreign rulers. He is proud to be a British subject, and we are proud of the reasons he has given in this book for his change of citizenship, but in every line he shows that he is an American. He reveals himself as no Englishman dare do, but if the reader will only call to mind the fact that there are other formulæ of behaviour than his own, he will find the book well worth reading.

Sir Hiram Maxim was born in 1840 in the State of Maine; he had very little school education; he had a childhood and youth full of hard work. We know from many sources the conditions of young life sixty years ago in Maine and the New England States. In many ways it resembled the conditions in country places, not in England, but in Scotland and the North of Ireland, only that in Maine there were no rich people and there were few who were even moderately well to do. There was almost no money; wages were paid in kind, in orders upon shops for provisions. Everybody had a rather hard life full of manual labour, and therefore young Maxim did not in the least repine at his lot, which might seem to some of us a very hard lot. He is still proud of his muscular strength, which is greatly due to the work of his youth. He recounts with pride how, when quite young, in woodwork, lathe work, and work with various hand-tools to which he was sometimes unaccustomed he greatly outstripped other and much older workmen. Whatever chances of school there were he seized, in spite of long working hours. In Maine and Canada there was little skilled labour, so that the ingenious, energetic young man found that he could make a reputation quickly in any trade that he took up, and he succeeded in many trades, even in what may elastically be called landscape painting.

To such a boy everything gave occasion for thought and invention, and the inventions which he seems to be most proud of are those early inventions with which his name is not much connected now. Many of them have been greatly developed, but he reaps no share of the large fortunes that they have created. He had plenty of opportunity of studying human nature. He was evidently always abstemious himself, but he even had the experience of tending a drinking bar for a short time. He was peace-loving, but he was compelled on many occasions to show that he could fight, and he seems to have been a fine fighter. He gives few dates, and his age when any particular event happened can only be guessed at very roughly. This does not much matter, because at the age of twenty and at the age of forty he was the same independent, optimistic youth, eager for work and invention, gradually becoming skilled in the use of the best tools in doing fine metal work, able to turn his hand to glass-blowing and draughtsmanship and half-a-dozen other arts, with a good working knowledge of chemistry, electricity, and other parts of physics; he was always proud of his strength and health.

He made many inventions: mousetraps, gas machines, sprinklers to put out fires, a steam trap, locomotive head-lights, incandescent platinum and carbon electric lamps, the electric regulator for which he received the Légion d'Honneur; he demagnetised watches, and did many other interesting things. He relates many amusing anecdotes which illustrate the condition of things fifty years ago in Canada and the northern and also in the southern States.

He was probably thirty-eight when he discovered that heating carbon in a hydrocarbon atmosphere caused carbon to be deposited in a very hard form; we are not sure that he really claims the method of "flashing" a carbon filament by keeping it hot in a hydrocarbon atmosphere, but the suggestion of a claim is evident. About the age of forty he was greatly engaged in the manufacture and use of dynamo machines, and he exhibited excellent lamps at the Paris Exhibition of 1881. Soon after this, in London, he invented and exhibited his automatic gun; a single barrel which discharged more than six hundred ordinary rifle shots per minute, and for the next twenty years his time was mainly taken up in developing automatic guns of greater sizes. He records some of the praise which has been bestowed upon his gun; no praise can be too great for it. We remember a toast which was drunk enthusiastically in London when the news of a certain conquest had just been published "To the Conqueror of Matabeleland, Hiram Maxim."

He made discoveries about gunpowder and other explosives. He seems to be the first inventor of a smokeless powder. He describes all these things, but does not seem to think them of much more importance than his experiments on the roasting of coffee.

He seems to have been the first to see clearly how a flying machine might be made to work, and spent a very great deal of money in driving inclined planes horizontally through the air by means of an engine and air propellers, so that there should be sufficient vertical lifting force upon the planes. His machine did lift, and he seemed to be succeeding slowly, but his real difficulty was in the great weight of engine required. The invention of the petrol engine easily made the aeroplane a real flight machine. His fellow directors seem occasionally to have thought that there was a loss of dignity in his allowing advertisements to appear of such things as his inhaler for asthma, and scientific friends deplored his "prostituting his talents on quack nostrums." His own comment upon this is that from their point of view the invention of a killing machine was very creditable, but it was a disgrace to invent an apparatus to prevent human suffering. Just so, there are the two points of view. All through his life Sir Hiram was keen upon inventing anything that might be useful. He does not feel a loss of dignity in describing how he invented a simple, thoroughly good method of giving a proper surface to a black-board in a school, and he is no more ashamed of advertising his inhaler than of advertising his gun.

His experience of lawyers and business men in America seems to make him rather bitter towards Americans. It is gratifying to find him saying: "The reception that I received in England and the straightforward honesty of the gentlemen with whom I had to deal, gave me a very favourable opinion of the English character." J. P.

APPEARANCE AND REALITY.

(1) *William James and Henri Bergson: A Study in Contrasting Theories of Life.* By Dr. H. M. Kallen. Pp. xi + 248. (Chicago: University of Chicago Press; London: Cambridge University Press, 1914.) Price 6*s.* net.

(2) *The Mirror of Perception.* By L. Hall. Pp. 129. (London: Love and Malcomson, Ltd., 1914.) Price 2*s.* 6*d.*

(3) *What is Adaptation?* By Prof. R. E. Lloyd. Pp. vii + 110. (London: Longmans, Green and Co., 1914.) Price 2*s.* 6*d.* net.

(4) *The Story of Yone Noguchi: Told by Himself.* Pp. xi + 255. (London: Chatto and Windus, 1914.) Price 6*s.* net.

(1) NOT the least useful contribution to philosophy made by William James was a negative one, viz., the ignoring of the traditional antithesis between reality and appearance. This antithesis may safely be said to have been the original sin of metaphysics since meditation began, and James's philosophy may most fruitfully be studied from this starting-point. The older philosophers, logical and static, discriminated between appearance and reality "in one or all of the compensatory terms of God, freedom, immortality, and cosmic unity"; and later, "in response to the pressure of rapidly growing sciences, men faced fact, only to change it in such wise as thereby to satisfy the inner need for logical consistency." But James "insisted

that each event of experience must be acknowledged for what it appears to be, and heard for its own claims. To neither doubt nor belief, datum nor preference, term nor relation, value nor fact, did he concede superiority over the others. . . . Pure experience knows no favourites. He admits into reality . . . evil as well as good, discontinuities as well as continuities, unhuman as well as human, plurality as well as unity, chance and novelty as well as order and law."

Though between James and Bergson there is no little spiritual sympathy, a profound difference exists in the methodology of the *Weltanschauung* of each thinker. "Where," says Dr. Kallen, "Bergson beholds a universe, James sees a multiverse. . . . James is a democrat in metaphysics. Bergson, on the contrary, is a monarchist. For him the distinction between appearance and reality is aboriginal and final. For James it is secondary and functional." For James, "being is neutral," and he ignores, practically, the difference between "being" and "not being." Hegel laboriously proved them to be the same. James deals with reality just as it comes to cognition. Reality to him is "alogical," as Dr. Kallen puts it. Kant began the attack on logical metaphysics, inventing "epistemology" to assist him towards a *locus standi*. He, no less than any of the ancients, would have nothing to do with "common-sense reality." And no one expects any philosopher to consider it. But, to return to Bergson and his notion of philosophical reality, it is remarkable with what *élan* the French thinker embraces his self-found "truth." It is *durée réelle* (pure duration), a *poussée formidable* (a formidable thrust), the *élan vital* (the onrush of life); but its eternal enemy is matter and space, which distort it and by which it is distorted. Bergson's "flux" is a richer concept than that of Heraclitus, but it is of the same order. You would expect him to prefer instinct to intellect. But no one nowadays would place intellect, reason, first in the cosmic hierarchy. Both Bergson and James have contributed to this result. From the pragmatist point of view truth is "what we live by"; "common-sense, religion, art, and science are tools and modes of life, and therefore pragmatic." But, for Bergson, "truth is absolute," and his "truth" is vitalism writ large, after a course of Plotinus, Driesch (?), and Darwin.

(2) It is somewhat stimulating to find a disciple of Berkeley crying in the wilderness of to-day. Mr. Leonard Hall puts forward a "metaphysical theory" which is "a particular form of psychophysical parallelism, in which it is maintained that the physical world is the appearance, or image, of the psychical world, *in the distorting mirror of perception*" (my italics). It is a clever *tour de force*, though it is apparently quite serious. Granted the major premiss, everything comes out satisfactorily. Mr. Hall commences with the old antithesis of appearance and reality, and argues that "the initiating cause of all perceptions of the same material body is, not the body itself, but a reality of which the body is the image in the distorting mirror of perception." For Berkeley the initiating cause was God; for modern science "the initiating cause of all perceptions of the same body is the body itself," which, by the way, is not the case; science does not dogmatise here. Material bodies are "unreal . . . they are the transfigured appearances, or images, of underlying realities. Further, according to this theory, space is unreal, a material body, like the image of an object in a mirror, being in unreal space." Mr. Hall concludes that every organism, from the protozoa upwards, is a "mind"; that man is the super-conglomerate of "minds," and that this hypothesis of summated minds explains evolution and the organic world.

(3) Prof. Lloyd has written a suggestive little book on adaptation. The proposition of the selection theory that "competition causes evolution" was made in order to explain adaptation and life in general. It regards organisms as fitting into something, which is called their environment, . . . and that this correspondence was brought about by the elimination, from the one side, of all that would not fit." But adaptation, according to Prof. Lloyd, does not, any more than life, require explanation. It is the teleological bias of man, the machine-maker, that institutes the wonder which leads to design, purpose, and adaptation theories. But adaptation is "its own explanation, since an unadapted thing could not live."

(4) The *Weltanschauung* of many philosophers has been based on æsthetic axioms. And in his way the artist is a philosopher; "the marbles of Phidias and the philosophy of Plato . . . obey the same impulse and express the same will—an impulse to make over unsuitable realities into satisfactory ideas, a will to remodel discordant nature into happy civilisation." The reminiscences of the Japanese poet, Mr. Yone Noguchi, are a case of æsthetic pragmatism. "Do you know," he says, "I am a shy, without-knowledge-of-the-world poet"? All his experiences have been acquired from the point of view of beauty. His description of Chicago is a good example. "Smoke means Chicago as flower means Japan; money means Chicago as art means Japan."

A. E. Crawley.

OUR BOOKSHELF.

A Manual of Oils, Resins, and Paints, for Students and Practical Men. By Dr. H. Ingle. Vol. I., Analysis and Valuation, by the author and J. A. L. Sutcliffe. Pp. 129. (London: C. Griffin and Co., Ltd., 1915.) 3*s*. 6*d*. net.

This small volume is intended for students, analysts, and works chemists who are familiar with general chemistry but have had little or no practical experience in analysing oils, or preparations which contain oils. It includes much of what one would put in a good notebook intended for personal use in the laboratory. A short introduction serves to refresh the reader's memory upon points in organic chemistry specially relevant to oils and fats, after which the authors give short accounts of the most approved chemical and physical methods used in examining these bodies. Theoretical explanations are included as well as practical details. For example, the chemical reactions concerned in the absorption of iodine by oils are described more fully than usual—though it is true that we have to look in more than one place for them. A chapter on technological analysis deals not only with oils, fats, and waxes as such, but with articles such as paints, pigments, and varnishes which may contain oil as an ingredient, and with allied substances, such as turpentine and gum-resins.

The correct interpretation of the results obtained would often require much more knowledge than could be obtained from the descriptions given. Information as to the origin and methods of preparation of the various oils is not within the scope of the work. It is understood, however, that further volumes are to follow, dealing with these matters. The book is a useful introduction to laboratory work in the subject.

Potting, for Artists, Craftsmen, and Teachers. By G. J. Cox. Pp. ix+200. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 5*s*. 6*d*. net.

The book will prove a distinct help to an artist craftsman who wishes to "do something" with clay. The author is right in saying: "Too much stress cannot be laid upon the importance of close study of the best work, both ancient and modern, for it is a truism that however handily a craftsman may work, his output will be worthless if he has not, with his increasing powers of technique, developed a sound judgment and refined taste." The description of the various simple processes of pottery work is very exact, and the illustrations are admirable.

The book, indeed, is a simple, though thorough and concise, first tutor to an artist craftsman, and should, to use the author's words, "set one or two sincere students to the making of some of the many beautiful objects of utility and art with which the craft abounds."

The list of pottery terms is useful, though there are a few which are not employed in this country in the sense given by the author, for example, *clammings* in England means the doors of the kiln, and not simply the sand or siftings applied to the cracks in them; *pug* in this country is used to mean the mechanical wedging of clay; *galena* is classed by the author as highly poisonous, and lead as poisonous, whereas galena is practically safe to use, but there may be considerable danger in using white lead carelessly.

Bernard Moore.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

The Principle of Similitude.

When Lord Rayleigh directs attention to the neglect among physicists of the principle of similitude (Nature, March 18), he has perhaps forgotten the excellent paragraph in which Tait deals with the question in his "Properties of Matter." Curiously enough, one of Lord Rayleigh's first illustrations is also Tait's, namely, the fact that the velocity of waves on deep water is as the square root of their lengths, to which Tait adds the corresponding fact that the velocity of ripples is inversely in the same proportion.

The principle is of great use in biology, as Herbert Spencer was the first to show. By its help we understand how there is a limit set to the possible growth in magnitude of terrestrial animals; how, on the other hand, the whale gains in activity and speed the bigger it grows; why the ostrich is unable to fly; why the bee's wing vibrates so much quicker than a bird's; and why the flea can jump well-nigh as high as a man. And not less does the principle deserve to be borne in mind when we consider what must be the conditions of life in the most minute organisms: especially if there be any so small as that Micrococcus of the rabbit, the diameter of which is given in the books as only 0·00015 mm., or not far from the limits of microscopic vision.

D'Arcy W. Thompson.

It is rather curious that Prof. D'Arcy Thompson should refer to Tait's "Properties of Matter," for I fancy I might claim some part of the credit for the paragraph in question. In a review of the first edition (Nature, vol. xxxii., p. 314, 1885) I wrote:—"There is one matter suitable to an elementary work which I should be glad to see included in a future edition, viz., the principle of dynamical similarity, or the influence of scale upon dynamical and physical phenomena. It often happens that simple reasoning founded upon this principle tells us nearly all that is to be learned from even a successful mathematical investigation, and in the numerous cases where such an investigation is beyond our powers, the principle gives us information of the utmost importance."

And, after an example or two: "I feel sure that in Prof. Tait's hands this very important and fundamental principle might be made intelligible to the great mass of physical students." Though I believe I was in correspondence with him at the time, I do not remember to have seen Tait's second (or later) edition, and I can only wonder that it has not had a more marked effect in popularising the general principle.

Prof. Thompson's illustrations from biology (attributed in part to Spencer) are, of course, of first-rate importance.

RAYLEIGH.

The Age of the Earth.

SOME fifty years ago Kelvin announced that the temperature of the earth could not have been anything like its present value for more than some 20–30 million years. This estimate was based upon three independent considerations, namely, the temperature gradient inside the earth's crust, the amount of tidal friction, and the total amount of energy radiated by the sun.

The first of these arguments has been invalidated completely by the discovery of the radio-active elements. The other two arguments are scarcely affected by this event.

The geologists always found some difficulty in compressing the history of the earth, more especially of the sedimentary strata, into the period allowed them by Kelvin. Prof. Harker's presidential address before the Yorkshire Geological Society, reprinted in your issue of March 25, seems to show that there is a general impression abroad that Kelvin's estimates have been superseded, and that the discoveries in radio-activity allow one to assume a period of the order of thousands of millions of years since the earth has reached a constant state as regards climate. I should like to be allowed to state as succinctly as possible what difficulties this view entails.

The mean temperature of the earth is about 280° absolute. It therefore radiates about $1{\cdot}7 \times 10^{24}$ ergs per second into space.

Assuming the latest value $1{\cdot}92 \frac{\text{cal}}{\text{cm.}^2\text{min.}}$ for the solar constant, the earth receives $1{\cdot}72 \times 10^{24}$ ergs per second from the sun. Therefore the radiation from the sun just compensates the amount lost by the earth; in other words, the temperature of the earth is determined by the temperature of the sun. The possibility that the earth's temperature might have been maintained by radio-active processes before the sun was incandescent, and that the radio-active substances have died off since then need scarcely be discussed seriously. For quite apart from the well-known sterilising effects of the rays, any radio-active substances with a sufficiently long life to keep up the temperature of the earth for any considerable length of time would not disappear quickly. Uranium, for instance, only diminishes at the rate of about 1·5 per cent. in 100 million years.

One may conclude, therefore, that the time during which the earth can have existed in its present state cannot be greater than the time since which the effective temperature of the sun has been about 6000°, its present value. This time cannot exceed about thirty million years. For the sun loses energy at the rate of about $3{\cdot}8 \times 10^{33} \frac{\text{ergs}}{\text{sec}}$, and the total energy to be gained by a mass of $1{\cdot}97 \times 10^{33}$ gm., contracting to a radius $6{\cdot}96 \times 10^{10}$ cm., is $2{\cdot}2 \times 10^{48}$ ergs, assuming approximate homogeneity. (Taking the increase in density towards the centre into account does not alter these figures much.) Now even if one assumes that the whole of this energy was radiated at a rate of about $3{\cdot}8 \times 10^{33} \frac{\text{erg}}{\text{sec.}}$, *i.e.*, at the present rate, it will only last 18·3 million years. But any other supposition, namely, that the sun at one time emitted more or less energy per second, leads to a shorter period for the earth in its present state.

To explain a greater age it was necessary to find other sources of energy, and since neither the heat of chemical combination nor any possible increase in the specific heat was anything like large enough, the heat of radio-active transformations was invoked. This was perhaps excusable in the early days before very much was known about the laws governing these processes, but it seems quite inadmissible to-day.

It has been suggested that at the enormous pressure and temperature inside the sun radio-active processes might be modified, and even that ordinary elements might break up. A consideration of the quantitative relations involved shows that this is most unlikely. Though one can scarcely apply ordinary thermodynamics to radio-active processes one can certainly apply the general rule, which may also be developed from the quantum theory if desired, namely, that a reaction the energy of which is A ergs per molecule is affected chiefly by the collisions of atoms of energy of the order A. Now A is of the order 10^{-5} ergs in radio-active processes, and one can therefore only expect the temperature to affect those if an appreciable number of atoms have an amount of energy of this order. The average energy of an atom would be 10^{-5} ergs at about $5{\cdot}10^{10}$ degrees. Therefore even at 500 million degrees only one atom amongst 10^{40} would be moving fast enough to influence a reaction which liberates 10^{-5} ergs. Obviously 500 million degrees is quite beyond the bounds of possibility in any part of the sun. One must conclude, therefore, that any process which liberates anything like the requisite energy is unaffected by solar conditions, and takes place at the same rate on the sun as on the earth. Thus one must fall back upon the ordinary radio-active materials, and as Sir Ernest Rutherford has pointed out, one would only gain a paltry five million years even if the whole sun were composed of uranium. The only way out would seem to be to suppose that the sun was created some 10^9 or 10^{10} years ago out of special radio-active material which produces an enormous amount of energy, and that it has been breaking up ever since. This material does not exist on the earth though, so the earth would have to be the object of a special creation. Such an assumption, of course, can neither be controverted nor even discussed. But unless some such hypothesis is introduced, *i.e.*, unless the presumably radio-active solar material which liberates a quantity of energy sufficient to keep up the sun's heat for the desired 10^9 or 10^{10} years, is supposed to have been created by some inconceivable force at the epoch at which the sun is supposed to have begun to radiate, this material would have disintegrated long ago. It might be objected that the same holds good of uranium, that the fact that uranium exists in measurable quantities proves that it has not existed for a time great in comparison to $5{\cdot}10^9$ years.

This is doubtless true, but there is no real difficulty about assuming uranium or other radio-active substances to have been produced if one supposes the solar system to have been formed by the collision of two stars.

At the moment of collision the velocity of two stars half the mass of the sun would be $\frac{1{\cdot}15 \times 10^{13}}{\sqrt{r}} \frac{\text{cm}}{\text{sec.}}$, r being the distance between the centres of gravity. Suppose they both contained some lead, this would reach a temperature of the order $\frac{1{\cdot}1 \times 10^{20}}{r}$, *i.e.*, of the order $2{\cdot}10^9$ degrees at the moment of collision. As has been shown above, an appreciable quantity of radio-active material might be formed at such a temperature if some helium were present.

But of course the heat used up in forming these substances would cool the rest of the mass: any energy gained in radio-active form would be lost in the form of heat. It could never avail to explain a solar constant such as has been measured for longer than Kelvin's 20 million years. In other words, radio-active substances produced would act only as accumulators of energy, not as primary batteries.

To recapitulate: As Kelvin showed, gravitational energy can only account for 18·3 million years of sunshine at the present rate. Invoking radio-activity as a source of energy implies the assumption that unknown radio-active materials liberating considerably more energy than uranium were created by some unknown agency within a measurable period of time, and that these are now breaking up. This assumption is not necessary to account for the existence of uranium, as it is quite conceivable that a certain amount of radio-active matter might be produced afresh during every stellar collision. The energy of substances formed in this way would not be available to explain a greater amount of energy on the sun as their energy is abstracted from the gravitational energy, and has already been taken into account.

F. A. LINDEMANN.

Sidholme, Sidmouth, April 5.

Harmonic Analysis.

IN a paper which I read to the Physical Society last January (see NATURE, February 11, p. 662) I suggested that the best way of analysing a wave, the graph of which was given, was to apply the rules for the mechanical quadrature of integrals which are given in treatises in the calculus of finite differences. I am convinced that these methods when applied intelligently are much simpler and ever so much more accurate than most, if not all, of the methods in everyday use.

In the paper referred to above I applied a well-known method of mechanical quadrature (Weddle's rule) to the case of a semicircular alternating wave, the equation to the positive half of which is $y=\sqrt{x-x^2}$. I chose this wave because I found that the evaluation of the Fourier integrals for it by analysis was laborious. Prof. A. E. Kennelly, of Harvard University, has kindly written to me to point out that the equation to the curve can be readily put in the form—

$$y=J_1(\pi/2)\sin\pi x-(1/3)J_1(3\pi/2)\sin 3\pi x+(1/5)J_1(5\pi/2)\sin 5\pi x- \ . \ . \ .$$

where $J_1(x)$ is the Bessel's function of the first order. Hence from tables of these functions we get:—

$$y=0{\cdot}567\sin\pi x+0{\cdot}0939\sin 3\pi x.$$
$$+0{\cdot}0422\sin 5\pi x+0{\cdot}0252\sin 7\pi x.$$
$$+0{\cdot}0171\sin 9\pi x+ \ . \ . \ .$$

Very close approximations to these numbers can be obtained very simply by Weddle's rule. For example, if b_1 denote the amplitude of the first harmonic, we have:

$$10b_1=5y_{1/6}+\sqrt{3}y_{1/3}+6y_{1/2},$$

where $y_n=\sqrt{n-n^2}$, and hence $b_1=0{\cdot}568$.

To get an accuracy of the same order for the third, fifth, seventh, and ninth harmonics we must calculate or measure the lengths of 8, 13, 18, and 23 ordinates respectively. Doing this, we find that $b_3=0{\cdot}0942$, $b_5=0{\cdot}0423$, and that b_7 and b_9 are given correctly. It will be seen that from the practical point of view the simplicity and accuracy of the method in this case leave little to be desired. It has the great advantage that the amplitude of each harmonic can be computed independently of the others.

When the wave passes smoothly through the extremities of the ordinates we measure, we can apply the rule with confidence. Jagged or very distorted waves must be treated more carefully. For example, if we apply the rule to a rectangular alternating wave of height unity we find from the formula given above that $10b_1=11+\sqrt{3}$, and so $b_1=1{\cdot}27321$ approx. The true value is $4/\pi$, *i.e.*, 1·27324 . . ., and hence the error is less than 1 in 40,000. For a triangular alternating wave of height unity, however, if we apply the rule intelligently we get $b_1=0{\cdot}88$ . . . instead of 0·81057 . . . The error in this case arises from applying Weddle's rule through a point of discontinuity. If we apply it over one-quarter of the wave, it being necessary to measure six ordinates instead of three, we find that $b_1=0{\cdot}81056$ . . .

A Mistaken Butterfly.

REFERRING to Prof. Barnard's letter so titled in NATURE of April 15, which describes the apparent mistake of a butterfly in visiting a peacock's feather as if expecting to "extract food," I think it probable that there are no animals that do not make mistakes at times. I observed an analogous mistake made by a species of Pieridæ—*Appias nero*—in Sumatra, as I have recorded in "A Naturalist's Wanderings," p. 130:—"In the open paths I netted scarlet Pieridæ . . . often flying in flocks of over a score, exactly matching in colour the fallen [withered] leaves, which it was amusing to observe how often they mistook for one of their own fellows at rest, and to watch the futile attentions of an amorous male towards such a leaf moving in the wind."

HENRY O. FORBES.

Redcliffe, Beaconsfield, Bucks, April 17.

The "Green Ray" at Sunset.

PROF. A. W. PORTER, in NATURE of February 18 (vol. xciv., p. 672), seems to think that the "green ray" is more of a subjective phenomenon than anything else, or at least often is so; but the fact that it is seen at sunrise also shows that in this case at least it is not a result of complementary colours. Besides, if it were a subjective phenomenon, one would expect to see it on every occasion when the sun set behind a clear horizon, whereas the sight is somewhat rarer. I once saw a lovely blue flash, and I read a description recently of a sunset in Palestine where the writer speaks of the sun vanishing like a blue spark. If you hold a lens almost edgeways on between your eye and a light and move it until it is quite edgeways on a few discs of light will be seen, and at last these vanish in a green or blue flash, the effect of dispersion.

35 Roeland Street, Cape Town, March 17.

HEALTHY ATMOSPHERES.

PHYSIOLOGICAL research has proved that the cause of discomfort felt in close, ill-ventilated rooms is due to the physical, and not to the chemical, properties of the atmosphere. We exclude gross contamination by products of imperfectly combusted coal gas, *e.g.* from defective gas fires imperfectly flued. These chemical products irritate the nose and throat, and one of them—carbon monoxide—is a poison. We exclude too, those mines and factories wherein certain poisonous products of industry may pollute the atmosphere. We are writing of rooms crowded with human beings, of over-heated, windless rooms. The percentage of oxygen in such crowded rooms is never reduced by more than 1·0 per cent., and at any of the mountain health resorts the concentration of oxygen is reduced considerably more owing to the attenuity of the air. Similarly the percentage of carbonic acid is never raised in crowded rooms to such a level that it has the least toxic effect. Within the lungs a constant concentration of carbonic acid of about 5 per cent. of an atmosphere is maintained. The acidity of the blood regulates the action of the breathing mechanism, so that both it and the concentration of carbonic acid in the lung are kept constant. The only result of breathing an atmosphere containing 0·5–1·0 per cent. of carbonic acid—the most crowded room does not contain more—is a slight deepening of the respiration by which the concentration in the lung is kept at the normal figure. It becomes difficult to maintain the normal concentration in the lung when the concentration in the atmosphere rises above 3·0 per cent.; the breathing of even a resting man then becomes over-laboured. The crew of a submerged submarine feels the need for fresh air when the CO_2 concentration rises above this level.

Exact experiment, made by many competent researchers, wholly fails to confirm the assertion, so confidently made in all popular books of hygiene, that the expired air contains a subtle organic poison. The air of a crowded room smells offensive to one coming in from the fresh ar. and it may, and often does, infect us with the living germs of disease, sprayed out from the mouth, or nose, of those who cough, sneeze, or speak, but it contains no organic chemical poison, and the fatigue and headache felt by the more sensitive occupants is certainly not due to such. These effects are produced by the physical properties of the atmosphere acting upon the nose and skin, on that enormous field of sensory nerves which supplies the surface of the body, contributes so greatly to our feelings of well-being, and regulates the metabolism of our bodies. The cutaneous and nasal sense-organs are influenced by the temperature, movement, and vapour pressure of the air, and the physical qualities of the atmosphere, which control the loss of body heat by convection or evaporation. Out of doors we are ceaselessly stimulated by the play of wind; cloud, and sunshine, cold and heat, wet and dry alternate; monotony, the curse of the nervous system, is repelled. Cool, moving air braces us up; we are made active, eat more, and breathe more to keep up our body furnace. The daily turnover of the body is thus enlarged, the appetite is stimulated, and the food eaten is completely utilised and does not become dross and waste, the generator of bacterial decomposition in the bowel. The blood is refined out of a larger choice of foodstuffs, and the organs receive from it an ampler supply of the more precious and rarer building stones; the muscular exercise which we are compelled to take to keep warm, occasions the blood to circulate in ampler and quicker streams, and deepens the breathing, thus ensuring the proper expansion of the lungs, and the natural massage of the organs of the belly.

We are built to be active, and keep ourselves warm by muscular action. By over-clothing our bodies and over-heating our rooms we weaken our vigour, expose ourselves to nutritive disorders, and debilitate the natural mechanism of defence against infective disease. Moreover, in these heated, stagnant atmospheres we expose ourselves to massive infection by those carriers of disease who have in their respiratory tract some strain of microbe exalted in virulence, and thus spread "colds" or influenza, pneumonia, or phthisis. Mere exposure to cold does not cause these ills. Arctic explorers and shipwrecked people who suffer the extremes of exposure do not suffer in consequence from such illness. Excessive cold may cause local death and gangrene, or kill by cooling the whole body below a viable temperature, but our power to withstand cold is enormous, innate, the result of a million years of an evolution spent in struggling against the forces of nature. The inclement and dark wintry weather impels people to shut up windows, crowd into close, over-heated rooms, and thus expose themselves to massive infection.

The sedentary worker in heated, windless atmospheres runs his metabolism at a low level, and if he over-indulges in the pleasures of the table, easily becomes the sufferer from digestive and metabolic ailments. It is not the bad weather that causes the ill-health prevalent in the winter, but the excessive precautions most of us take to avoid exposure to cold. Only the very old and feeble, in whom the lamp of life burns low, want such protection. The young and the able-bodied require the stimulus of exposure to the weather; the discomfort arising therefrom soon results in vigorous health, and ceases to be felt. The soldiers of our new armies taken from shop, desk, or factory, and exposed in trench or camp, have been singularly free from disease which is supposed to result from chill, in spite of the hardship of cold, wet, and mud. Adequately fed, clothed, and rested, the open-air life has made the clerk, shop, or clubman twice the men they were, given them a healthy hunger, steady nerves, a clear, ruddy complexion, and increased weight, and yet for days together their clothes may have been damp.

The fear of cold and damp instilled in the nursery often checks the physical development of the young, and leads to a lessening of national vigour and health. The open-air school works wonders on the badly nourished, defective children, and should become the school of every child in the community. The camps of to-day placed in the wind-swept open spaces of the land are founded on the emergency of war, but should become the week-end playgrounds of the nation in times of peace. Our cities have been built so as to satisfy regulations based on the chemical theories of ventilation and the nursery-bred fear of cold. They should be re-planned so as to allow the maximum of sunlight and wind, affording baths and exercise grounds for all. The conditions of life at present wage a deadly war against us. We listen for the whirr of the Zeppelins, and take little heed of the silent sowing of the germs of preventible disease.

FIG. 1.—The Wet and Dry Katathermometer. The Dry instrument is shown enclosed in a wire cage, which was used for taking observations in investigations on clothing.

To secure these healthier conditions we require instruments which will measure the physical conditions of the atmosphere and make manifest the differences between confined and open air. The thermometer registers the average temperature of the surroundings; it gives us no information as to the rate of heat loss from the surface of the human body. It is the rate of heat loss which matters to us. Out of doors, on ideal spring days, the ground is warm and the wind scarcely moves at foot-level, while our heads are blown upon by a variable cooling breeze; the sun warms one side of us while the other is cool. The clouds chasing each other across the blue sky give us shade alternating with sun. Our feet are kept warm, our heads cooled, and our cutaneous nerves are continually excited by the ever-varying rate of cooling. There is no monotony, but an agreeable energising of our nervous system. When the heating and ventilating engineer gives us a uniform summer temperature of 63° F. by means of steam coil (so called) radiators, he secures us a warm atmosphere above and a cold floor below, cold feet and warm heads, and a deadly monotony of conditions. The right system of heating and ventilation would give us a warm floor and a variable, gentle, cool breeze moving round our heads.

In the House of Commons the engineer forces air, heated to 63° F., through a perforated floor, and thus, cooling the Members' feet, gives them conditions which lead to congestion of the mucous membrane of the nose and its air-sinuses, resulting in obstruction of the nasal airway, feelings of stuffiness in the head, and increased liability to infection by the germs of "colds" and influenza. A system more contrary to the outdoor ideal conditions could not have been invented. To measure the physical conditions outdoors and indoors we require an instrument which will measure the rate of cooling by radiation, convection, and evaporation, and will tell us whether the atmosphere is monotonous or not. The present writer has introduced the katathermometer for making these measurements, and with Mr. O. W. Griffith has introduced an electrical instrument, the caleometer, for the purpose of recording not only rate of cooling, but indicating whether the atmosphere is monotonous or lively.

The katathermometer (Fig. 1) is a large-bulbed spirit thermometer, made (by Mr. J. Hicks, 8 Hatton Garden) as nearly as possible of a standard size. Each instrument is tested against a standard one, and a constant obtained by which the rate of heat loss can be deduced in calories per sq. cm. of surface. The katathermometer is heated in warm water until the spirit just rises into the top bulb, and the column is free from bubbles. The instrument is then wiped dry and suspended in the atmosphere, and the time observed taken by the meniscus in falling from 100° F. to 95° F. This gives the rate of heat loss by convection and radiation, the instrument being approximately at body temperature. A muslin finger-stall is then drawn over the bulb and the operation repeated after heating the instrument and jerking the excess of water off the muslin cover. The time taken in this case gives us the heat loss by radiation, convection, and evaporation. The difference between the dry and wet readings gives us the heat loss by evaporation only, and from this, when the readings are taken in still air, the vapour pressure can be determined.

The value of rate of heat-loss measurements are seen by the following examples:—(1) Inside a cottage room on the East Coast and outside on the cliff edge the summer temperature was the same, but outside the katathermometer cooled much faster. It registers just as the human body feels the bracing effect of the moving air. It acts as an anemometer, sensitive not only to currents in one direction, but to every eddy which the ordinary anemometer fails to register. The instrument shows the vast difference between the conditions of the indoor and outdoor worker. (2) In the debating chamber of the House of Commons the thermometer registers a temperature of 63° at foot and head level, but the katathermometer shows the rate of cooling is 50 to 100 per cent. greater at foot level than at head level. When the conditions were experimentally altered in one part of the House so that all floor inlets were closed, and the air introduced at the gallery level, the rate of cooling became slower at foot level than at head level. Then the congestion of the nose was relieved as the feet became warm and comfort was secured. (3) In a room heated by a gas (so-called) radiator with window open at top a few inches, and three doors, beneath

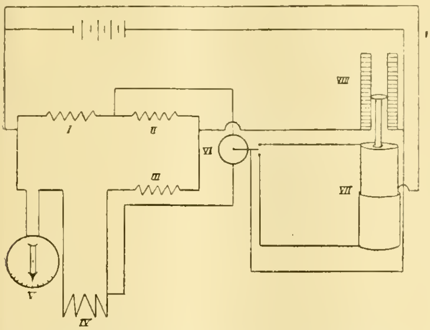

FIG. 2.—Diagram of the Caleometer. I., II., III. and IV. are the arms of a Wheatstone Bridge. When the caleometer coil IV. becomes warmer than 40° C. the index of the galvanometer VI. (used as a relay) goes upwards in the diagram and completes the circuit which includes the upper half of the electro-magnetic coil VII., the soft iron plunger moves then upwards and increases the resistance in VIII., less current then passes and the coil IV. cools. When the caleometer coil IV. cools below 40° C. the index of the relay VI. moves downwards and completes the circuit which includes the lower half of the coil VII. and this pulls down the slider and lessens the resistance in VIII. V indicates the watts or calories required to keep IV. at 40° C.

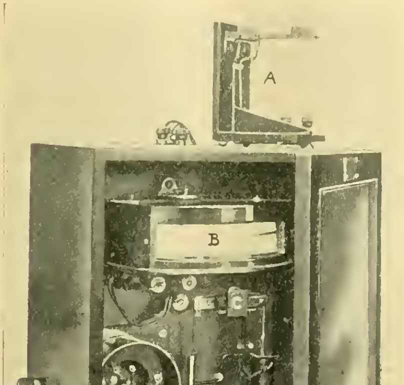

FIG. 3.—The Caleometer. A, caleometer coil. B, watt meter. C, travelling slider. D, magnetic coils surrounding soft iron plunger which moves in oil-bath. A string passes from the plunger over a pulley wheel on the slider to a counter-balancing weight and actuates the slider. E, the galvanometer acting as relay.

which the draught entered, the feet felt very cold and the head felt stuffy, the nose was congested, and the conditions for comfortable mental work at a desk were bad. The katathermometer showed that the rate of cooling at foot level was 40 per cent. greater than at head level. On heating the same room by a properly flued gas fire, and securing warm feet by exposing them to its radiant heat, comfort was at once secured. The katathermometer showed that the rate of cooling at the level where the feet were was 30 per cent. slower than at head level.[1]

The caleometer, by its automatic action, indicates the amount of heat energy required to keep a small coil of wire at body temperature. The oscillations of the indicator show the cooling effect of moving air and the variations of air currents. If the atmosphere is still and monotonous, the oscillations of the indicator will be small and few in number.

Records of any number (up to eight) of caleometer coils, placed in different parts of, say, a factory, can be taken by using a self-recording watt-meter.[2] The instrument is seen in Fig. 3.

LEONARD HILL.

AIDS TO NATURE-STUDY.[3]

(1) THE entomologist's walk in life is in many respects an enviable one, for it is his particular business to study creatures which often exhibit great beauty, amazing variety, and a strange subtlety of behaviour. The current of research as regards molluscs or mammals, let us say, has a strong, quiet flow, but that in entomology recalls a mountain stream with novelties and surprises at every turn. We feel this more than ever as we read Mr. Step's fascinating "Marvels of Insect Life." With the aid of beautiful photographs, many of them from his own camera, he gives us a lively sense of the wonderful intricacy of insect-behaviour, which often seems like a caricature of that of higher animals. But no one knows what its most accurate psychological interpretation may be.

The author writes with clearness and accuracy, and there is no fussiness in his enthusiasm. He is to be congratulated on having secured Mr. Theo. Carreras as a draughtsman, for the full-page plates are exceptionally clever, and most of those in colour are as successful as they are daring. In its whole get-up the book is certainly at high-water mark. Two minor features may be mentioned which show that there has been careful consideration of what an intelligent reader reasonably expects and rarely gets. One is that the technical names of the insects dealt with are

[1] Volunteers who will undertake daily readings with the katathermometer are asked to communicate with the writer (London Hospital Medical College, E.). He is seeking to secure during the next six months records of open-air conditions in representative parts of Britain, and of those conditions which obtain in houses, schools, and factories.

[2] The instrument is made by Mr. Robert W. Paul, Newton Avenue Works, New Southgate, London, N.

always given (at the foot of the page in this case); the other is that the illustrations are furnished with adequately detailed descriptions in small but clear type. We have but one fault to find, that we can discover no order in the marvels. They form a delightful volume, but not a unified book. Or are we overlooking some arrangement which is subtle as insect behaviour itself? Perhaps we are ultra-sensitive, but we like to be orderly, even in our pleasures. It is interesting to find that Mr. Step vouches for the mother-earwig's hen-like care of her offspring, as to the reality of which Mr. Brindley's careful observations recently raised some doubts. We may also note that the author's account of cuckoo-spit (Fig. 1) is not quite up-to-date.

Photo.] FIG. 1.—"Cuckoo-spit." From "Marvels of Insect Life." [*H. Bastin.*

These are small points, however, and what we particularly wish to say is that we can think of no introduction to entomology which surpasses the volume before us in its capacity of gripping the beginner and prompting observation. Would one know of the mouse-catching locust from the Congo, of the Kanchong Mantis which is so like a flower that butterflies visit it, of nightmare insects that look like jokes in morphogenesis, of the big blue wasps of Texas which are able to overcome the huge bird-spiders, of the growth of the caterpillar of the privet hawk-moth which increases its weight nearly ten thousand times in thirty-two days, of the long-necked ant-lion of the pyramids which has its prothorax pulled out into an instrument for reaching down into crevices, of the whimsical leaf-legged bug of South America (Fig. 2), of the maternal bug of the birch-tree which covers her offspring as a hen her chicks, of the peculiar aquatic larvæ of the fly whose bite is said to cause the strange skin disease called pellagra, of the stalk-eyed fly that has its eyes and minute antennæ borne on relatively long lateral extensions of the head, of the quaint way in which the larvæ of the pear-tree hover-fly deal with aphides, of the giant water-bug of Trinidad which sometimes kills frogs — of these and a hundred other marvels, is it not written in the captivating book of Mr. Step?

(2) Captains Carpenter and Wilson-Barker address themselves to the voyager who wishes to know something, but not too much, about what is to be seen from a ship's deck—the ocean itself and all that in it is. They deal in an interesting way, without going very deeply into things, with the physical features of the sea, with the whales

Photo.] [*H. Bastin.*

FIG. 2.—Leaf-legged insect from South America. The very long and slender hind-legs spread out at the top of the shank into prettily-coloured leaf-like growths which must tend to disguise the insect's true nature when seen upon foliage. From "Marvels of Insect Life."

and seals, the petrel and the albatross, the fishes and cephalopods, the Portuguese Man of War and the coral reef, with the seaweeds, the microscopic plankton, and the phenomena of phosphorescence, with the winds and the clouds, with the waves and their measurement. They have also something to say regarding old sea monsters and old sea customs and chanteys.

Captain Carpenter was a lieutenant on the *Challenger*, and has had other opportunities of deep-sea work; his collaborator, Captain Wilson-Barker, served afloat for twenty years, in part in connection with deep-sea telegraph cable work; so the joint authors have been for a long time in intimate association with the life about which they write. There is a pleasant directness in the book, and a not less pleasant smell of the sea. There are numerous excellent illustrations, many of them

FIG. 3.—Black-backed gull. From "Nature Notes for Ocean Voyagers."

old friends, others delightfully fresh (Fig. 3). We believe that many amateurs will enjoy this book very much and profit by it in proportion. It ought to be in all ship libraries.

We must note, however, that the authors would have been well advised if they had availed themselves of the services of some competent naturalist to remove numerous inaccuracies which are as flies in the ointment. Thus it is a blemish to speak of the parrot's beak of the sea-egg, of the air cells beneath the gannet's skin being the main factors in the bird's powerful flight, of the parrot-like beaks of the puffin, of the Ctenophora progressing by small hairs (cilia) which outline their bodies, or of Noctiluca as a small jelly. The figure of the octopus (on page 81) with irregularly branched arms requires some explanation.

(3) Miss Ritchie has written a delightful informal introduction to nature study in South Africa, which will take teachers and pupils in that interesting country further into the heart of things than a more informative primer is likely to do. While it is thoroughly objective, dealing mainly with the succession of flowers in a country with a fascinating flora, it touches things imaginatively as well as scientifically, and aims at the culture of appreciation and delight as much as at the diffusion of knowledge. There is a very interesting foreword by Prof. Patrick Geddes, and Mr. Allerston has supplied a fine set of illustrative photographs of characteristic South African plants. We wish the book good speed.

THREE NATURALIST-TRAVELLERS.[1]

THE chief feature common to these three books is that they deal with the researches of British naturalists in the belt of country which, from the Arctic Ocean to Equatorial Africa, lies along the boundary between Eurafrica and Asia.

(1) Mr. Bury's "Arabia Infelix" describes the eastern wall of the Great Rift Valley in south-western Arabia. The land lies low for about thirty miles from the Red Sea at Hodeida; it then rises by bold precipices to the height of from eight to ten thousand feet, whence the plateau sinks gradually eastward to the Great Red Desert of Arabia, at the level of from three to four thousand feet. The road inland to Sanaa begins its steep ascent through "The Gate of the Mountains," where a huge rock has fallen across the ravine and made a natural arch. By scaling cliffs of appalling steepness, up which the Turks have had the temerity to plan a railway, it rises to the height of 9000 ft. It passes through various zones of vegetation. The spurs and ravines are terraced for coffee or clad in thick jungle. The ravines are so steep and narrow "that one may almost touch the tree-tops which grow out of them, and so overgrown that only a green twilight penetrates to their recesses, where the lurid blooms of the snake-onion flame among the fern and the giant cobra drowses in the hush of noon." So steep are the precipices that "it gives one a crick in the neck to count the coffee-gardens up those outrageous steeps, while wondering if they are garnered with a derrick."

Mr. Bury writes with a unique knowledge of this part of Arabia, and his short book is packed with information. Unfortunately there are scarcely any references to the former literature,

1 (1) "Arabia Infelix; or, The Turks in Yamen." By G. W. Bury. Pp x+213. (London: Macmillan and Co., Ltd., 1915.) Price 7s. 6d. net.
(2) "Alone in the Sleeping-Sickness Country." By Dr. F. Oswald. Pp. xii+219. (London: Kegan Paul, Trench, Trübner and Co., Ltd., 1915.) Price 8s. 6d. net.
(3) "A Summer on the Yenesei (1914)." By M. D. Haviland. Pp. xii+328. (London: Edward Arnold, 1915.) Price 10s. 6d. net.

and no account of the structural geography, which is perhaps its most interesting feature. Mr. Bury is an ornithologist, and the natural history notes of most value are those dealing with the birds, the agriculture, and the climate. The book is enlivened with many flashes of humour, partly his own and partly quoted from the Arabs, such as the letters found on the bodies of those who fell in the war of 1871. "To my brother Gabriel. ——, son of ——, is coming to you; admit him to Heaven. (Signed) Mohamed Eyad, Emir of the Faithful."

Mr. Bury begins with a synopsis of the history of Yamen, and ends with a forecast of its political future. He hopes, in the interests of both Turks and Arabs, that the present war will lead to its independence, though he is obviously very doubtful whether the natives can manage the country by themselves. He appears to think that the best hope for Yamen is its annexation to the Aden Protectorate. He recognises the sterling merit of the individual Turk, and refers to Turkey's disastrous plunge into war with sympathetic commiseration; he attributes it largely to national anger at our retention of the two new battleships, for they had been built by public subscription, to which the Turks contributed their utmost as a religious duty. As he remarks, we should not like our subscriptions for a new cathedral to be arbitrarily diverted for the building of a mosque.

(2) Dr. Oswald, who is well known from his work on the geology of Armenia, visited the eastern shore of the Victoria Nyanza to search thoroughly some Miocene deposits which have yielded fragments of *Dinotherium hobleyi*, the most important palæontological discovery yet made in British East Africa. Dr. Oswald ransacked the beds, and traced them further inland, and obtained fragmentary remains of a fossil tortoise, an extinct elephant, the first baboons found fossil in equatorial Africa, and the first fossil Protopterus. He also found evidence of the once larger size of the Victoria Nyanza, as its beaches occur three hundred feet above the present lake level. He contributes a very interesting account of his experiences. He unintentionally interviewed a leopard, and was discovered by the ticks that carry relapsing fever, by tsetse fly, and other disease-spreading insects. He writes about the country with a naturalist's sympathy and insight. Even the white ants impressed him more as useful soil-makers than as destructive pests. He is too fond of animals to help the reduction of the diminishing herds of antelopes, and he strongly condemns the uselessness of killing the game to prevent the spread of sleeping sickness, since other animals and even insects can harbour the infection. The author has proved that the Miocene beds which he went to examine are disappointingly barren; but he has contributed a very useful addition to the geology of this part of British East Africa.

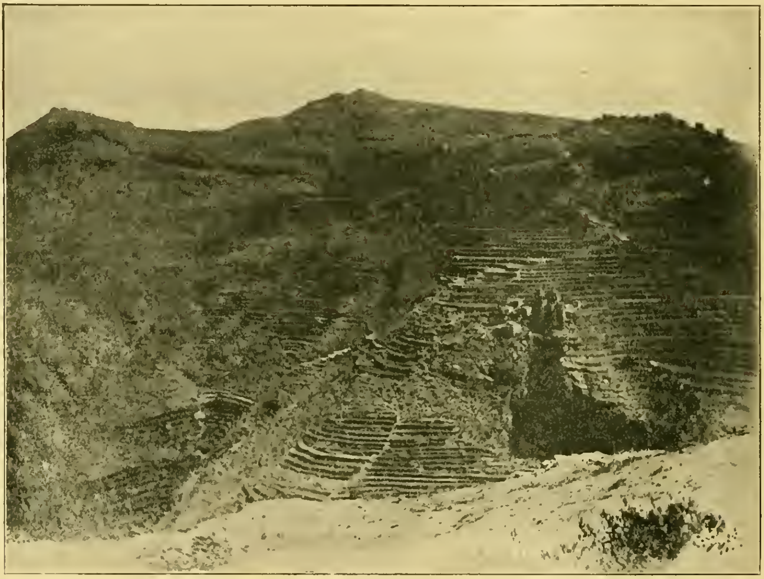

Fig. 1.—Field Terraces. From "Arabia Infelix; or, The Turks in Yamen."

(3) Miss Haviland is a well known ornitholo-

gist, who visited the northern Yenisei to continue the researches of Seebohm and Popham on the nesting habits of the birds which breed there. She tells the story of her expedition in a brightly-written volume, illustrated by excellent photographs, but lacking a map. The party consisted of four, of whom two, Miss Czaplicka and Mr. Hall, are wintering in the country of the Ostiaks, and may thus throw further light upon the affinities of these people. The declaration early in the book that "the journey across Asia by the Trans-Siberian Railway can never be anything but unspeakably tedious" is not an encouraging start; for though the author only saw the line in its most uniform section, the statement shakes faith in her geographical insight. But as soon as she reaches the Tundra she shows a truer appreciation of the country, and in many a graphic sentence expresses the charm of the northern nights, "when darkness was never deeper than a soft twilight glow, and the mysterious shining spears of the Aurora Borealis mingled with the glamour of a night-long dawn." She is very sympathetic to the people, though she gives a lurid picture of the prevalent drunkenness, for her visit was before the famous Ukaz of the Tsar which stopped the sale of spirits. She aptly summarises some of the most striking features in Russian conditions and culture. Russia she describes as "a country of enormous possibilities, of the crudest paradoxes. With the most autocratic government, hers is the most democratic society in the world; with a Church whose function has dwindled into the effete repetition of ritual, religion is the very fibre of her people."

In illustration of the severity of the climate Miss Haviland repeats the widespread saying that the population would die out at the third generation if not renewed by immigration; the statement is probably as trustworthy for Siberia as it is when asserted to prove the unhealthiness of city life and the impossibility of European settlement in the Tropics.

Miss Haviland spent most of her time photographing the nesting birds around Golchika on the estuary of the Yenisei; her chief prize was a curlew-sand-piper's nest, which was first taken by Popham in 1897. From that district she returned on the timber ships by which Mr. Jonas Lied is endeavouring to maintain annual communication between the Yenisei and western Europe, an enterprise on which depends the future of several Siberian industries. Her account of the Kara Sea in September will be a useful supplement to Nansen's account of his outward voyage with Mr. Lied at the beginning of the season.

PROF. W. GRYLLS ADAMS, F.R.S.

Born at Laneast, Cornwall, on February 16, 1836, William Grylls Adams, Emeritus Professor of Natural Philosophy in King's College, London, died at Broadstone, Dorset, on April 10, 1915, aged seventy-nine years. He was educated in a private school in Birkenhead, and entered St. John's College, Cambridge, of which afterwards he became a fellow. In 1865 he was elected professor of natural philosophy and astronomy at King's College, London, in succession to Clerk Maxwell, who had been appointed to the Cavendish professorship at Cambridge. In the same year he contributed to the *Philosophical Magazine* an article on the application of the principle of the screw to the floats of paddle-wheels, his sole contribution to applied mechanics. He took part in the eclipse expedition of 1871 to Sicily. In that year he investigated the action of a bundle of parallel glass plates on the polarisation of light, the results being published in vol. xli. of the *Philosophical Magazine*.

The next few years of Adams's life were very active. In 1872 his scientific merits were recognised by his election to the fellowship of the Royal Society. In 1875 he delivered the Bakerian lecture, on the forms of equipotential curves and surfaces, and lines of flow. The lecture was an exposition of an almost entirely experimental investigation of the curves which result when electric currents are passed through sheets of tinfoil between electrodes placed at different points; but some attempt was made to realise also some cases of three-dimensional flow. This paper has proved to be one of classical interest. In the same year he communicated to the Proceedings of the Royal Society a paper on the change of resistance produced by magnetisation in iron and steel. He observed a difference between the effects of longitudinal and transverse magnetisation. When the magnetisation was longitudinal, the electric resistance of hard steel was diminished, while that of soft steel or soft iron was increased; and in both cases the effect was approximately proportional to the square of the magnetising force. When the magnetisation was transverse a similar effect was observed.

The next subject investigated by Adams was the phenomenon of the effect of light in reducing the resistance of selenium, which had recently been discovered by Mayhew. With great patience and experimental skill he showed that the effect was not due, as had been supposed, to any heating of the selenium, but was a genuine result of illumination; and he proved that the change of resistance was greater for yellow-green rays than for any other part of the spectrum.

Adams was one of the founders of the Physical Society, in 1875; and to its first volume of Proceedings he contributed a description of a new form of polariscope for determining the angle between the optic axes of biaxial crystals. The crystal slice to be examined was placed between two pieces of glass, one being a hemisphere and the other a shallower section than a hemisphere, the convex surfaces having a common centre in the crystal slice. The combination was placed in oil between the usual crossed Nicol prisms, and could be tilted through any desired angles so as to bring first one and then the other of the optical axes of the crystal into alignment with the axis of the instrument, thus enabling the angle between the axes to be accurately measured without corrections for the refractive index.

In 1880 Adams was chosen president of section A of the British Association, and delivered an address dealing generally with recent progress in physics. He also presented a report of a comparison between the magnetograph curves from the magnetic observatories of Kew, Stonyhurst, Lisbon, Coimbra, Vienna, and Petrograd. In the following year he continued his magnetic investigations with a paper on the connection between magnetic disturbances and earth-currents. He wrote also on the development of lighthouse illumination, and with Dr. Hopkinson examined the performance of the De Meritens dynamos at the North Foreland lighthouse. As president, in 1884, of the Institution of Electrical Engineers, he took for the subject of his inaugural address the topics of the growth of electrical science and the testing of dynamo machines and incandescent lamps. He wrote a series of articles on electric light and atmospheric absorption, and another on lighthouse illuminants and apparatus, for publication in the *Electrician* in the years 1885 and 1886. After some years he returned to the subject of magnetic disturbances as recorded simultaneously on the magnetographs at several observatories, in a paper which was published in the Philosophical Transactions (vol. cviii.) in 1893. To the British Association report of 1898 he contributed an account of the determination of the Gaussian magnetic constants made many years previously by his elder brother, the astronomer, John Couch Adams.

Grylls Adams served on the council of the Royal Society from 1882 to 1884, and again from 1896 to 1898. He was president of the Physical Society in 1879. In 1883 he delivered a series of Cantor lectures on the subject of electric lighting. He retired from the professorship at King's College in 1906. He has left a widow, three sons, and one daughter.

NOTES.

WE record with much regret the death on April 16, at sixty-five years of age, of Mr. Richard Lydekker, F.R.S., distinguished by his original work and numerous writings on all aspects of natural science, and a constant contributor to NATURE for many years to within a few days of his death.

THE Paris Geographical Society has just made a special award of a gold medal to Dr. J. Scott Keltie, for his long and distinguished services to geographical science.

COLONEL G. W. GOETHALS, engineer of the Panama Canal, and Sir Thomas Shaughnessy, president of the Canadian Pacific Railway Company, have been elected honorary members of the Institution of Civil Engineers.

THE *British Medical Journal* announces that the Louis Livingston Seaman medal for progress and achievement in the promotion of hygiene and the mitigation of occupational diseases has been awarded to Major-General W C. Gorgas.

THE Warren prize of the Massachusetts General Hospital, of the value of 100*l*., and awarded triennially, is offered for the year 1916 for the best essay on some special subject in physiology, surgery, or pathology. Further particulars are obtainable from Dr. F. A. Washburn, at the hospital named.

WE learn from the *Lancet* that the Hutchinson Museum has been acquired by the Medical School of Johns Hopkins University. The collection comprises original coloured drawings; coloured plates taken from atlases, books, and memoirs; engravings, woodcuts, photographs, and pencil sketches, in some cases with the letterpress or manuscript notes attached. The collection illustrates the whole range of medicine and surgery, but particularly syphilis and skin diseases.

SIR THOMAS CLOUSTON, a leading authority upon the subject of mental diseases, died in Edinburgh on April 19, at nearly seventy-five years of age. He was lecturer on mental diseases at Edinburgh University, and was the author of a number of important works on disorders of the mind. He was president of the Royal College of Physicians, Edinburgh, in 1902–3, and was for some time editor of the *Journal of Mental Science*.

THE death is announced of Mr. J. B. A. Légé, who made the first tide-predicting machine for the late Lord Kelvin. He was the constructor of signalling lamps and other apparatus invented by Admiral Sir Percy Scott and used in the Navy. Among Mr. Légé's inventions may be mentioned horological mechanisms, torpedoes, and direct-acting petrol engines.

An International Engineering Congress will be held during the week September 20–25 next, at San Francisco, under the presidency of Colonel G. W. Goethals, chairman and chief engineer of the Isthmian Canal Commission, and under the auspices of the leading American technical and scientific societies. Applications for further information should be addressed to Mr. W. A. Cattell, secretary-treasurer, Foxcroft Building, San Francisco, U.S.A., from whom circulars and reply forms may be obtained.

The Christiania correspondent of the *Morning Post* announces the death of Prof. G. Gustafson, professor of Norwegian archæology in the University of Christiania. Prof. Gustafson was born at Gotland, Sweden, in 1853, and went to Norway in 1889 as keeper of the antiquarian section of the Museum at Bergen. He was appointed in 1900 professor of archæology at the University of Christiania, where he reorganised the archæological and prehistoric museum and conducted numerous excavations.

At a special meeting of the Conchological Society held at the University of Manchester in lieu of the ordinary February meeting, an illuminated address was presented to Mr. J. W. Taylor on attaining his seventieth birthday. The address directs attention to the fact that it is forty-one years ago since Mr. Taylor undertook the publication of the *Quarterly Journal of Conchology*, which later led to the inauguration of the Conchological Society. Mr. Taylor's great work has been the "Monograph of the Land and Freshwater Mollusca of the British Isles," of which three volumes are now completed.

We learn from the *British Medical Journal* that Dr. S. von Prowazek, director of the department of protozoology in the Institute of Marine and Tropical Diseases at Hamburg, has died at Lima of typhus fever contracted in the course of a research on the pathology of that disease. He was thirty-nine years of age, a native of Austria, and studied under Ehrlich, Hertwig, and Schaudinn. We notice also the announcement of the death of another worker in the field of tropical diseases, namely, Lieut.-Col. W. S. Harrison, formerly assistant-professor of pathology at the Royal Army Medical College. Lieut.-Col. Harrison was only forty-three years of age; and he appears to have contracted the disease from which he died on April 12 during research work in connection with tropical diseases in India and Jamaica.

The annual meeting of the Iron and Steel Institute will be held at the Institution of Civil Engineers on May 13 and 14. The Bessemer gold medal for 1915, which has been awarded to Mr. Pierre Martin, formerly of Sireuil, near Paris, will be received on his behalf by M. Paul Cambon, the French Ambassador, during the first meeting, and in the afternoon of the same day Prof. Hubert, of Liège University, will lecture on large gas engines. During the morning of the second day the Andrew Carnegie gold medal for 1914 will be presented to Mr. E. Nusbaumer, of Paris, and the award of research scholarships for the current year will be announced. Papers will be read and discussed on both days. The council of the institute has decided on account of the war that it will be inadvisable to hold the annual dinner this year. It has been decided provisionally that the autumn meeting of the institute shall be held in London during the week ending September 25.

It is proposed to place a bust of Sir Archibald Geikie in the Museum of Practical Geology, Jermyn Street, where there are already busts of all previous occupants of the post of Director-General of the Geological Survey and of the museum, as well as of several other distinguished geologists. Sir Archibald Geikie was connected with the Geological Survey for nearly forty-six years, during nineteen of which he was Director-General. A committee representative of the universities and the principal scientific institutions and societies of the United Kingdom has been formed to carry out the proposal. It is estimated that the cost of a bust and of a replica to be presented to Sir Archibald Geikie will be between 400*l.* and 500*l.*; and the committee invites subscriptions towards this sum. There should be no difficulty in securing the amount required for this modest form of memorial of a geologist of world-wide distinction, who was connected for so many years with the institution in which the bust is to be placed. Contributions for the fund should be made to the honorary treasurer, Mr. J. A. Howe, curator of the Museum of Practical Geology, Jermyn Street, S.W.

The South African Institute for Medical Research has issued a valuable monograph, "Anthropological Notes on Bantu Natives from Portuguese East Africa," prepared by Mr. C. D. Maynard, statistician and clinician to the institute, and Dr. G. A. Turner, medical officer to the Witwatersrand Native Labour Association, who have had excellent opportunities for studying these people. The paper supplies an elaborate series of measurements of this very mixed race—stature, brain weight, skull thickness, cephalic and cranial indices, spleen, liver, and kidney weights. The correlation of stature and brain weight is found to be only partially established, and the Bantu cerebrum appears to be rather lighter in relation to stature than that of the European. The current impression that the native's skull is thicker than that of the European is found to be incorrect. The article is provided with a useful bibliography of the subject.

The Smithsonian Institution has just issued an account, by Dr. J. W. Fewkes, of a collection of beautiful pottery from the Mimbres Valley of New Mexico, dating back to prehistoric times. This is the first collection received by the museum from this valley, and this type of pottery is unrepresented in other collections. Its importance lies in the fact that a comparatively large number of specimens have human or other figures painted upon them, and that they resemble those from Casas Grandes in Mexico. An interesting and significant custom of these people is that they buried their dead in urns, under the floors of their houses in a sitting posture, with a bowl inverted over the head like a cap, or, when the body is extended, over the face. Such bowls have always a small round hole in the bottom, which has been interpreted as due to the belief that pottery possesses spirits which can escape only when the vessels have been "killed"; possibly it is a mode of releasing the ghost of the dead man.

Dr. V. Ivanof has ascertained by microscopic observation the existence of leaves in saxaul (*Haloxylon ammodendron*). Other botanists have described the shrub as completely leafless or provided only with small, scaly growths. The leaves grow closely into the stem, and the apical parts and stalks form a continuous whole (Proceedings of the Society of Naturalists at the University of Kazan, 1912–13).

In the Journal of the Philadelphia Academy of Sciences for January, Mr. Matsumoto gives a preliminary account of a new classification of the feather-stars, or Ophiuroidea, the full details of which are to be published in Japan. The author, who has received valuable advice and assistance from Prof. H. Clark, finds that ophiuroids must be divided into two main groups, the first of which (Œgophiuroida) is mainly Palæozoic, and lacks most of the structural features by which Ophiuroidea are distinguished from Asteroidea.

According to an article by Prof. T. D. A. Cockerell in the issue of the Proceedings of the Philadelphia Academy for December, 1914, the well-known Miocene insectivorous beds of Florissant, Colorado, continue to yield a number of new forms, so that the time is still distant when it will be possible to publish a complete list of the fauna. Compared with the rich insect-bearing beds of Œningen, Baden, and of the neighbouring village of Wangen, on the Rhine, the Florissant fauna is markedly the richer, so far as definitely named species are concerned. The Œningen fauna, for example, comprises 250 beetles, 80 Hemiptera, 60 Hymenoptera, and 30 flies, but the members of these groups already named from Florissant number, respectively, about 494, 230, 220, and 100.

The Termites (so-called "white ants") afford unfailing interest to the entomologist. A valuable account of the bionomics of the species of these insects found in the eastern United States has been lately issued by T. E. Snyder (U.S. Dept. Agric. Entom. Bulletin, No. 94). Two species of the Leucotermes (*L. flavipes* and *L. virginicus*) form the subject of most of the observations recorded. The forms of these termites and the general course of their development have been fairly well known for many years past. Mr. Snyder has directed especial attention to the fate of the winged, sexual individuals that "swarm" from the nests at certain seasons. The survivors — often comparatively few — of these "swarms" usually cast their wings before courtship begins, and do not actually pair until they have established themselves in a new "royal chamber," which, in the case of Leucotermes, is a cavity in wood. It is not necessary for these "royal pairs" to be established by foraging workers and soldiers; they are apparently, as a rule, independent of help in the foundation of a new community. The provision of "neoteinic" royal individuals is associated with the foundation of fresh communities from old overcrowded societies.

In *Meddelelser fra Kommissionen for Havundersøgelser*, Serie Fiskeri, Bd. iv., No. 7, Dr. Johs. Schmidt discusses the classification of fresh-water eels (Anguilla). A considerable number of specimens from various localities have been investigated as regards the amount of variation occurring in different characters, the characters being additional to those which were discussed in a previous paper. It has proved possible to distinguish between three species, *A. vulgaris*, *A. rostrata*, and *A. japonica*. All European fresh-water eels belong to one and the same species, within which no constant local races can be shown to exist.

An attractive article in the April issue of *Wild Life* is one by Miss F. Pitt, illustrated by four reproductions of photographs, of the marten, in which particulars are given with regard of the past and present distribution of that species in Great Britain. Many readers of the same number will doubtless also be interested in a well-illustrated article by Mr. F. J. Stubbs on the plague-flea, and how it is carried about by rats, as well as the way in which it becomes infected with the plague-bacillus. It might have been added that the ultimate source of plague appears to be the indescribably evil-smelling burrows of the bobac marmot of the steppes of eastern Europe and western Asia.

In the January issue of the Journal of the Philadelphia Academy of Sciences Miss A. M. Fielde gives further particulars with regard to her investigations of the functions of the antennæ of ants. It has already been shown by the author that the function of these appendages is olfactory, and it is now demonstrated that their constituent segments take up particular kinds of odours. The distal segment, for example, warns an ant from approaching any colony other than its own. Again, the penultimate joint deals with the odour which renders one ant-colony inimical to others of the same species. Another segment serves to guide an ant on the homeward track by enabling it to pick up the scent left on the ground during its outward journey, while the function of yet another is to recognise the whereabouts of the queen and her undeveloped progeny on the part of a worker, and so on with other items in the olfactory functions of these insects.

When he first named a gigantic ungulate, with somewhat Dinotherium-like teeth, from the Lower Tertiaries of Patagonia, under the name of Pyrotherium, the late Dr. F. Ameghino regarded it as a proboscidean. His views have not, however, been accepted by the majority of palæontologists, and no mention of the genus is made by Dr. Andrews in his summary of the evolution of the Proboscidea in the "Guide to the Elephants in the British Museum." During a recent expedition to Patagonia, dispatched by Amherst College, Prof. F. B. Loomis obtained a couple of skulls of Pyrotherium, which he has described in a volume, published by Amherst College, under the title of "The Deseado Formation of Patagonia." He concludes that the genus is really proboscidean, but his views (which are supported by Señor C. Ameghino in *Physis* for December, 1914) are disputed in a review by Mr. R. S. Lull in vol. xxxviii., p. 482, of the *American Journal of Science*, where it is urged that the characters relied upon by Prof. Loomis are not of taxonomic value, and that Pyrotherium is not entitled to a place among the Proboscidea. The question has an important bearing, not only on the phylogeny and "radiation" of that group, but on mammalian distribution in general.

Great interest attaches to an article by Mr. A. H. Clark in Smithsonian Miscellaneous Collections, vol. lxv., No. 1, on the distribution of Peripatus and its allies, collectively constituting the group Onychophora. This group, which is apparently an ancient one, though there is no direct evidence on this point, occurs in the Malay Peninsula and Sumatra; Ceram, Papua, New Britain, Australia, Tasmania, and New Zealand; Ethiopian Africa; and Central and South America, and the West Indies. The distributional area is thus limited to countries with a mean annual temperature of from approximately 50° to 80° F.; most of the species, however, occur in countries where the mean is from 60° to 70° F. All the species are restricted to the region south of the tropic of Cancer, while the great majority are confined to the southern hemisphere, the West Indies and Central America being the only localities where an appreciable number of species occur north of the equator. The group is divided into the two families, Peripatidæ and Peripatopsidæ, and nowhere, so far as known, are species of the two families found in the same area. Moreover, the two subfamilies into which the Peripatidæ are divided are sundered by the entire breadth of the Indian Ocean. Then, again, the two subfamilies of the Peripatopsidæ inhabit separate areas in the Australasian region, one being restricted to Papua and the neighbouring islands, while the other is found in Australia, Tasmania, and New Zealand; both groups, however, co-exist in South Africa.

No. xxxix. of the Notes of the Royal Botanic Garden, Edinburgh, contains papers on some new Japanese mountain plants, by Mr. H. Takeda, an enumeration of the Chinese Astragali by Mr. N. D. Simpson, and contributions to the knowledge of the Asiatic Polypodiums by Mr. Takeda. The mountain plants come from the mountain group, Yûparodake in the island of Yezo, some 6000 ft. high, which has not been properly explored botanically before, and a great many interesting records have been obtained and new species collected, salient details of some of which are figured. Mr. Simpson's paper on a very difficult genus is of considerable value, since he has given a careful synopsis of the Chinese species, setting them out in clearly defined sections, and has assigned the specimens to their respective species. Seventeen new species, chiefly from Yunnan and Szechuan, are also described.

In the *Philippine Journal of Science* Mr. Frank G. Gates gives an account, illustrated by a map and plates, of the re-development of vegetation on Taal Volcano, a low mountain in the middle of Bombon Lake, Batangas Province, Luzon. The lake is 22 km. long by 14 km. wide, and the island is therefore not a very great distance from the surrounding shores. The devastating earthquake occurred on January 30, 1911, and the progress of the re-growth of vegetation has been carefully noted. Strand plants, *Ipomaea Pes-Caprae* and *Canavalia lineata*, first appeared, due to water transport of seeds, then grasses became established from wind-borne seeds. In contrast to Krakatoa, very few ferns have appeared, probably as only a few are found on the mainland. After the grasses came shrubs and small trees, and the latter are followed by trees and bamboos. The plants found are discussed in connection with the ecological formations in which they may be grouped.

The annual report on the Forest Administration of Southern Nigeria for the year 1913, recently received, is, like its predecessors, an interesting document, though it records much that is to be deplored. The destruction of forest which is taking place to give more land for cultivation is a very serious matter, for whole ranges of hills have been denuded of forest growth right up to their crests, and the sources of their many streams have been exposed. The result of this forest destruction will mean, not only the washing away of the soil from the slopes, but, even more important, the loss of a proper water supply to the fertile valleys. With bare hills, the rain precipitated will at once run off instead of being conserved by the forest and released gradually, and the cultivation of cacao and kola in the valleys will become impossible. The chief conservator, who has toured widely through the country, records the same tale of reckless destruction of forest on all sides. It is to be hoped that prompt action will be taken, as was done in India when roads and railways opened the country, to save the existing forest from the general wreckage and also ensure a continuous water supply.

Though it has been usual to regard the great Hawaiian earthquakes of 1868 as of volcanic origin, Mr. H. O. Wood, in a valuable paper, has recently collected evidence which seems to show that they were tectonic, rather than true volcanic, earthquakes (Bull. Seis. Soc. America, vol. iv., 1914, pp. 169–203). He points out that the most violent earthquake of the series, that of April 2, was preceded and followed by numerous accessory shocks, that it disturbed an area of about 375,000 square miles, that the depth of its origin must have been considerable, and that it gave rise to important seismic sea-waves. In all these respects, it differed from earthquakes of the ordinary volcanic type, many of which, however, are probably not *directly* connected with volcanic operations, but are due to fault-slips along radial and peripheral fractures of the volcano.

It has long been known that magnets are sometimes made to oscillate during the passage of earthquake-waves; and the phenomena, especially those observed with the Riviera earthquake of 1887, have given rise to considerable discussion. A recent memoir by Prof. H. F. Reid (Bull. Seis. Soc. America, vol. iv., 1914, pp. 204–14) ought to end the controversy. He shows that there are certain periods for horizontal and vertical disturbances that will cause marked oscillations of unifilar and bifilar magnets and magnetic balances; and that, if the periods of the earthquake-vibrations should approximate to any of these periods, they may cause the magnets to oscillate. Prof. Reid concludes that the broadening, blurring, or interruption of the magnetic trace at the time of earthquakes may be due to oscillation of the suspended magnets by purely mechanical vibrations, and does not require us to assume the existence of real magnetic forces or electric currents.

Mr. N. L. Bowen (*Amer. Journ. Sci.*, vol. xxxix., 1915, p. 175) describes and illustrates several interesting experiments which show that crystals separating from a molten silicate mixture tend to accumulate by gravitation in the lower layers of the mass. He thus gives strong support to Charles Darwin's view of gravitation as a factor in the differentiation of igneous rocks. Crystals of olivine have been gathered towards the bottom of a crucible, those in the lowest layers being smaller than those above them, since the latter have fallen through a greater depth of liquid. Both olivine and pyroxene crystals induce during cooling the formation of coats of amphibole round them. Seeing how quartz in lavas may become coated by a deposit of pyroxene, there is clearly room for further research as to these reaction-zones. The author has succeeded in separating tridymite in more highly siliceous mixtures, the crystals becoming in this case concentrated upwards by flotation.

The January issue of the Proceedings of the Academy of Sciences of Philadelphia contains a summary, in French, by Mr. Stanislas Meunier of his views with regard to the general theory of glacial phenomena and the origin of polished and striated pebbles. In many respects these views are of a distinctly revolutionary type, and subversive of current theories. Especially is this the case with regard to striated pebbles, generally held to be of glacial origin, but which, in the author's opinion, are rather the result of "subterranean denudation," as exemplified by formations in the Vosges and elsewhere. It is remarked that these polished and striated fragments are almost exclusively calcareous, and that the scratches have been made by quartzitic and other hard rocks. A portion of surface-water, it is observed, sinks into porous soil, where subterranean denudation brings these slowly moving quartz-fragments into contact with irregularly shaped *débris* of calcareous rocks, which are eventually ground down into the polished and striated pebbles hitherto regarded as affording decisive evidence of glacial action.

The replacement of limestone by hæmatite, so as to produce masses or beds of iron ore, has been long recognised. In a paper on the genesis of certain Palæozoic interbedded iron ore deposits, Mr. R. B. Earle makes a strong case for the similar replacement of sandstone by percolating ferruginous waters charged with carbon dioxide (Annals N. York Acad. Sci., vol. xxiv., p. 115). He uses the word "iron" freely in place of "iron oxide"; but we gather that the ore referred to is usually hæmatite. The Clinton formation that flanks the Appalachian Mountains includes oolitic iron ores, in which the nuclei of the oolitic grains consist of partly corroded sand-grains. The quartz can be seen in microscopic sections to be in various stages of discoloration and replacement. The crusts of ore finally protect the nucleus from complete decay. The removal of quartz from granite and its replacement by calcite has been noted in the north of Ireland; but a better parallel with the Clinton occurrences is to be found in the Karroo sandstones of the Orange Free State, as described by Prof. R. B. Young (Trans. Geol. Soc. S. Africa, vol. xvii., 1914, p. 55). Here nodules of pyrite have originated, in which the iron sulphide "is seen not only to fill the interstices between sand-grains, but also to replace the latter to a considerable extent, the metasomatic action being most intense as the centres of the nodules are approached." Felspar as well as quartz has been attacked in this case.

The Transactions of the Naturalists' Society of Kazan University contain several articles on the botany of western Siberia and the Steppes—"In the Mountains and Valleys of the Altai" (vol. xlvi., No. 1), and "Researches into the Botanical Geography of Saissan in Semipalatinsk" (vol. xliv., No. 5), by V. A. Keller, and "Botanical and Geographical Investigations in Semipalatinsk" (vol. xlv., No. 3), by V. Krüger. Both authors give lists of the plants collected, with details of the localities where they were found and their environment. They also paid close attention to the temperature of the soil during the summer months when they were at work. Mr. Keller found the absolutely lowest soil temperature in the Altai in the upper part of the forest zone, and this zone seems to be in general colder than the mountain tundra which lies at a higher elevation. In the latter region the soil was considerably warmer where lichens abounded than in the tundra of bushes and mosses. The absolutely lowest temperatures (34·3° down to freezing point) were found in July in the section of the forest zone, where the vegetation was of a character intermediate between those of sphagnum peat swamp and wet mossy forest. The highest temperature (70·5°) occurred in the stony section of the mountain steppe. Mr. Krüger also ascertained the proportion of moisture in the surface soil, and found that in the following six areas indicated by their predominant forms of vegetation—(1) *Festuca sulcata*, (2) *Artemsia pauciflora*, (3) *Atriplex canum*, (4) *Obione verrucifera*, (5) *Halicnemum strobilaceum*, (6) *Salicornea herbacea*—the percentage increased from (1) to (6). At about a foot below the surface the proportion also increased, but in a smaller ratio. The salinity of the soil was also smallest in the first and largest in the sixth area.

Discussions of the anemographic observations recorded at Port Blair and at Dhubri by Mr. W. A. Harwood are given in the Memoirs of the Indian Meteorological Department, vol. xix. In an introduction, Dr. G. T. Walker explains that the analysis of the winds at Port Blair was almost completed by Sir John Eliot prior to his death. The Port Blair discussion, which embraces the observations for ten years, September, 1894, to August, 1904, is of special interest, as it is the only purely insular and tropical station at which anemographic data are recorded in India. The position of the station is well described, and the records are said to represent correctly the winds of the surrounding portion of the Bay of Bengal. At Port Blair winds from north-easterly directions predominate from November to March, or for five months of the year, and winds from south-westerly directions predominate during the five months from May to September. In the transition months of April and October, between the monsoons, winds are very variable. The discussion of the anemograph observations recorded at Dhubri is for seven years to May, 1896. The situation of the station is given in detail, and the anemograph was mounted on a tower, 45 ft. above the ground; its exposure is said to have been excellent. The height of the instrument above the tower is not given. The predominant winds at Dhubri are said to be those up and down the Assam Valley. During November, December, and May down valley winds very largely prevail, but up valley winds are more numerous than down valley winds in February, March, July, and August. Seasonal and diurnal movements of the air are given in tabular form for both stations.

A copy of the annual report of the Board of Regents of the Smithsonian Institution, "showing the operations, expenditures, and condition of the Institution" for the year ending June 30, 1913, has been received from Washington. The volume runs to 804 pages, of which 140 are concerned with reports and proceedings. The bulk of the book consists of the general appendix which furnishes a miscellaneous selection of scientific papers, some of them original, embracing a considerable range of scientific investigation and discussion. Many of the papers are translations of contributions by distinguished foreign men of science. Among these translations may be mentioned: The reaction of the planets upon the sun, by M. P. Puiseux, astronomer at the Paris Observatory; modern ideas on the end of the world, by Prof. G. Jaumann, professor of physics at the Technical High School at Brünn; recent developments in electromagnetism, by Prof. Eugene Bloch, of the Lycée Saint Louis; oil films on water and on mercury, by Prof. H. Devaux, of Bordeaux; ripple marks, by M. Ch. Epry; the development of orchid cultivation and its bearing upon evolutionary theories, by M. J. Costantin; the problems of heredity, by Dr. E. Apert, principal at Andral Hospital, Paris; the whale fisheries of the world, by M. Charles Rabot; the earliest forms of human habitation and their relation to the general development of civilisation, by Prof. M. Hoernes; feudalism in Persia: its origin, development, and present condition, by M. J. de Morgan, of Paris; shintoism and its significance, by Mr. K. Kanokogi, of Tokyo, in *Zeitschrift für Religionspsychologie*; the economic and social *rôle* of fashion, by M. Pierre Clerget, of Lyons; and the work of J. H. Van't Hoff, by Prof. G. Bruni, of the University of Padua. As has been the case in former years, many of the articles in the appendix are illustrated by numerous beautifully executed plates.

Messrs. John Wheldon and Co., 38 Great Queen Street, Kingsway, London, W.C., have issued a catalogue of books and papers on economic botany which they have for sale. The list, which is conveniently classified, contains particulars of books on commercial plants, tropical agriculture, food plants, and many other branches of economic botany.

The following forthcoming books of science are announced by Messrs. Constable and Co., Ltd.:—"Textbook on Motor-car Engineering," by A. G. Clarke, vol. ii., Design; "Telegraph Engineering," by Dr. E. Hausmann; a new edition of "Wood Pulp," by C. F. Cross, E. J. Bevan, and R. W. Sindall. Mr. John Murray will shortly publish "Evolution and the War," by Dr. P. Chalmers Mitchell.

OUR ASTRONOMICAL COLUMN.

Comet Notes.—The Ephemeris Circular of the *Astronomische Nachrichten* (No. 482) contains the elements and ephemeris of comet Mellish (1915*a*), communicated by Dr. Fischer-Petersen. As this ephemeris differs somewhat from that given last week the new positions for the current week are as follows:—

	R.A. (true) h. m. s.	Decl. (true) ° ′	Mag.
April 22 ...	18 32 24 ...	−6 58·7 ...	7·6

The comet lies towards the southern portion of the constellation of Aquila, in the neighbourhood of the stars 1, 2, and 3 Aquilæ.

The only information to hand regarding the observed return of Winnecke's comet is that mentioned in the *Morning Post* of April 15. It is stated that Dr. Thiele, of the Bergedorf Observatory, Hamburg, recorded its position on a photograph, the object being of the 16th magnitude. This comet has a period of about 5·8 years, and was first discovered in 1858. At the present return perihelion will not be reached until September, so that later the comet may be a good telescopic object.

Prof. E. C. Pickering, in *Harvard Circular*, No. 187, gives some early positions of comet 1914*e* (Campbell). This comet, as the circular states, appears to have been first seen on Thursday, September 17 (astronomical date), at one o'clock in the morning, by Mr. Leon Campbell, at the Arequipa Station of the Harvard Observatory. The comet was then visible to the naked eye. It was discovered independently a few hours later by Dr. Lunt, at the Cape Observatory, and by Mr. Westland, in New Zealand. Six photographs taken by Mr. Campbell were sent to Cambridge, and the positions have been measured and are here recorded.

The Rotation of the Solar Corona.—M. J. Bosler, in the *Comptes rendus* for April 6 (vol. clx., No. 14, p. 434), describes the result he has obtained in an investigation on the velocity of rotation of the solar corona. The experiment was made during the solar eclipse of last August, and the apparatus provided the means of photographing the whole spectrum of the corona. It was thought that the green radiation at λ5303 would prove the most satisfactory line for measurement, but its absence rendered this impossible. However, the new red ray (λ6374·3) provided the opportunity for the determination, and the result obtained is here described. The photograph secured showed two strips of spectra of the corona at the east and west limbs, and, as comparison spectra, three other strips of spectra of diffused sky light were secured symmetrically on the same plate ten minutes after the eclipse. The resulting wave-lengths of the coronal line for the east and west limbs were found to be as follows, each wave-length being the mean of five complete series of measures entirely distinct:—

East λ 6374·43 (Rowland)
West λ 6374·59 ,,

Diff. 0·16

This difference corresponds to a velocity of 3·7 kilometres, and, making a correction for the inclination of the slit to the solar equator, gives an equatorial velocity of about 3·9 kilometres per second, a value correct to about 25 to 30 per cent. In the eclipse of 1898 Prof. Campbell, using the green radiation, deduced a tangential velocity of 3·1 kilometres a second (±2 km. nearly), the diffuse nature of the radiation preventing further accuracy. M. Bosler points out that the corona moves in the same direction as the surface of the sun, and appears to rotate more quickly. The higher levels of the chromosphere show a similar tendency only to a less degree. An apparent increase in velocity with the elevation is thus proved.

THE ANNUAL OF THE BUREAU DES LONGITUDES, 1915.—The very useful annual for the current year published by the Bureau des Longitudes is as compact as ever, and contains a mine of valuable information very handy for reference. Besides the usual numerous tables useful to the astronomer, several new communications are included. Thus M. G. Bigourdan writes on the subject of the constellations, and after a brief historical sketch gives the co-ordinates of the principal stars and star charts down to 50° S. latitude. Quite a long article, devoted to stellar spectra and their classification, is written by M. A. de Gramont. The author describes Secchi's classification with illustrations of the type spectra, and then refers to more recent classifications, giving a table showing the correspondence with each other. Sir Norman Lockyer's classification is dealt with in a separate section of the article, and is compared with the Harvard College Observatory classification. A very valuable article, covering 162 pages, is that on "Methods of Examination of Mirrors and Objectives," contributed by M. Bigourdan. The article is illustrated by a large number of very useful figures, which will considerably help the reader. The preliminary chapter includes numerous historical references, and this is followed by chapters on general methods of examination, their application to all reflecting surfaces, the examination of mirrors mounted in telescopes, and, finally, a very complete account of the examination and testing of objectives.

CHINESE RECORDS OF ECLIPSES.—In the Proceedings of the Tôkyô Mathematico-Physical Society (January, 1915, vol. viii., No. 1) Messrs. Kiyotugu Hirayama and Sinkiti Ogura discuss the interesting records of early Chinese eclipses. Their working list extends from the earliest solar eclipses to those recorded in the Ch'un Ch'iu. In the case of the latter, the calculations are in progress, and are expected to be soon finished. In the present communication the general plan of the calculations consists in determining the central line and the limiting lines for each eclipse. The eclipses of Shu Ching and Shih Ching are dealt with, and diagrams are given showing some of the limits of visibility.

TEACHING OF ENGINEERING IN EVENING TECHNICAL SCHOOLS.

THE "Memorandum on the Teaching of Engineering in Evening Technical Schools" (Circular 894), recently issued by the Board of Education, is a very welcome manual of suggestions to teachers and organisers of schools which provide evening classes in mechanical and electrical engineering.

This Memorandum fills nearly sixty foolscap pages, and is divided into nine sections. An introductory section points out the limitations of part-time courses—courses intended for students whose ordinary employment occupies the greater part of their time—when compared with full-time day courses. The second section, after referring to the fact that some of the serious disadvantages which characterise part-time courses conducted in the evening may be avoided by the growing practice of holding such courses during the day (the junior employees being allowed "time off" in order to attend them), proposes to classify "a complete curriculum of evening instruction" into three stages: the junior course (fourteen to sixteen); the senior course (sixteen to eighteen or nineteen), and the advanced course (eighteen or nineteen to twenty, twenty-one, or twenty-two). Senior courses are to be of two kinds: a minor course, complete in itself, for apprentices to engineering trades; and a major course, incomplete unless it also includes an advanced course, for technical men. The third section of the Memorandum gives outlines of typical major (senior and advanced) courses in mechanical and electrical engineering, and of minor (senior only) courses in some engineering trades. After making, in the next section, some valuable suggestions upon laboratory and class instruction for adolescent evening students, the Memorandum proceeds, in the following four sections, to consider in more detail the teaching of the various subjects which constitute these outline courses. The accommodation and equipment required for the various classes of work already discussed are considered in the ninth and final section.

The Memorandum is thus concerned with all kinds of evening classes intended for persons employed in engineering work, from the apprentice who is beginning to learn a trade to the designer or manager who attends a course of evening lectures delivered by a university professor. By concentrating attention upon evening classes as such, and especially upon those classes which are primarily intended for boys and young men between sixteen and twenty-two years of age, the Board's inspectors have succeeded in producing a document which cannot fail "to assist teachers and organisers to mark out for themselves the schemes of instruction best suited to the conditions of their classes." But this very concentration, to which the Memorandum owes much of its usefulness, will disappoint education committees or directors of education who look to find in it some treatment of the wider educational and economic problems of engineering training, such as the following:—The selection, on democratic lines, of the most suitable boys for each different type of training which should be provided for the different positions in engineering industry; the respective parts to be played, in the preparatory (full-time) training of engineers, by the elementary school and the junior technical school, the lower secondary school and the senior technical school, and the higher secondary school and the university or technical college; the point at which works training should begin; the co-ordination of practical experience in the shops with instruction in classes inside the works and with outside schools and colleges; and, more generally, the effective co-operation between engineering firms and education authorities in establishing and administering schemes for the advancement of apprentices.

Perhaps the most important feature of the Memorandum is the distinction which it draws between the major and the minor course. Industrial training has suffered hitherto from a lack of proper appreciation of the differences between the training required by the future artisan (or "tradesman") on the one hand, and the future "technical" man (whether designer, manager, or commercial representative) on the other. The distinction now drawn does not, however, go deep enough. The Memorandum does not sufficiently discourage the prevailing notion that the ideal evening student first enters evening classes at fourteen, and continues to attend such classes for seven years. Thus, instead of insisting that the technical student should remain at a secondary school until he is at least sixteen, and then, perhaps, enter his major (senior) course when he enters works, the Memorandum contemplates that the technical student and the trade student shall both follow the same junior (evening) course from fourteen to sixteen. It would surely be better that the trade student's own minor course should begin at fourteen instead of at sixteen, and attract him, by its special adaptation to the circumstances of his particular trade, from the moment when he leaves his day school. Moreover, since the trade student will as a rule have less opportunity for general reading in later life, his minor course might well include some "citizenship" subjects, such as industrial history considered at first from the point of view of his particular trade.

More than half of the Memorandum is devoted to "outlines of work" for various recommended courses. This portion is full of most useful suggestions. Some, however, are open to objection, or, at least, to criticism. Thus there is a curious confusion between *weight* and *mass* on page 20 ("$g \times$ force $=$ mass $\times$ linear acceleration," which would make g a pure number, independent of the system of units employed). It is also doubtful whether the conception of "work" is really so difficult as to justify the suggested postponement of its introduction until the second year of the senior course. Again, the four years' (major) course in mathematics outlined in the Memorandum might with advantage be less "practical" in its first two years, during which some time might well be found for geometry.

ENGLISH MATHEMATICS.

The *Mathematical Gazette* has recently published a translation of an address delivered by Prof. Gino Loria to the International Congress of Historical Studies. This is a well-proportioned and detached estimate of the main contributions of England to the body of mathematical science, from the earliest available records to the present time. An important suggestion is made that it may be possible to find in some of our libraries manuscript works by some of those early writers who, unlike ourselves, did not hasten to publish their discoveries, and were often surprised by death. In this connection the names of Bradwardine, Richard of Wallingford, John Maudith, and Tonstall are mentioned. Another note is that James Gregory made lengthy stays in Italy, and was therefore probably acquainted with the work of Galileo; so the question arises how far Newton may have been influenced by the achievements of the great Italian philosopher. Prof. Loria suggests inquiry about this as an important piece of research.

Prof. Loria emphasises, with justice, the fact that the renascence of English mathematics in the nineteenth century coincided with a better knowledge and appreciation of work being done abroad. The greatness of Newton, like that of Euclid and Archimedes, had a sort of benumbing effect upon his successors, and even contemporaries; although, of course, there are exceptions, like Maclaurin and Brook Taylor and Waring. It is also pointed out that even now there are certain branches of mathematics which Englishmen persistently ignore, or else treat by obsolete and clumsy methods. The example given is descriptive geometry; and it is noted that Brook Taylor laid down the principles of this subject in a way perfectly analogous to that adopted long afterwards, and independently, by Fiedler. It is not stated by Prof. Loria, but it is a fact that most of our text-books on descriptive geometry are simply contemptible, from a scientific point of view, and not to be compared with Fiedler's treatise, or the classic work of Monge, which does in the main follow the lines of what we call descriptive geometry, in the restricted sense of orthogonal projection.

Even able students who use these books, and attain great practical efficiency, have no conception at all of the subject as a whole, and are baffled by the simplest problems about traces of lines and planes. So far as we know, there is only one good treatise on descriptive geometry in the English language, and that is in the "Penny Cyclopædia," where so many other treasures have been buried and forgotten. This leads to the remark that Prof. Loria has a proper appreciation of the works of De Morgan, and laments that they are so inaccessible; with this sentiment we cordially agree.

An Italian is as likely as anyone to sympathise with English modes of thought; so any conclusion drawn from this address is likely to be flattering rather than the reverse. We must remember, too, that, when we speak of English mathematicians, we are apt to include such men as Maclaurin, Rowan Hamilton, and Sylvester, who were not Englishmen at all. But even in this inclusive sense of the term "English" one cannot but feel that Continental opinion about English mathematics is almost bound to be analogous to that about English literature in general. Newton *is* English, and, like Shakespeare, or Dante, or Goethe, incomparable; but we have lesser men, of a more distinctly national type, who may, perhaps, be more justly appreciated at home than abroad. As an example, we may instance W. H. Fox Talbot, now only vaguely remembered in connection with photography. As a mathematician he is, of course, not to be compared with Abel; nevertheless he did investigate some cases of Abel's theorem in a very instructive and fundamental way, implicitly showing that the theorem is really a deduction from the known facts about symmetric functions of the roots of an equation, and the elementary theory of partial fractions. We are inclined to believe that the simplest proof of Abel's theorem will ultimately follow the lines that Talbot has indicated.

There are many points in the address to which we cannot refer; but one that deserves mention is that Newton is reported to have said that the style of the ancient geometers is the only one appropriate to any mathematical treatise worthy of the name. Judging by the "Principia," it is probable that this story is authentic.

G. B. M.

PUBLIC HEALTH.

The Medical Officer's Supplement to the forty-third Annual Report of the Local Government Board for 1913–14 (Cd. 7612, price 1*s*. 11*d*.), while it deals mainly with matters primarily of medical interest, of necessity includes within its scope much that is of value to all scientific minds.

The question of infant mortality occupies a prominent place, and one notes with satisfaction that the general trend of the curve continues in a downward direction. Greater provision is likely to be made in the near future for the care of expectant mothers, and the official recognition of an ante-natal state, though somewhat belated, is none the less welcome. Much good work has been done by voluntary agencies in the past, and the linking up of this with the various organisations dealing with child welfare must inevitably tend to a healthier future race.

Some interesting figures are given regarding vaccination returns. It appears that in England and Wales as a whole one-half of the children whose births were registered in 1912 have been vaccinated, and nearly one-third have been exempted from vaccination by statutory declaration of conscientious objection. When compared with the returns for 1911, these figures show a percentage reduction of 52·3 to 50·1 in the proportion of children born who are vaccinated. The percentage of children born who were exempted under certificate of conscientious objection increased from 28·5 to 32·1.

Inquiries have been made regarding certain outbreaks of enteric fever supposedly due to the consumption of infected shell-fish. The medical officer of health of a seaport town has repeatedly referred to the danger incurred by persons in collecting shellfish of all sorts from areas obviously contaminated with sewage. While it is difficult in most cases to prove conclusively that an epidemic owes its origin to such a practice, yet, when local authorities have acted as if such were undoubtedly the case, the wisdom of such action has been abundantly shown by the nonrecurrence of the disease.

Progress is constantly being made towards securing purer and more wholesome food for consumption in this country. A careful watch has to be kept at the various ports of entry to prevent so far as possible the import of unsound and even poisonous material. As an instance of what is continually happening it will suffice to quote the following occurrence. During the unloading of a cargo of sugar in the Port of London it was noticed that some of the bags containing the sugar were covered with borax, which had been carried in the same hold and had become loose during the voyage. Samples of this powder were taken, and analysis showed them to contain arsenic in considerable quantities. The whole of the sugar was rebagged, and that portion of it that had already been sent out was recalled for suitable treatment under supervision.

The effect of certain types of waters on lead has again been brought into prominence by an outbreak, extensive though mild, of lead poisoning in an urban district in Yorkshire. The waters most liable to act in this way are acid, peaty supplies, and it is even asserted as conceivable that the treatment applied with a view of destroying the plumbo-solvent properties of the water may tend in some way to increase the ability of the water to erode the lead. At all events, further investigation is being made, as the case in point has proved a very difficult one to deal with.

More research has been conducted on the subject of ferro-silicon with special reference to possible danger arising from its transport and storage. This substance, of certain percentage compositions, is liable to disintegration in the presence of moisture, and poisonous gases are given off in quantity sufficient to produce fatal results in human beings. It is suggested that liability to spontaneous disintegration with evolution of poisonous gases may be related to the amount of aluminium present in the ferro-silicon. Further reports are now issued on ferro-chrome and other ferro-alloys, with special reference to aluminium content.

The work of Prof. Leonard Hill on the effect of open-air and wind in the metabolism of man is referred to. He points out that the physical qualities of the air—heat, moisture, and movement—are of paramount importance to health. The stimulating effect of cool and variable breezes acting on the skin leads to improved health, while a stagnant, windless, over-warm atmosphere tends to depression and diminished vitality. Two new instruments are described—the kata-thermometer and the caleometer—which enable the rate of cooling of the body and the variability of the rate to be measured (see p. 205 of this issue of NATURE). Prof. Hill's researches on the physical condition of the atmosphere have done much to elucidate the problem of "stuffiness," to which so many ailments are undoubtedly due.

THE CARNEGIE INSTITUTION OF WASHINGTON AND SCIENTIFIC RESEARCH.

THE Carnegie Institution of Washington was founded by Mr. Carnegie in 1902, when he gave to a board of trustees an endowment of 2,000,000*l.*, to which he added 400,000*l.* in 1907, and a further 2,000,000*l.* in 1911. The articles of incorporation of the institution declare "that the objects of the corporation shall be to encourage, in the broadest and most liberal manner, investigation, research, and discovery, and the application of knowledge to the improvement of mankind," and already, as the annual reports of the president and the directors of the various departments show, the objects of the institution are being fulfilled admirably.

The trustees have inaugurated and developed three principal agencies to forward the aims of the institution. In the first place, the departments of research attack problems requiring the collaboration of several investigators, special equipment, and continuous effort. A second agency provides means to enable individuals to complete investigations requiring less collaboration and simpler apparatus; while a third division deals with the publication of the results obtained as the result of the work of the first two agencies.

The reports by the president, the directors of the various departments of research, and the executive committee, contained in the 1914 Year Book, recently received, give full particulars of the financial resources of the institution, and of the activities of its different departments, during the year under review. The Year Book provides convincing evidence of the success of the trustees of the institution in their endeavours to encourage and advance scientific research.

The following table shows the amounts of the grants made by the trustees for the current year, and the purposes to which they are being devoted:—

	£
Administration	10,000
Publication	12,000
Division of Publications	2,000
Departments of Research	138,462
Minor Grants	21,860
Index Medicus	2,700
Insurance Fund	5,000
Reserve Fund	50,000
Total	242,022

The next table shows the departments of scientific investigation to which the larger grants were made for the financial year 1913–14, and the amounts of these grants:—

	£
Department of Botanical Research ...	8,428
Department of Economics and Sociology	1,000
Department of Experimental Evolution ...	12,696
Geophysical Laboratory	17,100
Department of Historical Research ...	6,220
Department of Marine Biology	3,830
Department of Meridian Astronomy ...	5,036
Nutrition Laboratory	9,159
Division of Publications	2,000
Solar Observatory	44,178
Department of Terrestrial Magnetism ...	31,481
Researches in Embryology	5,380
Total	146,508

The following extracts from the *résumé* of the investigations of the year included in the report of the president, Dr. R. S. Woodward, will serve to indicate the nature and extent of the scientific work accomplished during the year.

Although the greater part of the work of the Department of Botanical Research is carried on at its principal laboratory at Tucson, Arizona, it is essential to a comprehensive study of desert plant life to explore distant as well as adjacent arid regions. Thus, having published during the past year the results of an elaborate investigation of the region of the Salton Sea, the department is now turning attention to similar desert basins, of which there are several in the Western States that have been studied hitherto in their geological rather than botanical aspects. These researches are entailing also many applications of the allied physical sciences not heretofore invoked to any marked extent in aid of botanical science. Hence there results properly a diversity of work quite beyond the implications of botany in the earlier, but now quite too narrow, sense of the word. The facilities of the Desert Laboratory have been enlarged during the year by the completion and equipment of a specially designed small building for studies in phyto-chemistry, which has been proved to play a highly significant *rôle* in desert life.

The observational, statistical, and physical methods applied by the Department of Experimental Evolution are constantly adding to the sum of facts and of inductions essential to advances in biological knowledge. The range of application extends from the lowest organisms, like fungi, up to the highest, as typified in the race to which the investigators themselves belong. Thus, during the past year, observations and experiments have been made on mucors, plants, pigeons, poultry, and seeds, while the director has continued his fruitful statistical studies in the relatively new field of departures from normality in mankind. The variety of agencies employed in this wide range of inquiry now includes a permanent staff of about twenty members and a physical equipment enlarged during the year by the completion of an additional laboratory and a power-house. Early in the year the facilities of the department were increased by the successful transfer, from Chicago to Cold Spring Harbour, of the remarkable collection of pedigree pigeons recently acquired by the institution from the estate of Prof. C. O. Whitman.

An instructive example of the favourable progress, which may be confidently expected in any field of research when entered by an adequately manned and equipped department devoted solely thereto, is afforded by the experience of the Geophysical Laboratory. In less than a decade this establishment has not only accomplished the formidable task of constructing the necessary apparatus and of preparing many of the pure minerals concerned, but has already begun the processes of analysis and synthesis which are leading to extensive additions to our knowledge of rock and mineral formations found in the earth's crust. Among the problems under investigation, one of immediate economic as well as of great theoretical interest may be cited here by reason especially of the fact that funds for its execution have been supplied by industrial sources; this is the problem of the "secondary enrichment of copper ores," and the success attained in its treatment demonstrates the practicability of advantageous co-operation between the laboratory and industrial organisations without restriction to scientific procedure and publicity. The section of the director's report devoted to this subject should be of special interest to geologists and to mining engineers as well as to copper-mining industries. A more comprehensive idea of the productive activities of the laboratory may be gained from its publications, which embrace forty-nine titles of papers which have appeared in current journals or are in the press, many of them having been published in German as well as in English.

In accordance with plans recommended by the director of the Department of Marine Biology and approved by the trustees in 1912, an expedition to Torres Straits, Australia, was undertaken in the latter part of the preceding year. Early in September, 1913, the director and six collaborators arrived at Thursday Island in the Straits, expecting to use this relatively accessible island as a base of explorations; but it was soon found advantageous to proceed to Maër Island, one of the Murray group, about 120 miles east-north-east, and near to the outer limit of the Great Barrier Reef. Here a temporary laboratory was set up in the local courthouse and jail, generously placed at Dr. Mayer's disposal by the British authorities. The region proved to be one rich in coral reefs and in marine fauna for the work contemplated. Observations and experiments securing gratifying results were carried out during the months of September and October, 1913. In addition to the critical data secured by Dr. Mayer with respect to the corals about Maër Island, for comparison especially with corresponding data from the corals of Florida waters, observations and materials for important contributions to zoology were collected by each of his collaborators. On returning to America from the southern hemisphere, the director was engaged, during April and May, in two minor expeditions with the departmental vessel *Anton Dohrn*. The first of these was in aid of the researches of Dr. Paul Bartsch, on cerions, and required a cruise along the Florida Keys from Miami to Tortugas and return. The second expedition was in aid especially of Dr. T. W. Vaughan, long associated with the department in studies of corals and related deposits, and required a cruise from Miami, Florida, to the Bahamas and return. It appears that during its first decade forty-nine investigators have made use of the Tortugas Laboratory, twenty-eight of these having returned two or more times, making a total of 108 visits to this relatively inaccessible centre of research. Of the publications emanating from the department, sixty have been published by the institution, while upwards of forty have been published under other auspices.

The activities of the Department of Meridian Astrometry are concentrated on the derivation of stellar positions for the comprehensive catalogue in preparation, on supplementary measurements of stellar co-ordinates with the meridian circle of the Dudley Observatory, and on investigations of residual stellar motions. The latter have now become the most important element in the definition of stellar positions by reason of the extraordinary recent progress in sidereal astronomy, to which the department has contributed in large degree. Thus, along with the formidable computations required by the large mass of observations made by the department at San Luis, Argentina, researches are simultaneously continued on the problems of star-drift, including the speed and direction of motion of our solar system. In the meantime, the catalogue is progressing favourably and some portions of the observatory list of miscellaneous stars are approaching completion, although cloudiness during the past two winters has interfered with this part of the departmental programme. In the meantime, also, the manuscript of the zone catalogue of stars the positions of which were measured at the observatory during the years 1896 to 1900, is undergoing the final process of comparison and checking preparatory to publication.

The anticipations of a specially favourable environment, which were entertained when the Nutrition Laboratory was located in Boston near the Harvard Medical School and near several existing and projected hospitals, are now fully realised; and it would appear that the laboratory is reciprocally advantageous to the several establishments with which it is in immediate contact. Indeed, with this, as with all other departments of research founded by the institution, the only fears to be entertained seriously are those due to increasing capacity for usefulness and scientific progress, since such capacity tends quite properly to grow faster than the institution's income warrants.

Improvements have been made in the laboratory itself, and several additions to equipment have been installed. These latter include new respiration apparatus for studies of metabolism in muscular work of men and of small animals, a reconstruction of an earlier form of bed calorimeter, and additional apparatus for photo-electric registration of physiological action in subjects under observation, whether near by or at a distance.

As indicated in previous reports, the laboratory and its work are subjects of international as well as national interest, and many co-operative efforts are arising therefrom. Among the researches in progress by the laboratory staff, attention may be directed particularly to "The gaseous metabolism of infants with special reference to its relation to pulse-rate and muscular activity," by Francis G. Benedict and Fritz B. Talbot, and to "A study of prolonged fasting," by Francis G. Benedict.

The extensive operations of the Department of Terrestrial Magnetism on the oceans and in foreign countries have been adequately supplemented during the year by the new departmental laboratory, the completion and occupation of which took place nearly simultaneously with the beginning of the second decade of the department's existence. This laboratory and its site provide greatly enlarged facilities for research, as well as unsurpassed quarters for the resident departmental staff.

Near the end of the preceding year the non-magnetic ship *Carnegie* returned to New York City, where she underwent such extensive repairs as are always required by wooden vessels after long cruises in tropical waters. After refitting, she left New York, June 8, 1914, for a cruise in the North Atlantic. In this, the third of her expeditions, she traversed about 10,600 miles, making a first stop at Hammerfest, Norway, July 3, reaching the high latitude 79° 52′ off the north-west coast of Spitsbergen, touching at Reykjavik, Iceland, August 24, and returning to the base station at Greenport, Long Island, October 9, and to Brooklyn, New York, October 21. During this cruise the *Carnegie* was in command of Mr. J. P. Ault. She is now being refitted for a longer cruise during 1915–16, in southern latitudes (50° to 75°), where magnetic observations require supplementing.

An attempt at an ocean expedition into Hudson Bay was made under the charge of Mr. W. J. Peters during the past summer, but on account of unusual obstacles from ice this proved only partly successful. Entrance into the Bay with the auxiliary schooner *George B. Cluett*, chartered for this purpose from the Grenfell Association, was blocked until September 2, leaving less than a month's time available for surveys.

Determinations of magnetic elements on land have been continued in six parts of Africa, in as many States of South America, and in Australia, bringing the surveys of all these continental areas to a well-advanced stage.

With the end of the current year the Mount Wilson Solar Observatory, like most other departments of the institution, will have completed a first decade of its history. Quite appropriately, this establishment was founded at an epoch of maximum sun-spots, and a marked increase in solar activity during the past year furnishes similarly auspicious conditions for entrance into a second decade of research. But much more auspicious conditions are found in the extensive experience and in the effective equipment acquired along with the capital progress attained during this first decade. The most sanguine astronomer would have hesitated at the earlier epoch to predict that these latter conditions could be realised at the present epoch. Herein also is found a signal illustration of the superior effectiveness of establishments primarily designed for and exclusively devoted to research as compared with establishments in which research is a matter of secondary interest.

Progress in construction of the 100-inch telescope has been made as rapidly as could be expected in so formidable an undertaking. The delicate optical task of shaping the 100-inch mirror has been brought successfully by Mr. Ritchey to the stage of sphericity which precedes the final state of parabolisation. The difficulties due to distortion of the mass of the disc, referred to in previous reports, have been overcome, and other obstacles due to temperature inequalities in the optical room are likewise yielding to appropriate precautions. In the meantime, the foundations for this telescope have been completed, and the mounting and dome are expected to be ready for erection during the coming year. Several smaller parts and accessories for this instrument, requiring special exactness, are under construction at the shops of the observatory in Pasadena. Many additions and improvements in the apparatus already installed at the observatory have been made. The 60-foot tower telescope particularly, which was originally cheaply constructed in order to test the possible advantages of such a departure from earlier forms of telescopes, has been put in a state of efficiency comparable with that of the 150-foot tower telescope, leaving the latter free for the uses to which it is specially devoted. In these general improvements much attention has been given to rendering the plant on Mount Wilson more nearly fireproof. The mountain road has been repaired, widened, and strengthened in many parts in anticipation of the heavy traffic essential to transportation of the 100-inch telescope to its destination.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Adams prize for 1913–14 has been awarded to Mr. G. I. Taylor, Smith's Prizeman in 1910. The subject selected was "The phenomena of the disturbed motion of fluids, including the resistances encountered by bodies moving through them." The value of the prize is about 250*l*.

It is stated in *Science* that by the will of General Brayton Ives, of New York City, the largest part of his estate is bequeathed to Yale University for its general purposes. The value of the bequest is estimated at from 150,000*l.* to 300,000*l.*

We learn from *Science* that through the efforts of Dr. Ralph Arnold, and other alumni of the department of geology and mining, Stanford University has just added to its collections the working library and material of the late Prof. H. Hemphill, of Los Angeles. The collection contains between 8000 and 9000 specimens of shells and 150 volumes. The material is of great importance in the study of the Tertiary geology of the Pacific coast, and especially of the geology of the petroleum deposits of California.

The March number of the *Nature-Study Review* (Ithaca, N.Y.), the official organ of the American Nature-Study Society, is devoted to an elaborate prospectus of courses in nature-study for elementary schools. It has been prepared by Mr. G. H. Travers and Miss H. M. Reynolds, of the Minnesota State Normal School, and it is copyright. The authors take a big view of their subject, and emphasise "the æsthetic, the social, the economic, and the hygienic" aims of nature-study. (The old-fashioned teacher will rather miss the intellectual aim!) To help the pupils to enjoy the world they live in, and to acquaint them with the useful and injurious forms of life, these we understand as the æsthetic and economic aims, but the social aim, so far as explained, seems to us far-fetched, and the hygienic aim is lugged in by sheer force. The "disciplinary theory" of training the powers of observation, memory, reasoning, and imagination must be given up, we are told, for the researches of modern psychology have shown it to be unsound. But it seems to reappear under another name. To more purpose, as it seems to us, the authors emphasise that the nature-study should deal with the material available in the child's environment, which in urban conditions requires to be enlarged artificially. The starting point should always be in the child's experience, and the material should be of interest or capable of becoming of interest to the child. Each study should concern itself with a child's problem, and the child should be guided to solve it. And the solution should mean something in the life of the child. "If the problem does not seem to allow of any application, we may well inquire whether the problem is really worth while." This may be pushed too far, for a stimulated imagination may be a great gain and a search for applications a bore. The graded outlines of courses are carefully thought out, and the general arrangement—following the seasons—is admirable. Teachers will find the outlines very suggestive and the introductory essay very provocative. We would particularly commend the consistent way in which the authors have sought to get at the child's point of view, and to keep to the Socratic method, not in the letter alone, but also in the spirit.

SOCIETIES AND ACADEMIES.

London.

Royal Society, March 25.—Sir William Crookes, president, in the chair.—Prof. B. **Moore**: The production of growths or deposits in meta-stable inorganic hydrosols.—Prof. B. **Moore** and W. G. **Evans**: Forms of growth resembling living organisms and their products slowly deposited from meta-stable solutions of inorganic colloids.—H. **Onslow**: A contribution to our knowledge of the chemistry of coat-colour in animals and of dominant and recessive whiteness.This research was undertaken in order to discover a chemical method of differentiating the two similar forms of white animals known as dominant whites and recessive whites, or albinos. Hitherto this has only been possible by observing their genetic behaviour. Dark animal pigments are believed to result from the oxidation of a colourless chromogen by an oxydase. The skins of young black rabbits were found to yield a tyrosinase which converted tyrosine to a melanin. By means of this tyrosinase it was possible to test extracts from white rabbits of both types. Briefly, extracts from dominant whites contained an anti-oxydase which inhibited the tyrosinase of the black rabbit extracts. Extracts from albinos, on the other hand, had no inhibiting influence, and were themselves incapable of producing any pigment. The anti-oxydase was also found in those white parts of rabbits which are dominant to colour, such as the white bellies of the wild rabbit and of the yellow rabbit carrying agouti. These results tend to confirm the Mendelian view that dominant whiteness is caused by a factor which inhibits the pigment-producing mechanism if present, and that albinism results from the partial or total absence of the factors necessary for the development of pigment. The experiments also revealed facts which suggest that the difference between pigments producing black, chocolate, and yellow hairs is quantitative rather than qualitative, for, after extraction, the pigments in all three colours appear identical. That variation in colour is a structural modification is supported by the fact that dilute colours, such as blue, are caused by a lack of pigment in the cortex. In the corresponding intense colours, such as black, pigment being present in the cortex, the white light reflected from the vacuoles is absorbed, thus deepening the colour.

Paris.

Academy of Sciences, April 12.—M. Ed. Perrier in the chair.—E. **Guyou**: Remarks on the *Extrait de la Connaissance des Temps* for 1916. An account of the modifications introduced with the view of shortening and facilitating nautical calculations.—A. **Müntz** and E. **Lainé**: Study of the material brought down by watercourses in the Alps and Pyrenees. Determinations of the quantities of material carried by the principal watercourses in the Alps and Pyrenees. The erosion is much more intense in certain recent formations. The agricultural value of the deposits has still to be examined.—M. de **Forcrand**: A hydrate of hydrogen arsenide. The hydrate $AsH_3,6H_2O$ has been isolated and determinations made of its dissociation pressures at temperatures from 0° C. to 25° C. From these data, with the aid of Clapeyron's equation, the heat of formation has been found to be 17·75 calories. Comparisons are given for analogous data for the hydrogen compounds of sulphur, phosphorus, and selenium.—J. **Guillaume**: Observations of the sun made at the Observatory of Lyons during the third quarter of 1914. Observations were made of sixty-seven days, and the results are given in three tables showing the number of spots, the distribution of the spots in latitude, and the distribution of the faculæ in latitude.—S. **Chevalier**: The effect of atmospheric dispersion on the diameter of photographed celestial objects. Photographs of the sun and of Jupiter show that the effect of atmospheric dispersion on the diameter of a photographed celestial body depends very slightly on the brightness of the body or on the sensibility of the plates.—Ernest **Esclangon**: The limited integrals of a linear differential equation.—Ph. **Flajolet**: Perturbations of the magnetic declination at Lyons (St. Genis Laval) during the third quarter of 1914.—M. **Lubimenko**: Some experiments on the antioxydase of tomato fruits. Details are given of a method for estimating the amount of peroxydase in the tomato, and this method was applied to determining the proportions of peroxydase during the different stages of the ripening of the fruit. From the results obtained, it is concluded that the tissue of the tomato contains an enzyme which paralyses the oxidising action of the peroxydase. This is provisionally termed antiperoxydase, and it is much more sensitive than the peroxydase to the influence of antiseptics. Even toluene destroys it fairly rapidly. The relations between these two enzymes during the ripening of the fruit is discussed.—A. **Jungelson**: Chemical intoxication and mutation of maize. Studies in the variations produced by treating the seed with a solution of copper sulphate.—H. **Vincent** and M. **Gaillard**: The purification of drinking water with calcium hypochlorite. Compressed tabloids of 0·015 gram calcium hypochlorite with 0·08 gram salt are used. These contain 3·5 mgr. of active chlorine, and one is capable of sterilising a litre of water in about twenty minutes. There is no appreciable taste. Bacteriological experiments are given showing the removal of pathogenic bacteria.—J. **Vallot**: An installation permitting the application of intensive heliotherapy, in winter, to wounded and military convalescents.—MM. **Hirtz** and **Gallot**: A new radioscopic method for the determination of the depth of a foreign body in the organism.

THE VALUE OF THE RARER ELEMENTS.

The Rare Earths: their Occurrence, Chemistry, and Technology. By S. I. Levy. Pp. xiv + 345. (London: Edward Arnold, 1915.) Price 10s. 6d. net.

THE rapidly-growing importance of the rarer elements in both theoretical and technical directions makes the above volume a welcome addition to English chemical literature. Except for Browning's "Rarer Elements," there is little of importance to turn to for information since the well-known "Terres rares" of P. Truchot, published in 1898. The valuable researches of Urbain have removed much of the obscurity that at one time surrounded many members of the yttria group, and has demonstrated the complexity of several that had been thought to be elementary, and quite recently an exhaustive study of the very rare earth scandia by Sir William Crookes has directed attention to this somewhat neglected branch of science.

The title of the present work is rather misleading, for the author deals not only with the rare earths proper, bodies that have always been a perplexity to both the chemist and the theorist, to the former on account of the extreme difficulty that attends their separation and isolation (they have a provoking habit of often turning out to be complex even after their isolation) and to the latter on account of the hopelessness of finding a rational place for them in any of the periodic classifications that have appeared since the original work of Newlands and Mendeléeff. The author also discusses the elements zirconium, thorium, uranium, titanium, the incandescent mantle industry, and the manufacture of artificial silk! These latter are of great interest and importance, but one would scarcely expect to find them in a book under the title of "The Rare Earths."

The book opens with an interesting and suggestive introduction by Sir William Crookes, whose work on rare earths is well known, his numerous researches in this field extending over the last thirty-five years. His remarks refer chiefly to the closely allied elements of the cerium and yttrium groups, and with his characteristic forethought he states his conviction that by following the study of these bodies to their utmost limits "we may arrive at the explanation of what the chemical elements really are, and how they originated, and discover the reasons for their properties and mutual reactions."

The work is divided into three parts: The occurrence of the rare earths; the chemistry of the elements; and the technology of the elements. Each section is treated in detail, and contains a large amount of information, showing that the author has a thoroughly practical knowledge of his subject.

To have at hand in one volume such a store of mineralogical, chemical, and technical detail is in itself a great boon, and the work is likely to become a standard of reference.

In the chapter which deals with the rare minerals a somewhat novel classification is adopted "for the sake of convenience," and an alphabetical list is given of those minerals which contain the yttrium and cerium groups as well as titanium, zirconium, thorium, scandium, etc.; the list is said to include all but a few unimportant members of this class; of these the larger number, printed in heavy type, are fully discussed in a later section. No mention is made of carnotite, the hydrated vanadate of uranium and potassium that has recently come into prominence as a source of radium, nor of the brown wükite that occurs with the black variety in Finland. As a whole, however, the list is a valuable one; it gives the name, composition, specific gravity, hardness, etc., of some 150 minerals that could otherwise only be found by lengthy search in recent mineralogical literature.

The next section, occupying some sixty pages, discusses the minerals in detail, and contains an account of the interesting mineral thorianite, from Ceylon, containing 55—79 per cent. thoria and a considerable amount of helium from which radio-thorium has been prepared by Hahn; also the recently-discovered mineral thortveitite containing 37 per cent. of scandia.

Prominence is given to the thorium and cerium minerals on account of their bearing upon the mantle industry; in this connection the chapters on the monazite sands is of great practical value, although carrying as little as 2 per cent. of monazite, the Brazilian deposits are of enormous extent and have become the chief source of the thoria that is needed for the mantle industry. Besides the Brazilian deposits, monazite occurs in quantity in Canada, India, South Africa, and in North Carolina, where in 1906 the material was successfully worked by the British Monazite Company, representing the South Metropolitan Gas Company, of London. At this juncture, however, the price of thorium nitrate was suddenly lowered 50 per cent. by the German syndicate which largely controlled the Brazilian output; this caused the British company to cease operations, which have not been resumed. The American company working upon the same material shared a like

K

fate, and the German syndicate, together with the Austrian Welsbach Company, now practically meet the world's demand. What effect recent events will have upon this state of affairs remains to be seen, but it looks as if great opportunities are opening out for English and American technologists if they will but take them.

In a short chapter devoted to the radio-active minerals, reference is made to the recent estimation of the atomic weight of the lead contained in them; if this element is the end-product of the thorium disintegration, the *isotope* of Soddy, its atomic weight should be slightly higher than that of ordinary lead; the value found in a recent determination is 208·4, a result surprisingly in accord with theory.

Part ii. deals with the chemistry of the elements, and this section, occupying some 130 pages, is perhaps the most valuable part of the book. It commences with a discussion of the properties of the elements of the yttrium and cerium groups, and of the methods for their separation; the greatest success appears to follow the method of fractional crystallisation, first successfully applied to didymium by Welsbach in 1885, when he succeeded in separating that supposed element into two bodies, having slightly differing atomic weights, naming them neo- and praseo-dymium; it will be remembered by some that the values published at the time by Welsbach were inverted, praseodymium being given at 143·6 and neodymium as 140·8, and it was not until 1898 that Brauner discovered and directed attention to the mistake.

The discussion of the spectrum examination is a little disappointing; the use of the spectroscope in the analysis of the rare earths is of immense importance; the absorption spectra can now be photographed from the extreme ultra-violet down to the least refrangible limit of the visible spectrum if a suitable source of light is combined with the panchromatic plates that are now on the market.

In dealing with emission spectra it is suggested that to observe spark spectra one pole of an induction coil is embedded in the oxide to be examined and a spark passed! This seems to be a very unusual procedure; in general practice the spark is either passed between platinum wires in a strong solution of the earth or else carbon rods saturated with the solution are used as electrodes; reference is made to the "reversion spectrum" discovered by the late Lecoq de Boisbaudran, but no details are given; as in some cases this method is of considerable value, it may be worth while to note that it is described in the *Comptes rendus* for 1886 (vol. cii., p. 153).

We must take exception to the rather summary dismissal of the kathode luminescence spectra discovered by Sir William Crookes some years ago; it is stated that the researches of De Boisbaudran, Baur and Mare, and Urbain have shown that these spectra were due to minute traces of a coloured earth in a large quantity of a colourless one, and that the sensitiveness of the method is so great that it cannot be employed for the ordinary purpose of chemical analysis; this may be partly true, but there is abundant evidence of the value of the kathode spectra when applied to the rare earths if the technique of the application is thoroughly understood. The sulphates of many of the earths give discontinuous spectra of great beauty and minute detail quite distinct from the nebulous luminosities produced by mixing coloured and uncoloured earths and submitting the mixture to the action of kathode rays; the oxides also, when in a state of purity and under certain conditions, give rise to a further novel series of characteristic phosphorescence spectra, and it is a matter of regret that this method of analysis has not received the attention that it deserves. We feel that the possibilities connected with it are too valuable to allow it to be lightly set aside as worthless.

For the general examination of the rare earths arc spectra are stated to be the most trustworthy, and a valuable feature is the inclusion of lists of the dominant lines in the spectrum of most of the elements.

The last section, the technology of the elements, is largely occupied with an account of the "mantle" industry; from a very interesting historical sketch it appears that the employment of the rare earths had been suggested for the production of light from very early times; mantles of platinum coated with lime and rare earths were used so far back as 1839, and mantles made from gauze that had been impregnated with lime and magnesia were used in 1849. The success that has followed the invention of Auer von Welsbach is due in great measure to the accidental discovery that the combination of about 1 per cent. ceria with thoria greatly increases the luminosity of the material, and this composition is now universal.

The commercial preparation of thorium from monazite is fully set out, and the various fibres used for forming the skeleton of oxide are described. Cotton has been replaced by ramie thread, and this in turn is giving way to artificial silk and similar materials, which on account of their uniformity are found to produce more robust and lasting skeletons.

In addition to the mantle industry there are already many other valuable technical applications of the rare elements, and some of the more important are given. Zirconium in particular has properties that render it valuable in many ways; the metal has a very high melting point, and is so hard that it can be used as an abrasive and for glass-cutting; the oxide is largely used in the manufacture of crucibles and furnace linings, and for many other purposes; it has even been suggested as a toilet powder. Among the properties of the metals of the cerium group is the power of forming pyrophoric alloys; cerium with 20 per cent. of iron is said to form an alloy which gives showers of sparks when scratched or struck, and "lighters" made from this and similar alloys are already in use.

The last chapter of the book is devoted to a discussion of the technical possibilities of titanium and its compounds; there are many uses suggested for this interesting element; its very high melting point, 2350° C., renders its employment in metallurgy difficult unless first alloyed with iron, as ferrotitanium; from this many valuable alloys have been formed.

But enough has been said to show that Mr. Levy's book is no ordinary text-book; it is original in its design, contains a vast amount of valuable information connected with the rare earths and the minerals in which they are found, and gives a very complete account of the present technical application of many of them; and it offers great encouragement for further research in this interesting and little-worked branch of inorganic chemistry.

James H. Gardiner.

ABNORMAL PSYCHOLOGY.

(1) *Psychopathology of Everyday Life.* By Prof. S. Freud. English Translation with Introduction by Dr. A. A. Brill. Pp. vii + 342. (London: T. Fisher Unwin, 1914.) Price 12*s.* 6*d.* net.

(2) *The Unconscious. The Fundamentals of Human Personality, Normal and Abnormal.* By Dr. M. Prince. Pp. xiv + 549. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 8*s.* 6*d.* net.

(1) THERE has been a rapid growth of interest, during recent years, in the theoretical explanation and practical treatment of mental diseases, especially of those so-called "borderland" cases between the normal and the definitely insane. The problems involved have aroused vigorous controversy, and the most conflicting views have been put forward by different schools of thought. Among the exponents of these various doctrines two of the most distinguished are Prof. Freud, of Vienna, and Prof. Morton Prince, of America.

Broadly stated, Freud's psychological system is based upon a fundamental distinction between two classes of memories and mental tendencies, viz., ordinary memories and tendencies and those that have for one reason or another been *repressed.* The latter are those involved in mental conflicts and accompanied by pain. They constitute the true "unconscious" of the mind. The other memories are classed by Freud as "pre-conscious." Unconscious memories and mental tendencies retain their original intensity, and although outside of consciousness continue to act, and from time to time affect consciousness. "Like the shades in the Odyssey," says Freud, "they come to life again as soon as they have drunk blood." When especially intense, or when the repressing power of the mind is in one way or another diminished, they may produce the symptoms of hysteria and of other forms of mental disease. But they are also the cause of dreams in normal persons, and of the apparently unintentional mistakes in speech, writing, and other actions, to which we are all more or less subject when our attention is distracted. Freud tries to sustain this latter view in his "Psychopathology of Everyday Life." He contends that the method of psychoanalysis,[1] or free association, demonstrates conclusively that such slips of memory, speech, and writing are really intentional, and due to the concomitant working of unconscious mental tendencies. In his view the problem for psychology is not why we are able to remember, but why we come to forget, and his own solution of the problem is that we forget the unpleasant, except when special factors make this forgetting impossible.

The theory is a comprehensive one, and not so easy to refute as might at first sight appear. There can be no doubt that in quite a number of cases repression plays an important part in the forgetting of unpleasant incidents, and that unconscious mental tendencies sometimes prove their existence by disturbing our speech and other acts. But the exceptions are numerous, and even some of the cases which Freud himself analyses at length seem to admit of other explanations. The book is extraordinarily interesting, however, and full of hints for the student of human nature.

(2) Dr. Prince's book is an excellent introductory text-book for medical psychologists. It sets out very clearly the various senses in which the word "unconscious" has been used by different writers, and shows how important the concept, when adequately defined, is for abnormal psychology. Morton Prince distinguishes what he calls the co-conscious from the unconscious.

[1] See "What is Psychoanalysis?" Nature, February 5, 1914.

The former is the split-off or dissociated consciousness demonstrable in cases of hysteria, etc., the latter is to be thought of best in physiological terms. He recognises the existence of repression, in the Freudian sense, in certain cases, but is unable to verify its universal existence in pathological cases. Many of the instances which he quotes are also strong evidence against Freud's view that sexual experiences, especially those dating from early childhood, are invariable factors in the production of neuroses.

Towards the end of the book there are some excellent chapters on instinct, emotion, and sentiment, which form an important contribution to the question of the nature of personality. The book will be found extremely helpful by those medical men who desire a well-balanced statement of the facts and theories of medical psychology at the present day.

WILLIAM BROWN.

PASTEUR AND PREVENTIVE MEDICINE.

(1) *Pasteur and after Pasteur.* By Stephen Paget. Pp. xii+152. (London: A. and C. Black, 1914.) Price 3s. 6d. net.

(2) *On Pharmaco-Therapy and Preventive Inoculation applied to Pneumonia in the African Native, with a discourse on the Logical Methods which ought to be Employed in the Evaluation of Therapeutic Agents.* By Sir A. E. Wright. Pp. xii+124. (London: Constable and Co., Ltd., 1914.) Price 4s. 6d. net.

(1) IN this volume, one of a series of manuals on medical history, Mr. Stephen Paget, with his usual facile pen, outlines the life of Pasteur. Commencing with his early years, we have a glimpse of Pasteur's home and of the ideals which influenced his whole life:—

"Work hard, honour your country; put spiritual things above material, and other people before yourself; have courage, have patience." . . . "Work; love one another," he writes to his little sisters. "Once you have got into the way of working, you cannot live without it. Besides, everything in this world depends on it."

An excellent description follows of his chemical researches, his study of tartaric acid and of the tartrates, and the foundation of stereochemistry therefrom. In January, 1849, Pasteur is offered and accepts the professorship of chemistry at Strasbourg:—

"Friendship met him on the threshold, and Love was waiting for him just across it. Friendship was young M. Bertin, who had been at school with him, and was now professor of physics in Strasbourg: Love was Marie Laurent, a daughter of the rector of the academy. . . . Within a month, he had sent to her father his formal proposal of marriage. At the end of May they were married. She was everything to him: without her, his work would never have been accomplished: he would have died, long before he did, under the strain of it. To write of him, is to be writing of her: the two lives are one, from 1849 to the day he died."

Pasteur's studies on fermentation and its influence on Lister's work are next discussed, and a beautiful little picture is given of Lister, the man:—

"In 1893, the death of Lady Lister took the delight out of his life. . . . To recall him, is to think, first, of the dignity, gentleness, and refinement of his face: its delicate colouring, the tranquil, almost dreaming, look of his eyes. . . . He smiled, not laughed: a smile of singular beauty, but hard to interpret. . . . Tired, lonely, and, long before he died, broken in health and in the enjoyment of living, one thinks of him, still as a man serene through controversy, a spirit of invincible patience and of radiant purity."

One of the traits of Lister's character, which the reviewer likes best to remember, was his intense concern for the welfare of the patients who came under his care—an untoward incident was a real grief to him.

Subsequent chapters deal with Pasteur's other researches—diseases of silkworms, anthrax, chicken-cholera, rouget—culminating in his work on rabies, soon after which he began to fail:—

"Then came enfeeblement, a year of quiet resignation; and, in September, 1895, his death. It is recorded of him that he died holding the crucifix in one hand, and in the other his wife's hand. Here was a life, within the limits of humanity, well-nigh perfect."

All that is mortal of the great master rests—most fittingly—in the beautiful little chapel in the Pasteur Institute, Paris.

Pasteur's work is fundamental and must be regarded as the starting-point of modern bacteriology and of experimental immunity and preventive medicine. Mr. Paget is able from a consideration of all that has since been accomplished in the prevention of diphtheria, plague, cholera, typhoid, and yellow fevers, malaria and Malta fever to show how much we owe to the genius of Pasteur.

We heartily congratulate Mr. Paget on his book, which is deeply interesting, and holds the attention from start to finish.

(2) Three topics are dealt with by Sir Almroth Wright in this book: first, the use of an organic copper compound "optochin" for the treatment of pneumonia; secondly, the nature of the pneumonia which attacks the native labourers in the Rand mines, and the employment of prophylactic inoculations to prevent it; and thirdly, a discussion of the logical methods which ought to be applied

in inquiries into the efficacy of therapeutic agents as applied in actual practice. The last-named would perhaps have been better published separately, and need not be further considered here.

As regards "optochin," it is found that this drug exerts a specific bactericidal action on the pneumococcus in high dilutions in serum as well as in watery solution. It has been successfully used as an application in local pneumococcic affections, and though some have been favourably impressed with it in the treatment of pneumonia, others have not found it to be of value. There is also some risk to eyesight in its use.

The pneumonia of the Rand was found to be a pneumococcal infection, and the native seems naturally to possess much less immunity towards the pneumococcus than does the white man. Various trials were made of pneumococcus vaccine as a preventive of pneumonia, and it is finally recommended that a dose of 1,000 millions of pneumococci cultivated in glucose blood broth might be appropriately employed as an ordinary prophylactic dose, as this was found considerably to reduce the incidence of pneumonia among those treated, as well as reducing the mortality if pneumonia occurred among them.

A very large amount of experimental work was carried out in this inquiry by Sir Almroth Wright and his collaborators, and the manner in which the results were controlled and are tabulated are models of what a scientific investigation should be, and form a valuable contribution towards the control of a disease which causes serious loss of life, as well as being one of considerable economic importance in the Rand. R. T. Hewlett.

ELECTRICAL ENGINEERING.

(1) *American Handbook for Electrical Engineers: a Reference Book for Practicing Engineers and Students of Engineering.* Compiled by a staff of specialists. Harold Pender, editor-in-chief. Pp. xviii + 2023. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 21s. net.

(2) *Electrical Engineering in India: a Practical Treatise for Civil, Mechanical, and Electrical Engineers.* By J. W. Meares. Pp. xxxvi + 517. (Calcutta: Thacker, Spink and Co.; London: W. Thacker and Co., 1914.) Price 15s.

(1) In its thousand pages this "American Handbook" contains information on an enormous variety of subjects arranged alphabetically from "Abbreviations" to "X-Rays." The work is a sort of combination of a library of text-books with a collection of formulæ and data. In the latter department, which must be regarded as its true field, the book will be found of great service to electrical engineers, but the utility of the text-book portion is, perhaps, open to doubt.

Each section appears to have been written by a man having a thorough and practical knowledge of the subject, and the theoretical and descriptive matter is excellent so far as it goes; where it bears directly on the tabulated matter it is also most useful. But the necessary limitations of space prevent it from being anything like a satisfactory substitute for the detailed text-book. We get just a very brief summary of the leading facts, but we are also given references to other books in which fuller information can be obtained.

Although we would not agree with everything contained in the book (for instance, we do not approve of "abohms," "abamperes," and so on, and do not even admit any necessity for the so-called "absolute" systems of units), we must say that the volume is a useful accessory to the electrical engineer's desk or library.

(2) This book contains a considerable amount of information on electrical matters with special reference to the conditions as to climate, cost, and legislation as they exist in India, but we have some difficulty in imagining a class of engineers to whom it will be really useful. The elementary matter is too scrappy, and too much jumbled up to be of service to a beginner, or even to one who has forgotten; to the man who knows already it would be sheer waste of time to read it.

There is much descriptive matter, but there are very few illustrations; without them the written matter is almost worthless. Most engineers will, we think, prefer a good standard text-book, of which there are a few, for getting up the elementary theory, and one of the well-known "pocket-books" for tabulated data.

OUR BOOKSHELF.

English Folk-song and Dance. By F. Kidson and M. Neal. Pp. vii + 178. (Cambridge: At the University Press, 1915.) Price 3s. net.

It is only in recent years that with the active collection and study of European folk-lore the folk-song and folk-dance have begun to receive the attention which they deserve. The collecting of English folk-songs, begun by the Rev. J. Broadwood in 1843, has since that time been actively prosecuted by Miss L. Broadwood, W. Chappell, Dr. Barrett, and Mr. Baring Gould. In 1898 the Folk-song Society commenced its labours, and has year by year added to our knowledge of British and Irish folk-music. A summary of the progress already made and instructions to the collector were badly wanted. This has now been supplied in the present book, which deals satisfactorily with the problem of the origin of folk-music, and fully describes the methods of notation. The songs of the folk are classified under the heads of narrative ballads, love and mystic songs, pastorals, the songs of the poacher and the highwayman, the soldier and the sailor, the pressgang, hunting, sporting and labour songs, carols, singing games of children, the popular street ballad, and the broadside.

As for the folk-dance, much of the knowledge which we possess is due to the enthusiasm of Mr. Cecil Sharp, who has hunted down the veteran dancers, and taught them how to instruct the minor societies which have been started in almost every large centre. The authors deny that the Morris dance is connected with the Moors, and prefer without good reason a Celtic derivation which makes it to mean "noble." The suggestion that it may be in part due to the Salii or leaping priests of Rome is hazardous; there is more to be said for the theory which connects some of the figures with a primitive sun-worship. The sword-dance seems to be derived from some primitive rites of fertility. The manual is a good introduction to the subject, and the bibliography and illustrations leave little to be desired.

Masonry as Applied to Civil Engineering. By F. N. Taylor. Pp. xi+230. (London: Constable and Co., Ltd., 1915.) Price 6s. net.

The early part of this book contains descriptions of the various kinds of stones used in civil engineering, together with the methods of working and handling them. This portion cannot be described as altogether complete in itself; there are many references to another book by the same author. There is a certain off-hand manner in the treatment which has led to one, at least, unfortunate result. On p. 23 calculations appear giving the load which can be raised by a set of Weston's blocks when a given pulling force is applied. No allowance has been made for friction, hence the result of the calculation is altogether misleading.

In the later portions of the book the author deals with retaining walls, dock walls, dams, bridges, towers, monolithic and block concrete construction, shoring, and underpinning. It is probable that the reader will derive more benefit from the descriptions and drawings given in these portions than from the very brief theoretical discussions and calculations. On p. 43 there is an illustration showing a surcharged wall, together with a few lines of description supposed to indicate how to obtain the thickness of the wall. There appears to be some omission in the illustration; it is impossible to grasp the author's meaning. The treatment of the wedge method on p. 45 is imperfect, and again there appears to be omissions in the illustration.

In general, the author gives formulæ without any explanation of how these are derived. We do not think, therefore, that the book is likely to meet the requirements of modern students, who, for the most part, desire to be perfectly clear regarding the derivation, limitations, and assumptions involved in any formula which they are called upon to use in design.

The Nature of Gas Ions.

Our knowledge of the nature of gas ions is derived mainly from measurements of their mobility in an electric field. Experimental evidence has shown that as the pressure (p) is altered the mobility (k) of the ion alters generally in accordance with the law, pk=constant; when this law holds good it is safe to conclude that the ion remains unaltered at the different pressures. One of the most interesting results of experiment is that in the case of the negative ion formed in air the product pk increases as the pressure is diminished below about 10 cm.; this result indicates a simplification in the nature of the negative ion at the lower pressures. Prof. Townsend and his students have examined this phenomenon in great detail, and have come to the conclusion that the velocity (v) of the ion should be expressed as a function of the field (X) and the pressure (p) in the form $v=f(X/p)$, indicating that the nature of the ion depends on the field and the pressure. In his recently published treatise Prof. Townsend concludes that the negative ion in a dry gas is in general a cluster of molecules which for a certain range of electric forces and pressures passes through a transition stage until finally, when X/p exceeds a certain value, the negative carriers are practically all electrons.

In some experiments recently undertaken to determine the mobilities of the ions formed by the radiation from polonium in thoroughly dried air, I have been led to conclusions essentially different from those now generally held. From a pressure of one atmosphere down to about 8 cm. the results were normal; at pressures below 8 cm. the negative carriers were found to consist of two kinds, electrons and ions, the former increasing in number relatively to the latter with diminishing pressure. In no instance was there any evidence of an intermediate or transition stage, the separation between the faster and the more slowly moving carriers remaining throughout clear and distinct. I was able to measure the velocity of the negative *ion* at all stages until resolution between the two kinds of carriers was no longer practicable, and it was ascertained that the value of pk remained constant from one atmosphere down to the lowest pressure employed (1/7 mm.), indicating that the negative ion remains unaltered in nature over this wide range of pressures.

The fact that electrons exist in dry air at the lower pressures is, of course, well known, but at a pressure of 12 mm. the ions constitute at least 80 per cent. of the negative carriers and at 1/7 mm. more than 50 per cent. The proportion of ions and electrons depends solely upon the pressure, the effect of the field being for the most part small or negligible. For the negative ion at all pressures v was found to be directly proportional to X/p; there seems to be no necessity for introducing any unknown function of X/p.

The fact that the electrons travel through several centimetres of a gas at pressures as high as 8 cm. without attaching themselves to neutral molecules is remarkable, and seems to imply that the distribution of carriers between ions and electrons must be determined immediately after the act of ionisation; it would appear that the electron has to be fired into the molecule above a critical velocity, otherwise attachment is no longer possible.

It was found that the positive ion remains unchanged in nature down to 1/20 mm., which was the lowest pressure tried.

An account of these experiments will appear shortly in the *American Journal of Science*.

Migrations in the Sea.

The terms "anadromous" and "catadromous" are employed to distinguish fish which leave the sea to spawn in fresh water and fish which migrate from fresh water to the sea when they reach maturity. Gilson, in his paper, "L'Anguille" (1908, *Ann. d. l. Soc. roy. Zool. et Malacol. d. Belgique*, T. 43), proposed that the words should be used to define migrations to and from fresh water. The salmon, for example, is catadromous as a smolt, anadromous as a grilse, and so on. But unless new terms are to be created the words must be given a much wider significance than Gilson has suggested. The migrations of fish from the lower part of a river to the higher reaches, from a river to a stream, from the deep region of a lake to the shallows only differ in degree from the anadromous migration of the salmon. It cannot be said either that there is any difference requiring a new term in the migration of a fish from the sea into the lower part of a river or into an estuary. A fish which migrates from relatively deep water to the coast may also be said to have made an anadromous migration. There are species which may spawn in fresh or brackish water, and species which may spawn in salt or in brackish water. In short, it may be said that fishes present every degree of anadromous migration from mid-ocean to the upper limits of streams, and corresponding catadromous migrations. It is now proposed, therefore, that these words should be used to indicate the direction of the migration, however small or great that migration may be, whether passive or active, pelagic or demersal, seasonal or spawning.

But even with the wide meaning here suggested the words cannot be applied to an important feature of migrations in the sea—migrations brought about by current. The Gulf Stream is utilised by fish and other organisms for the conveyance of eggs and larvæ and young to, or towards, the continent, and its branches are no less importantly taken advantage of to convey the products from the spawning ground to a region which may be at some considerable distance. The drift may often be said to be an anadromous one, but it is sometimes catadromous, and frequently could not be defined by either term. The migration of the mature fish is in contrast to the drift of the larva.

This may be illustrated by reference to a species not a fish—the common edible crab, *Cancer pagurus*. The crabs on the east coast of Britain migrate, seasonally, catadromously from the coast for winter and anadromously to the shore region for summer. The mature females after ecdysis, sooner or later become ripe, and in response to the impulse thus conveyed migrate northwards along the coast. During or after this migration they become "berried." The larvæ, when liberated, are planktonic, and are carried by the current to the south. If there were, as there is some degree of evidence to show that there are, particular regions which present large associations of berried females, the young crabs would reach the bottom most numerously in areas to the south, which may be said to be related to the regions where the larvæ are liberated.

Thus with regard to this species there is a migration against the current of the mature females and a migration with the current of the larvæ, and these migrations are clearly quite distinct from the seasonal movements which characterise the species at the other periods of life.

The relationship of the spawning ground to the region where the demersal fry are deposited is better defined in the case of many of our species of flat fish and round fish, since it results in the formation of schools of seasonal migrants.

To define these and other migrations which are intimately associated with currents it is necessary, therefore, to introduce two terms which will serve to indicate movement against the current and with the current. My colleague, Prof. J. Wight Duff, recommends a Latin root, *natare*. The words suggested therefore are *contranatant*, swimming against the current, and *denatant*, swimming or drifting with the current. The words *contranatation* and *denatation* are also available to indicate the act or habit of migration against or with the current.

A Mistaken Butterfly.

In this connection the case should be recalled of the Cleopatra butterfly of southern France and Italy, the close relative of our English Brimstone. By waving a grass-green butterfly net in its vicinity I have frequently attracted the yellow and orange coloured males, which will flutter after the net and endeavour to settle on it. The female is similarly coloured to the female Brimstone, but is rather larger. A blue net fails to attract them.

G. H. Bryan.

THE "CRACKING" OF OILS AND ITS COMMERCIAL USE.

The great consumption of petrol as a motor fuel, which last year, in spite of the disturbing element of war, rose to the enormous volume of 120 million gallons in England, and to nearly ten times that amount in America, has led to the attempt being made to add to the natural supply by the so-called "cracking" of the heavy residual oils left after the petrol and the lamp oil have been distilled off from the crude oil.

The term "cracking" is one of those delightful Americanisms which express so exactly the meaning we wish to impart that it has been adopted universally—when a molecule is decomposed it is broken up: when it is merely resolved into simpler compounds it is "cracked." The term first came over with carburetted water gas, when the oils fed into the carburetting chamber were said to be "cracked," *i.e.*, converted into hydrocarbon gases of high illuminating value, but not "broken" into carbon and hydrogen.

A less violent form of the same operation can be utilised to convert the heavy hydrocarbon molecules in oil of high specific gravity and boiling point into volatile liquids fitted for use as a substitute for petrol. Most of the processes for doing this are based on a paper read by Sir Edward Thorpe and John Young before the Royal Society in 1871. This historical memoir was the first and only really scientific attempt to explain the actions that led to an increase in the yield of light hydrocarbons from a heavy oil under certain conditions of distillation, an action that had been first noticed in America in 1861, and was patented in England by James Young in 1865.

Thorpe and Young took $3\frac{1}{2}$ kilos. of paraffin wax obtained from shale and distilled it in an iron mercury bottle connected with a second by a bent tube carrying pressure gauge and stop-cock. The distillation was carried out over an open coal fire, one bottle containing the paraffin being heated, whilst the other acted as a condenser. In about four or five hours the distillation was completed, the pressure throughout being kept at 25 lb., and a magma of oil and unaltered paraffin resulted, which could be liquefied completely by the warmth of the hand. Four litres of liquid hydrocarbons were obtained, and on a preliminary factionation gave :—

Below 100° C.	0·3 litre
100–200° C.	1·0 „
200–300° C.	2·7 litres

Repeated distillations of the portion boiling below 100° C. resolved it almost entirely into three fractions :—

(1) 32°–38° C.,	consisting of	pentane and amylene
(2) 65°–70° C.,	„ „	hexane and hexylene
(3) 94°–97° C.,	„ „	heptane and heptylene

Members of the acetylene and benzene series were absent.

Extended experiments with the portions distilling from 100° C. up to 300° C., and the solid hydrocarbon left above 300° C., showed them to be mixtures of saturated hydrocarbons and olefines. In the fractions distilling below 100° C., these two classes of bodies were in nearly equal proportions, but above that temperature the proportion of paraffin hydrocarbon to olefine became gradually larger as the molecular weight increased.

In cracking a heavy oil there are two factors that govern the course of the actions taking place, and these are temperature and pressure. The first loosens the groups of atoms that build up the complex molecule; the second to a great extent determines whether the action is a dissociation or a decomposition.

The temperature at which the dissociation takes place is above the boiling point of the heavy hydrocarbons, and if no pressure is employed the oil vaporises and the amount of alteration that takes place is small and depends on the local heating of the vapours as they are formed, but if pressure is used the necessary temperature for dissociation is reached, and by suiting the temperature and pressure to the particular mixture of heavy hydrocarbons being dealt with, the maximum of alteration with the minimum of decomposition can be attained. Directly the action commences to be decomposition, gases are evolved, and carbon with heavy asphaltic bodies make their appearance in the residual liquid, while the volume of gas affords an index to the amount of decomposition taking place.

The more complex the original molecule the lower the temperature needed to loosen the bondage of the groups it contains, and therefore the easier to prevent decomposition; hence Thorpe and Young, using a nearly uniform compound like paraffin, were able to dissociate it entirely at a temperature of between 300° C. and 400° C., and prevent decomposition by distilling and condensing under a pressure of 25 lb., but when we come to deal with a mixture of complex molecules, such as are found in Solar oil, the dissociation temperature of some is well above the decomposition temperature of other molecules, and the temperature at which it is best to carry on the conversion can be found by determining the temperature at which part of the oil just commences to decompose, *i.e.*, gives off 10 or 12 cubic ft. of gas per gallon at atmospheric pressure, and then to regulate the pressure so as to prevent any gas being evolved.

With a Solar or other residual oil, what is wanted is a temperature round about 500° C., and a pressure that may run up to 1000 lb. or more if heavy oils are being treated. It is also clear that the heated hydrocarbons must be cooled down under pressure to prevent the chance of a decomposition temperature existing in the liquid and to prevent the escape of the more volatile products of the conversion as vapours.

It was this principle that was embodied in the apparatus which was patented by Sir Boverton Redwood and Sir James Dewar in 1889, and has been copied in the Burton process by which, at the present time, thousands of tons of heavy residual oils are being converted into lighter products by the Standard Oil Company. In both cases the form of apparatus is identical; large vessels or boilers are employed, and the pressure is restricted to 4 or 5 atmospheres, whilst the temperature is 400° C. to 500° C.

Burton's patent was granted on the grounds that by his process only hydrocarbons of the paraffin series were formed, whilst in all previous processes a mixture of the saturated and unsaturated series was produced, this idea being due to the fact that the bulk of the unsaturated hydrocarbons formed were naphthenes.

The inventor of another process obtains greater safety by heating the flowing oil in a coil of iron tube heated to about the same temperature (450° C.) in a bath of molten lead at a pressure of 40 to 50 atmospheres, the oil then flowing to a second coil in a water condenser; this process differs from the previous ones by the pressure being kept sufficiently high to prevent any vaporisation. These processes may be taken to represent simple conversion, and the products found in the low boiling portions are chiefly paraffins, olefines, and naphthenes.

A very interesting process for making "cracked" spirit is that devised by Mr. W. A. Hall, in which dissociation, decomposition, and recombination all play a part, as after vaporising the oil and passing the oil vapour at a rapid rate of flow through a great length of tube heated to about 600° C. under a pressure of 60 lb., he suddenly lowers the pressure by allowing the heated and decomposing oil vapours to pass into a 12-in. column and then through dephlegmators, which cut out the heavier portions of the residue, the vapours and gases passing on into a condensing chamber, where they are compressed to 100 lb., and under this pressure go through the condensing coils. There seems to be an endothermic reaction taking place during the condensation by pressure, as a fall of temperature takes place where one would have expected a rise from the compression, and the liquid finally condensed contains not only gas in solution, but excessively volatile hydrocarbons evidently formed by the nascent gases attaching themselves to other molecules or polymerising. Such a spirit is far more complex than one formed by dissociation acting alone, as, besides the paraffins, olefines, and naphthenes, we also find aromatic hydrocarbons, acetylenes, and bodies like hemiterpene and terpenes.

During the past ten years several processes have been introduced in which steam or water has been introduced with the oil into the cracking ducts, the idea being that hydrogen from the water would affix itself to the heavy hydrocarbons and hydrogenate them into lighter hydrocarbons; to aid this action catalysts have been frequently used, nickel being the most popular.

The idea of the use of nickel as a catalyst is twenty-seven years old, as, in 1888, Ludwig Mond took an English patent, 12,608 of that year, in which he mentions the treatment of hydrocarbons, together with steam, by passing them through heated vessels containing fire-brick or iron oxide, and he states that if metallic nickel is used in place of the iron oxide, then only a moderate temperature is required.

About 1900, Sabatier and Senderens studied the action of nickel and other metallic catalysts on the hydrogenation of oils, and in the following years there were many more patents taken covering its use. Still later there were a large number of patents taken in America by Dr. Day, Ellis, Kayser, and others, dealing with the use of nickel as a catalyst.

Mond, Sabatier, and Senderens all recognised that such surface action as the nickel exercised took place only at temperatures below, at any rate, 300° C., but the more recent exploiters of the idea have drifted back to the temperatures one would use for cracking, not for hydrogenation.

Mr. Edgar A. Ashcroft has been doing some extremely interesting and highly suggestive work. Starting with the theory that the crude oil, as we obtain it from the well, represents a mixture in which the groups of atoms forming the molecule have, under the influence of temperature and pressure existing during the formation of the oil, arranged themselves as compounds in a proportion that has given a natural equilibrium, he suggests that if the crude oil be distilled so as to eliminate the lighter fractions and the residue be again subjected to the same temperature and pressure as that at which it was formed, a natural equilibrium will again be reached by the formation of a mixture akin to the original crude oil, from which more light fractions can be distilled. In the same way, when coal is destructively distilled, the gas and tar represent a molecular arrangement which is in a state of natural equilibrium, so that by taking a middle fraction of the distillation of such tar, say creosote oil, and subjecting it to heat and pressure, tar, with its low boiling hydrocarbons, middle fractions, and pitch, should be again formed. That this is so is seen from the following experiment.

Two hundred c.c. of creosote oil, distilling between 240° C. and 350° C., were heated in an autoclave up to 490° C., which gave a pressure of 100 atmospheres; on allowing to cool down 180 c.c. of tar and 5 litres of very rich gas were found to have been formed. The tar on distillation gave:—

	c.c.	
First runnings, up to 170° C. ...	10	Benzol, toluol, and solvent naphtha
Carbolic oils, 170°–240° C. ...	20	Phenols, naphthalene, and anthracene
Creosote oils, 240°–270° C. ...	20	
Anthracene oils, 270°–350° C. ...	20	
Pitch (very fine)	30	

representing an ideal benzenoid tar.

The extreme suggestiveness of this work, both from the theoretical and commercial point of view, will be at once apparent as offering a method by which the least valuable fractions of tar and crude oil can be converted into those for which there is a greater demand.

SERVI SERVORUM DEI.

IT is not only His Holiness the Pope who is *servant of God's servants*; the title well becomes all who are saving or safeguarding the health of the British Expeditionary Force. To read the medical and surgical history of past wars—the American Civil War, or the Crimea, or the Franco-German War—is more pain than pleasure. To read what our Army Medical Service is doing now—a Committee has just been appointed for the writing of this history—will be not the least of the pleasures of peace. We have a foretaste of it, in the article which was published in the daily papers last week, by "an Eye-Witness present with general headquarters." He says, to begin with, that a war such as this, with so much hardship and exposure, would have cost our nation, a few years ago, an outbreak of disease that would have decimated our forces. He goes on to say that the low sick-rate in the Army to-day is due, partly, to the diligent instruction given of late years to our men in the first principles of health. "In the main, however, it is due to the preventive measures adopted by the medical service." And these preventive measures are of two kinds: those which prevent infection from gaining access to our men, and those which strengthen our men to withstand infection.

The article is mostly concerned, and no wonder, with typhoid fever. Yet, if we think of single cases, not of masses of cases, the protective treatment against tetanus, surely, is not a less achievement than the protective treatment against typhoid. Early in the war, the bad news came of many cases of tetanus; the heavily manured soil of France was full of tetanus; the very earth that our men were helping to defend was their enemy. It is a great blessing that a wounded man may indeed be safeguarded, with a dose of anti-tetanic serum, against this disease; and a great blessing that our men now are on soil which is fairly free from it.

But typhoid, after all, is the supreme test of the efficiency of an army medical service. We have learned of late years that the infection may be conveyed by flies, and by clouds of dust; we have learned also the danger of infection from mild, unsuspected cases, and from typhoid-carriers; we have left off thinking that typhoid cannot be spread without the help of a "polluted water supply." The present control of typhoid for our Army in France has been won by the bacteriologists; all honour to them:—

Mobile bacteriological laboratories have been installed expressly for this purpose (the early detection of cases). Each laboratory consists of a motor-lorry fitted with a complete bacteriological equipment, and is in charge of a specially-trained officer, and an attendant of the Royal Army Medical Corps.

Moreover, it is the bacteriologists who discovered the protective treatment against the disease. On March 5 we learned what our Army owes to that treatment. Of fifty deaths from typhoid fever among our men on active service, forty-eight had occurred among the non-protected, one in a man protected, and one in a man partly protected. Nobody in his proper senses can doubt that Nature finds it easier to kill the non-protected than to kill the protected.

It must not be forgotten that by far the most potent weapon in our armoury against typhoid fever has been forged by pathologists, before the war. Inoculation is the surest defence: and to its extensive use must chiefly be attributed the low incidence of this terrible disease in the British Army.

But the whole article ought to be read carefully, not in fragments.

Doubtless, when the hot weather comes, the work of safeguarding the Army's health will be no less arduous than it is now. For the present, let us be thankful for the splendid services rendered by men of science to our defenders, through all the bitter hardship and perils of the past nine months.

Stephen Paget.

THE USE OF ASPHYXIANTS IN WARFARE.

The use of asphyxiating gases by the Germans in forcing back the French lines to the north of Ypres has given rise to much conjecture as to the nature of the gases employed, and in a long article in a Sunday paper it is surmised that the gas used was carbon monoxide. The only foundation that can exist for such an opinion is that carbon monoxide is one of the most virulent gaseous poisons known, and that less than 1 per cent. in air rapidly proves fatal, but inasmuch as all the explosives in general use produce it in large quantities, the smokeless powders in use by England, France, and Germany, giving approximately 50 per cent. of the permanent gases formed as carbon monoxide, it is hard to believe that the enormous volume produced by firing the charge in the gun should have no deleterious effect on those using it, whilst the much smaller quantity given on the bursting of the shell should asphyxiate the enemy. The fact is, that carbon monoxide is slightly lighter than air, and when driven out by the explosion in a heated condition diffuses upwards so rapidly that scarcely a trace can be found at the breathing level, but when evolved underground in a confined space many accidents have been caused by its poisonous properties.

Moreover, carbon monoxide is in no sense of the word an asphyxiant, and one of its greatest dangers lies in the fact that air containing a poisonous amount can be readily breathed.

Later reports received on Monday and Tuesday make it evident that it was a true asphyxiant, such as sulphur dioxide, chlorine, or a mixture of the two that was employed, and that the fumes generated in front of the German trenches were borne down by a northerly wind upon the Allies. Some descriptions speak of the burning of some substance which gave a yellowish smoke and gases; others that the gases were contained in steel cylinders, the gases being conducted by hose-pipes some little distance in front of the trenches, whilst the men manipulating the cylinders wore divers' helmets, and the first German troops to charge over the gassed area wore smoke helmets or respirators. It is further probable that some shells containing a liquid giving gases of an asphyxiating character were also employed.

It seems to be clear from various descriptions that the gases floated close to the ground for a considerable distance, producing an effect of asphyxiation, which was felt as far as the Allies' second lines.

Both sulphur dioxide and chlorine would have produced the effects described, and the cylinders spoken of might have contained these gases in a liquefied form, whilst it is probable that shells used for asphyxiating purposes would be charged with chloride of sulphur which would itself decompose in moist air or in contact with water into sulphur dioxide, hydrochloric acid, and sulphur, or, if fired by the bursting of the shell, would give sulphur dioxide and chlorine.

Both sulphur dioxide and chlorine satisfy the requirements of being more than double the weight of air, and so might remain near the ground, diffusion being only slow, but it is difficult to understand how sufficient quantities of either gas were produced to render the air irrespirable at the distance of the Allies' lines from the German trenches.

RICHARD LYDEKKER, F.R.S.

Both zoologists and geologists lament the death on April 16 of Mr. Richard Lydekker, who had been for more than thirty years one of the most active workers in the natural history sciences. Born in 1849, of Dutch descent, he was educated at Cambridge, where he graduated in 1871, and was placed second in the first class of the Natural Science Tripos. Joining the Geological Survey of India in 1874, he began his scientific career in the mountains of Kashmir, of which he made a successful pioneer geological exploration. While there his opportunities for sport continued to foster his interest in zoology, and he soon acquired a good knowledge of the mammals and birds of the country. The great collection of Tertiary mammalian remains in the Indian Museum at Calcutta then attracted his attention, and he began a systematic study of these fossils, which he described in the *Palaeontologia Indica*.

With little material for comparison in India, and needing the corresponding collections in the British Museum for reference, Mr. Lydekker soon recognised the necessity of returning to London if his work was to be exhaustive. He accordingly retired from the Indian Survey in 1882, had the fossils from Calcutta sent in instalments to London, and by 1887 had completed the fine series of volumes describing not only the Siwalik Vertebrata, but also the pre-Tertiary Vertebrata of India. At the same time, between 1885 and 1887, Mr. Lydekker prepared for the British Museum a catalogue of the fossil mammals in the department of geology (in five parts), which was followed by similar catalogues of the fossil reptiles and amphibians (four parts, 1888–90), and fossil birds (one part, 1891). Though presenting only a somewhat hasty and superficial view of the subject, these catalogues were at the time of real utility; and they are noteworthy as the first systematic attempt to correlate the European with the more recently discovered American fossils.

In 1893, and again in 1894, Mr. Lydekker visited the Argentine Republic and spent some months in studying the wonderful collection of fossil vertebrates in the La Plata Museum. His work was published in two handsomely illustrated volumes ("Anales del Museo de La Plata," tomos II., III.), and gave the first satisfactory account of several of the peculiar extinct vertebrates of South America. His descriptions of ancestral Cetacea from the Tertiary, and Dinosaurian remains from the Cretaceous, formations are especially valuable. The visits to South America led Mr. Lydekker to appreciate more thoroughly the need for considering the evidence of fossils when dealing with questions of geographical distribution, and in 1896 he published a "Geographical History of Mammals," which is in many respects his most original and important work.

While occupied with purely scientific research, Mr. Lydekker did not overlook the needs of ordinary students, amateurs, and sportsmen, and during his later years most of his numerous writings were adapted for their use. So long ago as 1889 he contributed the volume on vertebrates to the third edition of Nicholson's "Manual of Palæontology," and in 1891 he co-operated with Sir William Flower in "An Introduction to the Study of Mammals." Between 1893 and 1896 he also edited the "Royal Natural History," and wrote the section on vertebrata. Work of this kind was facilitated by his occupation at the British Museum in arranging the exhibited collections of mammals and reptiles in the department of zoology, where he was employed from 1896 until the time of his death. He not only arranged the collections in an admirable manner, but also prepared several valuable guide-books. His last work was a catalogue of Ungulate mammals in the British Museum, of which three parts were published, and the fourth, completing the Artiodactyla, was left by him nearly ready for issue.

Mr. Lydekker was elected a Fellow of the Royal Society in 1894, and was awarded the Lyell Medal by the Geological Society in 1902.

DR. W. J. SELL, F.R.S.

WILLIAM JAMES SELL, university lecturer and senior demonstrator in chemistry at the University of Cambridge, died at Cambridge after a long illness on March 7. He was born at Cambridge in 1847, and for more than fifty years was connected with the chemical laboratories there, and contributed in no small degree to their development and success. He was barely fifteen when, on the recommendation of the master of the elementary school which he attended, he was employed at the chemical laboratory of St. John's College, at that time the only one in the University open to undergraduates. Here he learnt elementary analysis and the use of apparatus, heard the professor's lectures, and saw his experiments. He made good use of his opportunities, and soon made himself an efficient assistant. In 1865, when the Jacksonian professor of natural philosophy removed his apparatus into a new building, the room vacated by him was united with that of the professor of chemistry, and a room built above them for a students' laboratory, the first step taken by the University, in its corporate capacity as distinct from the colleges, to provide experimental training for its students. Here Sell was appointed attendant, and had charge of the apparatus, and not only assisted the professor in the experiments at his lectures, which at that time embraced physics as well as chemistry proper, but was much in demand to help the students, whose notions of making experiments were often crude. The laboratory was a poor place at best in comparison with modern laboratories, but it grew and became filled with students, to which result Sell's help contributed not a little.

In 1870 Sell married, and soon after entered Christ's College and matriculated in the University. He had acquired a good knowledge of chemistry, and of some other branches of natural science, and knew a little of modern languages, but no degree could be obtained at Cambridge without some acquaintance with Latin and Greek, and he had not learnt either. It was a formidable task to begin now, but he faced it with his usual quiet determination, studying Latin and Greek at all times when his duties at the laboratory permitted, passed the examination in both languages, and was then able to take the Natural Sciences Tripos for his B.A. degree. In this he obtained a first class in honours for chemistry in 1876. This success brought him private pupils, and therewith an increased income, very necessary for him because University posts were all meagrely paid; at the same time he took a demonstratorship instead of remaining assistant to the professor. A short time afterwards he succeeded to the place of principal demonstrator.

Although Sell's position in the University, thenceforward to the end of his life, was that of a demonstrator, it must not be supposed that his public teaching was confined to what is usually known as demonstrating, which is mainly done by the junior members of the staff. On the contrary, inasmuch as chemical science was constantly expanding and learners increasing in number, the lectures had to be more specialised and the classes subdivided. The University had not the means to multiply the professors, and so the staff of the laboratory had to meet the demand for more instruction as best they could amongst themselves. In this Sell was most serviceable. He shirked nothing so that the teaching might, so far as lay in his power, keep pace with the growth of knowledge, and for many years was in reality an effective professor, though in name only demonstrator. He was never what is called a brilliant lecturer, but was a sound teacher, who gained the confidence of his hearers, and attracted them by his painstaking sincerity and willingness to help anyone in difficulty.

Sell had been elected a Fellow of the Royal Society of London in 1900, and took the degree of Sc.D. at Cambridge in 1906. An attempt was made to get him promoted to the rank of reader in chemistry. The University has full power to do that, and there were similar applications in connection with other branches of learning, and Sell's friends thought that his distinction as a chemist, and his long and faithful devotion to the service of the University, gave him a claim to promotion at that time before any other aspirant to the same rank. The appointment of readers, however, does not rest with the University at large, but with a board composed of representatives of the various departments of knowledge, literary as well as scientific—in fact, with a body of specialists chosen as such. As always happens in such cases, every member of the board thinks that his foremost duty is to see that his own particular subject of study gets its share of money and places, and magnifies it accordingly, so that the board scarcely ever pulls together for the general advantage, still less to do justice to an individual. No readership was created at that time, and all the recognition Sell got was his appointment to a University lectureship with a stipend of 50*l.* a year.

In his younger days, when it was as much as he could do to maintain his family, he could scarcely spare time for original investigations; but later, when the laboratory was grown up and needed less nursing, he was able to show that he had the capacity for successful research and the will to advance knowledge himself, quite as much as to put others in the way of doing it. He will be best known by his work on pyridine derivatives, to which he was led by previous studies of citrazinic acid. These were the subjects of a large number of communications to the Chemical Society from 1892 onwards. In some of these researches he was assisted by one or other of the advanced students in the laboratory, while in other cases he worked alone. Without going into details, it may be mentioned that from pyridine he obtained eight distinct chloro-derivatives, and from pyridine hydrochloride, in addition, some remarkable dipyridyl compounds. Moreover, he did not fail to demonstrate the chemical constitution of most of the new compounds he discovered. Other subjects of interest investigated by him were the salts of a base containing chromium and urea, and colloid solutions of phosphates. All he did bore the stamp of careful accuracy, and he impressed on his pupils the necessity for sparing no pains to ensure this, if any real advance of knowledge were to be made.

He was so unassuming that only those who had known him long found how much was hidden under that modest behaviour. It really meant that he wished always to do what was right, whether convenient or inconvenient, and to believe other people to be as good as himself.

NOTES.

Dr. H. Kamerlingh Onnes, professor of experimental physics in the University of Leyden, has been awarded the Franklin medal of the Franklin Institute of Philadelphia.

In spite of the war, the usual Dutch biennial congress of Science and Medicine was held this year, at Amsterdam, the first day being April 8. In 1917 the congress will meet at the Hague.

Dr. J. Alexander Murray has been appointed general superintendent of the Imperial Cancer Research Fund, and director of the laboratories, in succession to Dr. E. F. Bashford.

The Meteorological Office announces that Mr. J. E. Cullum retires from the post of superintendent of the Valencia Observatory, Cahirciveen, Co. Kerry, Ireland, and that Mr. L. H. G. Dines has been appointed to succeed him, as from May 1. Mr. A. H. R. Goldie has been promoted senior professional assistant in succession to Mr. Dines at the observatory at Eskdalemuir.

At the beginning of the war the Meteorological Office ceased the issue of weather charts to the newspapers. Announcement is now made that from May 1 the weather forecasts from the Meteorological Office for the several districts of the British Isles will not be available for publication. The only forecasts issued will be in what is known as the harvest weather forecast service. These are entirely local in character, and are telegraphed to agriculturists upon payment of the cost of the telegrams.

The Civil Service Estimates for the year ending March 31, 1916, recently issued, contain various particulars with regard to the sums to be voted for carrying out the provisions of the National Insurance Act. The grant in aid of medical research, to be paid to the Medical Research Fund, is 56,500*l.*, which is the same as for the last financial year. The grant to pathological laboratories to assist in the provision of laboratory facilities with a view to the prevention, diagnosis, and treatment of disease is 25,000*l.*, which is only half that voted for the financial year 1914–15. The sums voted for sanatorium benefit and for the remuneration of panel practitioners remain the same as before.

For the meeting of the British Association to be held at Manchester on September 7–11, under the presidency of Prof. Arthur Schuster, Sec.R.S., the following sectional presidents have been appointed: Section A (Mathematics and Physics), Sir F. W. Dyson; B (Chemistry), Prof. H. B. Baker; C (Geology), Prof. Grenville Cole; D (Zoology), Prof. E. A. Minchin; E (Geography), Captain H. G. Lyons; F (Economics), Dr. W. R. Scott; G (Engineering), Dr. H. S. Hele-Shaw; H (Anthropology), Dr. C. G. Seligman; I (Physiology), Prof. W. M. Bayliss; K (Botany), Prof. W. H. Lang; L (Education), Mrs. Henry Sidgwick; M (Agriculture), Mr R. H. Rew. Evening discourses will be delivered by Mr. H. W. T. Wager on the behaviour of plants in response to light, and by Dr. R. A. Sampson, Astronomer Royal for Scotland.

A monument to the late Prof. J. H. van't Hoff was unveiled at Rotterdam on April 17. It consists of a bronze statue, double life-size, in sitting position, and has been placed in front of the school at which Prof. van't Hoff was educated. The monument is about 30 ft. high, and the statue itself is flanked by female figures representing "Imagination" and "Reason." On the front of the base is the following inscription:—

Van't Hoff,
1852–1911.
Physicam chemiae adiunxit.

The principal speaker at the ceremony was Prof. A. F. Holleman, of Amsterdam, who directed attention to the fact that owing to the war no foreign delegates were present, and that the proceedings in memory of an international investigator were entirely national in character.

It is announced that a committee, under the presidency of the Director-General, Army Medical Service, has been formed to provide the necessary co-ordinating authority for the compilation of an adequate medical history of the war. In connection with each of the chief subdivisions of the work, military and civilian members have been appointed, except in the case of the Section of Hygiene, in which both members are military. The constitution of the committee under the presidency of the Director-General is as follows:—*Medicine.*—Lieut.-Col. O. L. Robinson, R.A.M.C., and Sir William Osler, Bart. *Surgery.*—Lieut.-Col. E. M. Pilcher, D.S.O., R.A.M.C., and Col. F. F. Burghard. *Pathology and Bacteriology.*—Sir William Leishman, C.B., and Capt. F. W. Andrewes. *Statistics.*—Lieut.-Col. H. P. W. Barrow, R.A.M.C., Dr. John Brownlee, and Lieut.-Col. W. N. Barron, M.V.O., R.A.M.C. *Hygiene and Sanitation.*—Col. W. H. Horrocks, K.H.S., and Lieut.-Col. W. W. O. Beveridge, D.S.O., R.A.M.C. *Historical and Secretarial.*—Capt. F. S. Brereton, R.A.M.C., and Dr. W. M. Fletcher. In each section the members of the committee have been given authority to co-opt for the purposes of the section other persons, and it is hoped that in the various sections the best results of the varied experience now being gained will be selected and arranged for publication in the Medical History, and not left to be distributed in scattered communications published independently by individual observers.

The current issue of the *Quarterly Review* publishes a symposium on German "Kultur," and one of the four contributions is by Sir William Ramsay, K.C.B., who deals with the subject as illustrated by German science. He institutes an inquiry as to what share Germans have had in scientific discovery and invention and utilises the data found in "400 Jahre Pionier-Arbeit in den exacten Wissenschaften," by L. Darmstaedter and R. du Bois-Reymond, published in 1904. Between the years 1500 and 1600, out of a total of 176 names mentioned, 39 are German, or 22 per cent. Between 1600 and 1700, out of 312 entries, 48 are German, or 15 per cent. During the next century, the entries are 517, of which 72, or 14 per cent., refer to German discoveries. The period from 1800 to 1850 comprises 901 entries; of these Germans and Austrians form 234, or nearly 26 per cent. Between 1850 and 1900 the records comprise 1021 entries, of which 477, or 46 per cent., can be ascribed to Teutonic sources, but, as Sir William Ramsay points out, it should be remembered in connection with the large percentage of German names in the list that it was compiled by two German savants. The awards of the Nobel prizes are also summarised. "The awards of the Swedish Nobel Committee are unbiassed by any national spirit; four prizes of the approximate value of 8000*l.* are distributed annually, one for physics, one for chemistry, one for medicine, and one for literature. During the twelve years from 1901 to 1912 inclusive, 58 have been awarded, of which 17, or nearly 30 per cent., were received by Germans or Austrians." Similarly the ratio of German and Austrian foreign members and associates of the principal academies of the world is 28 per cent.

On April 20 Prof. H. E. Armstrong opened at Cardiff a conference on the extension of British trade, which had been arranged by the city's Technical Schools Committee and Development Committee. Prof. Armstrong, in his address, which is reported in the *Morning Post* of April 21, pointed out that there is at the present moment much fiery talk of capturing the enemy's trade, but that in view of its many defects an urgent need will be to develop and improve our own trade, and to preserve it from the attacks to which it will be subject, not only by our present foes, but by our Allies and the Americans. To ensure future progress, the general average of intelligence must be raised in the schools, receptivity and plasticity of mind, and some measure of alertness must be cultivated in the students. In addition to English and French, Spanish and Russian should be taught in place of Latin and Greek; for men will be needed to go out and discover exactly what is wanted in the countries which, after the war, will be opened to our trade. These men must be able to talk the language of the people whom they are seeking to make their clients. The proper use of coal is, in the future, one of the great problems which we have to face. No bituminous coal should be used directly as fuel; it should be first converted at least into soft coke, so that the ammonia and tar, which are ordinarily wasted, may be recovered and utilised. This is a duty we owe to ourselves and to posterity on economic grounds, as well as in the interests of agriculture and the internal-combustion industry in particular. Our future success as a nation will depend on the fruitfulness of our scientific research. The possession of enormous organisations such as they have in the great chemical works on the Rhine gives the Germans very great power. They do not hesitate to expend vast sums of money in research; they do not think in niggardly terms—as our Government has done within the past few weeks—of 10,000*l*. a year, but without hesitation spend 50,000*l*. a year on a single problem. Thanks to our schools and universities, not forgetting the Civil Service examiners, the ignorance of our commercial community on all matters scientific is lamentable in the extreme; whilst owing to a literary test only being applied, a specially unpractical type of mind has been selected during generations to administer our public affairs.

Although the wrought flints found in great numbers in Egypt have been discussed in various isolated papers, no detailed survey of them has as yet been accessible to students. This want is now being supplied by Prof. Petrie in the first part of an elaborate survey of the subject in *Ancient Egypt*, part ii., for 1915. Flint-working, he points out, began in archaic times, and gradually blossomed out into the grand style of the splendid forms characteristic of the Chellean and Achulean periods, which no later work has surpassed. The Mousterian and Aurignacian ages reflect the decadence of European man in the third glacial period. In this paper the Egyptian and European forms of implements are carefully and with abundant illustrations correlated. This survey, when complete, will be of great value to students of prehistoric antiquities.

Mr. W. Crooke contributes to part i., vol. xxvi., of *Folk-lore* a paper dealing with the Dasahra, an autumn festival of the Hindus. It is held on or about the autumnal solstice, and thus coincides with the harvesting of the autumn and the sowing of the spring crops. It is hence an important crisis in the life of the farmer, during which it is necessary to control, by means of magical rites, the evil spirits which are active at such seasons. It is also the time when after the close of the rainy season the roads become open, and in older times the warlike classes started on their annual raids. Hence it is regarded as an auspicious time for the commencement of any work of importance. A curious incident in the observances is the release of prisoners or their removal from the capital, lest by virtue of a sort of sympathetic magic the spiritual activities should be trammelled by their bonds or chains. It is thus in its original form a complex of animistic or pre-animistic usages, which have been worked over by Brahmans or courtiers, and have thus become associated with the later Hindu pantheon and with the ceremonial of native courts.

It has often been noticed that an interval of time, marked off by sounds, appears longer than an equal interval marked off by flashes of light. The illusion has commonly been attributed to the so-called visual after-sensation—the persistence of the effect of light upon the retina. A recent research, carried out in the psychological laboratory of the University of California, and reported in the *Psychological Review* for January, 1915, shows that when the intervals are very short (1 sec. or less) and the stimuli repeated, the rate in the sound-series actually appears quicker, as a rule, than the rate in the light-series, although the two rates are really the same. A sound-rate of 154 taps a minute appeared equal to a light-rate of 128 flashes a minute for one observer, and 134 to 150 flashes for others. The higher the rate and the longer the series, the more marked becomes the illusion. Those exhibit it most who depend either upon "general impression" or upon overt tapping with the hand.

The presidential address delivered by Prof. Tufts at the joint meeting of the American and Western Philosophical Associations had for its subject "The Ethics of States." The address is published in full in the *Philosophical Review* for March. The lover of paradox, says Prof. Tufts, can find no richer field than that of the ethics of States. "The State hales private persons before its bar if they violate person or property, break contracts, or enslave their fellows; but itself commits homicide and trespass, breaks treaties, and takes possession against their will of the persons and property of multitudes who have done no harm." The article analyses the historical and logical grounds for these paradoxes. Historically, States have been built by two great forces: lust for conquest and desire of gain. America has learnt the dangers implicit in corporations organised for profit when they are not themselves controlled. The evils of present international politics are due, not to too much, but to too little political organisation. Logically, the doctrine of the survival of the fittest should involve the conclusion that everything that exists is good—the victor is always the better, the king on the throne can never do wrong, the martyr on the cross has never been right. On the contrary, the article urges that competition between nations may be just as unfair and just as much in need of higher control as competition between individuals or companies in business. It concludes the present situation is bringing home to all nations the consequences of past political ideals in all their horror; and that the very appeals which both sides make for moral approval are indications of the emergence of a larger and higher international conscience.

The Ichthyological Laboratory of Astrakhan ascertained the existence of more than sixty representatives of the Caspian fauna in the branches of the lower Volga, some species of Mysidæ occurring at a distance of 180 miles from the sea. A dozen years ago also a number of Caspian forms were found near Saratof by the biological station at that town, and the same forms were found in 1911 by A. Derzhanin in the Volga below Kazan and in the lower Kama, one of which, *Metamysis strauchi*, occurs as far up as Yaroslavl. This is identical with the *M. volgensis* of Tretyakof, to which he assigned an Arctic origin. These Caspian forms Mr. Derzhanin believes to have been left behind on the regression of the Maeotis-Caspian sea (Proceedings of the Naturalists' Society of the University of Kazan, 1912–13).

The Journal of the Department of Agriculture and Technical Instruction for Ireland (No. 2) contains several papers of general interest. Mr. Falkner C. Mason describes a series of experiments which have been carried out during the past year in the veterinary hygiene division of the Department to ascertain how long an injection of tuberculin will confer upon a tuberculous animal the power of resistance to a second injection. This fact has occasionally been taken advantage of by unprincipled persons for fraudulent purposes. In the paper now referred to the trustworthiness of the test in such circumstances has been studied and methods are suggested to counteract any attempt to render the test abortive. The "Boom in Flax" is dealt with by Mr. A. L. Clark, who gives statistics of the extraordinary advance in the prices of this crop brought about by the war. All past records have been broken; not even during the American Civil War has flax realised so high a price as it is being sold at to-day. Mr. Hunter deals with the question of the improvement of the flax crop by propagation from selected plants, a field of work which apparently offers a very hopeful outlook.

The history of the plantation rubber industry of the east is given by Mr. T. Petch in the recently issued part of the Annals of the Royal Botanic Gardens, Peradeniya (No. vii. of vol. v.). The story affects Ceylon principally, where the records have on the whole been carefully kept. It is unfortunate that certain gaps in the early history are due to the lack of proper records during Thwaite's directorship. The successful introduction of Hevea is due to Wickham, and possibly also to Cross, through the agency of Kew; a few plants have probably also been derived from those collected by Collins near Para. Much diversity, both in leaf and bark characters, is noticeable among the trees of the plantations, but there appears to be no ground for supposing that the trees in the east differ essentially from those in Brazil from which fine hard Para rubber is obtained. The reports of Wickham and Cross are reprinted, and careful details are given of the distribution of the original trees in and from Ceylon. An account of the plantations in the east generally is also given, and is followed by chapters on tapping experiments, Brazilian methods, etc. The history of the introduction of Ceara and Castilloa in 1876 and of other rubber-yielding plants is also given.

The Geological Survey of Canada has published as Memoir No. 38, in three cloth-bound volumes, the report of the Chief Astronomer on the North American Cordillera, forty-ninth parallel. The author of this work, Prof. R. D. Daly, acted as geologist to the International Boundary Commission between 1901 and 1906, and the report, circulated in 1915, bears the date 1912 upon its title-pages. The recording of the field-observations in a highly mountainous region was hampered by the absence of large-scale and accurate maps; but coloured geological maps and sections are here published of the whole traverse across British Columbia, from long. 114° W. almost to the coast. Fossiliferous horizons are unfortunately scarce; but the igneous phenomena provided ample material for so keen a worker as Prof. Daly, and have led him to insert as chapter xxiv. an "introduction to the theory of igneous rocks." The possible origin of pre-Cambrian dolomites and limestones by chemical precipitation is discussed with similar breadth of view in chapter xxiii. During hard mountaineering work, the author's mind always sought for explanations, and this adds considerable brightness to his description of the structure of the Rocky Mountains, the Selkirks, and the Cascade Range. An overthrust of forty miles is suggested as one explanation of the grouping of strata in the Clarke Range.

Among recent Bulletins of the Commission Géologique de Finlande, H. Hausen issues (No. 31) a study of types of porphyry found in the glacial beds of south-west Finland, and points out that many of these are still of uncertain origin and cannot be used as guides in estimating directions of ice-movement. In No. 32, he utilises well-recognised types of erratics in tracing the spread of glaciers from Fennoscandia into Russia, and shows how the "Baltic ice," moving mainly from north to south, has locally obscured the traces of the earlier and greater glaciation of Russia by ice from the north-west. One of his maps shows interesting features of drumlins near Dorpat, and a lake at the south end of the Gulf of Riga, held up between the ice-front and an abandoned terminal moraine. W. W. Wilkman (No. 33) deals with the later shore-lines in eastern Finland, and indicates wave-like movements of the ground; while the director, J. J. Sederholm, in No. 37, emphasises the influence of fracture-lines in controlling existing features in Fennoscandia. He urges that fracturing and faulting may characterise the cover which conceals folded masses, and that this zone is commonly removed from considerable mountain-chains. Students of igneous contacts and metamorphism will find much to interest them in P. Eskola's detailed memoir (No. 40), written in English, on the Orijärvi region. The alterations undergone by limestones, siliceous "leptites," and basic igneous rocks consist almost uniformly in the introduction of iron and magnesium and the leaching out of lime and alkalies.

The Canadian Department of Mines continues the issue of its useful publications with the object of directing attention to the mineral wealth of the Dominion and of assisting all who may be inclined to take part in its development. A compact summary of the subject is to be found in a pamphlet of some eighty pages, "Economic Minerals and Mining Industries of Canada," which has been prepared especially in view of the Panama-Pacific Exposition of San Francisco. It contains indeed no particularly novel features, but brings the subject well up to date. Messrs. H. T. Kalmus and C. Harper have published the second portion of their researches upon cobalt and cobalt alloys, this part dealing more particularly with the physical properties of the metal cobalt. Elaborate tests have been made, and are recorded with much minuteness of detail; it might be suggested that the full plate illustration of the testing machine used in making the tensile tests is decidedly superfluous. An elaborate report is published by L. H. Cole upon gypsum in Canada. From the technical point of view this appears to give all the necessary information, but somewhat more attention might have been devoted to the geological problems involved; thus there is no mention of the accessory minerals, such as the native sulphur and the borates, the existence of which in some of the Nova Scotian gypsum deposits has long been known, and which shed a very interesting light upon the probable mode of origin of these deposits. The third part is also issued of the Report on the building and ornamental stones of Canada, this dealing with the province of Quebec. This report also is very rich in detail, and contains much valuable information; attention may be directed to the beautiful coloured plates illustrating the appearance of some of the more notable of the ornamental stones, which are admirably executed.

In the Tôhoku Mathematical Journal, vi., 2, 3, Mr. Kichiji Yanagihara, of Sendai, discusses the history of the Pythagorean equation connecting the sides of a right-angled triangle in Japanese mathematics. Methods of obtaining integral solutions of this equation were given by Matsunaga (eighteenth century), Ammei Aida (1747–1817), who gave a table of the first 292 primitive solutions, Shôzô Kikuma, Tanehide Chipa (1830), and Sôhei Kaneko (1845). The theorem of Pythagoras was in constant use in Japanese mathematics, and many wasanists gave their demonstrations in their works, but owing to the lack of systematic establishment of geometry many of their demonstrations are found to resemble that of Bhaskara's "Behold" method in his *Vîja Ganita*.

It is easily shown that the ordinary linear differential equation of the first order between two variables represents a family of curves such that the tangents at all points having the same abscissa pass through a fixed point on an associated curve S. This method was used by Czuber to obtain an approximate graphical solution of the equation by building up the curve out of consecutive small elements much after the fashion of the common construction for the logarithmic curve. In the Science Reports of Tôhoku Imperial University III., 6, Mr. Tetsuzô Kojima gives a method of obtaining a better approximation than that afforded by the original construction, and further employs graphic methods of a similar character to the approximate solution of certain other first-order equations, including the general equation of the first order and second degree.

The majority of recent researches on thermal radiation deal exclusively with stationary phenomena such as occur in a field when it has attained a state of constant temperature. In a note communicated to the *Atti dei Lincei*, xxiii, (2), 9, 10, Prof. T. Levi Civita has formulated a scheme applicable to the case of a variable field subject to given arbitrary initial and boundary conditions. The investigation is based on the assumption that energy of radiation is propagated with constant velocity, but that the specific intensity of radiation across any surface is not only a function of the temperature, but depends also on the direction of the surface. This hypothesis is necessary in order to account for the transference of heat from a hot to a cold region, Levi Civita represents this effect by the addition of a term in the expression for the intensity containing as a factor the temperature gradient along the direction of the normal. The analytical work leads to the deduction of an equation closely resembling that applicable to conduction of heat in a variable medium.

The April number of *Science Progress* contains an article by Mr. F. Hyndman in which the recent work of Prof. Kamerlingh Onnes and his pupils on the high electrical conductivity of metals at very low temperatures is summarised. In the case of mercury the conductivity at 2·5° absolute is 10^{10} times as large as at the freezing point of water, but Ohm's law no longer holds—the electromotive force required to drive the current increases a thousandfold for a 10 per cent. increase in the current. If the metal is tested in a magnetic field a small increase in the field may produce a similar large increase in the resistance. Dr. C. Davison, in another article, points out that increase of seismic disturbances along a geological fault may herald a serious earthquake and that attempts should now be made to foretell earthquakes in this way. In a further article Dr. J. Johnstone shows the uselessness of considering the organism as a thermodynamic mechanism, since it is continually arresting the increase of entropy which goes on in inorganic bodies. In an essay review of mathematical text-books the author directs attention to the need of mathematical books which will help men of science to use mathematics without having to wade through the present-day text-books, which seem only intended for the use of schoolboys and undergraduates.

Publication No. 9 of the Central Meteorological and Geophysical Institute of Chile consists of a discussion by Dr. Walter Knoche of the Hertzian waves recorded at San Carlos de Ancud in 1913. The wireless apparatus employed gives a continuous record from which the number of Hertzian waves, or atmospherics, can be enumerated. Assuming the apparatus equally sensitive throughout the whole period, and the nature of the atmospherics always the same, the daily and monthly totals show remarkable variability. July had more than 16,900 occurrences, the total for the year—allowing for failures to register—being about 40,000. One July day is credited with the enormous number of 8604. The winter months—the station is in 41° 52′ S. latitude—showed the largest numbers. No clear connection was established with barometric pressure, temperature, wind, humidity, or cloudiness. Rain fell on almost all the days of greatest frequency; but 107 days of the mid-winter months, May to August, were rainy days, so no inference could be drawn. In winter there seemed a distinct increase of atmospherics on days in which thunder was recorded, but in summer this was not the case. The data, however, as to distant thunderstorms do not seem to have been altogether adequate, owing to paucity of stations. A series of tables shows the number of atmospherics recorded for each hour of each day from April to December. For the first three months of the year only daily totals are given.

The damage done to telephone systems in the tropics by animal life was mentioned in the course of a paper and discussion published in the last number of the Journal of the Institution of Electrical Engineers. The culprits are of all sizes, from elephants and giraffes down to white ants and spiders. Mr. W. Ll. Preece described how the giraffes in East Africa, when their progress is impeded by a telephone line, have not the sense to draw back or "duck" their heads, but push on and carry the wires with them—and sometimes the poles too. The only wood which is respected by white ants is teak, and instrument cases should be made of this or of metal. A telephone instrument was shown which had been persistently used as a hive by a swarm of "bee-like insects," who entered by the slot for the switch-hook, and formed a comb inside which they re-formed as often as it was cleared away by the engineers. Instruments and also insulators have an attraction for spiders, and are often rendered *hors de combat* by their webs, but apparently they leave glass insulators alone, although much trouble is experienced in this connection with the ordinary porcelain type. The webs get coated with dew, and the insulation resistance is brought down to a few ohms only. Sir John Gavey said that the trouble was not always caused by the spiders building their webs in the insulators themselves, but that, in the Argentine these insects breed in millions in the pampas grass; as soon as they come to life they spin a single web, which the wind carries across the country, and veils of these webs sometimes collect from pole to pole and cover the whole of the wires. Cases of beetles boring holes in lead cable and laying their eggs in them have also been well authenticated, and Mr. J. E. Kingsbury had an instance of moths making their home in a multiple switchboard cable. Finally, owing to the troubles which not infrequently occur in bringing difficult local conditions into line with the requirements of home administration, one speaker said that the engineer in charge ran the risk of becoming a mere "red-tape worm" himself.

A long and important paper on the compressive and flexural properties of a series of Scottish building and road stones was presented by Mr. Robert Boyle to the Institution of Engineers and Shipbuilders in Scotland on March 23. Twenty varieties of stone, consisting of 211 specimens, were tested. The principal deductions from the tests on Scottish sandstones are as follows. The average ultimate compressive strength for specimens tested dry, at right angles to the bedding, was 479·4 tons per square foot. The average percentage difference in individual results for compression tests varied from 4·3 to 50·3, with a mean of the averages of 23·2 for sixteen varieties. The average percentage differences in individual results in bending tests were much less than in compression, whether dry or saturated. Plaster of Paris coating appeared to have no effect on the ultimate strength of the stone. The crushing strength, hardness, and specific gravity vary approximately as the lime and magnesia compounds, and the crushing strength and specific gravity as the percentage of iron oxides. The crushing and bending strengths vary directly as the specific gravity. The percentage ratio of absorption of water and the percentage porosity diminish as the specific gravity increases.

Engineering for April 23 gives an account of the Brooks Aqueduct, Alberta, Canada. This aqueduct forms part of the irrigation works of the eastern section; last year construction on this section was completed for the irrigation of 440,000 acres. The aqueduct is the first in which the hydrostatic catenary has been adopted for the shape of the water section; it has a length of 10,500 ft., and a capacity of 900 cu. ft. per second, and is the longest aqueduct yet constructed for carrying such a large quantity of water. The reason for adopting the hydrostatic catenary was that the total fall was limited to 4·85 ft. in 10,000 ft., and that consequently it was necessary to use this head to the very best advantage. The water section chosen is the most suitable, as it gives a maximum hydraulic radius for the given area, and a consequent low friction head. Structurally it is economical, for, when full, the shell is in simple tension and free from bending moments and shears. The idea of using this catenary for the water section is due to Mr. H. B. Muckleston, assistant-chief engineer, and it was adopted after experimenting with a full-sized model.

We regret that by an accident at the printing office after last week's Nature had been passed for press, the letter on "The 'Green Ray' at Sunset," appeared on p. 204 without the name of our correspondent, Mr. T. B. Blathwayt.

OUR ASTRONOMICAL COLUMN.

Comet 1915*a* (Mellish).—The following ephemeris of Mellish's comet (1915*a*) is published in *Astronomische Nachrichten*, No. 4796, and communicated by Dr. J. Fischer-Petersen:—

	R.A. (true) h. m. s.	Dec. (true) ° ′	Mag.
April 30	18 43 48	−10 44·6	7·1
May 2	46 54	11 56·8	
4	50 8	13 17·0	6·8
6	18 53 31	−14 46·2	

The comet is still situated in the southern portion of the constellation of Aquila, and lies towards the south-east of the stars 2 and 3 Aquilæ.

A note in the *Astronomische Nachrichten*, No. 4795, gives some further details about the discovery of this comet. In the Monthly Register of the Society for Practical Astronomy (vol. vii., No. 1, January and February, 1915), Mr. Mellish narrates how he first saw the comet on the morning of February 9. Daylight made it impossible to determine any motion of the object, and he had to wait until the following morning, February 10, before he was able to observe its slow movement, and thus recognise the object as a comet. Its position was R.A. 17h. 2m., and declination $+3^{\circ}$ $15'$. The comet is described as being $3'$ in size, bright, and having a very short, fan-shaped tail.

Astronomy and the War.—A correspondent of the *Morning Post* (April 23), writing from Paris on April 22, relates how astronomy is found among the victims of the war. At Nantes, he relates, "an electric tramway built out to an English camp put all the instruments in the observatory for the registration of terrestrial magnetism out of order, and made observation impossible. The observatory of the Puy de Dôme found itself cut off from the outside world at an altitude of 5000 ft. The funicular on which it depended in time of peace stopped working, and all the horses had been commandeered, so that the astronomers had the choice between leaving their post and being starved. Happily the problem was solved by the artillery depôt of Clermont-Ferrand, which undertook the task of provisioning the observatory."

Electric Furnace Spectra of Vanadium and Chromium.—The results of some very interesting experiments with regard to the variation with temperature of the electric furnace spectra of vanadium and chromium appear in the current number of the *Astrophysical Journal* (March, vol. xl., No. 2, p. 86), by Dr. A. S. King. The author has been able to record his observations at three separate temperatures, which he denotes as high, medium, and low. The temperatures on which the classification is based were recorded by a Wanner pyrometer, and were 2500–2600° C. for the high, 2300–2350° C. for the medium, and 2000–2150° C. for the low temperature. The metals used were metallic vanadium and crystalline chromium of "fair purity," and the furnace tubes used were of regraphitised Acheson graphite. The paper gives two tables of the intensities of the lines measured under the three temperatures, together with the arc intensities; several reproductions from the spectra are also included. The conclusions drawn indicate that the spectra of these substances develop similarly to those of iron and titanium, vanadium being very like titanium. The chromium spectrum near the temperature at which the vapour begins to radiate predominates in Class I. lines (lines relatively strong at low temperatures and strengthen slowly at higher temperatures), which change little at higher temperatures. Certain chromium lines, very diffuse in the arc in air, may be resolved into sharp components in a vacuum source, either furnace or arc. A large number of lines belonging to various furnace classes are relatively weak in this arc. The spectrum increases into the utra-violet as the temperature rises. The ability of lines to show self-reversal in the furnace distinctly increases with decreasing wave-length. The absence in the furnace of banded spectra which appear in the arcs of vanadium and chromium indicates that they are probably due to the oxides of the metals.

Recent Papers in the "Astronomische Nachrichten."—A large number of the issues of the *Astronomische Nachrichten* came to hand together last week, and while the material included is of too great and varied a nature to be dealt with in this column, it may help readers to know some of the chief contents. For this reason the following curtailed list of communications is given:—No. 4797: Observations of long-period variables (1914), by A. A. Nijland. No. 4796: Observations of the planet Jupiter, by H. E. Lau. No. 4795: Numerical investigations on a class of periodic orbits, by Carl Burran and Elis Strömgren; observations of comet 1913*f* (Delavan), by A. Abetti. No. 4793: The variable star W Cygni, by G. Hornig; Observations of SS = V 19 Cygni, by A. A. Nijland. No. 4792: Tables for the computation of precession for stars near the pole, by L. de Ball; ephemeris of the periodic comet of Tempel 2, Johannes Braae. No. 4791: Determination of the position of third order points on the moon's surface, by K. Graff and W. Voss; observations of the star BD 89·1°, with the large refractor of the Berlin Observatory, by L. Courvoisier. No. 4787: Observations and elements of the Algol star 10, 1914, R. S. Canum Venaticorum, by Cuno Hoffmeister; elements and ephemeris of the periodic comet of Winnecke for the appearance in 1915, by K. Hillebrand. No. 4786: Definite orbit of comet 1890 III., by S. Ogura and H. Kaneko; observations of Algol stars, by R. Lehnert; the orbit of comet 1913*f* (Delavan), by G. van Biesbroeck. The contents of the Nos. 4777 to 4785 will be given next week.

The "Gazette Astronomique."—In this column for December 24 last reference was made to the proposed publishing in this country of the *Gazette Astronomique*, the monthly bulletin of the Antwerp Astronomical Society, should sufficient financial aid be forthcoming. It is satisfactory to be able to record the appearance of the first number, but its continuance will depend on the support given to it in the future. The present issue contains an interesting account in English of the Uccle Observatory under German occupation, a description of a photograph of Delavan's comet, taken by M. G. van Biesbroeck in September last, a series of notes on astronomical current literature, etc. The first number promises well for future issues.

BRITISH GEOLOGY.

The series of memoirs published by the Geological Survey of Great Britain on the South Wales Coalfield reaches part xi. in the description of "The Country around Haverfordwest" (1914, price 3*s.* 6*d.*). Dr. Strahan is fortunate in having colleagues who, like himself, have become devoted to this particular ground. The district here described includes a considerable development of the Llandovery series, which is divided into local stages, the lowest of which rests, with an occasional conglomeratic facies (pp. 78 and 201), on rocks of Upper Bala age, while the highest stage laps over on to far older series. The Lower Old Red Sandstone is unconformable with the beds below it, and contains plant-remains, which are unfortunately indeterminable. The structure and economic features of the eastern part of the Pembrokeshire Coalfield are described.

The pre-Glacial wave-cut platform recognised in southern Ireland is shown to exist also at Milford Haven (p. 214). Dr. Strahan (p. 220) points out how the older glacial drift of the area was brought in from the north-west, and even from the west, by a lobe of the Irish Channel ice. Through a recent subsidence, the rock-floors of the valleys tributary to Milford Haven lie far below sea-level, and a submerged forest with flints worked by man, which were recognised by A. L. Leach, occurs at Amroth on Carmarthen Bay.

Memoir No. 83 of the Scottish series (1914, price 2*s.*) deals with "The Country round Beauly and Inverness." The names of J. Horne and B. N. Peach are still to be seen happily associated on its cover, with those of younger colleagues. One of the most striking features of the district is the Great Glen fault, which, despite its Caledonian trend, is later than some of the folding of the Old Red Sandstone, and has here a minimum throw of 6000 ft. The river-scenery is finely illustrated, and attention is directed (p. 82) to a deep pre-Glacial channel at the mouth of the valley of the Ness, the rock-floor of which has not been reached at 290 ft. below Ordnance datum. The Strathpeffer Spa, with its sulphur-bearing springs, is the main economic feature of the district. In a region so rich in human history, we wish that a geological survey might trench farther on the field of the geographer and the archæologist.

Drs. Peach and Horne have provided a description of the "Geological Model of the Assynt Mountains" (1914, price 1*d.*), which is exhibited in the Museum of Practical Geology, the Royal Scottish Museum, Edinburgh, and elsewhere. This modestly priced pamphlet, with its numerous sections, forms an excellent introduction for the student to the classic district of the Highland overthrusts.

The memoir to Sheets 110 and 116, entitled "The Geology of Caithness" (1914, price 4*s.*), is by C. B. Crampton and R. G. Carruthers. The maps (2*s.* 6*d.* each) with the memoir show a thinly populated country formed mainly by Old Red Sandstone, and descending from the Highland region northward, until it becomes, in comparison, a plain with "monadnocks," now stretching at about 150 ft. above the sea. Peat, as the useful system of shading shows us, covers a very large area. We miss a reference in the memoir to the old tale of the "Caithness grin," which was said to be developed among a hospitable folk by sighting a stranger across miles of level flagstone. The evidence for a Middle Old Red Sandstone Series, which was sustained by J. W. Evans in 1891, is fully substantiated in this memoir, in consequence of the studies made by Traquair on the fossil fishes. These include the interesting Palæospondylus at Achanarras. We should like to have a further account of the flora of the Caithness strata, beyond the brief references on pp. 5 and 81. The successive stages of deposition of the Old Red Sandstone in "Lake Orcadie" are well shown in diagrams on pp. 84 and 85. A downward warping of the Caledonian continental surface allowed of the accumulation, as Sir A. Geikie long ago estimated, of some 16,000 ft. of Caithness flags. The origin of red strata in a warm and fairly dry climate, where vegetation exists, but not in sufficient quantity to acidify the soil, is discussed in chapter ix. The considerable amount of calcium carbonate in the flagstones is attributed to an arid epoch, here called a cycle, affecting the deposits on the shores.

Thurso Flags (Upper Caithness Flags) cut by a typical ravine or "goe," south of Duncansby Head. Many of these "goes" are of pre-Glacial origin. Reproduced from the Memoir to Sheets 110 and 116, by permission of the Controller of H.M. Stationery Office.

The suggestion (p. 100) of the sudden suffocation of fish by the inflow of alluvium is supported by a recent observation of E. Kolb during his descent of the Arizona canyons. The gills of the fish were, however, in this recent case choked by mud during flooding of the stream, and not in a period of marginal recession.

The nearness of Cretaceous masses to the north-east coast of Scotland, and the possibility of the existence of outliers beneath the Glacial drift, is shown by the account (p. 131) of the Cretaceous sandstone of Leavad, which was recognised by D. Tait in 1906. This block, 240 yards in length, is used as a sand-quarry, and rests on a green clay which, from its foraminifera, G. W. Lee regards as perhaps of Pliocene age. This in turn rests on boulder-clay, so that, as happens in Ostpreussen (NATURE, vol. lxxxv., p. 470), local geology has been distinctly enriched by material imported during the Ice age.

The Geological Survey states that the issue of some of its colour-printed maps is delayed by work necessitated by the war; but it makes its own contribution to military needs in a pamphlet on "Sources of temporary water supply in the south of England and neighbouring parts of the Continent" (1914, price 2*d.*). The waters of sand-dunes, alluvium, and river-gravels are especially considered, and useful warnings are given as to pollution. It is remarked (p. 10) that a well sunk in sand or gravel on a chalk hill may lose its water if carried down to the surface of the porous chalk.

The proceedings of local societies, especially where universities are at hand to provide a stimulus, afford valuable supplements to the publications of the official surveys. The second part of vol. xv. of the Transactions of the Geological Society of Glasgow (price 7*s.* 6*d.*) forms an admirable example. All the papers record original observations in southern Scotland. Prof. J. W. Gregory (p. 174) treats of the red rocks of the Isle of Arran, which he regards as including Permian desert-beds at Brodick. These terrestrial deposits are, he urges, Lower Permian, and the appearance of conformity with the Keuper Marls above may be deceptive. G. W. Tyrrell (p. 188) describes critical sections in spots which he visited at Prof. Gregory's request, and is unable to discover any break in the sedimentation. The papers by P. Macnair, R. G. Carruthers, and J. E. Richey on the lower beds of the Carboniferous Limestone Series will do much to help workers in other districts, such as the north of Ireland. G. A. J. C.

EXPERIMENTAL BOTANY AT TRINITY COLLEGE, DUBLIN.

IN "Notes from the Botanical School of Trinity College, Dublin," No. 5, vol. ii., 1915, Prof. H. H. Dixon gives experimental proof that morbid changes spread through plants from branches killed by heat. If a portion of a branch be killed by heat and the substances dissolved as the result of the heating be washed away, morbid changes only take place after some fourteen days. In cases where no steps are taken to remove the poisonous substances liberated by the heating, the branches above the heated portion show morbid changes in the course of five days. It is clear from the experiments that with the killing of the cells by heat, substances are liberated into the sap which contaminate the water supply to the living tissues above, and that the morbid changes are not due to the cutting off of the supply of water.

In a further paper in the same number of the "Notes" Prof. Dixon gives the result of his investigations into the nature of the changes which are produced in the sap by the heating of the branches. Sap was extracted by means of a centrifuge from pieces of branches, and was examined both fresh and after steaming for the acidity, colour, presence of oxydases and quantity of dissolved substances. The steamed sap showed marked acidity, a much higher percentage of dissolved substance—indicated by the depression of the freezing point—and a development of colour, any oxydase present being, of course, destroyed. The presence of poisonous properties was proved by placing leaves of *Elodea canadensis* in the steamed and in fresh sap, when it was noticed that lethal effects were produced quickly by the steamed sap, and that the leaves would not recover when placed in water.

In a paper on the tensile strength of sap, Prof. Dixon records tensions of about 207 atmospheres and 132 atmospheres in a tube of sap collected from a branch of *Ilex aquifolium*. The former of these is probably the highest yet recorded for the cohesion of any liquid. The tensile strength of the sap of trees, like that of water, is considerable, but it is probably somewhat more stable under tension than pure water. Prof. Dixon and Miss Marshall have also examined the elements of the wood of trees in relation to the ascent of sap, and find no evidence to support Janse's hypothesis as to the intervention of the living cells in the ascent of sap in stems.

Mr. W. R. G. Atkins publishes a series of careful papers on oxydases and their inhibitors in plant tissues, and his work confirms that of Keeble, Armstrong, and Jones. The distribution of oxydases in the flowers of Iris has been particularly studied; when they are kept in darkness, the quantity of active peroxydases increases. In the Pogoniris group an active peroxydase is absent. The localisation of oxydases and catalases in some marine Algæ has also engaged the attention of the author.

ENGINEERING, EDUCATION, AND RESEARCH.[1]

RESEARCH.—Research for the solution of new problems is of great importance, but it is not a task for young and immature students. Many so-called researches, in which well-understood methods are applied to materials or subjects not themselves important, scarcely deserve the name. They amount to little more than class exercises. Most scientific societies receive papers in which a much over-elaborated description is given of known proceedings and precautions, in which the new results are of limited value without establishing any general law. But the value of real research, based on a clear formulation of a definite unsolved problem, cannot be overestimated.

Unfortunately, in engineering, the solution of unsolved but important problems is generally both difficult and expensive. Much, no doubt, is done by manufacturers who have a financial interest in the work. But their researches are, in general, not fully published. It is of great interest to the public at large and to other engineers that a scientific institution like this feels it part of its duty to advance knowledge by research, and is able to devote a fraction of its income for such researches as are beyond the means of private engineers. In most cases, a research committee of this institution begins by an investigation of what has been done before, and the summary of previous investigations which the institution publishes is not only a safeguard against mere repetition of experiment, but is valuable in itself. Prof. Martens, the director of the great State laboratory at Gross-lichterfelde, has said that in four cases out of five when a manufacturer brings him a problem, it is found that it has already been solved somewhere by somebody.

The War and Engineering.—We meet in circumstances not foreseen a year ago. A war of unprecedented magnitude, extending over a vast area, has broken on us with the suddenness and fury of a tropical storm. We are already proud of the courage

[1] From the presidential address delivered to the Institution of Mechanical Engineers on April 16 by Dr. W. Cawthorne Unwin, F.R.S.

and military skill of our Army, the magnificent work of the Navy, and the resource of the Government in meeting extraordinary emergencies. As engineers, we know that our dockyards, arsenals, and armament firms are great schools of technology where the utmost resources of science and experience have been utilised. Victory, if we reach it, as we confidently trust we shall, will largely be the result of the general progress in mechanical engineering and in the capacity of our factories and workshops, due to the concurrent exertions of all engineers, civilian and military.

In this war the question of transport for troops, for munitions, and for food has assumed an importance never experienced before. It is only by the use of every mechanical appliance that a war on the scale of the present one is possible. Conveyance of food, munitions, and troops beyond railheads to the nearest possible point to the firing line depends almost exclusively on motor traction. The vehicles comprise columns of motor-lorries, box-cars, motor-ambulances, motor-omnibuses for troops, motor-cars for officers, steam-tractors for guns and travelling kitchens. It has been necessary to provide large stores of spares and well-furnished repair shops.

I think we may regard the conveyance of the Expeditionary Force as a triumph of organisation. A committee of railway managers, formed before the war, had studied the necessary arrangements. Three hundred and fifty trains were at work, and they arrived at Southampton from all parts of the country, between dusk and dawn, at twelve-minute intervals, during ten days. The troops and their heavy equipment were detrained and embarked without a hitch, and, guarded by the Navy, were transported to Boulogne without molestation.

As engineers, we may recall with pride the words of Mr. Churchill in regard to the ships at the Falkland Islands battle and the cruiser raid. He pointed out that "all of a sudden the greatest trial was demanded of the engines, and they excelled all previous peace time efforts. Can you conceive," he said, "a more remarkable proof of the excellence of British machinery, of the glorious industry of the engine-room branch, or of the admirable system of repairs and refits by which the Grand Fleet is maintained without exhaustion?" In this connection I should like to refer to the reform effected by Lord Fisher, conferring military rank upon the old entry engineers of the Royal Navy. Hitherto, in spite of their invaluable service and the risks they ran, they were rated as civilians. Lord Fisher said that "the unapproached efficiency of the engineers in the Navy merited this tardy recognition of their all-important part in the splendid fighting condition of our whole Fleet."

If in this war the work of the mechanical engineer has assumed a new importance, if success depends on an enormous supply of munitions, if, as Mr. Lloyd George said, "the turning out of munitions of war not merely means success, but means the saving of lives," then a great responsibility is placed on the shoulders of engineers. They are called on for the utmost exertions and perhaps for more sacrifices than others, except those at the front.

Foreign Competition.—Nevertheless a retrospect of our methods and activities is not entirely favourable. *Fas est et ab hoste doceri,* and it is no condonation of the military crime of Germany to recognise that the enormously rapid industrial advance in that country has serious lessons for us. Consider these facts. In sixteen years the aggregate income of Prussia has nearly doubled. While our Mercantile Marine increased from 9 to 10 million tons, that of Germany increased from 1 to 2½ million tons. In 1870 Germany had seven shipyards employing 3000 hands; in 1900 she had thirty-nine shipyards employing 40,000 hands. Although Germany has on the whole poorer qualities of iron ore and coal, her production of pig-iron increased from 11 to 19 million tons annually, while ours increased only from 9 to 11 million tons. To-day her production of steel is nearly twice as great as ours.

Various artificial conditions have fostered German trade, some of which might, and others could not, be imitated with advantage. The German Government is poorer than ours, but it has much more clearly recognised the interdependence of science and industry, and the duty of the State to assist industry in matters beyond private initiative. It has spent very much more in providing the highest type of technical instruction and State research laboratories. The railways and canals being under State control, differential rates can be adopted to help traders. The banks, advised by a staff of scientific, legal, and commercial experts, have been ready to promote the trial of inventions, and to subsidise promising but necessarily speculative industrial undertakings on a scale unknown in this country. Amongst other influences which have adversely affected our manufacturers may be reckoned some perversities of the Patent Law. Hence it has come about that, since the war began, we find ourselves in want of important products we can no longer obtain, and we realise that Germany fights not only with her army, but with her science and industry.

The most striking examples of the plight to which we have been reduced are found in the chemical industries, which, however, involve a good deal of mechanical engineering. Aniline mauve was discovered in this country in 1856, but the Germans, and to a certain extent the Swiss, have practically captured the whole colour industry. Prof. Meldola stated that, in 1886, nine-tenths of the dyeing colours used in this country came from Germany. Yet these are essential to textile industries having an annual output of 200,000,000*l.*, employing 1,500,000 workers. The production of synthetic indigo in Germany has largely destroyed the cultivation of natural indigo in India. The value of imported indigo from India in 1895 was about 3,500,000*l.* At the present time it is about 70,000*l.* Baeyer discovered synthetic indigo in 1880, but nearly twenty years were employed in research and nearly a million pounds was spent before commercial synthetic indigo was placed on the market. That is immensely creditable to German faith in science. Before the war the world's demand for electrical porcelain was practically met by Germany alone. There are many other similar cases. In these industries Germany had no natural advantages, but only a greater scientific intelligence and greater confidence of financiers in supporting scientific advisers.

To take another instance of more interest to engineers. Germany has acquired a practical monopoly of the treatment of the complex ores of the baser metals. The whole of the ores of zinc, lead, and silver from the mines of Australia, the richest in the world, are under contract sent to Germany for reduction. The Australian Attorney-General stated that "German influence exercised a monopoly over the world's base metal industry, so complete that it excluded effective competition."

Happily, in the iron and steel industries we are in a better relative position. Metallurgists here and in Germany, Belgium, and the United States have learned much from each other, and we have no reason for dissatisfaction with our part in the progress made. We had a long lead, and the discoveries of Bessemer, Mushet, William Siemens, Thomas, and Gilchrist, and others kept us in the front rank. We have been outpaced in volume of production, but in the higher qualities of steel and steel alloys, both in investigation and the quality of our product, we still hold a lead.

The large demand for warships, guns, and projectiles has no doubt been a favourable factor. The establishment of laboratories directed by competent experts in steel works and the works of large consumers like the railway companies has tended to the improvement and standardisation of quality.

Nevertheless we do not maintain superiority in all departments. In the heavy steel and machinery trades we have a dominant position, but for lighter machines Germany, the United States, and Scandinavia have secured a large market. In the case of light and medium steel castings—those required for motor-cars, for instance—this country has become almost dependent on Germany and Switzerland. The use of steel castings has very greatly increased, and they add in an important way to engineering resources. So far as a reason can be found for the better and more uniform quality of Continental steel castings, it lies in the adoption abroad of the electrical furnace, and great attention to heat treatment. Many of the steel castings come from Switzerland, where the cost of raw materials must be greater than in this country, and the cost of carriage must balance the lower labour cost.

There is another point. After the war, when happier conditions return, our manufacturers must be willing to give designs, specifications, and estimates in metric measures for countries where the metric system is adopted. The use of the metric system is legalised, but its compulsory adoption is not likely to be enacted, at any rate for a considerable time, if indeed it is desirable, about which a good many of us have doubts. Meanwhile, in many branches the use of a double system of metric and English measures involves little difficulty. In fine machinery no doubt it is troublesome, but that at present must be faced.

Technical Education.—Samuel Butler said that life is the art of drawing sufficient conclusions from insufficient premises. It is certainly true of the engineer, not engaged in mere repetition work, that he has constantly to arrive at conclusions and to act on insufficient data. Probably no difficult engineering problem has ever in the strict sense been completely solved. The engineer has to make assumptions, to use approximate theories, to decide between material and negligible considerations, and to allow for unknown contingencies. Now, scientific training, if sufficiently advanced, does enable us to solve most problems which are clearly stated and data given, but its usefulness does not end there. The trained engineer with incomplete data reasons correctly, estimates probabilities, and knows the limit of the trustworthiness of his conclusions. He does not snatch at a pocket-book rule and ignore the assumptions on which it is founded.

Among the various causes which have contributed to German industrial development, a thorough and widely diffused technical education must be given an important place. The branches of industry in which Germany has acquired a dominant position are those in which advanced applications of science are most necessary.

In the highest branches of scientific discovery this country has held a very distinguished place. That has been largely due to men who pursued science without regard to any practical end, or even with a certain disrespect for the fruitful applications of science. The value of this pursuit of pure science is, of course, not to be underrated. Manufacturers, on the other hand, who are interested only in applications of science, have been a little contemptuous of scientific men who seemed indifferent to business. All that is no doubt gradually changing. The means of obtaining technical knowledge, and the desire to take advantage of it, have increased. But even yet we have no institutions quite equivalent in buildings, equipment, and staff to the great technical high schools on the Continent. In Germany and Austria, excluding chemists, there are four or five times as many students in technical high schools as in colleges of corresponding rank in Great Britain. America, Belgium, and Switzerland in this respect have closely followed Germany.

But now, putting aside political and moral considerations, it is the thorough and advanced character of the education in the technical high schools and the researches of their professors, to which indeed many of us are greatly indebted, which have so directly promoted German industry. It is sometimes said that the Germans only pick up other people's discoveries and apply them. I think that is untrue, or at least greatly exaggerated. As Dr. Ormandy has well said, "those who adapt scientific discoveries to industrial use are as entitled to honour and reward as those who made the original discovery." But there is another aspect of education in Germany which has a lesson for us—the German secondary school is far more efficient than ours. Lord Haldane said that "in this country we have never understood the significance of the secondary school. In Germany the whole educational fabric rested on it." Secondary education in Germany is State-supported and definitely graded. The Gymnasium, the Real-Gymnasium, and the Real-Schule are organised to meet the wants of boys intended for different careers. Further, the universities, the professions, and higher Government appointments (including those on railways) are practically closed to all who do not pass a severe State maturity examination after nine years' schooling. The precise arrangements differ in various States, but in each there is an organised system and great pressure on boys to reach a high standard. Also those who pass the maturity examination are excused one year's military service. The importance of that for us is that a great obstacle to really efficient technical instruction in this country is the inadequate preparation for it in the schools. Practically a year of the three years' college course must be given to work which could well be, and ought to be, acquired in school by lads of seventeen or eighteen. Perhaps the excessive attention to athletics has something to do with our intellectual shortcomings.

I have spoken of the value of an advanced type of technical education for engineers who aspire to positions of responsibility, but I do not overlook or underrate the necessity of practical experience. Both are necessary, but one should not be cut down at the expense of the other. There are many branches of engineering, and as to the relative importance of technical instruction, workshop, field, and office training, in different cases, there may be differences of opinion. Further, I am far from advocating the Germanisation of English education. Only it seems to me that some of our educational tools, like some of our workshop tools, are medieval and out of date, and that some of our faults need a remedy. If, as I suppose, the cost of the war must be paid out of the profits of industry, it is of importance that our efficiency should be increased. Sir George Reid has said that "captures of German trade in time of war will only be retained in time of peace by the capture also of the scientific methods of the Germans."

Testing Materials.—Half a century ago, most materials of construction were selected and bought on the reputation of the manufacturer. Experience roughly indicated the sources from which the most trustworthy supplies could be obtained. Now scarcely any material in large use is accepted without special testing in the interest of the purchaser. Such testing is primarily intended to distinguish suitable and unsuitable material and to protect the user from carelessness or fraud. But it has also acted as a stimulus to manufacturers to standardise and improve their products. Once it is known how good a quality can be produced, all manufacturers strive to reach it, and the average quality is raised. The rapid development of cement and of the higher qualities of steel has depended on the determination of their superiority by accurate tests in the properties required for special services.

With the introduction of mild steel, the quality of which ranges between wide limits, the need of systematic testing became urgent. Now there are testing laboratories in the works of most railway companies and in steel works. Also the practice of testing has been adopted in the case of many other materials. With the extension of testing has come the need of standardising tests themselves, a work now largely accomplished by the International Association and the British Standards Committee. But with the increasing stringency of specifications, perhaps more attention should be given to the calibration of the instruments used in testing. In physical investigations great attention is given to the determination of the errors of instruments and methods, and perhaps in material testing this has received too little attention. I do not suppose there are important errors in the indications of large testing machines, though a comparison of results in different laboratories would be interesting. Errors in subsidiary apparatus are probably more frequent. It is possible with a standard bar and a good extensometer, used by the same practised observer to measure the agreement or disagreement of different testing machines. I have found also the use of copper cylinders subjected to crushing to be a very convenient means of checking load indications of machines.

On the Continent and in the United States there are public laboratories, supported by the State, where anyone can have tests made, at moderate fixed rates, by a trained scientific staff and with great accuracy. Such institutions assist industry if, on one hand, they meet industrial requirements, and, on the other, are unbiassed by private interests. They have the advantage over private laboratories that they are under the direction of experts of exceptional experience and reputation, and are able to pursue investigation, continued often for long periods, beyond immediate requirements into fruitful by-paths. The view taken in Germany is that the work accomplished is partly of advantage to the manufacturer who calls for assistance, and so far should be paid for by him, and partly is of advantage to the nation in advancing science, which is the justification for a State subsidy. Hence it is incumbent on the public institution to publish results as freely as is possible without injuring private interests.

At Grosslichterfelde the annual income from fees for testing amounts to 20,000*l*., and the annual State subsidy is 12,000*l*. On the staff there are 230 persons, of whom seventy-five have had university training and thirty-eight technical high-school training. Since 1880 the work accomplished has steadily and regularly increased.

The Bureau of Standards at Washington is on a still larger scale, and does very similar work. It receives an annual subsidy from the Federal Government of 100,000*l*. The equipment is extraordinarily complete. For instance, it has a 600-ton testing machine at Washington, and a 1000-ton testing machine at Pittsburgh, both of the highest sensitiveness and accuracy. Such machines do not exist in this country. Happily, we have now a similar institution in the National Physical Laboratory at Teddington. Its functions are somewhat restricted by the characteristic English jealousy of State action, which I think is diminishing. It would be difficult to overestimate the service it has done in the solution of various mechanical, electrical, and physical problems which were unlikely to be attacked by private persons. Some of the researches started by this institution have been carried out there, and valuable papers contributed to our Proceedings. The superiority of English aeroplanes has been demonstrated, and their services for scouting and for directing artillery fire have been invaluable. When the Government required difficult experimental investigations to be carried out on aeroplanes, it found at Teddington a staff and an organisation already in existence and suited to the purpose.

It is a condition of commercial testing that the results should be available in a short time and at small expense. Hence ordinary tests are of a somewhat arbitrary character, and do not completely imitate the conditions of actual service. We test specimens of steel to destruction and measure ductility by plastic deformation, though in use the stresses do not exceed the elastic limit and the deformation is elastic. We test cement in tension and use it in compression. There is need for constant criticism of methods of testing and for the invention of new tests, such as tests for hardness and brittleness, although new tests must be cautiously introduced.

One small change could be easily made, and in some cases would be interesting. When a set of tests on a material has been made, the mean of the results is taken as the best value of the property measured. In physical investigations generally a further step is taken by calculating what is termed the "probable error," which broadly is a measure of the trustworthiness of the results. Calculation of the probable error is troublesome, but Martens has pointed out that the "mean error" is nearly as accurate, and good enough for practical purposes. The mean error is the sum of the deviations of the individual results from the mean, irrespective of sign, divided by the number of observations. The mean error is conveniently expressed as a percentage of the mean value. If the mean error is large, either the method of testing, the uniformity of the material, or the preparation of the test specimens is at fault. Generally the source of the error can be inferred. A large mean error in tests of steel would indicate want of uniform quality in the material, in cement—probably faults in preparing the test briquettes. Of two supplies of a material, that with the smallest mean error is preferable.

There is another kind of testing, likely in the future to be of increasing importance—that is, the measurement of strains in members of completed structures in order to determine the stresses to which they are actually subjected in service. Some years ago, after the loss of the *Viper*, measurements of the strains in the skin of a torpedo-boat slung in various ways were made at the request of the Admiralty. The object was to obtain information on the stresses in a structure supported on waves. Strain measurements on the members of bridges during the passage of trains have been made in Holland, in France, by Mr. La Touche and Mr. Sales in India, and by Prof. Turneaure in the United States. These observations throw light on two points—the trustworthiness of theoretical calculations of the stresses and the magnitude of the stresses due to dynamical actions which cannot be calculated. Recently Mr. I. E. Howard, engineer-physicist at the Bureau of Standards, has initiated a very extensive investigation which is to extend to large bridges, the Panama lock-gates, and steel-framed buildings. Some results on the stresses in the shell of a simple cylindrical tubular boiler have been published. A cylindrical boiler shell is a very simple structure, and the straining action is statical. It might be expected that theoretical calculations of the stresses would in that case be approximately verified by the observations. In fact it is not so. The distribution of stress is very much less uniform than it is assumed to be in theory and in the design of boilers. Of course, this is chiefly due to angle-irons and joints, which in most cases reduce the stresses, but, at any rate, greatly modify the stress distribution.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Glasgow.—The course of instruction in engineering for the B.Sc. degree is conducted upon the "sandwich" system. Under this plan, the laboratory staff is occupied during the six winter months in providing the prescribed lectures and demonstrations for the students. During the months April to October the ordinary students obtain their practical training as pupils in the various engineering works of the district. In summer the laboratories are accordingly employed only for special forms of instruction and for research. This year, at the close of the winter session, Prof. Cormack and his colleagues—lecturers, assistants, demonstrators, and mechanics—offered their services through the principal of the University to Lord Kitchener for any purpose connected with the production of munitions of war, which he might think fit to indicate. The Secretary of State, through the Master-General of the Ordnance, has cordially acknowledged the offer of the staff, and promises speedily to inform the University as to the manner in which it may be utilised to the best advantage. In the meantime, the Admiralty has, with the sanction of the University Court, made arrangements for using the equipment of the laboratories, and in particular of the testing machinery, for the purpose of testing the specimens of steel and other metals employed by the contracting firms who are manufacturing shells, etc. Prof. Cormack and Mr. Morley, lecturer on heat engines, have undertaken to supervise the operations under the direction of the Admiralty inspector. A large proportion of the engineering students, who completed their course at the graduation in April, have found places in the munition factories.

London.—Among the public lectures, which are open to the public without fee, to be delivered at University College, during the present term, are the following:—April 29: Prehistoric Egypt, Prof. W. Flinders Petrie; April 30: Serbian ideals, Miss Annie Christitch; May 3: The principles of technical evaporation and distillation, Dr. W. A. Caspari; May 4: Hindu religions, Prof. L. D. Barnett.

Oxford.—Prof. J. Mark Baldwin, honorary professor of the University of Mexico, formerly professor of philosophy and psychology in the Johns Hopkins University of Baltimore, has been appointed Herbert Spencer lecturer for the year 1915–16.

According to the *Korr. Norden*, lectures in the University of Berlin will be greatly reduced, on account of the number of professors and students at the front.

We learn from *Science* that under the will of the late General Charles H. Pine, recently published, Yale College will eventually receive an addition of 30,000*l.* to the 10,000*l.* scholarship fund established by General Pine about three years ago. The will also provides for the creation of a fund of 50,000*l.* to be devoted to manual training of Ansonia boys and girls. From the same source we learn that by the will of General William D. Gill, of Baltimore, the Johns Hopkins University is made residuary legatee after the death of his wife. The bequest is to be used for the establishment of a chair of forestry. The sum of 5000*l.* has been contributed by Mr. P. S. du Pont toward the University of Pennsylvania Museum extension building fund, which now amounts to more than 20,000*l.* As soon as the fund amounts to 100,000*l.*, the building of the next extension will be started.

The Civil Service Estimates for the year ending March 31, 1916, include a vote of 145,000*l.* for special grants in aid of certain universities, colleges, medical schools, and agricultural institutions, to meet loss of income arising during the war. It is pointed out that certain of the universities, colleges, and other similar institutions which are in receipt of Parliamentary grants have been adversely affected by the war, more especially by the loss of fee income arising from the widespread response among men students to the call for recruits. The special grants in aid will be used to give such assistance as may be necessary to save the institutions in question from suffering serious permanent detriment from the temporary emergency. The expenditure of the universities, colleges, and other institutions out of the grants will not be accounted for in detail to the Comptroller and Auditor-General, nor will any unexpended balances be surrendered by the payees at the close of the financial year.

Dr. H. B. Gray, formerly headmaster of Bradfield College, has recently been appointed official lecturer at the Imperial Institute in order to give short lectures on the resources of the countries of the Empire, illustrated by the collections of exhibits which are to be seen in the various courts assigned to those countries in the public exhibition galleries of the Institute at South Kensington. Since the beginning of last month a succession of such lectures has been delivered at the institute by Dr Gray, chiefly to schools in London and its neighbourhood, in connection with the school teaching of the geography of the Empire. In addition to these lectures to schools, it is now intended to arrange a weekly lecture in the exhibition galleries, of a less formal kind, for members of the general public in connection with the exhibits illustrative of the present condition and resources of the Colonies and India. The first of these lectures will be given on Wednesday, May 12, at 3 p.m., on Canada and Newfoundland, and will be followed each week in May on Wednesdays, at 3 p.m., by short illustrated lectures on other countries of the Empire in turn. A separate announcement will be made with regard to the lectures in June. No charge will be made for these lectures. Admission will be by ticket, to be obtained at the Imperial Institute, South Kensington. The number attending each lecture will be limited to fifty.

The Journal of the Institution of Electrical Engineers contains an interesting paper and discussion on training for the industrial side of engineering. The paper is by Mr. A. P. M. Fleming, who described the apprentice school which the British Westinghouse Company established a year ago at their own works. Instruction averaging about five hours a week is given during working hours to all bound apprentices, numbering altogether about 300. The regular rate of wages is paid during the time spent in this way, and the cost of books and stationery is also defrayed. Teaching is done by twelve members of the engineering staff, supplemented by lectures from the leading foremen and shop engineers. Ten of the most promising apprentices are selected each year and sent for one whole day a week to the course for engineering apprentices at the Municipal School of Technology, Manchester. Mr. Fleming emphasised the unsuitability of the evening classes in most industrial centres for "trade" instruction, which he thought was of comparatively little use to the youth who would be a workman all his life. On the other hand, he considered evening technical instruction excellent to give youths possessing ability and determination a means of rising from non-technical to technical employment. Prof. E. W. Marchant endorsed what Mr. Fleming had said with regard to evening classes, and said that it seemed to him a physical impossibility for a man engaged in manual or other labour during the day time to study effectively if he gets his technical education in the evening. On the other hand, Prof. Miles Walker, of the Manchester School of Technology, said that although day classes were better for those who could attend them, as the students would be fresher and better able to utilise their faculties, yet the men who came after their day's labour was over and did really good work three evenings a week with home lessons on Saturdays and Sundays must possess admirable qualities. Mr. J. Collinge referred to the difficulty of training young men engaged in central stations, who had not been able to afford college training, as owing to the character of the work and the hours they had to be employed they were largely prevented from regular attendance at technical schools, and consequently frequently found themselves in a "blind alley."

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 22.—Sir William Crookes, president, in the chair. Lord **Rayleigh**: Deep water waves, progressive or stationary, to the third order of approximation. The principles of hydrodynamics are applied to form the equations of wave-motion to the third order of approximation without restriction other than that the motion is irrotational and in two dimensions. The results are then applied to the progressive wave of permanent form, as investigated by Stokes, and to stationary waves. It appears that the form of the latter at the moment of greatest deviation from mean level is the same as that of the permanent progressive wave, but that the periods of vibration corresponding to the same wave-length are different.—Hon. R. J. **Strutt**: A chemically active modification of nitrogen, produced by the electric discharge. VI.—Dr. C. **Chree**: The difference between the magnetic diurnal variations on ordinary and quiet days at Kew Observatory. The paper considers the difference between the diurnal variations of magnetic force at Kew Observatory on quiet days and ordinary days (*i.e.* all days with the exception of those of large disturbance). The data employed are from the eleven years 1890–1900. Taking mean data for the whole year, the difference in the horizontal plane may be regarded as consisting, to a first approximation, of a harmonic oscillation of twenty-four hour period along a direction inclined 64° east of north and of a regularly progressive non-cyclic change in a second direction which is perpendicular to the former. The result, while true of the days of the year as a whole, is only imperfectly exhibited in most individual months.—F. **Horton**: The effects of different gases on the electron emission from glowing solids. An investigation has been made of the ionisation produced by a glowing Nernst filament when used as a kathode in a discharge tube in the presence of various gases of different chemical affinities for the material of the filament. It has been found that the actual electron emission from the filament is independent of the nature of the surrounding gas, at least for the gases, air, nitrogen, oxygen, and hydrogen, for at low pressures the thermionic currents measured under similar conditions in these gases were practically the same. At higher pressures the thermionic currents differ considerably owing to the effect of ionisation by collisions being different in the different gases. The increase in the current due to ionisation by collisions in hydrogen is much greater than it is in air, oxygen, or nitrogen. The experiments were repeated with a Nernst filament covered with lime, and it was similarly found that the electron emission from lime under these conditions was not increased by hydrogen, although earlier experiments have shown that lime heated on platinum gives a much larger electron emission in hydrogen than it does in air. This appears to be caused by the hydrogen increasing the emission from the platinum, an effect which has been shown by H. A. Wilson to be due to the absorption of hydrogen by the metal. Lime and the oxides of a Nernst filament do not absorb hydrogen, and the electron emission from these substances is therefore unaltered by the presence of this gas. That the electron emission from an oxide kathode is the same in oxygen and in hydrogen, gases which have very different chemical affinities for the material of the kathode, is evidence against the theory which has lately been put forward, that the electron emission from a glowing solid is due to chemical action between the solid and the surrounding gas.—W. S. **Tucker**: Heats of dilution of concentrated solutions. More detailed study of the variation of heat of dilution with concentration is here described than has hitherto been published. Dilution was performed by short steps by addition of water at air temperature. Specific heats of solutions were accurately obtained for various concentrations so that heats of dilution could be calculated for any mean concentration. Solutions of hydrogen and lithium chlorides and sodium hydroxide give results which appear to show a linear relation with mass concentration, for the range over which heat of dilution has an appreciable magnitude. Curves are shown which indicate that this heat of dilution, if that linear relation be accepted, will vanish at such concentration as will suggest the formation of some simple hydrate of the solute. Thus the straight line connecting heat of dilution and mass concentration for hydrochloric acid solutions will, if produced, cut the axis of concentration at $HCl,15H_2O$. Solutions of lithium chloride and sodium hydroxide similarly yield hydrates $LiCl,8H_2O$ and $NaOH,8H_2O$.—T. R. **Merton**: The origin of the "4686" series. An attempt has been made to obtain some information as to the origin of the "4686" series by measurements of the relative breadths of the "4686" line and the helium lines, from which the relative masses of the atoms concerned can be calculated according to the relations which have been found by Lord Rayleigh, Michelson, Buisson and Fabry, and others. The conclusion arrived at is that either the breadth of the "4686" line is controlled by circumstances at present unknown or that the line originates from systems of subatomic mass.

Zoological Society, April 13.—Mr. E. T. Newton in the chair.—E. **Gibson**: The Ñato cattle of the Argentine. The author exhibited the skull and a photograph of some specimens formerly in his possession which he believed to be the last of the breed.—Dr. G. E. **Nicholls**: The Urostyle (*Os Coccygeum*) of the anurous Amphibia.—G. A. **Boulenger**: The snakes of the Belgian and Portuguese Congo, Northern Rhodesia, and Angola. The paper contained a list of all the species known to inhabit this region, with keys to the identification of the genera and species, and the descriptions of two new forms from Angola and Katanga.—Dr. R. **Broom**: Some new carnivorous Therapsids in the collection of the British Museum. Most of the specimens described have been for many years in the collection, but owing to their small size and imperfect condition they have not hitherto been recognised as new. Five species, belonging to four new genera, are Therocephalians. Two species, one of which belongs to a new genus, are Gorgonopsians, and one is a new species of a previously known Cynodont genus.—Dr. R. **Broom**: The organ of Jacobson and its relations in the "Insectivora" Tupaia and Gymnura. Gymnura is shown to have the same type as is found in Erinaceus, Sorex, and Talpa, and most higher Eutherians such as Felis, Lemur, Miniopteris, Ovis, Bos, Equus, Procavia. Tupaia, on the other hand, has, like the allied Macroscelides, the primitive marsupial type. Peters and Haeckel in 1864 and 1866 had suggested separating Tupaia and Macroscelides as a suborder of the Insectivora, but the condition of the nasal cartilages shows that the Menotyphla should form a distinct order, not even closely allied to the typical Insectivora.

Linnean Society, April 15.—Prof. E. B. Poulton, president, in the chair.—C. F. M. **Swynnerton**: Experiments and observations on the interpretation of form and coloration in plants and animals. Food-preference and other experiments were carried out over five years on insectivorous and (later) carnivorous, egg-eating herbivorous, and other animals, and numerous field-observations made. The work was attempted on a large scale and with every precaution, experiments on captive insectivorous birds were checked (and confirmed), by a series of experiments on wild birds, and various objections to a selectionist view specially tested. Numerous "deterrent" defences were found definitely to exist; also the finest gradation from those species of animals and plants that are only eaten through hunger, to the few that an individual enemy will eat to repletion-point. This indicated that the need for distinguishability from pleasanter forms (apparent and otherwise) is, and has been, widespread, and, with the numerous mistaken attacks and unmistaken refusals witnessed, suggested a contributory explanation for "distinctiveness" and diversity generally. Wild fruits were also "graded" by their eaters, and preferences shown by insects and birds as between even their own flowers; insect-hunting bird-parties were watched on a few occasions visiting exclusively particular temporarily-infested species of trees; and the utilisation of appropriate characteristics by animals for intra-specific recognition was amply illustrated by field-observation. Thus "distinctiveness" (and differentiation) may have been very widely selected in relation to "friends" too. Abundant observation of unmistaken attacks on prey and the latter's reply thereto testified to the great importance of the procryptic and actively evasive defences and to the fact of their appropriate utilisation. Moreover, enemies were seen to return expressly to stationary prey that they had not been hungry enough for on first discovery, and the view that a special handicap may prohibit conspicuousness in a group, a species, a stage, or a sex was confirmed otherwise too. That it is through the existence or development of suitable counter-agents (as flight, nauseousness, procryptic underside, and special habits) that whatever factors make for conspicuousness have been together enabled (in another species, sex, etc.) to produce it, was shown; and several such factors were indicated, including sexual selection. Animals were deterred by resemblances in prey, and a double potential basis for mimicry was found definitely to exist; also a basis for synaposematism (in flowers synepisematism) in the observed effect of the more numerous reminders and simplified recognition that a link in appearance or smell would afford. Probable cases of mimicry were seen and tested in plants, eggs, and birds. More than 800 attacks on butterflies by wild birds were witnessed. Discriminative action that might contribute to selection was actually observed at work, interspecifically (as in the preferences shown), and intraspecifically (in choice of largest available prey, destruction, or artificial entry of inconvenient ornithophilous flowers, and individual destruction through the inactivity of extra-floral nectaries).

Mathematical Society, April 22.—Sir J. Larmor, president, and afterwards Prof. Love, vice-president, in the chair.—G. H. **Hardy**: Note on Dirichlet's divisor problem.—Col. R. L. **Hippisley**: Note on a new form of closed linkage.—G. B. **Mathews**: Division of the lemniscate into seven equal parts.—Sir J. **Larmor**: The influence of the oceanic waters on the law of variation of latitude. The prolongation of the periodic time of the small free orbital motion of the pole over the earth's surface from 304 to 428 days has been recognised to be due to the centrifugal strain of the earth's rotation changing in step with the changing axis of rotation. This regular circular precession is found to be strongly disturbed by irregular surface displacements of terrestrial masses. But among these disturbances the adaptation of the ocean surface to the changing axis ought not to be included, for being synchronous with the precessional motion it must affect its period, and so fundamentally alter it instead of merely disturbing it. It is roughly estimated that if the earth were elastically unyielding, the effect of the existing ocean would be to lengthen the period of free precession from 304 to about 332 days. The remainder of the actual increase to about 428 days would be, as now, ascribed to elastic centrifugal strain of the solid earth, and the necessary slight revision of current estimates of its yielding is made on this basis. The question is broached, What would be the course of history of a planet so nearly spherical that the incumbent ocean would destroy secular stability for all possible axes of rotation?

Dublin.

Royal Irish Academy, April 12.—Rev. J. P. Mahaffy, president, in the chair.—Rev. P. **Browne**: An integral equation proposed by Abel, and other functional equations related to it. The paper deals principally with the equation, $\int_a^b G(t)f(tx)dt = g(x)$, where G and g are known functions, and f is to be discovered; a and b are constants. Abel gave this equation as a generalisation of the problem of the isochrone, stating he had solved it, but the solution does not appear in his published works. A solution is found involving integration along an infinite straight line in the plane of the complex variable. By extensions of the method, the equations,

$$\int_b^a G(x, t) f(tx)dt = g(x), \quad \int_0^{r}\int_0^{t} G(t, \tau) f(tx, \tau y) dt d\tau = g(x, y),$$

and others, are solved.—A. J. **Rahilly**: Some geometrical determinants. The geometrical determinants dealt with are of the type exemplified in Frobenius's theorem connecting the mutual powers of two quintets of circles. It is shown by a very simple method that similar determinantal relations exist between many sets of geometrical entities; in fact, a large part of the metric geometry of the point, line, circle, plane, and sphere may be reduced to such determinant-equations. Some new applications are given; in particular, Ptolemy's theorem, which is a special case, is given several extensions.

Royal Dublin Society, March 23.—Prof. W. Brown in the chair.—Prof. J. **Wilson**: Simplified solutions of certain Mendelian problems in which factors have inseparable effects. The author makes use of two simple observations to prove certain problems discussed in a previous paper on unsound Mendelian developments. The observations are:—(1) If one or more groups in a set of hybrids' progeny carry a character outside those producing the set, that character is common to all the groups in the set. For instance, if the characters carried by the four following groups have been found as set down, namely: agouti, 9XY; cinnamon agouti, 3Xy; black, 3xYZ; chocolate, 1xy; then the character Z is carried by the three remaining groups, for otherwise black would differ from agouti and chocolate in more than one pair of characters, and from cinnamon agouti in more than two. (2) A character carried by more than half the groups in a set of hybrids' progeny is common to all the groups in the set. For instance, if the characters of three of the four groups in a set have been found as follows: agouti, 9XYZ; dilute agouti, 3; black, 3xYZ; blue, 1xYz; then dilute agouti must also carry Y, and, by the symmetry of the set, the additional characters X and z.—Miss A. **Wilson**: Changes in soils brought about by heating. The increased productivity of soil which has been subjected to different degrees of heat has been studied by E. J. Russell and F. J. Seaver and E. D. Clark. Russell suggests that the increased productivity is due to the increase in the number of nitrifying bacteria consequent on the destruction of the larger organisms by heat. Seaver and Clark and others maintain that the heated soil owes its greater productivity to the increased amount of soluble matter due to the decomposition of soil constituents. In these experiments extracts of suitably prepared soil heated to various temperatures between 60° and 150° during periods of two hours were obtained. The depression of freezing point and the electrical conductivity of each solution were then determined. It was found that there was a marked range in the coloration of the solutions thus obtained, and each solution gave a marked reaction to litmus. The amount of water retained by the heated soil was also noted in one set of experiments, and found to increase with the temperature to which the samples were heated. Throughout the experiments the depression of freezing point and electrical conductivity showed a marked increase in the solutions obtained from samples heated at the higher temperatures.

Paris.

Academy of Sciences, April 19.—M. Ed. Perrier in the chair.—A. **Müntz** and E. **Lainé**: Studies on the agricultural value of the sediments carried by the watercourses of the Alps and Pyrenees. From the chemical point of view, these sediments have nearly the same proportions of fertilising materials as good average arable soils. They vary greatly in physical properties and measurements were made of the apparent density, porosity, capacity for water, and permeability of sediments from different sources. The permeability varies greatly, and the fine sediments tend to choke the irrigated soil. Experience has shown agriculturists making use of irrigation the best means of dealing with this tendency to impermeability.—C. **Guichard**: A series of surfaces and the equations of Laplace which are reproduced by a transformation (m, n) of Darboux.—V. **Grignard** and Ch. **Courtot**: Benzofulvanol and benzofulvene. Starting with the magnesium compounds of *cyclo*pentadiene, indene, and fluorene, and treating these with aldehydes and ketones, secondary and tertiary alcohols are obtained which have been named fulvanols, benzofulvanols, and dibenzofulvanols, and these, by dehydration, give the corresponding hydrocarbons. The preparation is described of the benzofulvanol obtained from indene magnesium bromide and trioxymethylene and the hydrocarbon benzofulvene obtained by its dehydration.—M. **Riquier**: Partial linear systems composed of equations equal in number to those of their unknown functions.—Rodolphe **Soreau**: Circular anamorphosis.—Pierre **Humbert**: The piriform figure of equilibrium of a fluid mass. Prof. Poincaré and Sir G. H. Darwin came to opposed conclusions as to the presence of points of inflexion on the section by a symmetrical plane of the equilibrium figure of a fluid mass in rotation. The author concludes that there are no points of inflexion and the calculations of Poincaré, pushed to the end, lead to the same result as those of Darwin.—B. Globa **Mikhaïlenko**: Modification of the ellipsoidal figures of equilibrium of a fluid mass in rotation under the action of capillary pressure.—M. **Drzewiecki**: Wind motors.—A. **Leduc**: The velocity of sound in gaseous mixtures. The application of a formula deduced in a previous communication to consideration of the velocity of sound in moist air, carbonic acid (Regnault's experiments), and mixtures of air and methane. The deviations between experiment and the author's theory are explained by the assumption that the latter is correct and that the gases used by Regnault and Capstick were impure.—Daniel **Berthelot**: The kinetics of photochemical reactions.—Ch. **Courtot**: The theory of the oscillation of the indene double linkage. The theory put forward by Thiele to explain his experimental results is unnecessary, since owing to an isomeric change unperceived by him he was dealing with only one benzylindene, the γ compound. The α-benzylindene has been prepared by the author, and is shown to be distinct.—M. and Mme. Fernand **Moreau**: Nuclear evolution and the phenomena of sexuality in the lichens of the genus Peltigera.—M. **Fonzes-Diacon**: Copper spraying fluids. THE TECHNOLOGY OF ILLUMINATION.

Modern Illuminants and Illuminating Engineering. By Leon Gaster and J. S. Dow. Pp. xiv + 462. (London: Whittaker and Co., 1915.) Price 12*s.* 6*d.* net.

WHEN a new branch of science, art, or industry becomes recognised, the literature on the subject might at first be expected to be scant in quantity and meagre in scope. But illuminating engineering is a new branch only in so far that attempts have been made to collect and arrange scattered facts and principles, and very few individuals call themselves illuminating engineers. So far as means, methods, and appliances for producing artificial light are concerned, the new movement has done little else than to record ancient and modern practice, but certain advances have been made on the scientific side by the development of photometry, and the extension of theoretical considerations of the distribution of illumination which are not to be found in text-books on optics. Some attention has been given to the subject of "glare" which is difficult to define, and to the artificial production of light not differing visually from ordinary daylight.

Having regard to the keen rivalry between the advocates of gas and of electric lighting, the success of an illuminating engineering society at one time appeared to be doubtful. It was founded in 1909, and has as its official journal the *Illuminating Engineer.* The membership has reached nearly five hundred, and many useful papers and discussions have resulted. This has been largely due to the tact and zeal of Mr. L. Gaster and Mr. J. S. Dow, the editors of the journal and the secretaries of the society. Even if the former of these were not a linguist or had a taste for antiquarian research and a genius for bringing competitors into harmony, and if the latter were not trained in physics and had not done any original work in photometry, they would have been in possession of a vast amount of material for a book, and well qualified to use it.

In accordance with the traditional opening of a Friday evening discourse at the Royal Institution, the first chapter begins with "the very earliest conceptions of light" in remote antiquity, and its use "among primitive peoples," and runs through history up to the Home Office Departmental Committee on Illumination, and the formation of the International Photometric Commission. The second chapter deals with gas burners, and does not touch on the chemistry or the making of gas. The section on high-pressure gas is compressed into only about five pages. The third gives as much on electric lighting can be packed into thirty-six pages, while the fourth describes oil, petrol-air gas, and acetylene lighting. These constitute one-third of the book, and appear at first to be of a sketchy character, but almost every page has foot-notes, and most of these refer to English and foreign periodical literature. A bibliography is provided at the end, but it does not include more than a small portion of the publications referred to in the valuable foot-notes.

The fifth and sixth chapters on the human eye and colour vision are a useful epitome. The last half of the book consists of chapters on the measurement of light and illumination, shades and reflectors, problems of interior and of outdoor lighting. These are well illustrated by reproductions of photographs, many of which have appeared in the *Illuminating Engineer.* Although this does not profess to be a treatise or even a text-book, an omission or two must be noticed. Polar curves are given in considerable numbers, and the solitary place in which an integral expression is used warns the reader against a common mistake which is sometimes made in deducing mean spherical candle-power from such a curve. "The well-known Rousseau method," which achieves this result graphically, is not described or even foot-noted, but is merely alluded to. The Ulbricht globe which is experimentally used for the same purpose has a full-page illustration and a foot-note with eight references, but only eleven lines are allowed for a description of it. Prof. Clinton has shown that the illumination of a room may be pre-determined by calculation, and possibly his treatment was not suitable for a book of this type, but, on the other hand, there are several rule-of-thumb methods and tables for finding how many lamps or how much candle-power or flux in lumens are required for interior work, and some of these might have been included. An American trading concern cannot perhaps be blamed for giving the name "X ray" to a type of reflector, but it should not be mentioned without a disparaging "so-called."

The subject is still developing so rapidly that it must have required some courage to produce a volume of this kind, and it is so wide that to decide the proportion to be allowed to different sections must have been a matter of difficulty. Such questions of proportion are necessarily matters of opinion, and books, after all, are what publishers allow authors to offer us, and not what the reviewers think or even what the readers may desire that they should be. Some would like more mathematics, others data on economical points. The authors have succeeded admirably in the task which they have set themselves, and the book is well produced.

L

PLANT LIFE IN ICELAND AND CYPRUS.

(1) *The Botany of Iceland.* Edited by Dr. L. K. Rosenvinge and Dr. E. Warming. Part I. 2. An Account of the Physical Geography of Iceland, with special reference to the Plant Life. By Prof. Th. Thoroddsen. Pp. 191–343. (Copenhagen: J. Frimodt; London: J. Wheldon and Co., 1914.)

(2) *Bergens Museums Skrifter. Ny Raekke.* Bind i., No. 2. Studies on the Vegetation of Cyprus. Based upon Researches during the Spring and Summer, 1905. By Jens Holmboe. Pp. 344. (Bergen: John Griegs, 1914.)

(1) THE present instalment of "The Botany of Iceland," by Prof. Thoroddsen contains five chapters. The first chapter deals with general topography and geology. The island is a continuous table-land with an average height of 700–1000 metres above sea-level, excepting narrow borders of coastal land, valleys which cut into the table-land on all sides, and a few small areas of level land towards the south and west. More than two-thirds of the entire area is at so great a height above sea-level that almost no vegetation can thrive there. The sandy and stony deserts of the interior plateau, the lava tracts, and the glaciers are not fit dwelling-places for man, and it is almost exclusively, therefore, the coasts and valleys which are inhabited. The volcanic element is the most striking feature in the geology, and is treated at some length.

The second chapter deals with conditions of surface and soil. Basalt is the fundamental rock; the tuffs and breccias are for the most part basalt split and pulverised, and the mineralogical and chemical component is essentially the same throughout the island. The climate, discussed in chapter iii., is, owing to oceanic currents, much milder than would be expected from the position of the island. Evidence of the Gulf Stream is found in the drift material, which includes sugar-cane and seeds of *Entada* and other West Indian beans. The winter is long, but generally not severe; the summer is comparatively short and cold and the weather usually changeable and damp.

The general distribution of plant life and a sketch of the chief plant-formations form the subjects of the remaining two chapters. Only a small part of Iceland bears a continuous carpet of vegetation. The number of species of flowering plants and ferns is from 400 to 450, as compared with 380 in Greenland and about 1450 in Denmark. Of these eighty-four are grasses and sedges. Man, with his sheep and cattle, has exercised considerable influence on the vegetation. The coppice woods of birch (*Betula odorata*) which were once extensive are rapidly disappearing, and their destruction has affected the general vegetation. The nature of the country and the vegetation are well illustrated by a number of photographic figures.

(2) The detailed study of the botany of Cyprus is the result of a desire on the part of a Norwegian botanist to compare with the flora of his own country that of an area in which there had been no glacial epoch. The author gives a brief sketch of the topography, geology, and climate of the island, and a short history of our knowledge of the flora, including a list of plants mentioned by authors before 1787. The main part of the volume is devoted to a carefully annotated systematic list of the vascular plants hitherto observed spontaneously growing in Cyprus, and some remarks on the most important plant-societies of the island. During his seven months' stay the author was able to add considerably to the number of plants previously recorded, and also to study critically various elements of the flora. The cedar of the island he regards as a distinct endemic sub-species, with affinities partly with the cedar of Lebanon and partly with that of the Atlas range. Several new species of flowering plants are described, and these as well as many others of special interest are illustrated by excellent plates and text-figures.

Large deposits of calcareous tufa were discovered containing excellent leaf-impressions consisting mainly of *Laurus nobilis* and *Platanus orientalis*, with fragments of *Ficus carica*, *Smilax aspera*, and *Rhamnus oleoides*, all of which are represented in the present-day flora. The account of the plant-societies, though not exhaustive, is a valuable contribution, greatly enhanced by a number of photographic reproductions. There are also short chapters on the means of distribution of some of the plants and on the affinities and history of the flora; also a list of topographical names derived from plant names, and a bibliography.

PRIME NUMBERS AND THE COMPLEX VARIABLE.

(1) *List of Prime Numbers from* 1 *to* 10,006,721. By D. N. Lehmer. Pp. xv+133. (Washington, D.C.: Carnegie Institution of Washington, 1914.) Price 5 dollars.

(2) *Functions of a Complex Variable.* By Prof. J. Pierpont. Pp. xiv+583. (London: Ginn and Co., 1914.) Price 20*s.* net.

(1) THE table is similar in form to Mr. Lehmer's previously published factor-table (see NATURE, August 10, 1911, p. 178), and the same elaborate precautions have been taken to avoid error. Thanks to the work of Glaisher and

his predecessors, we may now be fairly confident that the primes in the first nine millions have been correctly determined; the introduction to the present table describes the checks used for the tenth million, and contains other very interesting matter. First we have an account of Kulik's remarkable work, which, although not accurate, has been found to be of great value as a check, and actually goes beyond 100,000,000; unfortunately the second of the eight MS. volumes is missing. Then we have an admirable summary of the work done in the theory of the distribution of primes, ending with Gram's series, which is a transformation of Riemann's celebrated formula. Finally we have a table, at steps of 50,000, giving comparisons of the actual count with the values found from the formulæ of Legendre, Tchébicheff, and Riemann respectively.

The superiority of the last-named becomes more and more evident the further we go; the errors fluctuate in sign, and their ratios to the true value diminish in a most remarkable manner. The error is actually zero for a table going from 1 to 9,050,000; and for 10,000,000 it is only +87, the number of primes, as counted, being 664,580. The errors in the other two calculated values are always in excess and Legendre's value is less accurate than the other; but the comparative smallness of the errors is noteworthy, being only 560 and 338 respectively for a ten-million table. Perhaps there may be a simple modification of Legendre's formula which would bring it into closer agreement with Gram's.

The liberality of the Carnegie Institution of Washington has made it possible to publish this table at a price which is remarkably low, considering the labour involved. We hope that English universities and colleges will provide themselves with copies, and make an announcement that they have done so; this would be a great benefit to scattered arithmeticians, who now and then wish to know whether a particular number is prime or not, and may not be able to afford even a sovereign for the luxury of possessing this work. The same thing may be said, with greater emphasis, about the factor-table.

(2) Prof. Pierpont's treatise on the complex variable is very good, and a judicious mean between elaborate works addressed to the expert and specious outlines which ignore all difficult points, and tempt the reader to draw all sorts of false conclusions. The method is practically that of Cauchy, as developed by Briot and Bouquet, and Hermite, no use being made of Riemann surfaces. On the whole, we think this is the preferable course, because, although in simple cases the Riemann surface provides a visual image of great simplicity, and is invaluable for purposes of research, we cannot *construct* it until we have worked out the analytical theory of the algebraic functions we are considering, and this comes to discussing a system of Cauchy loops.

Readers of Dedekind and Weber's memoir on algebraic functions will remember that the authors laid great stress on the precise meaning of "a point on a Riemann surface"; this is the main crux of the whole theory, and another way of putting it is to determine the complete characteristics of a singular point on a given algebraic curve. This last way was that of H. J. S. Smith and Halphen. The present writer is no doubt prejudiced; but he ventures to say that in his opinion Dedekind's notion of algebraic divisors, as expounded, for instance, in Hensel and Landsberg's treatise on algebraic functions, is the best way to express the analytical facts in a concise symbolical form. For one thing, it brings into prominence the idea of a compound modulus, which is bound to lead eventually to a great simplification of the theory of algebraic functions.

A good feature of the treatise is that special functions such as those of Legendre and Bessel, and the hypergeometric function and elliptic functions, are treated in the light of the general theory.

There are two points about which the author might have written differently with advantage. It is not correct to say that the argument (amplitude) of $x+yi$ is $\tan^{-1}y/x$; otherwise we should have $\arg(x+yi)=\arg(-x-yi)$. The author does not say this, but (p. 11) he invites this false conclusion. The correct statement may be written—

$$\arg(x+yi)=(\sin, \cos)^{-1}(y/r, x/r),$$

where $r=+\sqrt{(x^2+y^2)}$, and $(\sin, \cos)^{-1}(a, b)$ means an angle of which a is the sine and b is the cosine.

Thus $\arg(x+yi)$ is determinate up to multiples of 2π; and this is the only way to avoid error arising from the definition.

The second point is this. Suppose we have two infinite series—

$$s=a_1+a_2+a_3+ \ . \ . \ .$$
$$s'=b_1+b_2+b_3+ \ . \ . \ .$$

of such a nature that $a_i=b_j$, where i is uniquely determined by j and conversely, we can define s' as a *permutation* of s, on the ground that every term of s' occurs in s and conversely. But it does not follow that the sum of s' is equal to the sum of s, even though both are convergent. We are, however, able to say that if s is absolutely convergent, and s' is such a permutation of s that the relation $b_j=a_i$ makes j finite whenever i is finite, and conversely, then s' is absolutely convergent, and its sum is equal to that of *s*. The essential thing is to note that an infinite series is defined not only by its terms, but by the order in which they are written. The author fails to emphasise the fact that in dealing with permutations of series we must keep any term in a finite place in a finite place. G. B. M.

FARM MANAGEMENT AND RURAL IMPROVEMENT.

(1) *Soil Management.* By the late Dr. F. H. King. Pp. ix+311. (New York: Orange Judd Co.; London: Kegan Paul, Trench, Trübner and Co., 1914.) Price 1.50 dollars.

(2) *Hunt and Burkett's Agriculture: Farm Animals, covering the General Field of Animal Industry.* By Prof. T. F. Hunt and Prof. C. W. Burkett. Pp. ix+534. (New York: Orange Judd Co.; London: Kegan Paul, Trench, Trübner and Co., 1914.) Price 1.50 dollars.

(3) *A Handbook for Farmers and Dairymen.* Sixth edition. By Prof. F. W. Woll. Pp. xvi+490. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 6*s*. 6*d*. net.

(4) *Rural Improvement: the Principles of Civic Art Applied to Rural Conditions, including Village Improvement and the Betterment of the Open Country.* By F. A. Waugh. Pp. xi+265. (New York: Orange Judd Co.; London: Kegan Paul, Trench, Trübner and Co., 1914.) Price 1.25 dollars net.

(1) THE book on soil management, which has been prepared from various notes and lectures of the late Dr. King, bears eloquent testimony, not only to his wealth of knowledge of the subject he had made so thoroughly his own, but also to much painstaking inquiry into the systems of agriculture and soil treatment in China, Korea, and Japan. Much of the book is naturally devoted to the consideration of productive capacity as determined by water supply, soil structure, and the physical features of the soil generally, and also contains many original observations on the effect of cultivation, mulching, and drainage. Teachers of agricultural science in this country will not fail to find much useful matter and many apt illustrations in this portion of the book. Not the least valuable portion of the work, however, will be found in those pages descriptive of the practices adopted in the Far East, by means of which soil fertility has been conserved to such a remarkable degree that a greater number of people are fed per unit area than in any other country in the world. Strict economy of all fertilising material is the main consideration, but the practical experience of centuries of Asiatic agriculture has evolved modes of conservation, fermentation, and crop production in respect to which we stand, at the present day, merely on the fringe of investigation.

(2) The perusal of Messrs. Hunt and Burkett's book on farm animals leaves one with a number of dissimilar impressions. The work is primarily intended for use by high-school pupils of fourteen to eighteen years of age, and aims at providing a survey of the whole range of animal industry. The scope of the book is certainly wide enough for all ordinary requirements, and there seems to be no reason to doubt that by a process of judicious mental winnowing sufficient concrete impressions may be obtained to impart an intelligent recognition of the issues upon which successful husbandry depends. A number of admirable practical exercises constitute the most valuable portion of the book, but one is inclined to deplore the inclusion of matter such as the first lesson on the "sorting of animals" and the apparent lack of discrimination in respect to many illustrations of the kindergarten type.

(3) Prof. Woll's handbook comprises in tabular form many of the data of value in agriculture generally, and dairying in particular, and the fact that it is now in its sixth edition may be taken as evidence of the useful function it is performing. The various sections, *e.g.*, those on farm animals, poultry, veterinary science, seeds, weeds, farm pests, forestry, etc., are prefaced by short articles by American authorities, and give an excellent digest of the subject. A certain proportion of the data bears, of course, reference to American conditions only, but the majority of the subject-matter will be found useful by English and colonial readers. Most of the tables are taken from trustworthy sources, and only one or two of doubtful authenticity have crept in. It is perhaps a matter for regret, from an agricultural point of view, that soils have not received any attention.

(4) Although much of the attention of the dweller in American rural districts has, in times past, been occupied by the necessity of making both ends meet, signs are not lacking at the present time that the main problem now is "not how to make more money, but how to live more comfortably." Whilst the value of co-operation in the purchase and sale of commodities, however, has been extensively realised, that of common effort in the development of civic life and institutions has not received the attention which it must ultimately do, and Mr. Waugh in his interesting book on rural improvement makes a strong plea for the appreciation of civic art—the art that builds a sound physical frame for the

support of a healthy community life. Even if the American farmer is indifferent to the appeal for better surroundings as set forth in these pages, many of the problems discussed demand consideration on account of their economic importance. In the matter of roads, for instance, only 8 to 9 per cent. of the total roads of the States have been improved by surfacing with gravel, oyster shells, etc., whilst the remainder are often so despicably bad that the cost of haulage of farm products is three to four times the legitimate amount. The one-street town is passing away, and many of the suggestions advanced by Mr. Waugh as to farm and town planning are well worthy of practical adoption.

TEXT-BOOKS OF PHYSICS.

(1) *Cours de Physique.* By Prof. E. Rothé. Pp. vi+183. (Paris: Gauthier-Villars et Cie, 1914.) Price 6.50 francs.

(2) *Traité de Physique.* By Prof. O. D. Chwolson. Translated by E. Davaux. Pp. vi+266. (Paris: A Hermann et Fils, 1914.) Price 9 francs.

(3) *Preliminary Practical Science. Some Fundamental Principles of Physical Science, with their Practical Applications.* By H. Stanley. Pp. viii+128. (London: Methuen and Co., Ltd., n.d.) Price 1*s.* 6*d.*

(4) *Outlines of Applied Physics.* By H. Stanley. Pp. viii+227. (London: Mills and Boon, Ltd., 1914.) Price 2*s.* 6*d.*

(5) *Preliminary Practical Physics.* Part ii. *Heat.* By A. E. Lyster. Pp. vii+73. (Dublin: Educational Co. of Ireland, 1914.) Price 7*d.* net.

(6) *A School Electricity.* By C. J. L. Wagstaff. Pp. xi+250. (Cambridge: At the University Press, 1914.) Price 5*s.* net.

(7) *Elementary Geometrical Optics.* By A. S. Ramsey. Pp. xi+173. (London: G. Bell and Sons, Ltd., 1914.) Price 6*s.*

(1) AS judged by the size of the first two books of the "Cours de Physique," which Prof. Rothe is writing, the whole work will be of very considerable magnitude. According to the author's foreword, these two books represent the introduction only to the course itself, which is intended for students who have already studied physics, and primarily for those who are proceeding to technical institutes. In several ways this introduction is rather remarkable. The subjects covered in the first book are (i) units, and their transformation from one system to another; (ii) the principle of similitude in physics; and (iii) methods of measuring the fundamental physical quantities, and the errors involved. In the second book, the statics of fluids and the experimental measurement of densities and pressures are dealt with. There is, perhaps, too little stress laid upon theory, but there can be no doubt that the detailed descriptions of the methods of measurement with great precision, together with the diagrams illustrating these methods, are in every way excellent.

(2) Many physicists regard Prof. Chwolson's treatise on physics as the best in existence—and with justice. Prof. Chwolson has not only given us a most complete and accurate survey of experimental physics in practically all its branches, together with an exhaustive bibliography, but he has also contrived to make his work a critical essay. The translation of this work into French, making it—as it will do—available to those students who do not know Russian and read German with difficulty, is a most desirable event. That now published is the tenth part, and contains the chapters on electromagnetic induction, Maxwell's theory, the basis of electronic theory, and the principle of relativity. The translation has the advantage of having been revised by the author himself, who has, at the same time, considerably augmented the edition. The chapters on the theories of electrons and relativity have, consequently, an added interest, and it will be found that they give a very comprehensive survey of these subjects which are at present so much under discussion.

(3) This little volume adds another to the already large number of similar books which have been published within recent years, and follows much the same lines of treatment. A considerable number of simple physical experiments are described, principally in mechanics, heat and light, those in electricity and magnetism numbering only half-a-dozen. Each exercise combines a simple statement of the theory of the experiment and a description of the method of procedure. In some of them, however, the results obtained would not be what the student is led to expect. For example, in the experiment on the spectrum, no lens is used to focus the light on the screen, and we are told incidentally that the spectrum consists of *seven* colours. A refreshing feature of the book, however, consists of some excellent notes on experimental work which, if all students would follow, would bring about a great improvement in their practical records.

(4) In the main, this book is a series of examples in theoretical physics, for not only are there numerous numerical exercises at the end of each chapter, but more than four hundred of a miscellaneous character at the end of the book. The work, as the author himself points out, is

in no way descriptive, and therefore could not serve as a text-book. Indeed, it seems rather to partake of the "cramming" nature, and would tend to make physics appear to consist of a series of mathematical formulæ. Still, provided that it does not lead students to neglect the experimental side of physics, the book will probably be found quite useful.

(5) This is a little paper-covered pamphlet containing descriptions of some forty simple experiments in heat, and, although small, is well printed and arranged. The diagrams all represent *sections* of the apparatus, and are free from elaborate details. This is a good feature, for, as the author points out, it will encourage the reader to do the same in his practical records, instead of wasting time over sketching the exact apparatus—a thing which but few students can do well.

(6) It is not often that there appears a physical text-book so generally good as this one of Mr. Wagstaff. It is the outcome of the author having been persuaded to publish a book comprising the notes of his lectures at Oundle School, and he is to be congratulated on the result. Not only is the treatment obviously based upon experience in teaching the subject, but the descriptive work and the methods of explaining those parts of the theory which present difficulties to the average student have an originality which is very refreshing. Besides this, all the diagrams and plates are excellent, and these features, together with the good printing of the text, give the book a general appearance which is very pleasing. One or two criticisms may be made. These, however, detract but little from the value of the book. The first is with reference to the definition of the ampere in terms of silver deposited during electrolysis. One knows, of course, that it is so defined by law, but it cannot be clear to a student why the special amount, 0·001118 gram per second, is chosen. In fact, we disagree entirely with the position which the author advocates in his preface, viz., that it is desirable to begin teaching current electricity using direct reading instruments such as ammeters, instead of by means of the tangent galvanometer, which, besides having a mode of action which is simpler than that of an ammeter, serves also to measure the current absolutely.

In the second place, the study of electrostatics and magnetism ought to be taken earlier than it is in this book. The book opens with a very short chapter on magnetism, then proceeds with current electricity, and the treatment proper of magnetism and statical electricity is not reached until half-way through. It would, however, be possible for these chapters to be read first, and the objection would thereby be partially removed. In any case, it is not of great importance, and the book is to be thoroughly recommended.

(7) This book, also, is well produced, and deals with a subject somewhat neglected. Although the treatment is not advanced, it comprises a wide field, including the important subjects of achromatism, thick lenses, and optical instruments. There are frequent examples which will, no doubt, be useful for training the students. It is quite certain that there has been for some time an opening for a book of this kind, and the present volume is well fitted to supply the demand which exists. In fact, students of the subject of light would be well advised to read this volume in conjunction with their text-books of physical optics; and those who intend becoming optical instrument makers would benefit greatly by studying it.

OUR BOOKSHELF.

Œdema and Nephritis: a Critical, Experimental, and Clinical Study of the Physiology and Pathology of Water Absorption in the Living Organism. By Prof. M. H. Fischer. Second edition. Pp. x+695. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1915.) Price 21*s.* net.

THIS is the second edition of a work which has already attracted some attention in the physiological world. The author's main theme is that dropsy is not due to disorders of the circulation, or to changes in osmotic processes, but is wholly produced by the tissues themselves sucking up water from the blood, and that increase in acidity of the tissues is the sole factor in their being able to attract more water into their colloid structure. The main experiments upon which this theory depends were performed by placing dead frogs' legs and pieces of gelatin in fluids of different composition and reaction. Even the swelling which occurs in a limb when reflux of blood from it is prevented by occluding the veins is explained on the acid theory. Addition of such salts as sodium chloride to the experimental fluid lessens the amount of swelling; yet it is well known that excess of such salts favours dropsy during life. This is ingeniously explained by saying that the excess of salt lessens vital oxidative processes, and this leads to formation of acid, and therefore indirectly to œdema. The only piece of evidence advanced in favour of this view is that rabbits on an excessive salt diet become cyanotic; an impartial observer might quite reasonably argue that cyanosis may be the result of the dropsy.

Prof. Fischer argues that disturbances of the circulation cannot be the cause of dropsy because in his dead frogs or strips of gelatin, no circulation was going on at all, and yet they became dropsical. Acidity may be, and probably is, one cause in œdema-production; but this is a very different thing from maintaining that it will explain everything; one might just as well search for a universal pill which will cure all the ills to which human flesh is heir. W. D. H.

The Chemistry of Paints and Painting. By Sir A. Church. Fourth edition. Pp. ix + 387. (London: Seeley, Service and Co., Ltd., 1915.) Price 7s. 6d. net.

The facts that this is a fourth edition, and that the author has been before the world for more than fifty years as a student of the subject on which he writes, are sufficient reasons for welcoming it with respect. But the volume itself fully justifies its existence, and it is difficult, if not impossible, to suggest any change in it that would better fit it to serve the purpose for which it was originally issued. The temptation to use a material that facilitates or immediately improves one's work without due regard to its lasting qualities is always very strong, and especially is this the case with those who are so absorbed in the study and practice of pictorial art, that the scientific aspect of their work becomes distasteful to them. But it is not right to accept ignorantly the opinion of the salesman, however honest he may be, or to trust to a few superficial experiments made by one's self or one's friends. The author deals with painting grounds, vehicles, varnishes, pigments, methods, and results, giving just such details concerning them as the artist wishes, or ought to wish, to know.

The previous edition of the treatise was translated into German and edited by Prof. Ostwald, who added a few paragraphs. The author has incorporated the substance of these in the present edition, definitely indicating such paragraphs, and adding to their value by comments of his own. He gives, in short, the results of probably all those who are known to have systematically tested pigments for permanency, and usefully, and we think fairly, criticises the methods and results of these investigators. The preservation and restoration of pictures receive due attention, and throughout the volume the style of the author is such that a previous acquaintance with scientific principles and nomenclature is not necessary for the understanding of it.

Machine-shop Practice. By W. J. Kaup. Pp. xii + 199. Second edition. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 5s. 6d. net.

In this little book will be found descriptions of the hand- and machine-tools employed in an up-to-date workshop, together with clear instructions for their use. The author has desired to lead the pupil in the shop to think, and not merely to do. For this reason the why of each step or operation is emphasised as much as the how. The function of college workshops is to familiarise students with the working properties of the materials employed and with the tools in general use. Such information cannot be adequately obtained from any book, but a book may be very useful for the purpose of supplementing the verbal explanations of the instructor. It is not easy to make other than mental notes in the course of workshop practice, and it is often inconvenient to pull a machine, or part of a machine, to pieces for the purpose of explanation.

The book before us will be found to be very helpful in such matters. Probably the most noteworthy feature in it is the clearness of the illustrations. Where most books of the kind contain merely half-tone illustrations of machines (generally from makers' catalogues), the author has given perspective line drawings, and has named the parts clearly on the drawings. These drawings will be found to be of much value, even when the machine installed in the students' workshop differs in detail from that in the book. Nomenclature is not so serious a barrier in this volume as in some American books. We can heartily commend this book to workshop instructors.

The Age of the Earth.

While reading through Dr. F. A. Lindemann's defence of Lord Kelvin's estimate of the age of the earth, I was reminded that in spite of the sympathetic spirit in which he always entered into any discussion, he would never allow the least doubt to be thrown on the correctness of his estimate of the earth's age. Yet it is open to several objections: he assumed that the solidified crust, as it was being formed, would sink toward the centre of the earth until it was solid throughout, whereas there can be no doubt about its core being so heavy that the crust material could not possibly sink. He also assumed a diminishing rate of cooling, whereas the greater portion of the earth's surface is covered by water the bottom temperature of which must have been practically constant for millions of years. He also cuts down the temperature in the earth's centre from 410,000° F., which it would be according to his assumption, to 7000° F.; whereby the available heat is reduced enormously. However, if radio-active processes can supply the earth's radiation losses there is no need to deal with the older question.

I notice that Dr. F. A. Lindemann draws the conclusion that the sun's radiation just compensates the amount lost by the earth, but this is not correct. The earth's loss is estimated from the known temperature gradient in the earth's crust; it is a net loss over and above any possible interchange of heat with the sun. Then, also, Dr. Lindemann limits the earth's age by the sun's age, but amongst the several possible sources of its heat supply he does not even mention the heat-producing power of a meteoric bombardment. Yet, as I have shown in my work, "Unity in Nature," in the chapter on matter (pp. 85–92), it is not at all unlikely in comparatively recent time the sun may have passed through a large cloud of heavy meteoric matter. One effect of a comparatively slight addition of heavy meteoric matter would have been to increase its density from, say, 1·00 to 1·38, and the other effect would have been to raise the sun's surface to such a high temperature that it would have evaporated and formed an atmosphere extending perhaps beyond the orbits of the asteroids. In fact, the difference in the densities of the inner and outer planets and the sun, and the fact that practically all rotations and revolutions are in the same sense, suggest that our solar system once consisted of a sun and the outer planets, all having a very low density, and that on passing through a cloud of heavy meteoric matter, the density of the sun was slightly increased, and the inner heavy planets created; but it is impossible here to go into the details of these interesting questions.

As regards the nearer evidence of the earth's age to be sought for in the sedimentary rocks, no notice seems to have been taken either of the time required for the innumerable raisings and lowerings of level which certainly occurred during the coal periods or of the time which it must have taken to tilt horizontal strata through 90° and more. Thus Japan is being tilted at the rate of about 0·5″ per century, and if this tilting rate were steadily maintained in one locality, which is highly improbable, the Japanese strata would stand on end like our Cambrian strata in about forty million years' time. Yet a few such tiltings were completed before some of our oldest strata were formed and overthrusts suggest a still greater antiquity for the age of sedimentary rocks. C. E. Stromeyer.

"Lancefield," West Didsbury, April 26.

Man's True Thermal Environment.

In connection with Prof. Leonard Hill's very interesting and instructive article on "Healthy Atmospheres" (Nature, April 22), perhaps I may be allowed to direct attention to a paper which I contributed to the Journal of the Scottish Meteorological Society for 1912, entitled "On Atmospheric Cooling and its Measurement: An Experimental Investigation." In that paper will be found a description of an instrument termed a psuchrainometer (ψυχραίνω = I become cold; and μέτρον = a measure) which traces on a moving paper strip, a continuous record of the amount of electrical heating needed to maintain at blood heat a body freely exposed to the atmosphere. This seems to serve much the same purpose as Prof. Hill's caleometer. In the same paper I also gave a table of preliminary numerical results obtained by its use in conjunction with an anemometer and self-recording thermometer, and from these data deduced an empirical formula giving the rate of cooling (ψ) as a function of temperature and wind velocity.

The question as to whether ψ could always be thus expressed as a function of already existing meteorological data can only be settled by a long continued series of observations with appropriate instruments, in the construction of which I have been engaged for some time. If ψ can be so expressed, then evidently there would be no need for a widespread installation of special apparatus for its measurements. If, however, this hope be disappointed, a new apparatus must be placed in the hands of meteorologists, and the simpler this is the better. I have now constructed a simple psuchrainometer, consisting essentially of a thermometer furnished with a small heater through which a constant current is always passing. This may be termed a "constant energy" psuchrainometer, and I propose to calibrate it against the necessarily more complicated form of "constant temperature" psuchrainometer, different patterns of which are described both in Prof. Hill's article and in my paper.

James Robert Milne.

Physical Laboratory, Edinburgh University, April 30.

THE AUSTRALIAN ANTARCTIC EXPEDITION.[1]

The most vexed question in antarctic geography has been the nature of the region west of South Victoria Land. D'Urville and Wilkes, who explored that region in 1838 and 1839, reported land in so many localities that it has been generally believed that their tracks skirted a continuous ice-covered and ice-barred land. Ross, however, sailed across the site of some of the land reported by Wilkes, and later explorers have had the same experience. The view has therefore often been held that this part of Antarctica consists of an archipelago. The first material step toward the solution of this problem was the sledge journey of David, Mawson, and Mackay during Shackleton's expedition. Their journey afforded strong evidence in favour of the continuity of the land; but this land might end far south of Wilkes's track and be separated from it by a fringe of islands. This question has been finally settled by the Australian expedition of 1911 to 1914 under Sir Douglas Mawson. The narrative of its experiences with some indications of its scientific results are given in two massive and superbly illustrated volumes.

The expedition sailed in the *Aurora* under the skilful command of Capt. Davis, whose soundings between Australia and the opposite coast of Antarctica are themselves of the highest geographical importance. Two bases were established in Antarctica, the main base in Adelie Land (about 142°40′ E.), and a western base under Wild in Queen Mary Land (95° E.); at each of these stations elaborate observations were taken, and the expedition established on Macquarrie Island a wireless station, which should be permanently maintained in the interests of Australian meteorology. From each of the bases extensive sledging expeditions were made to explore the surrounding areas. Wild sledged 4° eastward along the northern coast to Queen Mary Land in the hope of reaching Knox Land. A second party under Dr. S. E. Jones travelled westward to the Gaussberg, and thus reached the field of work of the German Antarctic Expedition under Drygalski. From the main base in Adelie Land one sledging party went eastward to Deakin Bay; a second under Bage nearly reached the Magnetic Pole; a western party sledged 4½° along the coast which had been seen by D'Urville. A sledge journey eastward over the ice-covered plateau led to one of the most tragic of Antarctic adventures, for Mertz and Ninnis perished on the journey, and only the lucky finding of a food depôt enabled Mawson to crawl back to his base.

The journey toward the South Magnetic Pole under Dr. Bage was one of the most arduous and successful of the sledging expeditions. The party reached lat. 70°36′5″ S. and 148°10′ E., where the magnet had a dip of 89°43½′ or only 16½

[1] "The Home of the Blizzard. Being the Story of the Australasian Antarctic Expedition, 1911–14." By Sir Douglas Mawson. Vol. i. Pp. xxx+349. Vol. ii. Pp. xiii+338. (London: W. Heinemann, 1915.) Price 36*s.* net two volumes.

min. from the vertical. This locality was 175 miles from the point reached by David's party in 1909, so the two journeys gave a nearly full section across Antarctica from South Victoria Land to Wilkes Land.

These great sledge journeys, combined with Capt. Davis's soundings along the coast, have proved the existence of land all along this part of Antarctica, though somewhat south of the positions where it was reported by Wilkes. Thus the *Aurora* sailed in clear weather over the site of the land marked by Wilkes to the east of his Cape Carr. Nevertheless, the result of the expedition is to confirm the general belief that from Cape Adare, for more than 80° westward, is one continuous ice-capped land, which forms the northern coast of Antarctica. Mawson attaches the name of the American explorer to a small part of this area, but the name of Wilkes Land appears too firmly established for the whole of it to be easily displaced. The discovery by the expedition of Queen Mary Land in the west, the long line of land to the west of Adelie Land, and of King George V. Land on the east has definitely established the northern coast of Antarctica in this district as approximately along the line of the antarctic circle. There are indications, however, from the charts that either shallow water or land extends in some places north of the circle.

FIG. 1.—The *Aurora* lying at anchor, Commonwealth Bay. In the distance the ice slopes of the mainland are visible rising to a height of 2000 feet. In the foreground is a striking formation originating by the freezing of spray dashed up by the hurricane wind. From Sir Douglas Mawson's "The Home of the Blizzard." (W. Heinemann.)

The greatest trial of the expedition was the terrific violence of the wind. Gusts of wind are recorded with a velocity of two hundred miles per hour. The rate of 180 miles per hour is said (vol. i., p. 168) to have been common. The average velocities recorded for whole days are unprecedented. Thus on May 15 the mean for the whole twenty-four hours is given as ninety miles per hour. On May 18, a year later, it was 93·7 miles. The average for May was 60·7 miles per hour. The most appalling testimony to the wind strength is the record that the average speed for the whole year was fifty miles per hour (vol. ii., p. 157). Both volumes contain repeated references to hardships due to these hurricanes, and the prevalence of winds blowing at 100 miles per hour with a temperature of −28° F. (vol. i., p. 134) justifies Sir Douglas Mawson's lament that owing to "the rushing might of these eternal blizzards" Wilkes Land is "an accursed country" (p. 134). The wind records were apparently mainly made by a Robinson anemometer, which we are told was the greatest source of worry; and as meteorological authorities have issued frequent warnings of the untrustworthiness of anemometers, opinion as to the exact value of the records may be suspended until more detailed accounts of the observations are issued. There is, however, abundant evidence in the book to show that the main base is abnormally windy, and perhaps to justify the claim that it is the windiest place on earth. The "Roaring 'Forties" must give place to the "Shrieking 'Sixties." The author explains the power of the wind as due to the torrent of air rushing outward from a high pressure area around the south pole; but it is difficult to reconcile this theory, as now stated, with the experiences of Amundsen and Shackleton.

Fig. 2.—A view of a rocky stretch of the Adelie land coast west of Commonwealth Bay. From Sir Douglas Mawson's "The Home of the Blizzard." (W. Heinemann.)

The book, like much Antarctic literature, must have its usefulness restricted by its bulk; private students can scarcely afford the book space for such cumbrous volumes, a fact the more regrettable in this case owing to the exceptional beauty of the illustrations. Colour photography has been used with excellent results, and those of the starfish show the great value of this process in biology. The work includes only preliminary notices of the scientific results, but it shows that the Australian Expedition must rank as one of the most successful of modern antarctic expeditions.

J. W. G.

RECORDING RAIN GAUGES.

Of mechanical devices for the registration of rainfall there is no end, and from the early date of most of them it is scarcely too much to say that in this direction there is no new thing under the sun. Up to 1898 Mr. G. J. Symons had described and figured in "British Rainfall" no fewer than forty-five different patterns of self-recording rain gauges, and now there are at least a dozen more. Very few of these have proved fully satisfactory. The diversity between the various forms consists mainly in subordinate details. With the exception of Mr. W. J. E. Binnie's electrical drop-counter and Wild-Hasler's over-shot water wheel, I cannot find more than three principles which have been applied singly or in combination for the automatic recording of rainfall by a pen writing on a rotating drum. These are (1) the double tipping-bucket on a fixed pivot; (2) the descending counterpoised receiver, and (3) the ascending float.

Tipping-bucket rain gauges are amongst the oldest forms, and they have been constructed to record directly or through an electrical device, by an escapement wheel, a cam in the axle of which raises the pen by a step at a time, the value of the interval shown by the step being the capacity of the bucket, which empties as it tips. The best instrument of this type is that in use by the United States Weather Bureau, which has a bucket tipping with one-thousandth of an inch of rain, and so gives a fairly continuous line, even in moderately light showers. Attractive and well-made tipping-bucket rain gauges have been put on the market by the firms of Negretti and Zambra, and Pastorelli and Rapkin, of London, and by Richard Frères in Paris. These tip with one-hundredth of an inch, or sometimes with half that amount, but are useless for measuring duration of any but heavy rain, though under careful inspection fairly satisfactory for measuring amounts. The amount of rain can always be measured more accurately by means of a direct reading rain gauge of the Snowdon or Meteorological Office pattern, of which the former is, in my opinion, better as well as cheaper.

The only scientific purpose served by a recording rain gauge is to furnish a measure of duration and intensity. The two types of gauge involving the respective use of a counterpoised receiver or of a float give their record in the form of a continuous curve. Each type has several modifications rendered necessary by the practical convenience of using a shallow drum while retaining an open scale. Where expense and space are no objects rain gauges of unimpeachable accuracy can be made on either principle by having a drum deep enough to record the whole rainfall of the wettest day possible with the necessary degree of magnification.

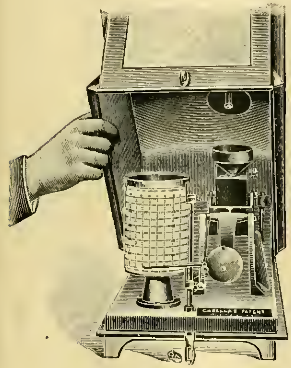

FIG. 1.—New Casella recording rain-gauge.

In order to keep the moving parts compact and the drum small, the capacity of the receiver is in practice usually limited to from 0·20 in. in the case of a counterpoised vessel to 0·50 in., or rarely 1 in., in the case of a float, and an automatic contrivance for emptying the vessel whenever it fills has to be employed. This is the weak point of most recording rain gauges, for when the receiver has to be emptied five times for every inch of rain it is subject to much friction and wear, and when it empties only once or twice for an inch of rain the time of clearing is appreciable and introduces a risk of error.

The Beckley rain gauge made by Mr. Hicks and used in the observatories of the Meteorological Office for about forty years is the best example of a counterpoised receiver writing directly on the drum as it sinks vertically and discharging automatically by means of a self-starting syphon. The Casella recording gauge, which has been in use at Camden Square for about thirty-five years, is undoubtedly the best example of the counterpoised receiver emptying by automatic tipping when it comes to the lowest point. It writes by means of a system of levers on a drum with a horizontal axis. A modified form of this gauge (Fig. 1), recently introduced by Messrs. Casella at a low price, has a simpler mechanism, the receiver only tipping far enough to start a syphon, through which it is emptied, while the pen writes on a vertical drum by means of a hinged piece at right-angles to the main lever, thus securing a curve with approximately rectangular co-ordinates.

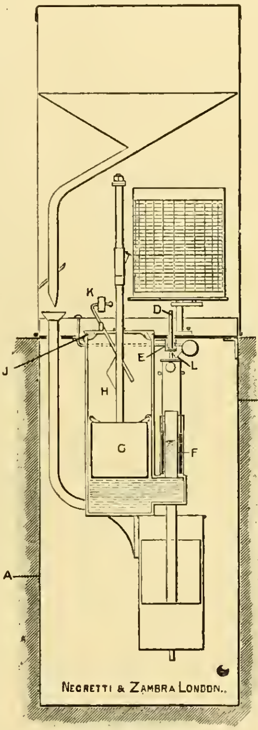

FIG. 2.—Section of Halliwell standard recording rain-gauge.

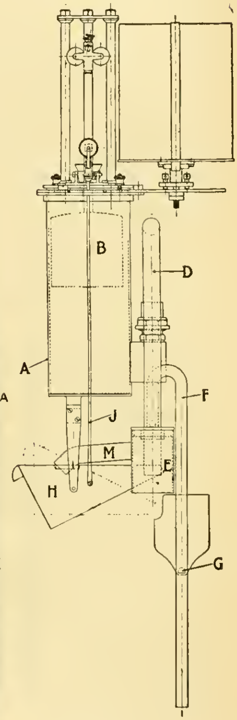

FIG. 3.—Mechanism of the Fernley recording rain-gauge.

Of float rain gauges the best of which I have had experience is the improved form of the Halliwell rain gauge (Fig. 2) first constructed by Mr. F. L. Halliwell with the advice of Mr. Baxendell, the well-known director of the Fernley Observatory, Southport, and now manufactured by Negretti and Zambra. The theory is to make use of a pen actuated directly by a rod rising with the float (G), the receiver emptying by means of a syphon of large bore (F) started by being dropped a little by the action of a trigger (K) set off by the float rod when the receiver is full, and reset automatically by the escaping water entering a lower cylinder. In its first form this instrument was troublesome, sometimes failing to discharge, sometimes discharging too soon, but these difficulties have now been overcome, and when it is in careful hands I know of no better recording gauge. It gives an exceedingly clear and steady trace, and is much more sensitive to light rain than the Standard Casella gauge, while its less frequent discharges and rapid emptying give great accuracy in the case of heavy falls. The main drawback is the employment of mercury in connection with the syphon.

The Fernley recording gauge (Fig. 3), also constructed by Messrs. Negretti and Zambra, is the most recent product of Mr. Baxendell's ingenuity, and I have had it under observation along with the Casella and Halliwell gauges at Camden Square for six months. The record it produces is as clear and sensitive as that of the Halliwell gauge, from which it differs only in the simpler method of starting the large-bore syphon, avoiding the use of mercury. This is accomplished by the interposition of a small tipping bucket (H) filled with water. The bucket is tipped by a trigger actuated as in the Halliwell gauge, and discharges into the lower part (E) of the long leg of the syphon, which is started by the water pump action thus set up. The mechanism is certainly simpler than that of the Halliwell gauge, and the action is perhaps more certain than that of the first form of Halliwell. The principle is sound, and was employed in Osler's famous recording gauge of 1837.

The difficulty presented by all accurate recording instruments of different types is to ensure comparability, so that regional variations in duration and intensity may be worked out. To insist on the use of one make of instrument would hamper progress and discourage that competition between inventors and instrument makers on which so much depends for the progressive improvement of practical details. As the result of many years' experience I have formulated the requirements of a satisfactory recording rain gauge for general use, as follows:—

(1) A recording rain gauge is not a labour-saving contrivance which will work by itself for a week or more. The time scale should be so open that a drum of reasonable size cannot include more than the record of twenty-four hours, and it must be visited daily and the pen set to the correct time every morning.

(2) If a recording rain gauge is to be generally adopted its price must be less than 10*l.*, substantially so if possible, hence great size and elaborate mechanism must be avoided.

(3) The depth scale must be magnified at least four, and preferably eight times, and to avoid the inconvenience of having a very high drum some mechanical arrangement must be made by which the pen, on reaching the end of the chart, returns to zero automatically.

(4) The usual method of bringing the pen back to zero by emptying the receiver when half an inch or less of rain has been accumulated necessitates the use of uncertain or complicated mechanism, hence the receiver should be large enough to contain at least four inches of rain, and the automatic return of the pen should be secured by some device unconnected with the discharge.

(5) Friction is the only other serious practical difficulty, and this should be minimised by having as few moving parts as possible and these with the shortest bearings compatible with rigidity.

It was in order to meet these views that Messrs. Casella introduced their modification of their old standard recording gauge, but though most of the conditions were complied with, No. 4 was not. The Hyetograph (Fig. 4) devised at the same time by Negretti and Zambra, carries out my views more nearly than any other gauge I know; but it has not quite overcome the difficulty of friction in the float chamber, though when signs of this appear a very slight adjustment puts things right. Its curve also presents the inconvenience common to those of the ordinary barograph and thermograph of being referable to a straight co-ordinate for time and to the arc of a circle for amount.

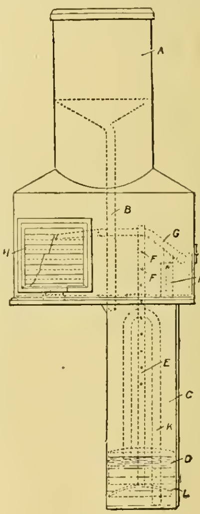

Fig. 4.—Section of Hyetograph.

Its advantages are that the receiver takes four inches of rain without overflowing, an amount which, it is true, may be exceeded in twenty-four hours in any part of the country, but which cannot be expected to be exceeded twice in a lifetime at the same place. It is emptied by a syphon actuated by suddenly depressing the float by hand, and should be so emptied each morning when the amount collected exceeds a small fraction of an inch. The pen drops on reaching the top of the chart by the edge of a plate fixed on the pen lever dropping from a peg (F) on the float rod (E) on to another peg below, an oil brake (M) at the short end of the lever (G) absorbing the shock. The record is thus not interrupted so long as rain is falling. During snow, a night-light placed in the instrument under the funnel ensures instantaneous melting.

I may perhaps be allowed to mention that neither the British Rainfall Organisation nor I personally have any financial interest in any rain-measuring appliances, and we thus retain perfect freedom for the helpful criticism of all such instruments.

HUGH ROBERT MILL.

INSECT PESTS AND WAR.[1]

WAR is associated in the popular mind with the summoning of armies, the thunder of the guns, and the carnage of blood-stained battlefields. Patriotism is manifested in personal sacrifice in many directions, some public, many unsuspected. All cannot help in the direct attack on our enemies, but all are able to assist in preventing disease that plays so important a part in the progress of a campaign. Horrible as are the features of any war, times arise when the destructive "minor horrors," or insect pests, that are the inevitable accompaniment of the concentration of large numbers of men, assume a major import. The victims of the typhus now ravaging Serbia know this only too well. It is, then, a patriotic action on the part of Dr. Shipley to have set forth the life-histories of many noxious and disease-carrying arthropods, as well as certain leeches, together with very practical hints as to their prevention, in his book, "The Minor Horrors of War."

At the present time there is an undoubted need for the dissemination of knowledge regarding the *rôle* of various pests, both insect and others, in a simple yet practical form. The advantage is considerably increased when the information is presented in a lucid manner, with numerous illustrations, and in a style that may perhaps be best described as fully human. The accounts of the habits of lice, bugs, fleas, flies, mites, ticks, and leeches, which all have a share in injuring man, are set forth in a form that arrests the attention, stimulates personal interest, and, at the same time, by humorous interludes, neither repels nor disgusts the reader. The practical side, as before mentioned, is kept in view throughout.

Lice undoubtedly are unpleasant, but to ignore their existence does not minimise the danger arising from their presence. At least two diseases that are known to occur in certain areas of the present war zone are transmitted by lice (Fig. 1). Relapsing fever is due to a spirochæte that develops in the body-louse. The spirochæte reaches man when, in his endeavour to alleviate the irritation due to the insect, he scratches his skin. Simultaneously, he crushes one or more of the unwelcome insects, and spirochætes are unwittingly rubbed into the slightly damaged skin. Troops operating in Africa understand how easy it is to touch the eyes to remove sand or dust, and a finger soiled by a crushed louse has been shown to convey relapsing fever when so used. Typhus fever also is spread by lice, and there is no need to dwell on the fearful rapidity with which this fell disease may spread.

It must be remembered that the irritation of the body due to insect pests reacts on the mind, and is manifested in mental restlessness and lowered spirits. The clearly expressed preventive measures recommended against lice will doubtless be appreciated during the present campaign.

Bugs are very undesirable intruders in houses, and troops operating in India and Persia have reason to fear their attentions. Ticks occur in the Eastern theatre of war, and also in African territory where other troops are engaged. One tick, *Ornithodorus moubata,* transmits *Spirochaeta duttoni,* the cause of a more severe form of relapsing fever. The young tick is unlike the adult, and being so much smaller, is more easily overlooked, and is therefore more dangerous, especially as it may be born infected. Knowledge of its life-history, as set forth by Dr. Shipley, is important.

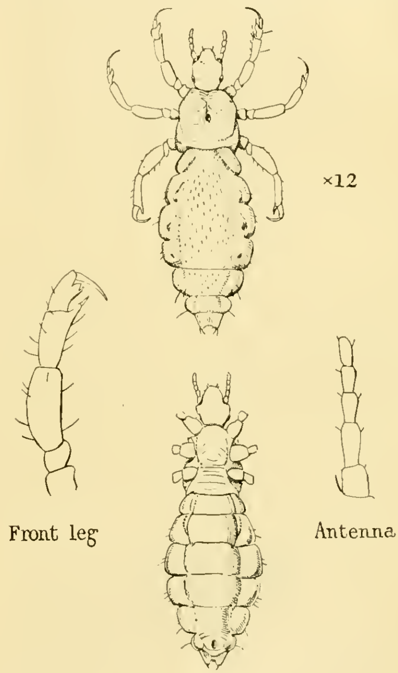

FIG. 1.—*Pediculus vestimenti.* The louse. Dorsal and ventral views. From "The Minor Horrors of War."

Mites are small relatives of ticks, and those that infest man are often known to soldiers and field-workers by the name of harvest mites. The habits of these small pests, as well as those of the "itch insect," together with the modes of dislodging them, are facts that should be better

[1] "The Minor Horrors of War." By Dr. A. E. Shipley. Pp. xvii+166. (London: Smith, Elder and Co., 1915.) Price 1*s.* 6*d.* net in paper covers, 2*s.* net in cloth.

known. Fleas, too, need attention. The dreaded plague is spread by means of infected rat-fleas that leave their natural host and pass to man. Fleas also convey other diseases, and apart from this, the broken rest due to flea-bites is a factor that makes even such an insignificant insect worthy of consideration.

Blood-sucking leeches occur in Belgium and Germany, and also in parts of India, Ceylon, Egypt, and Palestine. These animals, although not belonging to the arthropoda, constitute a

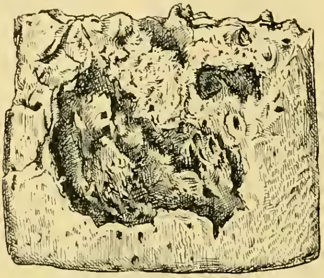

Fig. 2.—*Ephestia kühniella*. Moth-infested biscuit. From "The Minor Horrors of War."

very real pest in some places, as they may occur in drinking water. The straining or filtering of drinking water and boiling it before use are simple means of avoiding distressing throat and lung troubles. The existence of voracious Indian land leeches, lurking among foliage in wait for their prey, will probably be news to many, but provides a useful hint with regard to sites for camping.

Man is affected by insect parasites not only through direct attacks upon himself, but also by infestation of his dwellings and his food. Flies

Fig. 3.—*Musca domestica*, the house-fly, in the act of regurgitating food. ×4½ (After Gordon Hewitt.) From "The Minor Horrors of War."

and flour moths are therefore discussed. Fortunately, the occurrence of "maggotty" biscuit (Fig. 2) is not so common as formerly, but the possibility of its recurrence under war conditions should be remembered. Flies are a more serious pest. House-flies are concerned with the conveyance of several diseases to man, typhoid fever perhaps being the best known. The typhoid bacilli can live for six days in the intestine of a house-fly, and food and milk can be polluted by its promiscuous visits during this period (Fig. 3). Insight into the life-history and habits of flies is sufficient to cause anyone to join in the anti-fly crusade. The love of filth and carrion displayed by the various blow-flies or meat-flies, too, is a means of spreading disease, and there are records, even in the present war, of wounded men suffering agony from the presence of fly larvæ in their neglected wounds. The abolition of filth is the simplest means of securing freedom from flies by destroying their breeding places.

The relation of insect pests to the health of men and animals is a subject of interest to all, and it is not surprising that the large first edition of Dr. Shipley's book was practically exhausted in a month, and that a second edition is in preparation. The combination of literary charm and scientific information of practical utility, particularly at the present time, is certain to ensure its continued success. H. B. Fantham.

THE SUPPLY OF OPTICAL GLASS.

THE serious position in which this country was placed at the outbreak of hostilities by the almost complete stoppage of the supply of optical glass and of the import of optical instruments, is at last attracting the attention of the public which should have been much sooner focussed upon it. The importance of the subject was early recognised by the British Science Guild, which referred its consideration to its Technical Optics Committee. This committee, after fully investigating the evidence then available, reported, and the guild forwarded an important report to the Board of Trade; the report was printed in full in our issue of March 25 (page 104). So far as can be ascertained, however, no official action appears to have resulted.

Quite recently, Sir Philip Magnus, the member for the University of London, put on the order paper of the House of Commons questions addressed to the representatives of the War Office and the Admiralty, asking whether the supply of optical glass and optical instruments for the use of the Services was keeping pace with their immediate requirements. To these questions official replies of the stereotyped order were given and, in addition, the representative of the Admiralty informed the House that a large firm of makers of optical glass in this country "had greatly increased their output and were still adding to their plant." Before these replies were given, a long letter on the subject was published in the *Times* over the signature of Dr. Walmsley, the Principal of the Northampton Polytechnic Institute, an institute which is intimately associated with technical instruction in applied optics. There had also been other allusions to the matter in the Press.

In the report of the British Science Guild, referred to above, the main points involved are clearly indicated; and with regard to the supply of optical glass for instruments required by the Government, the report states that at the time of its issue there seemed to be no call for any special effort. This statement, however, was made in January, and things have not been standing still since. More especially there was no indication then that either the country or the Government was aware of the necessity for enormous efforts for the adequate supply of "munitions," amongst which must be included "optical appliances." As is well known, the only firm supplying optical glass in this country is the firm referred to in the House of Commons, namely, Messrs. Chance Brothers, of Birmingham; and a paragraph appeared in the *Times* on April 26 to the effect that this firm will now supply optical glass only to those manufacturers of optical instruments who can produce a War Office or Admiralty certificate showing that the glass is needed for the fulfilment of a Government contract. This means that, notwithstanding the large increase in the capacity of the plant at Birmingham, the whole of the optical industry of this country, other than that engaged in Government work, cannot be supplied at the present time with any optical glass whatever. When we consider the important trades which require such glass in fairly large quantities for other than Government purposes, there is no doubt of the great seriousness of the position. But so optimistic is the Government that it has declined a patriotic offer of Lieut.-Col. J. W. Gifford to hand over to the nation free of cost practically the whole of a collection of fine optical glass, considerably over a ton in weight, which he has accumulated during twelve years of laborious research, some of the results of which have been published by the Royal Society from time to time.

The definite proposal made in Dr. Walmsley's letter to the *Times* is that the Government should at once take over the optical glass branch of Messrs. Chance's factory. We understand that this proposal is, as yet, a suggestion of Dr. Walmsley's only, and that, for obvious reasons, he did not communicate beforehand with the firm in question. In passing, we may say that great credit is due to this firm for its very vigorous and patriotic efforts to deal with the situation, but the matter appears to us to have got beyond the point at which any private firm should be required, for the good of the whole community, to undertake such heavy capital expenditure as it has already made and to risk the great sacrifices which may be called for if this expenditure be rendered unproductive after the war. As pointed out by Dr. Walmsley, the natural solution, that competing firms should instal plant and enter the market, is not applicable in this case, because the whole amount involved is too small to make it worth while for any important firm to enter into competition. The supply of fine optical glass for the United Kingdom involves probably an outside turn-over of not more than 20,000*l.* a year, an amount which is not worth dividing. But the supply of this small quantity of raw material, in the form of unwrought optical glass, affects an industry in which the value of the finished products runs to millions of pounds' worth of goods per annum, and in which the greater part of the cost of output goes in wages to highly skilled labour.

It is true that the firm named already has risen to the occasion, has octupled its plant, and, if Ministerial replies are taken at their full face value, has succeeded so far as to supply present Government requirements. But what of the rest of the industry, and, moreover, what is to happen when the war is over? The foreign supply of this vital "key" product will doubtless be resumed, surrounded by the *ante bellum* "wire entanglements" to which Dr. Walmsley refers, such as restrictive contracts on users, the lodging of dummy and blocking patents in our Patent Office, and all those means by which officially-nurtured foreign competition in the past has endeavoured to kill the production in this country of the far more vital and more costly finished products. Is it too late in the day to ask that these methods of competition should not be used against private firms without any greater safeguards available than those which have proved so ineffective in the past?

It seems to us that the proper course is to act generally in the direction of Dr. Walmsley's suggestion, with such modifications as may be found desirable on full investigation. This would mean, in substance, that the Government should undertake the supply of this "key" product. With a Government department empowered to deal with eventualities, full attention could be given to the other important matters dealt with in the report of the British Science Guild, namely, the adequate development of research, better provision for the testing of the physical and optical properties of samples of glass, and, most important of all, provision for adequate technical training and research in applied optics, so that this country may recapture speedily the position it held for so long in the forefront of the world's optical developments.

ASPHYXIATING GASES IN WARFARE.

DR. J. S. HALDANE'S report on his investigation of the nature and effects of the asphyxiating gases, used by the Germans in their attack last week on the French and British lines near Ypres, leaves but little doubt that chlorine or bromine was the chief agent employed, whilst shells containing other irritant poisons were also used.

Prof. H. B. Baker, who accompanied Dr. Haldane, is carrying out an investigation as to the chemical side of the question, and until his report is available, surmises as to the nature of the poisonous gases and the methods adopted for their use would be premature, but the evidence seems to point clearly to the fumes floated by the wind on to the Allies' lines being chlorine, as at ordinary pressure bromine is a liquid below 59° C., and at ordinary temperatures would not give off its vapour with sufficient rapidity to cause the seven-foot bank of vapour that drifted on to the Allies' trenches, whilst the colour of the cloud would have been a rich brown and not the "greenish" or "yellowish-green" colour so frequently described, which undoubtedly points to chlorine.

Chlorine gas is 2·45 times heavier than air, and if discharged "down wind" would only slowly rise, so that at a distance of one hundred yards from its point of disengagement the bank of fume might be expected to be six or seven feet deep, but with bromine vapour, which is more than five times the weight of air, the thickness of the layer of vapour would, under the same conditions, be much less. Liquid chlorine has, for many years, been a commercial article: the gas is liquefied by a pressure of six atmospheres at 0° C., and is stored in lead-lined steel cylinders, being largely exported for use in the extraction of gold in localities where, from difficulties of transport, plant and materials for making the gas *in situ* would be more expensive.

It is said that such cylinders, 4 ft. 6 in. long, were sunk in the German trenches and were connected to pipes six feet long pointing towards the Allies' lines: under these conditions, intense cold would be produced at the point where the cylinders discharged into the delivery pipes by gasification of the liquid and expansion; this would soon check the rapid production of gas, and the white smoke seen behind the greenish cloud of gas may well have been caused by brushwood fires lighted above the delivery pipes to warm them and prevent stoppage.

Although all the evidence and the symptoms found in the unfortunate victims overcome at this particular section of the line point to chlorine as the gas employed, there seems every probability that liquid bromine has also been used in shells or grenades, which, bursting in the air, would scatter the liquid under conditions that would rapidly gasify it, when the weight of the vapour would cause it to descend on the troops below.

Both chlorine gas and bromine vapour, when present to the extent of 5 per cent. in air, rapidly cause death by suffocation, by acting on the mucous linings of the nose, throat, and lungs, so causing acute inflammation; but bromine poisoning is generally distinguishable by the skin of the victim being stained yellow, and the intense action on the eyes, which is much greater than with chlorine.

The Germans have an unfailing source of bromine in the crude carnallite, worked at Stassfurt for the production of potassium chloride, but when full particulars are available it will probably be found that, besides such obvious asphyxiants as chlorine, bromine, and sulphur dioxide, they have also employed compounds of a more complex character.

CHEMICAL STANDARDS FOR WHISKY.

It may be remembered that the Royal Commission on Whisky, which in 1908–9 gave a lengthy consideration to the matter, did not find a very satisfactory answer to the query "What is whisky?" The Government of Western Australia has also been debating this question, and some years ago it issued regulations under which certain chemical standards for "pure pot-still whisky" were proposed for adoption. The proposals met with some criticism. It was alleged, in fact, that many pot-stills employed in Great Britain could not produce whisky which would comply with the requirements.

In order to investigate the matter further the Government analyst for Western Australia was deputed last summer to visit this country. Here, conjointly with an analyst representing the distillers, he inspected some forty Scotch distilleries and analysed a large number of samples of the whisky produced. In addition, twelve distilleries in Ireland were visited alone by the official analyst. The papers now issued[1] give an account of the investigation. They are prefaced by the statement that the proposals, as now modified, have been approved by the Governor in Executive Council and gazetted accordingly.

Briefly, the stipulations are that, as regards Scotch whisky, it shall have been distilled at a strength not more than 35 degrees above proof and matured in wood for not less than two years; and that "standard pot-still whisky" shall contain at least 45 grams of esters, 3·5 of furfural, and 180 of higher alcohols per 100 litres of absolute alcohol, as estimated by methods prescribed. For Irish whisky no furfural standard is proposed at present, but the proportion of esters is required to be not less than 35 grams, and of higher alcohols 200 grams, per 100 litres of absolute alcohol.

Whisky other than "standard pot-still," whether Scotch or Irish, is required to be sold as "blended" whisky. Of this there are three classes, containing respectively at least 75 per cent., at least 50 per cent., and less than 50 per cent. of standard pot-still whisky. For the first and second classes minimum limits are fixed for the proportions of esters, furfural, and higher alcohols—omitting the furfural, however, in the case of Irish whiskies. The third class includes all whisky which does not comply with the requirements for any of the other classes. The respective kinds are to be labelled with the appropriate designations.

A good deal of the criticism to which the original proposals were subjected has been turned aside by the change of a single word in the regulations. "Pure" has become "standard" pot-still whisky. There was just cause of complaint when specifications for the "pure" pot-still product were drawn up, because in certain cases these requirements could not be satisfied by whisky distilled in an apparatus which had certainly hitherto been regarded as a "pot"-still, even if somewhat modified from the simple form. To stigmatise by inference such products as adulterated because they did not comply with the stipulations for "pure" pot-still whisky was indefensible. But, obviously, a community has the right to say what it will regard as a "standard" whisky, and this has now been done.

[1] "Papers in Connection with the Establishment of Standards for Whisky in Western Australia." (Perth: The Government Printer.)

The effect of the regulations will be that as regards the amount of the chief "secondary" constituents (esters, furfural, and higher alcohols), which distinguish whisky from "silent" or patent still spirit, the whisky sold in Western Australia will be classified into four varieties, and the consumer will know, within limits, what is the proportion of these secondary products in the beverage he drinks. C. S.

NOTES.

WE regret to see the announcement of the death on May 4, at seventy years of age, of Sir William R. Gowers, F.R.S., distinguished by his work on diseases of the nervous system and related subjects of medical science.

PROF. SYDNEY J. HICKSON has been elected president of the Manchester Literary and Philosophical Society for the ensuing year (1915–16).

THE council of the Institution of Civil Engineers has made the following awards for papers read and discussed during the session 1914–15:—The Telford gold medal to Mr. A. L. Bell (Rosyth); Telford premiums to Mr. C. W. Anderson (Chakradharpur, India), Sir Thomas Mason (Glasgow), Dr. H. F. Parshall (London), and Mr. H. E. Yerbury (Sheffield), and the Crampton prize to Mr. F. D. Evans (Kuala Lumpur, F.M.S.).

IN reply to a question asked in the House of Commons on May 4, Mr. Tennant said:—"The latest information with regard to the incidence of enteric fever among the British troops in the Expeditionary Force is as follows:—Up to date 963 cases have occurred, and of these 780 have been analysed; 142 cases have occurred in men inoculated fully with two doses of vaccine. Among these ten deaths have occurred, giving a case mortality of 7 per cent.; 157 cases have occurred in men partially protected by inoculation—that is, who have had only one dose of vaccine. Among these there have been ten deaths, giving a case mortality of 6·36 per cent.; 481 cases have occurred in non-inoculated men. Among these there have been 100 deaths, giving a case mortality of 20·79 per cent. To appreciate the full value of these figures it must be brought to notice that 90 per cent. of the troops forming the Expeditionary Force have been inoculated voluntarily. Therefore, among 90 per cent. of the force (*i.e.* inoculated men) there have been 299 cases and twenty deaths. In the other 10 per cent. (uninoculated men) there have been 481 cases and 100 deaths.

ON May 1, at about 5 a.m., the instruments of the seismological observatories of this country registered an earthquake of quite unusual strength, of which, however, we have as yet received no other news. At West Bromwich, the oscillation was so great that one of the recording needles was dismounted. The approximate position of the epicentre, as deduced from the Eskdalemuir seismogram, is latitude 47° N., longitude 156° E., or on the east side of the Kurile Islands. The earthquake is evidently one of the most interesting of the last decade. The Kurile Islands and the Japanese Empire are, as is well known, in the form of festoons, the convex, or eastern side, of which slopes steeply into the deeper waters of the Pacific Ocean. In the Kurile Islands, earthquakes are weak and infrequent as compared with Japan. The recent earthquake thus visited a district in which great shocks are almost or quite unknown. Moreover, the epicentre lies (at a depth of about 4000 fathoms) near the base of the western slope of the great depression which forms the north-easterly continuation of the Tuscarora Deeps.

IN view of the Chancellor of the Exchequer's proposals for a differential tax on beer, it may be of interest to note in what manner the specific gravity of beer is related to its alcoholic strength. As explained in an article in NATURE of April 8, the basis of the beer duty is not the actual amount of alcohol in the beer, but its potential amount as measured by the "original" specific gravity of the wort. In beer as it is sold, the proportion of alcohol varies somewhat even for worts of the same original specific gravity, because they may be fermented to somewhat different degrees either in the primary fermentation or in the slow after-fermentation which generally supervenes. Broadly, however, it may be said that in light beer of original gravity 1043 (water = 1000), the tax on which is not affected by the present proposals, the proportion of alcohol is usually about 6 or 7 per cent. of proof spirit. This represents $3\frac{1}{2}$ to 4 per cent. of real alcohol—that is, of ethyl hydroxide, $C_2H_5.OH$, by volume. Beer of original specific gravity 1050 to 1055, on which a supertax is to be levied, contains about 9 to 11 per cent. of proof spirit when sold, corresponding with $5\frac{1}{4}$ to $6\frac{1}{4}$ per cent. of real alcohol. This represents the beer ordinarily drunk, such as dinner ale, pale ale, "porter," and the beer generally supplied on draught in public-houses. Heavier beers and stout range from about 1060° to 1090° of original gravity; these contain from 11 to 14 per cent. of proof spirit, or $6\frac{1}{4}$ to 8 per cent. of real alcohol. In special "strong ale" the original gravity may be more than 1100°, and the amount of proof spirit as much as 20 per cent., or approximately $11\frac{1}{2}$ per cent. of alcohol.

WE have sadly to record the death of Erasmus Darwin, the only son of Mr. and Mrs. Horace Darwin, of Cambridge, and a grandson of Charles Darwin, and of the first Lord Farrer. He was killed on April 24, leading his men in action in Flanders. On the outbreak of war in August last he instantly applied for a commission, and was gazetted Second Lieutenant in the 4th Battalion Alexandra Princess of Wales's Own Yorkshire Regiment in September last. He went into camp at Darlington until November, and then was stationed at Newcastle-on-Tyne, and was put in command of the scout work, which he entered into with all that quiet zest which was characteristic of him. He delighted in the work of training himself and his men in long expeditions by night and by day over the moors. Not even the pressing offer, which was made to him a few days before he went to the front, of an important post at home in connection with munitions of war would move him from his desire to give his personal services at the front with the scouts to whom he had become so attached. He was a man of very lovable disposition and unusual ability. He was born on December 7, 1881, and was educated at Marlborough and Trinity College, Cambridge. He took the Mathematical Tripos in his second year, 1903, and afterwards passed out in the Mechanical Sciences Tripos in 1905. For some time after taking his degree he worked at Messrs. Mather and Platt's at Manchester. For a time, too, he carried out important work in the test-room of the Cambridge Scientific Instrument Company, and by his exceptional business ability and foresight he rendered highly valued service as a director of the company. About seven years ago he went to Messrs. Bolckow Vaughan's at Middlesbrough, and his sound practical judgment and administrative ability soon won for him a very important position in the firm. In this war the country has to mourn the loss of many valuable lives, and Erasmus Darwin was one of those whose fine, modest conscientiousness and unswerving strength and loyalty made us know that we lose a man whom we should have been proud to see taking his part in the guiding of public affairs in the country.

THE director of the Meteorological Office, Dr. W. N. Shaw, has sent us a copy of a new scale of velocity equivalents of the numbers of the Beaufort scale of wind force which he has received from Prince Boris Galitzin, the director of the Russian Meteorological Service. The table has been drawn up at the Observatoire Physique Central Nicolas, and expresses the wind force determined by the Wild wind-gauge in terms of the Beaufort scale. These values will be used by Russian Meteorological stations as from May 1. The table has been compiled in accordance with the decisions of the International Meteorological Committee, at the meeting held at Rome in 1913.

Beaufort scale	Velocity in metres per second	Beaufort scale	Velocity in metres per second
0	0	7	14–17
1	1	8	18–20
2	2–3	9	21–24
3	4–5	10	25–28
4	6–8	11	29–33
5	9–10	12	34 and more.
6	11–13		

THE Smithsonian Institution announces that fossil bacteria have been discovered in very ancient limestones collected in Gallatin County, Montana, by Dr. C. D. Walcott, secretary of the institution. For some time Dr. Walcott has believed that these bacteria existed, and mention of the fact was made before the Botanical Society of Washington on April 6, when attention was directed to their existence in association with fossil algal deposits of the Newland limestone. The belief that bacteria were the most important factor in the deposition of these ancient limestones was also mentioned by Dr. Walcott in a preliminary publication of the Smithsonian Institution. At that time, however, no definite bacteria had been discovered, but in thin sections of limestone from the collections made in 1914 the microscope now shows these very minute forms of life, some twenty to thirty million of years old. The bacteria were discovered in three sections cut from an algal form included under the generic name Gallatinia, named after the great American explorer Gallatin. The bacteria consist of individual cells and apparent chains of cells which correspond in their physical appearance with the cells of Micrococci.

THE Art Museum of Boston has recently acquired one of the gems of Minoan art, which is described by Prof. E. Gardner in part ii. of *Ancient Egypt* for 1915. It is an ivory statuette with gold ornaments and details, 6½ in. in height. The resemblance of the figure to that of the famous Snake Goddess found by Sir A. Evans at Knossos is obvious. But it resembles not so much any art of ancient Greece as that of Gothic work of the thirteenth century. At the same time, the character of the materials seems to preclude the possibility of forgery. She wears a dress of Cretan type, and her head is adorned with a splendid crown, on which a gold ornament was probably fixed. The statuette exhibits for the first time a treatment of the human figure which is comparable with the fine studies of animals characteristic of Cretan or Mycenæan art. It may be placed not far from the high-water mark of Cretan pottery, and it may go back to the Middle Minoan age. This new discovery emphasises more than ever the contrast between the art of Crete and that of ancient Hellas. It is much to be regretted that this fine work of art has not found its home in our national collections.

MR. T. ERIC PEET has issued in the Publications of the Manchester Museum, No. 75, an account of the Stela of Sebek-khu, which contains the earliest record of an Egyptian campaign in Asia, one of the most important documents ever found in Egypt. It was unearthed at Abydos in 1901 by Prof. Garstang, and is now in the Manchester Museum. It measures 16½ by 10 in., and the inscriptions and representations are somewhat carelessly incised. Its importance lies in the fact that this is a record of an early campaign in a period hitherto unknown preceding the age from which date the Hyksos invasion, the great wars of Thotmes III. and Rameses II., down to the campaign of Sheshonk, mentioned in the Old Testament. It represents the beginning of reprisals in the Asiatic field at the beginning of the twelfth dynasty. The people now attacked by Egypt were the Mentu of Sebet, or nearer Asia, and the Mentu were an Asiatic tribe living close to the Egyptian frontier. On this occasion the Mentu were aided by their allies, the Retenu, probably inhabiting the Peninsula of Sinai. Sekmem, the place attacked, was somewhere in Palestine. However the details of the campaign may be worked out, this Stela remains our best authority for Egyptian conquest in Asia prior to the eighteenth dynasty.

ACCORDING to the *Victorian Naturalist* for March, examples of parasitic Copepods belonging to the family Monstrillidæ, have been discovered for the first time in Australia by Mr. J. Searle, but as yet their specific identity has not been determined. These small crustacea are parasitic on Serpulid worms, whence they escape, by rupturing the body wall of the host, to liberate their ova. This they do as free-swimming organisms, but lacking a functional alimentary canal, death ensues on the completion of the reproductive functions.

IN the *Australian Zoologist* for February, Mr. Allan McCulloch gives a brief, but extremely interesting account of the hitherto unrecorded migration of the larval eel-gudgeon (*Galaxias attenuatus*) from the sea to fresh water. He found numbers of these larvæ, about 38 mm. long, and quite transparent, making their way through the surf into a small fresh-water stream about 6 ft. wide. Very little is known of the habits of Galaxias, but some interesting notes on the occurrence of *G. truttaceus* in damp soil in Tasmania have been made by Mr. T. Hall and Mr. J. Fletcher. It would seem that this species is capable of burrowing into soft earth to a depth of eight or nine inches, when the water dries up in times of drought, and there æstivating until released by the rains.

How insect pests extend their range into new and distant areas is shown by Mr. W. J. Rainbow in the *Australian Zoologist* for February, where he records the occurrence of the carpet beetle (*Attagenus piceus*) in woollen goods imported from London by a large drapery establishment, and of a West Indian longicorn beetle (*Eburia binodosa*), which had worked its way out of of an imported oak chair. This insect, doubtless in a similar manner, has also made its way into England, but so far with no evil results. The discovery of the carpet beetle in Australia is, however, a more serious matter, for much damage had been done before it was detected. Hence there is a possibility that its ravages may spread.

THE peculiar methods of feeding displayed by the starfish are well known; but Mr. H. N. Milligan, in the *Zoologist* for April, describes for the first time the means adopted for disposing of a victim so unusual as a pipe-fish. After some experimenting the body was seized between two of the arms, and held in position by means of the suckers, while the three remaining arms were made to serve as the legs of a tripod. The upper portion of the abdomen of the still living captive was brought immediately under the mouth of the captor, when the stomach was everted in the usual manner to envelop this unwieldy morsel, which was held there until hunger was appeased. No similar case seems ever to have been recorded. Two excellent figures add not a little to the interest of this strange record.

FROM the annual report of the Zoological Society of London, it is apparent that the war has not only curtailed its income, and made rigid economy necessary, but it has further hampered the smooth running of the menagerie. More especially is this true in regard to the fish supply. Early in August the contractor was unable to continue his supply, and fish had to be bought daily at from $4\frac{1}{2}d.$ to $7d.$ per pound, instead of $1\frac{1}{2}d.$ per pound. Then the inspector of the Fishmongers' Company at Billingsgate came to the rescue, and allowed the society to take away from the market quantities of fish good for immediate consumption, but not fit to distribute through the retail trade. But this source of supply failed when the cold weather came. Happily, so far it has been possible to arrange for a regular supply from Grimsby. We would suggest that should this fail recourse should be had to netting some of our inland waters for "coarse fish," of which there must be an abundance for a long time to come.

IT is extremely gratifying to learn, from the spring number of *Bird Notes and News*—the organ of the Bird Protection Society that the colonies of the great skua are still increasing on the Shetlands, though they have to be guarded jealously against the raids of the egg-collector. Strenuous efforts are being made to save from extermination the red-throated diver, the black-tailed godwit, and the harrier. It is to be hoped that these efforts will meet with their due meed of success during the coming nesting season. The largest colony of great black-backed gulls in Great Britain, we are told, is to be found on Noss. But this does not afford us unmixed satisfaction. This bird is ruthlessly destructive of the eggs of other species, and of late years has become unduly numerous; measures might, therefore, with advantage, be taken to reduce their numbers. In the same number we learn with much pleasure that the choughs and buzzards are more than holding their own in Cornwall, thanks to the efforts of the society's watchers.

THE report for 1913 of the periodic variations of glaciers (*Annales de Glaciologie*, vol. ix. (1914), pp. 42–65) includes the Swiss, Eastern, and Italian Alps, and gives some information about the glaciers of Norway, Russia, the Himalayas, New Zealand, and North America, especially Alaska. The Alpine glaciers, on the whole, are still retreating, though a few advances are recorded. For instance, of sixty-one Swiss glaciers, twenty-five continued to recede in 1913, and ten probably did the same, while only one certainly and ten probably advanced; the movements of the rest being doubtful. In the other two Alpine districts the observations are less numerous, but on the whole they point in the same direction. In other countries the evidence, which, however, is sometimes rather imperfect, shows that glaciers in the same neighbourhood are uncertain in their movements, but are generally receding, the small being more sensitive than the large to the annual snowfall. This, however, seems certain, that in the Alps the ice-streams have not nearly regained the ground which they began to lose rather more than half a century ago. At present information about these variations, though in a few cases it goes back some three centuries, is too imperfect to admit of any satisfactory explanation. Oscillations such as have been observed during several years, including the last one, are probably due to variations in the temperature and snowfall during one or more preceding seasons, but the great advances, with corresponding thickening of the ice-streams, such as those which culminated approximately in 1820, and in 1850, lasting, perhaps with occasional slight recession, until well past 1860, must be due to a more general cause. For determining this the records, accumulated by the Commission Internationale des Glaciers, will be ultimately very valuable.

Bulletins 41 and 42 of the Agricultural Research Institute, Pusa, deal with investigations on sugar-yielding plants in India. In No. 41 Mr. H. E. Annett deals with sweet sorghum and the variation in composition of this crop during growth, giving extensive and valuable data resulting from experiments and analyses. He concludes that owing to the high glucose ratio and other difficulties, sweet sorghum is not worth growing in India as a source of sugar, but that it seems likely to prove a valuable source of fodder, being a fairly quick-growing crop; also that soon after flowering the plant shows no increase in total weight or in sugar, hence it should not be allowed to grow beyond this stage, after which its value as fodder decreases. Bulletin 42, by Mr. G. Clarke and others, deals with cane-crushing. It is pointed out that in order to ascertain the value of a variety of sugar-cane and the possibility of its succeeding as a field crop in any given district, it is necessary to investigate in the field the general crop characters; in the laboratory the sugar content and quality of the juice; and in the mill what proportion of juice and total sugar can be extracted, and the cost of doing so. Tabulated details are given, representing the results of a long-continued series of experiments on sugar-crushing and the sucrose yields of different varieties of cane; and the authors conclude that future increase in area under cane in the United Provinces and in number of mills will depend upon the introduction of cheaper and quicker methods of dealing with the produce, the present crop being as much as the bullock-power of the provinces can deal with, and the industry unlikely to increase unless some cheaper form of crushing is introduced.

The general deficiency of rainfall in March as shown by *Symons's Meteorological Magazine* for April in the tentative table for the British Isles is of more than ordinary interest. The wet spell which was so characteristic of the recent winter has fortunately come to an end. Statistics previously given by the British Rainfall Organisation show that the aggregate rainfall for the four months—November, 1914, to February, 1915—was 168 per cent. of the average over England and Wales, and more than 200 per cent. of the average over the Thames Valley. The rainfall table for March shows a totally different result. Rain measurements are given for fifty-five stations scattered over the entire kingdom, and of these only five have the total rainfall for the month in excess of the average; they occur along the east coast of England and in the north of Scotland. The greatest excess from the normal occurs at Gordon Castle, where the rainfall was 147 per cent. of the average, and at no other station was the percentage of the average more than 110. At twenty-one stations out of fifty-five the rainfall was less than 50 per cent. of the average, and at two stations, Launceston and Killarney, the rainfall was less than 25 per cent. of the average. For the British Isles as a whole the rainfall was 58 per cent. of the average, whilst for the several parts of the United Kingdom the percentages are: England and Wales, 54; Scotland, 79; and Ireland, 40.

Circular No. 24, issued by the Bureau of Standards, contains a list of the papers which have appeared in each of the ten published volumes of the Bulletin and a classified list of the papers, with a short account of the contents of each. The Bureau also announces that in future the Bulletin will be supplied to subscribers at one dollar a volume unbound, plus 50 cents for postage to this country. Subscriptions should be sent in advance to the Superintendent of Documents, Washington, D.C. We have no doubt there are many in this country who will take this opportunity of getting a valuable series of papers which up to the present could only be found in the libraries of scientific societies.

In a paper read before the Royal Society of Arts on April 14, and published in the Journal of the Society for April 18, Mr. T. Thorne Baker gave a short account of the industrial uses to which radium is at present put. Radium residues left over after treatment of the ores may or may not improve the growth of plants, according to the materials other than radium contained in them, but if the metals have been removed during the process of extraction of the radium the residue in suitable quantities appears to facilitate growth. These residues may also be utilised in the treatment of disease and as bactericides. In the discussion which followed the reading of the paper, it was pointed out that in much of the plant growth work which had been done with radium, sufficient care had not been exercised to enable it to be affirmed with certainty that the increased growth found in some cases was not due to the nitrates and phosphates in the residues, rather than to the radium. Until this question is settled, there appears no justification for the use of radium in horticulture.

An account of "Röntgen Motion Pictures" is given in the *Scientific American* for April 3. An illustration of the apparatus designed for the purpose of producing them, by F. Dessaur, is also given, together with a number of somewhat indefinite results. During the meeting in London of the International Congress of Medicine, we had the advantage of seeing this remarkable arrangement in action, and we brought away the impression that it added at least a new terror for the patient who has to come in contact with the already rather alarming armament of a modern radiologist. While it is certainly a model of ingenuity, the plate-changing operation is accompanied by a good deal of noise and clatter, and there is no doubt that beyond fixation of the image little or no more is to be learned from the results than can be ascertained by an ordinary screen examination with a far simpler outfit. The apparatus, however, is not without special significance to us in these days. To have brought it to perfection must have involved great expenditure of time and money, nor is it likely, on account of its price and size, to find a very ready sale. Yet this sort of thing is done in Germany, and done well, to attract and to create the impression of progress and thereby to catch the market in X-ray apparatus generally. In the end it pays and incidentally leads to much interesting work, as well as fostering a spirit of enterprise.

WE have received from Kodak, Limited (Wratten Division), a copy of the third edition of their booklet on photomicrography. As compared with the second edition, it is somewhat enlarged, and it comprises within its thirty-six pages simple and straightforward instructions as to the arrangement of the apparatus, undisfigured by diagrams and directions with regard to the illuminating system that are too often found in the text-books, although they can never be realised. We refer to "parallel light," and so on. The price of the pamphlet is 3*d*., and, of course, its strong point is the photographic side rather than the microscopical side of the art, and especially the use of colour filters. The spectrum transmissions of nine filters are given, and also the dominant wave-lengths of ten, most of the latter being a combination of two. Another table gives the absorption bands of the eighteen principal stains used in microscopy, with the suitable filters for securing maximum contrast in the photograph. Other tables give the relative sensitiveness of various Wratten plates to different light sources, and exposure factors for different focal lengths and apertures of objectives, for various magnifications, for different light sources, and for fifteen different light filters, in connection with the "M" plates. The illustrations include two excellent reproductions of stained preparations, and two little colour filters in a pocket of the cover, for viewing them through, serve to demonstrate the potency and usefulness of colour filters.

THE March number of the *Journal of Chemical Technology* contains a report of a special meeting of the London Section of the Institution of Chemical Technologists which was held on March 11 to discuss "The Future of British Chemical Industry." In opening the discussion, Colonel C. E. Cassal emphasised the fact that the chemical profession in this country stands alone among the professions in that it is utterly without organisation, and is split up into a number of different camps. At the present time there is little sympathy between the college laboratory and the technical laboratory; it is on the closer union of these that future progress of chemical industry will depend. Colonel Cassal, in referring to the ignorance of the general public and of State departments as to the value of science, illustrated his remarks by a reference to the now notorious advertisement of the Royal Arsenal, referred to in NATURE of April 1 (p. 119), and to the organisation of "British Dyes, Ltd." Mr. W. J. Dibdin remarked that the chemical department of the London County Council, of which he was formerly the chief, effected a saving of 10,000,000*l*. capital expenditure in the plant necessary for dealing with the sewage of London. The general trend of the debate was that only by the education of the chemist supplemented by the education of the employer will it be possible successfully to fight Germany in the field of industrial chemistry.

ALTHOUGH it is perhaps one of the minor chemical products, allyl alcohol has been used extensively in research, and is by far the most readily accessible of the series of unsaturated alcohols. Originally prepared through the iodide from glycerol, it was a very costly product, but came into common use when Tollens showed that it could be prepared directly from glycerol by heating it with oxalic acid. A greatly improved preparation has recently been described by Dr. Chattaway in the Journal of the Chemical Society (vol. cvii., p. 407). Five hundred grams each of glycerol and of anhydrous oxalic acid are heated at 100° in a vacuum during four or five hours, whilst a certain amount of formic acid is distilled out; the product, which contains much dioxalin, is then decomposed by heating under ordinary pressure to 220°–240°, when carbon dioxide is set free and allyl alcohol and allyl formate are produced. The oxalic acid is decomposed almost completely, leaving a residue of glycerol, which can be made up again to 500 grams, mixed with 500 grams more of oxalic acid, and used over again; this can be repeated four or five times. The waste of material is therefore very small, and the glycerol used up is converted almost quantitatively into allyl alcohol, whilst the oxalic acid is converted on one hand into carbon dioxide, and on the other into formic acid.

THE importance, both to the manufacturer and the consumer, of having at disposal adequate facilities for the scientific investigation and testing of the quality of textiles is very great. At the present time when immense quantities of such materials are being manufactured for military and naval purposes such facilities are exceptionally valuable. The Public Textile Testing and Conditioning House carried on under the auspices of the Corporation of Belfast, and located in the Municipal Technical Institute of that city, has just issued the fifth edition of its regulations and schedule of charges, and this publication indicates very strikingly the extent to which textile testing has now been elaborated and perfected. The Belfast testing house is one of the more recently opened, having been established in the year 1910 by the corporation at the direct request of the textile trades of Belfast and district. The house is carried on under Parliamentary authority, has power to grant certificates respecting the articles submitted for examination, and certificates so issued are receivable as evidence in a court of law. The schedule of charges shows that a very wide range of tests are undertaken in the testing house. The tests include physical, chemical, and microscopical investigations of fibres, yarns, cloths, and bleaching and dyeing materials. A noteworthy section of the testing scheme is that concerned with the determination of the cause of defects in cloth, more especially such causes as are classed under the technical heading of "tendering."

PART 4 of the Proceedings of the Institution of Mechanical Engineers for 1914 has just been issued, and contains the recommendations of the refrigeration research committee. There are also given charts of entropy and total heat for each of the three substances in common use for refrigerating purposes, viz., carbon dioxide, ammonia, and sulphur dioxide. The use of these charts is explained in a note by the chairman of the committee, Sir J. A. Ewing. The chart for carbonic acid uses Dr. Mollier's figures, but with British units of pressure and with some additions based on the recent researches of Prof. Jenkin and Mr. Page. For the other two substances the experimental data available are much less complete. For ammonia, the chart must be regarded as no more than provisional; values given by Prof. Goodenough and Mr. W. E. Mosher have been adopted. The chart for sulphurous acid is also provisional; values given by Dr. J. Hýbl have been employed. Tables giving the properties of these substances are also included.

ERRATUM.—In NATURE of April 29, p. 238, col. 1, line 10 from bottom, for "solstice" read "equinox."

OUR ASTRONOMICAL COLUMN.

COMET 1915*a* (MELLISH).—The following is a continuation of the ephemeris of Mellish's comet (1915*a*) taken from *Astronomische Nachrichten*, No. 4796:—

	R.A. (true) h. m. s.	Dec. (true) ° ′	Mag.
May 6	18 53 31	−14 46·2	
8	57 6	16 25·9	6·5
10	19 0 55	18 17·3	
12	5 2	20 22·2	6·2
14	19 9 32	−22 42·1	

The comet is rapidly moving southwards, and is situated a little to the north of π Sagittarii.

A third series of elements and an ephemeris of this comet are published by Mr. R. T. Crawford, of the Berkeley Astronomical Department, in the Lick Observatory Bulletin, No. 270. It is pointed out that there seems to be a similarity between these elements and those of comet 1748 II., and computations are being undertaken to test the possibility of the identity.

ORBIT OF JUPITER'S NINTH SATELLITE.—A more rigorous reduction of the elements of the orbit of the ninth satellite of Jupiter is given by Seth B. Nicholson in the Lick Observatory Bulletin, No. 271, this being a continuation of the investigation previously published in the Bulletin, No. 265 (see this column for April 1). The following are the new elements derived:—

Epoch and Osculation = 1914 August 21·0 G.M.T.

$$M = 135^\circ\ 57{\cdot}2'$$
$$\left.\begin{aligned}\omega &= 359^\circ\ 53{\cdot}5'\\ \Omega &= 310^\circ\ 30{\cdot}6'\\ i &= 156^\circ\ 57{\cdot}9'\end{aligned}\right\}\ 1914{\cdot}0$$
$$e = 0{\cdot}1105$$
$$\mu = 0^\circ{\cdot}4518$$
$$P = 2{\cdot}182 \text{ years}$$
$$\log a = 9{\cdot}2192$$

As a result of the alteration in the elements it is stated that the errors in the final elements do not exceed 2 per cent. of their values. An ephemeris for the coming opposition is promised at an early date.

THE SATELLITES OF URANUS.—Two communications regarding measures of the satellites of Uranus are published in the Lick Observatory Bulletin, No. 269. The first, by Prof. R. G. Aitken, were made in 1914 with the 36-in. refractor using a 350 power eyepiece. An interesting opportunity presented itself on July 21 to estimate their relative brightness. The four satellites were all south of the planet, Ariel and Umbriel almost in line with it, and only a few seconds of arc apart. Ariel was seen at the first glance, and was conspicuously visible while measuring the other satellites; Umbriel was seen with much more difficulty, and made no impression on the eye except when special efforts were made to see it. By direct comparison it was estimated to be from ½ to ¾ magnitude fainter than Ariel. The latter appeared to be a magnitude fainter than Titania; Oberon, from ¼ to ½ magnitude fainter than Titania. While these observations were being made the sky was very clear, the seeing good, and the planet screened by an occulting bar. Measures of the satellites were made by Mr. S. B. Nicholson from photographs taken with the Crossley reflector at the Lick Observatory during 1914. The positions of Uranus and of the satellites were measured in rectangular co-ordinates, so that the distances of the satellites from either Uranus or one of the outer satellites could be obtained.

THE GREENWICH SECTION OF THE ASTROGRAPHIC CATALOGUE.—The third volume of the Astrographic Catalogue 1900·0 deals with the Greenwich Section, declination +64° to +90°, and is deduced from photographs taken and measured at the Royal Observatory. The first portion contains a catalogue of 2212 stars within 3° of the north pole in standard rectangular co-ordinates. In the original scheme of publication this, the third volume, should have included a general discussion of results, but the Astronomer Royal has deferred this discussion for a fourth volume. The present catalogue includes: (1) stars used as reference stars for the astrographic plates; (2) other stars contained in the catalogues of the *Astronomische Gesellschaft;* (3) stars contained in Carrington's Catalogue (1855·0); and (4) stars in the Bonn Durchmusterung Zone, 80°. The right ascensions and declinations depend throughout on the places of stars observed with the transit circle at Greenwich in the years 1897 to 1905. The proper motions given in the Greenwich Catalogue have been used in forming the constants of the plates. In the main catalogue the epoch is 1900·0. The stars are arranged in zones of declination 1° wide, and the photographic magnitudes are on the scale of Prof. E. C. Pickering's north polar sequence.

RECENT PAPERS IN THE "ASTRONOMISCHE NACHRICHTEN."—The following is a continuation of the chief contents of some of the earlier numbers of the *Astronomische Nachrichten* referred to in this column last week:—No. 4785: Trial of the photographic magnitude-scale of the bright Pleiades stars, by E. Hertzsprung. No. 4784: Observations of Halley's comet 1910 II., made at the Chamberlin Observatory of the University of Denver, by Herbert A. Howe. No. 4783: Photographic observations of some bright double stars, by E. Hertzsprung; observations on the brightness and form of comets, by M. Ebell. No. 4782: The special motions of stars with known parallaxes, by R. Klumak. No. 4781: Observations of planets and comets made with the 360-mm. refractor of the Copenhagen Observatory, by C. F. Pechüle and E. Strömgren and R. Andersen. No. 4780: Observations of the planet Venus, by W. Rabe; definite orbit of comet 1906 VII. (Thiele), by E. Waage. No. 4779: Observations of the planet Mars, by H. E. Lau; observations of the variables U Sagittæ and R. S. Vulpeculæ, by M. Maggini. No. 4778: Test for variability of 113 Herculis and α Sagittæ, by E. Hertzsprung; photographic measures of the magnitude difference between the two components of ν Draconis, by E. Hertzsprung; observations of the variables o Herculis, g Herculis, and RZ Cassiopeiæ, by M. Maggini. No. 4777: Mean elements of sixty minor planets, by M. Brendel; ephemeris for Polarissima (BD +89° 37′) for 1915, by L. Courvoisier.

SMITHSONIAN INSTITUTION EXPLORATIONS.

THE report of Explorations and Field-work of the Smithsonian Institution for 1913 (Smithsonian Miscellaneous Collections, vol. lxiii., No. 8, 1914), including the National Museum, Bureau of American Ethnology, and Astrophysical Observatory, represents much activity in various directions, even if, owing to scarcity of funds, some promising enterprises were abandoned.

In geology the most important work was a survey by Dr. C. D. Walcott of the Robson Peak district in British Columbia and Alberta, and the Field region in British Columbia, which he regards as one of the finest geological sections in the world (see NATURE, December 24, 1914, p. 468). A series of admirable photographs, one of which (Fig. 1) is here reproduced by the courtesy of the secretary of the Institution, illustrates the splendid mountain and glacier scenery of this region. At Field a large collection of specimens was made from the great Cambrian fossil quarry. Mr. F. Springer's exploration in Illinois produced numerous examples of fossil crinoidea, and in Montana Mr. E. Stebinger discovered a new ceratopsian or horned dinosaur, the first example possessing a complete articulated tail and hind foot, which contributes greatly to our knowledge of the skeletal anatomy of this group of extinct reptiles. Dr. W. L. Abbott continued his work in Kashmir, his acquisitions including a curious silvery-grey shrew about 74 millimetres long, quite different from anything he had before seen, and a fine snow leopard with complete skeleton.

In the field of anthropology Dr. A. Hrdlicka continued his exploration in Peru with the object of determining the relations of the ancient Peruvians of the mountains with those of the coast, with the result that he finds no evidence of any great antiquity of man in Peru. Except the cemeteries or burial caves of the coast or mountain people, there was no sign of human occupation and no trace of anything older than the well-represented pre-Columbian Indians, neither the remains of the coast nor of the inland people disclosing an antiquity greater than some twenty centuries. In the Antilles Dr. Fewkes finds a race of sedentary people possessing a form of culture extending from Trinidad to Porto Rico, preceded in Cuba and Hayti by a cave-dwelling race, and followed by the comparatively late Carib immigration.

As regards the Indian tribes of the States, the most interesting information is that collected by Mrs. M. C. Stevenson among the Tewa tribe, where the rain-priests retire into an underground ceremonial chamber, symbolising the lower world, and, after undergoing a strict fast, pray for rain. It is startling to learn that this tribe still propitiate the rattlesnake in order to prevent it from injuring them, by a quadrennial human sacrifice, either of the youngest female infant or of an adult unmarried childless woman. The victims are drugged until they seem to be dead and are then exposed to the sacred snakes, who are allowed to devour the corpse. The skeleton is then buried with offerings under the floor of an adjoining room.

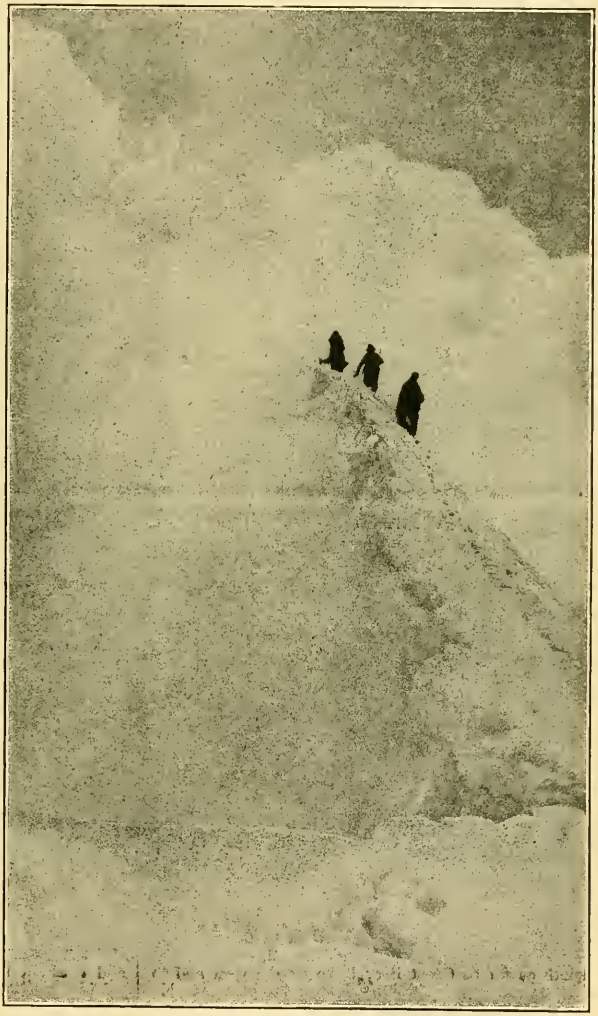

Photo.] FIG. 1.—Summit of Mount Resplendent, British Columbia. [*P. L. Tait.*

The account of the tattooing ceremony among the Osage tribe (Fig. 2), by Mr. F. La Flesche, is noteworthy. Formerly the honour was restricted to warriors distinguished in a campaign. Now, as they have gained wealth, it has become a means by which any person can publicly display his affection towards a relative.

Mr. V. Stefánsson contributes to Museum Bulletin No. 6 of the Department of Mines, Canada, a paper on prehistoric and present commerce among the Arctic coast Eskimo. This was, as might have been anticipated, usually conducted by sea. The main route ran along the coast from Mackenzie Bay on the east to King William Island on the west, diverging to the north through Victoria Island, and reaching south as far as Great Bear Lake on the west and to Thelon River and Chesterfield Inlet on the west. He finds a certain tribal specialisation of industries and some division of labour resulting from the varied natural resources of this wide area. But each tribe believes the articles made by its members to be superior to those of neighbouring tribes. Though the people are very conservative, there is a constant interchange of manufactures between distant districts, and with this arises a commerce of ideas which are readily assimilated with the indigenous beliefs and practices.

Bureau of American Ethnology.

FIG. 2.—An Osage Indian with tattooing.

RECENT WORK ON VERTEBRATE PALÆONTOLOGY.

UNDER the direction of Prof. H. F. Osborn a number of expeditions have been dispatched from the American Museum of Natural History to collect the mammalian faunas of the Lower Eocene Wasatch and Wind River beds of Wyoming, and the collection of such remains in that institution is consequently very large, especially as it includes the extensive series brought together by Prof. Cope, which was purchased in 1895. The stratigraphical observations made during these expeditions and the careful record of the exact horizon of each fossil have rendered it practicable to correlate the various faunas, and to trace out the evolution of the different species and groups in a manner which was previously impossible. With the object of putting these new facts before the scientific public, Messrs. Matthew and Grainger have undertaken a revision of our knowledge of these faunas, the first portion of which appears as vol. xxxiv., art. 1 (pp. 1–103), of the Bulletin of the American Museum of Natural History. This, which is by Dr. Matthew alone, treats of the creodont carnivora, seven families of which are represented in these formations, and of which three genera and a large number of species are described as new.

Quarto Bulletin No. 89 of the U.S. National Museum is devoted to the first portion of a descriptive account of the osteology of the armoured dinosaurs, with special reference to the genus Stegosaurus, by Mr. C. W. Gilmore. The memoir, which includes 136 quarto pages and thirty-six plates, is dated December 31, 1914, but copies did not reach this country until the latter part of the following March; it is based almost exclusively on specimens in the collection of the National Museum, and gives the first detailed description of the entire osteology of Stegosaurus. The material includes considerable portions of the skeletons of several individuals, among which the one most nearly approaching completeness, and which alone exhibits the true arrangement of the dermal armour, is the type of *S. stenops*. With few exceptions, the entire series of stegosaurian remains were obtained from two quarries, situated respectively in Albany County, Wyoming, and Fremont County, Colorado.

Nine species of the genus—all American—are at present provisionally recognised, the European forms described by Owen as Omosaurus being regarded as generically distinct, under the name of Dacentrurus, the original designation being pre-occupied. In some of the later restorations of Stegosaurus the double series of upstanding dorsal plates were ranged alternately, and the number of pairs of spines on the tail reduced from four to two; in the latest restoration, however, there is a return to the paired arrangement of the plates, and the retention of four pairs of tail-spines. Stegosaurus, which attained a length of about 20 ft., had relatively small and feeble teeth, which appear to indicate that it fed on succulent plants. The structure of the feet suggests that these reptiles inhabited low, swampy tracts rather than uplands; and there is good reason to believe that the members of the genus are descended from bipedal dinosaurs specially adapted for locomotion on land.

Until quite recently remains of man-like apes were almost unknown from the Indian Siwaliks, the only specimens being a canine collected by Falconer and Cautley, and a palate from the Punjab described in 1879 by Mr. Lydekker as Palæopithecus. During the past few years the collectors employed by the Geological Survey have, however, brought together a considerable series of teeth and fragmentary jaws of these and other Primates. These form the subject of an illustrated article contributed by Dr. G. E. Pilgrim to the February number of the Records of the Geological Survey of India (vol. xlv., pp. 1–74). Among the remains of man-like apes, a considerable number are referred to the European genus Dryopithecus, of which the author recognises three Siwalik species. These specimens include one exhibiting two of the upper molars *in situ*, which were previously unknown. A separate tooth, characterised by the roughness of its enamel, is described as a new genus, under the name of *Palaeosimia rugosidens*.

The greatest interest attaches, however, to specimens described as *Sivapithecus indicus*, and referred to the family Hominidæ. This genus and species were originally described on the evidence of a single tooth, but the author now proposes to take as the type part of a lower jaw with several teeth; this, of course, being totally unjustifiable. The author gives an ideal restoration of the whole mandible, but it is somewhat difficult to realise all the evidence on which it is based. A special feature of the restoration is the extreme shortness of the symphysis, which is found elsewhere (save in the Hominidæ) only in gibbons. The author is at great pains to show that Sivapithecus is generically distinct from Palæopithecus, but as the latter is definitely known only by the palate, his arguments do not appear absolutely conclusive, especially when it is borne in mind that the occurrence of a number of types of ape-like creatures in the Siwaliks is unlikely.

The author concludes his article with observations on the evolution of the Anthropoidea, in the course of which it is suggested that Sivapithecus should take its place as a side-branch from the main stem which gave rise to man himself. On the other hand, the Piltdown Eoanthropus, which Dr. Smith Woodward considers to be a direct ancestor of man, is thrown altogether out of the line of human ancestry. While the article is full of interest, further consideration is advisable before the author's views are accepted in their entirety.

In an earlier paper in the same serial (vol. xliv., pp. 265–79) Dr. Pilgrim describes and figures a number of Siwalik teeth referable to the creodont genus Dissopsalis, named by himself in 1910. The genus is regarded as forming the summit of a branch of the Hyænodontidæ, running nearly parallel to the one culminating in Hyænodon and Pterodon. It is also shown that a Siwalik tooth described by the present writer as *Hyaenodon indicus* is really inseparable from *Hyotherium sindiense*, named by him at an earlier date. Later on in the same issue Dr. Pilgrim points out that the name Progiraffa proposed by himself for a Siwalik giraffe-like ruminant, has to give place to Propalæomeryx of the present writer.

R. L.

THE UNITED STATES BUREAU OF STANDARDS.

IN his report for 1913–14, Dr. Stratton, the director of the U.S. Bureau of Standards, shows how very extensive and varied is the work carried on at the Bureau. During the past few years its growth has been exceptionally rapid, and increased accommodation is still asked for. Much of the work carried on is strictly technical and includes tests on paper, paints, and varnishes, the shrinkage of wools, the properties of lime and cements, and the study of ceramic glazes. In the electrical division an important electrolysis survey was conducted in Springfield, Massachusetts, and useful information obtained with regard to the bonding of tracks, etc.

The unfortunate accident to the *Titanic* centred attention on possible methods of detecting the near presence of icebergs, and assistants of the bureau conducted experiments on two naval vessels. The general conclusions reached are that the temperature variations in parts of the ocean far removed from ice are often as great and as sudden as in the immediate neighbourhood of icebergs, and that it is not possible to draw positive conclusions as to the absence or presence of icebergs from the temperature variation of sea-water. An attempt was also made to detect by means of submarine telephones, the submarine echoes from the submerged portion of a large iceberg. Sound waves were produced by striking the ship's bell under water. The experiments were not completed owing to lack of time and facilities, but the results obtained merit further trials.

Researches of a strictly scientific nature are numerous. One of considerable interest is the determination of standard wave-lengths throughout the entire spectrum. This is being carried out in accordance with the recommendations of the International Solar Union, and the results, while needed mainly by men of science, will also be of value in the industries. For example, the spectroscopic analysis of steel and other substances cannot be successfully undertaken until the characteristics of the spectra of the constituents are more accurately observed.

Another optical research deals with the transmission of glass for the ultra-violet rays, mainly with a view of determining their fitness for spectacle-making.

An interesting innovation is the establishment of standards of radiation in the form of incandescent lamps. In these standards the intensity of the radiant energy per unit area at unit distance from the lamp, has been established in absolute value. A long-felt want has thus been supplied.

In the chemical department work is in progress on the methods and standards employed in volumetric analysis. The final scheme for this research was prepared after criticisms and suggestions had been received from about 150 experienced chemists. A beginning has been made with the study of acidimetry and the subject of indicators. The quality of chemical reagents on the market is also being investigated. It has become the practice of many well-known dealers to attach labels to the bottles containing reagents, setting forth the nature and amount of the impurities. In many cases it has been found that the labels do not state the truth, and as a consequence some action will probably be taken. One suggestion is that the bureau shall purchase material and assume all the duties of bottling and sale.

In the division of metallurgy, among other interesting results are included the melting points of various metals. The results given are:—Nickel, 1452° C.; cobalt, 1478°; iron, 1530°, manganese, 1260°; chromium, 1520°; vanadium, 1720°; and titanium, 1795°. It is stated that accurate measurements of the melting point can be made with the micropyrometer on samples as minute as 0·001 milligram. The micropyrometer has also been employed to measure the monochromatic emissivity of microscopic samples. This constant has been determined for some twenty elements. It is expected to determine the melting points and emissivities of all the available refractory elements and of numerous oxides.

One of the most important recommendations of the director is to establish a radio-laboratory at the bureau. The importance of wireless telegraphy to the United States Government is pointed out, and a grant of 10,000*l.* for the construction of such a laboratory is asked for. For maintenance an additional 2000*l.* is required.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

ABERYSTWYTH.—Prof. Alexander Findlay has been appointed Thomson lecturer in chemistry for the session 1915–16 in the United Free Church College, Aberdeen.

CAMBRIDGE.—The Linacre lecture will be delivered by Prof. E. H. Starling, in the anatomy lecture-room, at 8 p.m., Thursday, May 6, on the governor mechanism of the heart. The Rede lecture will be delivered by Dr. Norman Moore, at 5 p.m. of the same day, in the Senate House, on St. Bartholomew's Hospital in peace and war.

In view of the difficulties of the present financial situation, the Special Board for Biology and Geology has decided to allocate only such sums of money from the Gordon Wigan Fund as are necessary to prevent the extinction of research work already in progress. The grants made are: 10*l.* to Prof. Hughes, for research among the Pliocene deposits of the Cambridge district; 40*l.* to Prof. Punnett, to ensure that the Botanic Garden Syndicate will continue to offer special facilities for plant-breeding experiments; and 21*l.* to Mr. H. Scott, curator in entomology, for the care and development of the collections of insects.

SHEFFIELD.—Sir Joseph Jonas has given the University 5000*l.* to found, endow, and equip a laboratory, in connection with the applied science department, for testing metals, minerals, and similar substances, especially those involved in the production and manufacture of steel.

LADY HUGGINS, who died on March 24, leaving unsettled estate valued at 12,586*l.* gross, with net personality 12,109*l.*, made the following bequests, among others:—A sum not exceeding 1000*l.* to the Bedford College for Women (University of London); 500*l.*, and, if her estate is sufficient, a further sum of 500*l.* for the erection of a memorial in St. Paul's Cathedral to the memory of her husband; 1000*l.*, and, if her estate is sufficient, a further sum of 1000*l.* to the City of London School, Victoria Embankment, for the endowment of a scholarship for the study of astronomy, tenable at Cambridge, to be called the "Sir William Huggins" Scholarship; and a sum of not more than 300*l.* for finishing, editing, and illustrating the book on which she was engaged, being the life of her husband. The residue of the estate, if any, is also left to the City of London School.

WE learn from *Science* that Princeton University has received from Mrs. W. C. Osborn 25,000*l.* to establish the Dodge professorship of medieval history, and 20,000*l.* from an anonymous donor to endow a professorship of economics. Our contemporary also states that the Schools of Mines, Engineering, and Chemistry of Columbia University have received an anonymous gift of 6000*l.*, to be applied to the reconstruction and new equipment of the laboratories of quantitative, organic, and engineering chemistry in Havemeyer Hall; that a gift of 4000*l.* is announced from Mrs. S. W. Bridgham, daughter of a trustee of Columbia University from 1860 to 1903; and that Mr. G. W. Brackenridge has given to the University of Texas his yacht *Navidad,* valued at 20,000*l.*, to be assigned to the biological department of the institution. A preliminary survey of the Texas coast is to be made in the *Navidad,* starting from Port Lavaca.

THE ninth annual report, that for 1914, of the Apprenticeship and Skilled Employment Association, shows that in common with other bodies dependent for their support on voluntary contributions from the public, the association has suffered already financially as a result of the war, and would welcome an addition to its income. The work of the association has continued on its now familiar lines. Interesting tables are provided in the report classifying according to trades the numbers of boys and girls placed in employment by the various London committees. During the year 1914 the total number of boys placed was 532, and of these 60 went into office and clerical work, 47 took up mechanical engineering, 41 scientific instrument making, 40 electrical engineering (including wiring), and 34 motor work. Of the 333 girls who were found employment, 93 took up dressmaking, 34 office and clerical work, and 29 machining. The remaining girls were distributed among thirty-four different trades. Full particulars of the work of the association can be obtained from the offices, 53 Denison House, Vauxhall Bridge Road, S.W.

THE Benares Hindu University Bill was introduced in the Viceroy's Legislative Council at Delhi on March 22 by Sir Harcourt Butler, the vice-president, and the introduction of the Bill was carried *nem. con.* During the course of his speech, which is reported in the *Pioneer Mail* of March 26, Sir Harcourt Butler said:—"The main features of this University will be, first, that it will be a teaching and residential university; secondly, that while it will be open to all castes and creeds it will insist upon religious instruction for Hindus; and, thirdly, that it will be conducted and managed by the Hindu community and almost entirely by non-officials." The University is to be an All-India University. It is incorporated for the teaching of all knowledge, but will commence with five faculties of arts, science, law, Oriental studies, and theology. Many of the promoters desired to add a faculty of technology, and this desire has the full sympathy of Sir Harcourt Butler. The Governor-General will be Lord Rector, and the Lieutenant-Governor of the United Provinces of Agra and Oudh will be Visitor, of the University. The governing body will be a numerous and very representative Court, with an executive body in a council of not more than thirty members, of whom five will be members of the Senate. The academic body will be the Senate, consisting of not fewer than fifty members, with an executive body in the Syndicate. The Senate will have entire charge of the organisation of instruction in the University, and the constituent colleges' curriculum and examination and discipline of students and the conferment of ordinary and honorary degrees. The following large subscriptions have already been received:—Maharana of Udaipur, 1½ lakhs; the Maharaja Holkar, 5 lakhs; the Maharaja of Jodhpur, 2 lakhs, with a grant in perpetuity of 2000 rupees per month; the Maharaja of Bikanir, one lakh, with a grant in perpetuity of 1000 rupees per month; the Maharaja of Kashmir, a grant in perpetuity of 1000 rupees a month; the Maharaja Bahadur of Darbhanga, 3 out of 5 lakhs; and one lakh from each of the following—the Maharao of Kotah, Dr. Rash Behari Ghose, Dr. Sundar Lal, the Maharaja of Casimbazar, Babu Bijendra K. R. Chaudhri of Ghorepur, and Babu Moti Chand. The Maharaja Scindia of Gwalior has promised five lakhs of rupees and others have promised liberal donations, of which, in many cases, part payment has been made.

SOCIETIES AND ACADEMIES.

London.

Royal Society, April 29.—Sir William Crookes, president, in the chair.—H. **Hartridge** and A. V. **Hill**: The transmission of infra-red rays by the media of the eye, the transmission of radiant energy by Crookes's and other glasses, and the radiation from various light sources. The different eye structures were found by the authors to absorb infra-red rays of different length to approximately the same extent as would a layer of water of the right equivalent thickness. From the values of the percentage absorption of water at different wave-length they have, therefore, calculated the amount of heat absorbed by cornea, iris, and lens. The heat absorbed by the lens was found to be too slight for cataracterous changes to be due to direct action. The condition might still be caused, as Parsons suggested, by impairment in the nutrition of the lens brought about by the action of heat rays on the ciliary body and iris. Samples of Crookes's glasses were tested and were found to absorb the heat waves strongly, and also to some extent the ultraviolet.—E. **Beard** and W. **Cramer**: Surface tension and ferment action. The action of a ferment on a substrate is retarded or inhibited by extending the surface of the system in which the reaction proceeds. This effect has been studied in some detail in the system cane-sugar—invertase.—W. **Cramer**: Surface tension as a factor controlling cell metabolism. The considerations developed in this paper are based on the fact demonstrated experimentally that the action of ferments is conditioned by surface tension. The great surface development in the cell and the living organism must therefore produce conditions which markedly affect the action of ferments *in vivo* when compared with their action *in vitro*. It is shown how the cell may, through the factor of surface tension, control and regulate its metabolism. It is thus possible to form a conception of the chemical organisation of the cell without having to assume the existence of hypothetical membranes in the cytoplasm which are supposed to surround the different chemical systems and separate them from each other. Lastly, it is pointed out that if the conceptions formulated in this paper are correct, substances which are strongly surface active, but which do not affect protoplasm chemically, should exercise a profound effect on the metabolism of the cell. This expectation is realised in the action of narcotic and cytolytic substances.

Challenger Society, April 28.—Capt. Alfred Carpenter in the chair.—Dr. G. H. **Fowler**: Investigations on drift currents in British waters.—Dr. S. F. **Harmer**: Records of Cetacea stranded on the British coasts during 1913 and 1914. The paper was based on an arrangement which had been made by the Board of Trade, which had issued an instruction to coastguard officers to report the stranding of Cetacea by telegram to the British Museum (Natural History). In this way, and aided by written reports, sketches, and photographs supplied by persons on the spot, much valuable information has been obtained, and a certain number of interesting specimens have been secured. By procuring a blade of baleen, in the case of the whalebone whales, or the lower jaw, in the case of the smaller toothed whales, it has been possible to determine the species in a considerable proportion of the records. Seventy-six records were obtained during 1913, and fifty-seven during 1914. The outbreak of war was clearly responsible for the smaller number during 1914. The common porpoise proved to be far the commonest species, as might have been expected. Several records of the occurrence of the common dolphin were obtained, principally on the more exposed parts of the coast-line. Other species which were represented by several records were the bottle-nosed whale, the pilot-whale, the white-beaked dolphin, the bottle-nosed dolphin, Risso's dolphin, the lesser rorqual, the common rorqual, and Rudolphi's rorqual. The most interesting record was a Sowerby's whale, stranded at Rosslare in September, 1914. Contrary to expectation, the district where strandings were most numerous was the coast-line of Lincolnshire and Norfolk, though a number of specimens were found on the shore of the southern counties (see Nature, April 15, p. 182).

Paris.

Academy of Sciences, April 26.—M. Ed. Perrier in the chair.—Gaston **Darboux**: The representation on a plane of the surface of the fourth order which admits a conic as a double curve.—G. **Bigourdan**: Scintillation. Comparison with the undulations of instrumental images of celestial bodies. There seems to be no identity between scintillation and undulations, as might at first sight appear probable. More quantitative data are required for the undulations.—A. **Haller** and Edouard **Bauer**: The action of sodium amide on the allyldialkylacetophenones. The preparation of 3 : 5-dimethyl-3-ethyl and 3 : 3-diethyl-5-methylpyrrolidones.—A. **Laveran**: The artificial acentrosomic varieties of the Trypanosomes. For *Tr. Evansi* and *Tr. Brucei* the disappearance of the centrosome produced by the action of oxazine is permanent after three or four hundred passages through animals. Morphologically, this might be regarded as a new species, but its biological characters are unchanged. Animals immunised against trypanosomes with centrosomes have acquired immunity for the acentrosomic trypanosomes and inversely.—J. **Guillaume**: Observations of the sun made at the Observatory of Lyons during the fourth quarter of 1914. Observations were possible on fifty-eight days, the results of which are given in three tables showing the number of spots, their distribution in latitude, and the distribution of the faculæ in latitude.—A. **Perot**: Variation of the wave-length of the telluric lines with the height of the sun. Particulars of measurements made with an interference spectroscope installed at the Observatory of Meudon. A line of the B group of oxygen was chosen; the wave-length increased from morning to noon and then decreased.—E. **Bompiani**: Laplace equations with equal invariants.—L. **Bouchet**: Electric pressures acting at the surface of a liquid insulating sheet. The displacements are very rapid for conducting liquids such as water and mercury, but with turpentine, vaseline oil, benzine, and petroleum ether there is a slow displacement. The instantaneous depression was deduced graphically and a relation established between this figure and the strength of the field.—Ph. **Flajolet**: Perturbations of the magnetic declination at Lyons (Saint Genis Laval) during the fourth quarter of 1914.—C. **Sauvageau**: A new species of Fucus, *F. dichotomus*. This is distinguished from *F. platycarpus* by its ramification and by the cylindrical form of its receptacles.—Jules **Amar**: Principles of professional re-education. A discussion of the problem of the work possible for wounded soldiers discharged as cured; from the physiological point of view.—MM. **Viallet** and **Dauvillier**: A new radioscopic method for the localisation of projectiles.—H. **Morize**: The determination of the position of projectiles in the human body by radioscopy. Remarks on a note by Dr. Foveau de Courmelles (January 18) on the same subject.—Marc de Selys **Longchamps**: Autotomy and regeneration of the viscera in *Polycarpa tenera*.—Lucien **Semichon**: The use of heat for fighting insects and parasitic cryptogams in cultivated plants. Hot water may be used provided its temperature does not exceed 70° to 75° C. Details are given of the temperatures required to kill various forms of mould and larval pests.—Em. **Bourquelot**, M. **Bridel**, and A. **Aubry**: The biochemical synthesis of the β-mono-*d*-galactoside of ethylene glycol. The synthesis was effected with the aid of emulsin.

PHYSICAL CONSTANTS.

Société Française de Physique, Recueil de Constantes Physiques. By Prof. H. Abraham and Prof. P. Sacerdote. Pp. xvi+753. (Paris: Gauthier-Villars, 1913.) Price 50 francs.

THIS large and handsome volume of 753 pages is a collection of physical constants compiled under the auspices of the French Physical Society by Profs. Abraham and Sacerdote, and printed in the excellent style with which one is familiar in the publications of Messrs. Gauthier-Villars.

Following the custom of the more recent editions of Landolt and Börnstein's Tables and the new Annual International Tables of Constants, the work has been divided among a number of specialists, and each page bears the name of the individual responsible for it.

The system adopted has particular advantage in a volume planned with the idea of giving in general only one value for each constant. Reference is usually given to the name of the authority cited and the year of publication, but the source of the particular information is not specified. A useful explanatory paragraph with formulæ generally precedes each table.

A novelty is the introduction of a large number of curves. For example, the curves of the physical properties of gases given by Amagat impart at a glance an amount of information which would have required a table of many columns. Some very fine reproductions of spectra are given, including a large-scale reproduction of the iron spectrum, which should be extremely useful.

An examination of the book and frequent reference to it for constants required in actual work has revealed only few errors, and on the whole the work of the compilers appears to have been well done and the subject matter judiciously chosen.

Among the more interesting novelties are the useful sections devoted to wireless telegraphy and to physical measuring instruments, and no one could have been found to write with more authority on alloys than M. Le Chatelier.

Some eccentricities appear in the initial table on units; few physicists are familiar with such terms as "volume massique" and "masse volumique," "degré carré," and "steradian."

In the table of the specific heat of water the results of nine different observers are given, in most cases to four decimal places. But the "valeurs combinées" are given to *five* places, although examination of the individual values shows large discrepancies in the third decimal. It is much better to avoid in a case of this kind a fallacious air of precision, and it would have been wiser to have followed the example of Commandant Defforges, the well-known authority on pendulum observations, who told an eminent physicist with whom he was discussing his work:—

"Each year, as I know a little more of the difficulties, I suppress a decimal place in my results."

A good feature of the index of organic bodies is that in many cases the common name of a substance is given as well as its other names, perhaps only adopted by the chemists during a period of some passing fashion. For example, benzophenone is to be found in the index, as well as its synonyms, diphenylmethanone, diphenylketone, and benzoylbenzene. On the other hand, formaldehyde is *not* to be found, although four other names of this body appear in the index.

It is, however, surprising to find repeated the old familiar error, the confusion of benz*ine* and benz*ene*, words which in no language mean the same thing, although in some their pronunciation is unfortunately identical.

In some cases almost too much information is given. Thus, for example, the work of Tammann and his associates on the influence of pressure on the melting point of a large number of substances is quoted in detail, while practically nothing is to be found on the even more important effect of pressure on the boiling-point, excepting for a few organic bodies. For dp/dt for sulphur vapour is given Regnault's old value, 0·82° per mm., now known to be considerably too low.

Perusal of a work of this magnitude is suggestive in showing how great is our ignorance in many important branches of knowledge, where it might have been imagined much more precise and accurate data would have been to hand. A good example is the subject of thermal radiation, transparency, etc., where we still depend on Leslie, Rumford, Melloni, and other pioneer workers, who showed the way, where comparatively few have followed to repeat their work with modern appliances.

J. A. Harker.

THE PRESERVATION OF WILD LIFE IN AMERICA.

Wild Life Conservation in Theory and Practice. By Dr. W. T. Hornaday. Pp. vi+240. (New Haven: Yale University Press; London: Oxford University Press, 1914.) Price 6*s.* 6*d.* net.

NORTH AMERICA, when first opened up by Europeans, possessed a big-game fauna which, although poor in species, in point of numbers was equalled only by that of southern and central Africa; and it was likewise the home of an extensive and varied fauna of game and other edible birds. To this abundance of wild life is attributable the comparative facility with which the country was explored and settled; but no sooner was the settlement well advanced than ruthless slaughter led to the more or less complete extermination of some species, like the bison and the carrier-pigeon, and a vast reduction in the numbers of others, such as the prongbuck and bighorn. Fashion, sport, and other factors led, later on, to equal havoc among birds of many kinds.

Having permitted all this to come to pass, the country is now gradually waking up to the loss it has sustained, and to the remedial measures still possible in order to ensure the preservation of at least a remnant of the ancient superfluity of life. In this crusade Dr. Hornaday has for many years been a leader, and in the volume now before us he reviews what has been done and what still remains to be accomplished in a manner worthy of all commendation.

So urgent, however, is the case that the author calls upon all biological workers to abandon such comparatively unimportant matters as the description of species and races, the protective coloration of eggs, etc., and to devote all their energies to the cause of protecting and re-habilitating their country's fauna, not only as a food-supply, but, in the case of insectivorous birds, as a protection against the ravages of insect-foes, which are specially severe in America.

In his opening chapter—on the value of wild life—Dr. Hornaday enunciates the axiom that no species of wild land animal can long withstand systematic hunting for commercial purposes, as witness the destruction of the millions of the southern bison-herd within four years. He also points out that when a species has become reduced below a certain number it loses all recuperative power, and, like the heath-hen, fails to respond to protection. Instant action is, therefore, imperative in order to save the present remnant of the game-fauna, which is estimated to be only 2 per cent. of its former numbers. For this purpose "bag"-limitations have proved practically useless; and the conversion of national forests into reserves where shooting shall be absolutely prohibited, is a *sine qua non* (p. 49).

The period from 1885 to 1900 saw the great boom in the plumage-trade, to check which the Audubon Societies were organised; other agencies, which in many cases are proving victorious, came into action soon after; but the greatest hope for ultimate salvation is the federal law of 1913 for the protection of migratory species, which, by bringing recalcitrant States into line, saved the situation. Lastly came what it is hoped will prove the winning card in the shape of the Feather Bill.

R. L.

FOUR DIMENSIONS.

Geometry of Four Dimensions. By Prof. H. P. Manning. Pp. ix + 348. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 8*s.* 6*d.* net.

PERHAPS the main interest of this work is that it treats the subject in a way that is comparatively new, and one that is likely enough to be generally adopted. Until quite recently, most works on hypergeometry might be roughly divided into three classes: popular or semi-popular outlines, which, however stimulating or suggestive, have little or no scientific value; frankly analytical disquisitions, such as those of Riemann, etc.; and works which, although couched in geometrical language, give the impression of being, so to speak, translations of previous analytical demonstrations. It must be admitted, of course, that some authors (such as Segre) have obtained new and valuable results for surfaces in three dimensions by considering them as sections of hyper-surfaces, and have pursued other four-dimensional researches in a way which has much more the aspect of being purely geometrical. But since it is a psychological fact that so far we have no true intuition of four-dimensional space, the inference seems to be that these authors have become so familiar with the analytical arguments underlying their theorems that they pass without an effort to the corresponding geometrical form of statement; much in the same way as dualisation of a projective theorem becomes almost mechanical after sufficient practice.

The method of the present work may be described as a logical induction based upon explicit geometrical axioms about strictly geometrical indefinables. The primary element is the point; the primary undefined relation is that of a point P being collinear with a given segment AB. From this the definition and properties of a straight line are deduced; thence we proceed to the definition of a triangle; and from this, with the help of Pasch's axiom (a line meeting one side of a triangle and another side produced meets the third side), we arrive at the definition and properties of the plane.

Assuming, now, that after reaching a plane field of points there is at least one point not belonging to that field, we can construct a tetrahedron, and, by arguments strictly analogous to those employed before, arrive at a three-dimensional space (S_3), which is determined by any four of its points which are not coplanar. There is no logical reason why we should not assume the existence of at least one point which does not belong to S_3; if we do so, we are able, by similar arguments, to show that there will be a space S_4, containing S_3, which is determined by any five of its points which are *independent;* that is to say, which do not belong to the same three-dimensional field.

The important thing to notice here is that the argument is of such a kind that it does not appeal to intuition at all. It is true that by drawing figures, or making models, we can provide images which help us to see that for an S_1, S_2, or S_3 our assumptions are not self-contradictory—or rather to give us an irrational conviction that things are so; for, of course, nothing but a formal proof can demonstrate the consistency or inconsistency of a set of formal propositions, such as we are ultimately dealing with here.

When the reader has reached this point, he will see that we can define and investigate a sequence of spaces:—

$$S_1, S_2, S_3, \ldots S_n, \ldots$$

(each being a field of points) on the assumption that when we have reached a space S_n there is at least one point which does not belong to it. A space S_n is determined by $(n+1)$ independent points; namely, such as do not belong to one and the same S_{n-1}.

The author does not go further than the S_4. After establishing its (logical) existence, he proceeds to discuss perpendicularity and angles; symmetry, order, and motion; hyper-surfaces and polyhedra; the theory of parallels; and that of volume-measurement. Finally, there is a chapter on the regular "polyhedroids" (hyperpolyhedra) in the S_4.

There are many interesting details and illustrations; we may refer to one of these, as it shows very well the way in which we are brought to a halt in trying to make actual images of things in the S_4. If, in an S_2, we draw a square, then a square on each of its sides, and finally a square on one of the outermost sides (so as to make a Latin cross) we can see how to fold the squares about common edges until they form the faces of a cube in our S_3. Suppose, now, that in our S_3 we draw a cube; then a cube on each of its faces; and finally a cube on one of the outermost faces of the last. If we could get this solid into an S_4, we could "fold" the eight cubes about adjacent faces so as to form the boundaries of a hypercube. Until we can "see" how to do this, we have no proper intuition of an S_4, such as we have of the lower spaces. G. B. M.

THREE BOTANICAL BOOKS.

(1) *Mikrographie des Holzes der auf Java vorkommenden Baumarten. Vierte Lieferung.* By Dr. J. W. Moll and H. H. Janssonius. Pp. 336. (Leiden: E. J. Brill, 1914.)

(2) *Practical Field Botany.* By A. R. Horwood. Pp. xv + 193. (London: C. Griffin and Co., Ltd., 1914.) Price 5*s.* net.

(3) *All About Leaves.* By the late F. G. Heath. Pp. ix + 228. (London: Williams and Norgate, 1914.) Price 4*s.* 6*d.* net.

(1) IN this, the fourth instalment of his work on the intimate structure of the wood of Javan trees, the author deals with the families Connaraceæ, Leguminosæ, Rosaceæ, Saxifrageæ, Hamamelideæ, and Rhizophoreæ. The Leguminosæ occupy more than half the volume. In this family 118 specimens were examined, representing forty-nine species and four varieties contained in twenty-six genera. Under the heading of each family is a list of the literature in chronological order, followed by an enumeration of the species and varieties examined by the author. A general review of the gross and minute anatomy of the family as represented by the forms studied is then given, and the bearing of the results on the generally accepted sub-division of the family is discussed. These are, in the main, in conformity with the sub-division based on floral structure, but it is worthy of note that in Rosaceæ the differences between the groups are greater than is usually the case in a single family, and suggest the recognition as distinct families of the Amygdalaceæ, Chrysobalanaceæ, and Pomaceæ. A key for determining the species by means of the wood-structure is also given. Then follows a detailed description of each species or variety; first the general topography, which is sometimes illustrated by figures, and then an elaborate description of the various elements—wood-vessels, libriform fibres, wood-parenchyma, medullary rays, etc. The account includes measurements and the behaviour of the various elements to reagents. It is to be regretted that the author did not include photomicrographic reproductions of his sections; the few figures which are given are poor and show no detail.

(2) The title of Mr. Horwood's book is somewhat misleading. The book contains much useful information on the practical study of plants in the field, but also much extraneous matter often set down in a loose and desultory manner. The impression formed by the reader is that the author is a man of great industry and some knowledge, but does not realise his limitations. The book, if judiciously pruned and edited, would make a useful little volume. The author's intention is

"to explain and set forth the principles by which the ecologist should be guided, and the apparatus and plan to be adopted to enable him or her to work upon sound and approved lines." But the directions or suggestions will often lead to bewilderment; for instance, the section on pp. 4–6, entitled "What to Study," contains a curious medley of suggestions from the study of the form and size of pollen-grains to the procuring of "fruits and berries of foliage" (*sic*) for decoration at Christmas. On the other hand, the same chapter contains a useful section on flower-photography. Chapter ii., on methods of collecting, preserving, mounting, and storing plants for herbaria, contains much that is helpful, though the student will find puzzling matter in the section on "the arrangement to be adopted in the herbarium"; among other things the author suggests the preparation of "a printed list of all the species published since the year 1895 when the 'Index Kewensis' and Durand's 'Appendix' brought things up to date," thus ignoring the three supplements of the "Index Kewensis" which carry us on to the end of 1910.

A great part of chapter iii., which has the tremendous title, "The necessity for encouraging the study of botany on ecological lines, by the popularisation of pure life-histories of plants, through nature study, museums, scientific societies, and other associations, and in the university," might well have been omitted; much of it consists of extracts from the addresses or writings of well-known botanists. The next chapter, on the study of the life-history of a plant, would have been more helpful if in the brief paragraphs on the various divisions, such, for instance, those on "plants and fungi and insect-pests" or "names of wild plants" reference had been given to a good standard work on the subject. The last chapter (v.), "An outline of plant formations," is the best; it includes a brief description of various plant-formations and lists of the species which occur in them.

(3) The little book on "leaves" contains eighty photographs, mostly of British wild plants, which on the whole are good. They were specially prepared for the work, but were not seen by the author owing to his death in 1913. The text is in the style with which readers of the late Francis George Heath's botanical works are familiar. One example must suffice. Of the seed we read, "A created organism of wonderful and infinite skill confronts our marvelling sense in the remotest confines of the great vegetable world—so that we cannot begin at the beginning because we cannot comprehend the beginning! Power—unquestionable—hovers, so to speak, undiscernible in the tiny seed."

OUR BOOKSHELF.

The Golden Bough. A Study in Magic and Religion. By Sir J. G. Frazer. Vol. xii. Bibliography and General Index. Pp. vii + 536. (London: Macmillan and Co., Ltd., 1915.) Price 20*s*. net.

No book has ever been written which contains so large a mass of facts as "The Golden Bough." Nor has any book had its data more thoroughly documented. The bibliography and index, forming the twelfth and final volume of the work, fill 536 octavo pages. The index, 392 pages, is fuller than the indices to the separate volumes. Every author knows the labour of cross-references; a simple instance here is "propitiation of vermin by farmers," involving three entries. There are cases of overdoing, a good fault in an index, *e.g.* "*Nat*, spirit, in Burma, ii. 46." "*Nat* superstition in Burma, ix. 90 n¹." "*Nats*, spirits in Burma, iii. 90; ix. 175 *sq.*; propitiation of, ix. 96." Here a distinction is actually drawn between a singular and a plural. Technical generic terms in foreign languages are, like botanical and zoological terms, etc., printed in italics. But why "Oschophoria," yet "*Aiora*," both Greek feasts; and "Farwardajan," yet "*Sada*," both Persian feasts; also "Ogboni" and "Belli-Paaro," African secret societies, yet "*Ndembo*" and "*Hametzes*," also secret societies? But these are minor inconsistencies in a monumental index.

The bibliography comprises probably six thousand books, including serial publications and dictionaries. The curious may find instructive items, *e.g.* Macletius (Maletius, Meletius, Mencius, Ian Malecki), who, by the way, wrote on the religion of the Borussians (the present-day Prussians). Many periodicals, *e.g.* *L'Année Sociologique* and *L'Anthropologie*, have not their year of institution, nor, what is far more important, their place of publication attached. How are "readers who desire to have further information," to find "*Fasciculi Malagenses, Anthropology*," or "Dinkard, a Pahlavi work"?

The distribution of anthropological research among the civilised nations may be well estimated from this bibliography. England, America, and Holland are prominent; Germany has done much, so has France. The native authorities on uncivilised peoples are an interesting addition.

A. E. CRAWLEY.

The Plateau Peoples of South America. By A. A. Adams. Pp. 134. (London: G. Routledge and Sons, Ltd., 1915.) Price 3*s*. 6*d*. net.

THE people discussed in this monograph are those inhabiting the South American plateau within the boundaries of Bolivia, Peru, and Ecuador. Bolivia, however, seems to be more closely associated with the past history of the plateau than either of the other republics. Its government is largely drawn from the plateau population, and its general culture is more clearly influenced by the plateau than that of Peru, which looks to Europe for light and guidance. The writer finds in this upland race a condition of progressive degeneration. The people who occupied the country in what may be called prehistoric times were skilled in stone-working, as is shown by the great megalithic ruins at Tiahuanaca, described by Sir Clements Markham in his book, "The Incas of Peru." Since the building of this city, geological changes seem to have been in action which caused the elevation of the plateau and the shrinkage of the body of water now known as Lake Titicaca.

These changes brought about the present conditions: a very dry atmosphere, with a small percentage of oxygen and a high range of temperature, inducing nervousness and mental instability, a lack of forethought and industry, an overweening contempt of foreigners, and a perfervid patriotism. Many physiological facts indicate this retrogression, resulting in administrative incapacity, and neglect of regularised education. The poorness of the food supply, ill-cooked potatoes and maize-flour cakes, promotes physical degeneration and leads to over-indulgence in stimulants. The writer takes, perhaps, too gloomy a view of a people whom he dislikes and despises, but he appears to write with adequate knowledge, and his monograph, if his conclusions be accepted, furnishes a good example of the action of an unfavourable environment upon a race exposed to its influence.

A Pilgrim's Scrip. By R. Campbell Thompson. Pp. xii + 345. (London: John Lane, 1914.) Price 12*s.* 6*d.* net.

These slight, discursive sketches of the life of a wandering archæologist in the Nearer East are interesting and instructive. The studied archaism of the style, a trick which may have been learned from Mr. Doughty's famous "Travels in Arabia Deserta," becomes, after a time, a little monotonous, but it gives a piquant flavour to his accounts of eastern life and character. The writer is one of the school of scholarly antiquaries, trained by the British Museum, who, in spite of many hardships and the necessity of making scanty funds go a very long way, have done noble service in adding to our national collections.

Mr. Campbell Thompson's experience has given him a considerable insight into the back of the oriental mind,and his hints for dealing with these races and conducting excavations will be serviceable to those who may follow his tracks. His wanderings have extended widely: Mosul, Behistun, the Sinaitic Peninsula, the Sudan, Angora, and Carchemish, are some of the stages. Perhaps the most interesting episode is his excursion, in company with Mr. L. W. King, to make a fresh copy of the famous inscription of Darius at Behistun, the riddle of which was solved by the genius of Sir H. Rawlinson. Swung from cables suspended over the precipice the explorers collated Rawlinson's copies, which proved to be wonderfully accurate, and succeeded in photographing, from a five-foot range, the splendid head of the warrior king—a fine piece of work told modestly and clearly.

The book is well illustrated by photographs and, which is unusual in popular works of travel, is provided with an excellent index.

Morale Fondée sur les Lois de la Nature. By M. Deshumbert. Cinquième et Sixième Mille. Pp. 191. (London: Watts and Co., n.d.)

The Comité International de Propagande pour la Pratique de la Morale fondée sur les Lois de la Nature has representatives in eighteen countries. Its Bureau Central is at Dewhurst, Dunheved Road West, Thornton Heath, England. It issues a propagandist volume on the subject of a natural morality, written by the secretary, M. Deshumbert, which has been translated into eight languages. Much has been written on morality "according to nature," since the Stoics invented the idea, but this book, partly because the author understands both physiology and biology, has a freshness of appeal. "Good is all that contributes to the conservation and increase of life . . ." by co-operation and mutual aid of individuals each of whom is thus aided towards complete self-realisation. Evil is all that diminishes life. The end of Nature is life and more life.

These and connected axioms are well illustrated by examples of anti-natural human superstition and of the importance in the animal world of intellectual and moral qualities. The way in which, *e.g.* the tiger depends for existence upon observation, judgment, patience, self-control, decision, and perseverance, is quite a fresh object-lesson. A collection of practical rules of personal hygiene and a detailed list of physiological functions are useful, and might form the nucleus of a modern scheme of individual morality. Some quotations from J. Payot are interesting here. A set of parallels between the intelligence of nature and of man is interesting, and might be augmented. "Man in many cases is inferior to nature," but this simply points the truth that man is part of nature.

Ultra-Violet Excitation of the D Line of Sodium.

It is well known that the D line of sodium is the first member of a series of lines, the other members being in the ultra-violet region of the spectrum. It is known also from the investigations of R. W. Wood that sodium vapour at a moderate temperature illuminated by D light gives rise to a secondary emission of D light. This secondary emission is appropriately called by him resonance radiation. It has been further investigated by Dunoyer.

The first ultra-violet line of the series is situated at wave-length 3303. It is very probable for a number of reasons that this or any other line of the series would give rise to resonance radiation, though I do not know of any experiment directly establishing the fact.

A more doubtful question is whether stimulation by the line 3303 would give rise to D light. The question is not new. It has been proposed by Prof. Wood, and he has looked for the effect, but without success. The matter seemed important enough, however, to justify a fresh effort, and within the last few days I have been able to get the effect as satisfactorily as could be wished.

The chief essential is a source giving a sharp line of great intensity at λ 3303. This was found in a sodium vapour lamp in quartz analogous to the mercury lamps in general use. Details of the construction and manipulation of these sodium lamps will be published later. The visible light from such a lamp was filtered out by means of a screen consisting of cobalt-blue uviol glass, combined with nitrosodimethylaniline. The light which came through was photographed with a quartz spectrograph, and was found to consist of λ 3303 exclusively.

This radiation was concentrated by means of a quartz lens on a quartz bulb containing some sodium. The bulb was made nearly red-hot with a bunsen burner, which was then extinguished. A patch of luminosity could be seen on the wall of the bulb when the ultra-violet beam fell upon it. As the bulb cooled and the vapour pressure of the sodium diminished, this patch of light gradually expanded, and filled the entire bulb; it then faded away, and had disappeared when the bulb was cold. This behaviour is exactly the same as is seen when D light is excited by the incidence of D light, and although in the present case the light is much fainter, the conditions of observation are in some respects more favourable, for there is no disturbance from visible light scattered or reflected by the walls of the vessel.

Critics of this experiment will naturally concentrate their attention on two questions :—

(1) Was the light observed really due to ultra-violet excitation?

(2) Was it of the same wave-length as the D line?

As regards (1), a sheet of plate-glass 1·2 cm. thick was interposed between the source and the bulb. The excited light was completely extinguished.

As regards (2) the light was rather below the intensity which would easily allow of direct spectroscopic examination, though with a little further improvement of the conditions it might be made strong enough. I have, however, proved it to be of approximately this wave-length by absorption methods. The luminosity was seen undiminished through a thick cell containing potassium bichromate solution, held before the eyes. It was absolutely invisible through a cell containing praseodymium nitrate. Thus the wave-length must lie in the region from λ 5820 to λ 6020, for this is the only region transmitted by bichromate and absorbed by praseodymium. The D line at λ 5890 lies in this narrow region, and I think, therefore, that there is no reasonable doubt that the emission does consist of D light. Discussion of the theoretical bearing of this result is deferred.

The Green Flash.

MANY descriptions of the green flash have been published in letters to NATURE and elsewhere, but I do not remember to have seen a satisfactory explanation of this curious phenomenon. Atmospheric dispersion is invoked, but this does not explain the absence of the red end of the spectrum. My observations agree in every particular with those described by Mr. Whitmell in NATURE of March 11, p. 35. At sea I have observed a violet or blue tint occasionally, and on one occasion a red flash as the lower limb of the sun emerged from a cloud into a clear space very near the horizon.

Normal atmospheric dispersion will, of course, produce a red fringe to the sun's lower limb, and a blue fringe at the upper limb, as may be seen at any time with a telescope free from secondary colour when the sun is as high as ten or fifteen degrees above the horizon. When, however, a point of sunlight only is visible, the rest of the disc being hidden beneath the horizon, atmospheric dispersion, if it could be perceived with unaided vision, should produce a complete vertical spectrum from blue to red, as in the case of stars when near the horizon. The red end of this spectrum should be most evident, since these rays are least absorbed. In the flash, however, the red is completely suppressed, and the vivid green which is obvious to the naked eye can only be seen at very low horizons. Moreover, it is not always seen, as Mr. Whitmell remarks, when the conditions seem otherwise favourable.

It seems to me very probable that the phenomenon is in some way connected with the abnormal conditions which at sea produce mirage effects. The layer of dense air in contact with the sea might produce total reflection for solar rays refracted from below the horizon, but the critical angle of reflection will depend on wave-length, and it is possible under certain conditions that the green rays may be totally reflected whilst the red are refracted.

I have one more observation to add to those described by Mr. Whitmell, and this will, I think, give the *coup de grâce* to the theory of a subjective effect due to retinal fatigue. In May, 1900, I happened to observe the setting of Venus in the sea from my eclipse camp on the Algerian coast. Observing with a 3-in. inverting telescope, I saw the planet when very near the horizon suddenly change in colour from dull red to vivid green, and as I lowered the telescope to the point where the sea horizon about bisected the field of view I was amazed to see *two* green images of Venus, one, the normal image, ascending from below, and the other sloping down from above. This was probably reflected from the sea itself. The setting took place at the moment of meeting of these two images. The whole apparition, from the moment when the colour changed from red to green, to the instantaneous disappearance of the two images, cannot have lasted more than four or five seconds. The sea about this time was found to be excessively cold, although the air was hot during the daytime, and this state of things would doubtless favour the production of a relatively dense layer of air on the surface of the sea in calm weather.

JOHN EVERSHED.

Kodaikanal, April 13.

The Larger Ions in the Air.

IN addition to the well-known small ions, which are of a type common to all gases, two classes of larger ions exist in the air under ordinary conditions. One of these consists of the large ions of Langevin which have a mobility of about 1/3000, while the other contains ions with a mobility of about 1/50. As the latter value lies between those of the mobilities of the small and large ions, the members of this latter class may be called the ions of intermediate mobility, or, shortly, the intermediate ions.

The slow movement of these larger ions in an electric field clearly indicates that they are molecular clusters of more or less complexity. Ordinarily the value of the mobility is the only guide to the nature of the ionic structure, but in the case of the large ion, at least, an important deduction is to be made from the outcome of experiments on the formation of clouds in closed vessels.

It is well known, since Aitken's notable work on the subject, that, in ordinary circumstances, the air is crowded with particles, in suspension, on which the water vapour condenses into visible drops if the air becomes slightly supersaturated. These particles, the number of which varies greatly from time to time, can be removed by filtration of the air through cotton-wool, or, in closed vessels, by settlement with the drops formed by expansions. In general, these nuclei are electrically uncharged, and whatever their nature, are conveniently known as dust particles.

C. T. R. Wilson has shown that in air recently freed from dust, with increasing supersaturations, the first visible condensation takes place on the small ions. It is now known that the circumstances of the condensation remain unchanged during intervals of time extending to days after the removal of the dust. The intermediate and large ions are eminently suitable nuclei for the condensation of water vapour, as their mobilities are largely affected by changes in the hygrometric condition of the air, so the results just mentioned indicate not only that these ions are removed with dust particles, but also that they are not produced in air once made dust-free. There is no doubt that the large ions are present in ordinary saturated air; it appears, then, that filtration removes some rigid nucleus without which at least the large ion cannot be developed.

From the facts which have been stated, the picture of the large ion most readily formed is that of a dust particle round which water molecules are adsorbed to an extent depending on the vapour pressure, the whole being electrified by the attachment of a small ion.

Some idea of the nature of the relation between mobility and vapour pressure which is to be expected in connection with such an ion, may be obtained by comparing, on simple thermodynamic lines, the working of two Carnot's engines, one with unit mass of a mixture of ions and water vapour as the working substance, and the other with unit mass of water and its vapour. The vapours are to be taken as perfect gases, and it is to be assumed that the density of a vapour is small compared with that of the substance in the corresponding denser state. With these assumptions the result is readily obtained that $(p_1/p_2)m = (P_1/P_2)^{1/n}$, when only the change of state is being considered. p and P are the values of the vapour pressures in the two engines at the same temperature, and n is the ratio of the latent heat of vaporisation of water to that of the fluid surrounding the nucleus of the ions. It is convenient here to take m as the mass of the denser part of the substance. The expression, which holds for all cases of adsorption, states that at two temperatures the mass adsorbed will be the same if the ratio of the vapour pressures, in equilibrium with the adsorbed fluid, is the nth root of the ratio of the saturated vapour pressures at those temperatures. It is the formula of reduction for adsorption observations taken at different temperatures, and a clue to the condition of the adsorbed moisture is to be obtained from the value of n found necessary to make the observations fall into line. As the mobility of the ions under consideration, at constant temperature and air pressure, is constant if the mass of the adsorbed fluid remains the same, the formula is directly applicable to mobility determinations if m is taken to refer to the mobility reduced to constant air density.

Trouton, and Masson and Richards, find that the mass of contained moisture in the case of flannel and cotton-wool is a function of the relative humidity. This means that n is unity in the preceding expression. n is also unmistakably unity in connection with the large ion, the determinations of mobility only falling into line if plotted against the relative humidities. The result of such a plot is shown in Fig. 1.

No heat change due to a variation of surface energy is involved in the value of n, so in these cases where $n=1$, as the heat per unit mass necessary to annul a temperature change due to the mere alteration of state is the same as that required to keep the temperature constant when water evaporates, it may be definitely concluded that the molecules in the contained or adsorbed fluid are in the same condition of aggregation as those of water.

In the case of the intermediate ions the determinations of mobility are not accordant enough to allow the value of n to be found in this way with any accuracy, but the fit of the points to a line is on the whole better if the mobilities are plotted against vapour pressures than when set out against the relative humidities. This, according to the preceding expression, corresponds to the physically extreme case when n is equal to some large number, though, so far as could be inferred from the plot, n might not be greater than some small integer. In any case, here the latent heat of vaporisation of water is sometimes greater than that of the adsorbed fluid.

The result of the preceding line of argument, though not conclusive in the present instance, at least suggests the idea that the intermediate ion consists of a rigid core enveloped by a collection of water molecules existing as a dense vapour rather than in the liquid condition.

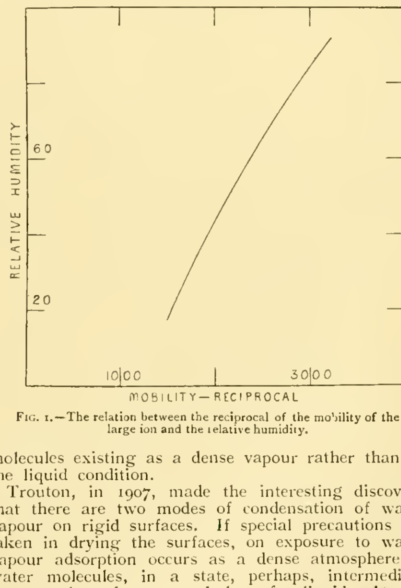

FIG. 1.—The relation between the reciprocal of the mobility of the large ion and the relative humidity.

Trouton, in 1907, made the interesting discovery that there are two modes of condensation of water vapour on rigid surfaces. If special precautions are taken in drying the surfaces, on exposure to water vapour adsorption occurs as a dense atmosphere of water molecules, in a state, perhaps, intermediate between that of a gas and that of a liquid. At any rate, a change to the liquid condition somewhat abruptly takes place in these circumstances when, according to Trouton, the humidity is about 50 per cent. in the case of glass, and about 90 per cent. in that of shellac.

The fluid surrounding the nucleus of the intermediate ion is, no doubt, in a state corresponding to that of the moisture condensed at low pressures on carefully dried surfaces in Trouton's experiments.

Further evidence supports the preceding view of the ion. Fig. 2 shows the relation between the reciprocal of the mobility of the intermediate ion and the vapour pressure as deduced from a plot of the determinations. At a pressure of about fifteen millimetres the mobility decreases very rapidly with increase in the value of the vapour pressure. Simultaneous observations of the intermediate and large ions were obtained on many occasions, but with vapour pressures exceeding seventeen millimetres, while the observations of the large ion were equally good, all trace of the intermediate ion disappeared.[1] Disintegration of the ion at a critical vapour pressure is unlikely, and it is much more probable, assuming a rigid nucleus, that the adsorbed fluid is in the condition of a dense vapour, and that at the critical pressure it changes its state to that of a liquid, like the moisture adsorbed by glass and shellac in Trouton's experience.

Such a change means a decrease in the energy of the aggregation, and is to be expected when the molecules of water vapour around the nucleus become sufficiently closely packed. The advent of a liquid surface involves a diminished rate of molecular escape; rapid condensation will therefore occur, with a decreasing unit-surface energy, until further increase in the size of the ion means an increase in the total energy of the mixture of ions and vapour. The final result is no other than the large ion. The assumption of a rigid core for the intermediate ion appears, thus, to be justified.

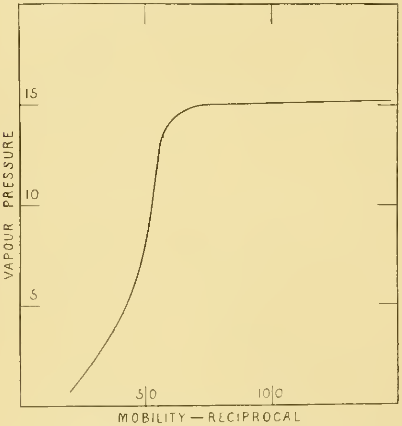

FIG. 2.—The relation between the reciprocal of the mobility of the intermediate ion and the vapour pressure.

To sum up the whole evidence, the large ion consists of a rigid nucleus surrounded by moisture in the liquid condition, the size of the drop at constant temperature depending on the vapour pressure. The intermediate ion is to be considered as a similar nucleus enveloped by a dense atmosphere of water vapour. The mass of the ion increases with the vapour pressure, until at a critical pressure the adsorbed fluid assumes the liquid state, and the aggregation develops, by the rapid condensation which ensues into the large ion of Langevin.

It is not quite clear how the electrical energy of the ions is related to their diameter. The charge is, however, not essential to the equilibrium of molecular structures such as those just mentioned, and it is not unlikely that the conclusions as to the nature of the ions, only rendered possible by the happy chance of their electrification, may apply with, perhaps, little modification to the far more numerous class of unelectrified nuclei which exists in ordinary air.

University of Sydney. J. A. POLLOCK.

[1] Details of these observations will be found in two papers published in the *Philosophical Magazine* for April and May, 1915.

Similitude in Periodic Motion.

IT may interest those of your readers whose attention has been direction to periodic motion to know that by reducing extremely large and extremely small frequencies to a musical base, and employing the middle C (256) as a standard the following results are obtained:—

Green light (frequency $5{\cdot}6\times10^{14}$) corresponds to the note C in the forty-first octave above the standard.

The colours—orange, green, and violet—roughly correspond to the musical chord ACE.

Human heart-beats (seventy-five a minute) correspond to the note E (320) in the eighth octave below the standard.

The earth's daily rotation corresponds to the note G (384) in the twenty-fifth octave below the standard.

Neptune's sidereal period almost corresponds with E flat (422) in the forty-first octave below the standard. HERBERT CHATLEY.

Tangshan Engineering College, Tangshan, North China, March 17.

A Simple Direct Method for the Radius Curvature of Spherical Surfaces.

THE following device was developed to obtain the radius of curvature of some lens surfaces that were too small for the available spherometers. It has proved so satisfactory that, not finding it in any of our

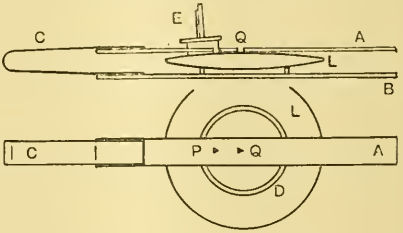

FIG. 1.

laboratory manuals, it has been thought to be of possible interest to others.

Two brass strips, A and B (Fig. 1), are connected by a flat spring, C. To B is soldered a brass ring, D, to serve as a bed for the lens, L, the surface of which is to be examined. A is pierced with two triangular holes, P and Q, as indicated in the sketch, the forward one having its vertex over the centre of the ring. A three-legged optical lever, E, is set with its legs on the glass surface, the front leg being as far forward as possible in one of the triangular holes, P (as shown). The other legs straddle the strip A, one being in contact with A. The lever E is not shown in the lower sketch.

If the mirror be lifted from its position in P to a similar one in which the front leg is at the vertex of Q, it will have been given a linear displacement (s) and an angular displacement (θ). The former of these quantities is the same as the distance between the vertices of P and Q. It is a constant of the instrument, and may be determined by means of a travelling microscope. The angular displacement (θ) depends on the lens surface, and may be obtained by telescope and scale in the usual way. The radius of curvature is then written by $\rho=s/\theta$.

The vertex of Q is placed over the centre of the ring, as this is the simplest way to ensure that the displacement lies along a great circle of the surface.

WILL C. BAKER.

Physical Laboratory, Queen's University, Kingston, Ont., April 19.

HOUSE-FLIES AS CARRIERS OF DISEASE.

THE discovery of the rôle of insects in the transmission of human and animal diseases is one of the most striking achievements of medical science during the last twenty-five years. Filariasis, Texas fever, nagana, malaria, sleeping sickness, yellow fever, dengue, sandfly fever, relapsing fever, plague, typhus, and many other diseases of the lower animals, have been shown to be transmissible by blood-sucking insects—mosquitoes, ticks, tsetse flies, fleas, or lice, as the case may be. The pioneers in this line of inquiry were Manson, Smith and Kilborne, Bruce and Ross.

In a number of cases the necessity of intervention by an insect has been established by the discovery that a portion of the life cycle of the parasite is passed in mosquito, tick, or tsetse fly respectively. In other cases, the evidence rests upon the correspondence in time and space of the incidence of the disease with the presence of some particular insect which has been experimentally shown capable of transmitting the infection. In yet other cases, such as plague, the microbe can also pass directly from patient to patient, as happens in the pneumonic variety of the disease, but the paramount importance of flea transmission in bubonic plague gains in recognition daily.

The rich harvest of discovery reaped by the investigations into the part played by blood-sucking insects in the spread of the above-mentioned diseases naturally stimulated inquiry into the possibilities of insect carriage as a factor in outbreaks of cholera, typhoid, dysentery, and epidemic diarrhœa. These are not diseases in the transmission of which a blood-sucking insect is likely to play a part, for in none of them is the infecting microbe present in the blood-stream in sufficient quantity, but the dejecta, fæces, and often urine, contain the bacilli in countless numbers. A small proportion of convalescents continue to excrete them for weeks, months, and, in the case of typhoid, for years afterwards, although enjoying perfect health. These people are particularly dangerous to the community as they form an unsuspected reservoir of infection.

To produce an epidemic of typhoid, cholera, or dysentery, the bacilli dejected by persons sick or convalescent from the disease must find access to the alimentary tract of others. There are, however, ways in which this may happen independent of the agency of insects. A water supply may become contaminated with infected material; the dejecta may dry up and be distributed as dust, and fall upon food materials (a method, the importance of which may easily be exaggerated, as these bacilli are readily killed by desiccation), or, owing to bacteriologically inadequate attention to cleanliness, food-stuffs, in which the microbes can multiply, may be infected with bacilli from patients or convalescents. Typhoid and cholera bacilli are small objects, less than one-thousandth of an inch in length, so that fingers may be easily soiled by considerable numbers without this being obvious, and the microbes are not removed by perfunctory washing.

Although these three means of spread do produce and maintain epidemics, one has but to consider the habits of the house-fly to realise that this insect may be an able and willing assistant in the distribution of the bacilli which are the cause of cholera, typhoid, dysentery, and diarrhœa, and that flies, if in sufficient numbers, and under conditions favourable for their operations, may constitute the principal way in which infection is distributed. In order to appreciate how this may happen it is necessary to be in possession of some few points in the life-history and structure of the fly.

These subjects have been submitted to careful inquiry during the last few years, particularly in America and this country, by Newstead, Howard, Griffith, Hewitt, and Graham Smith, and we are now well acquainted with this insect, intimate knowledge of which was, until recently, curiously lacking.

The female fly lays about 120 eggs at each laying, and may produce four broods. The eggs are mostly laid on horse manure or other fermenting refuse; they are about 1·5 mm. in length and 0·3 in their greatest diameter, and hatch in from three days to eight hours, according as the temperature ranges from 50° F. to 80° F. The larva is a little active grub 2 mm. long; and on hatching out burrows into the manure or other material on which the eggs are laid. The larval stage lasts five days to three weeks, and pupation five days to a month, according to temperature. Thus the whole cycle from laying of the egg to emergence of the fly occupies ten days to two months, according as the weather be warm or cold. The young female is ready to lay its first batch of eggs in about ten days, or even sooner in warm weather. Owing to this influence of temperature upon the rate of development of egg, larva, pupa, and imago, the number of flies in August depends on the temperature during June and July.

During winter a few flies survive in warm and secluded places. In the spring these start the next year's supply. Dr. Howard, of the United States Department of Agriculture, estimates that in forty days the descendants of one fly might number twelve million, or 800 lb. weight.

It will therefore be obvious that any attempt to overcome the nuisance from flies must, if success is to be achieved, be directed to their breeding haunts, and as early in the season as possible.

The points in the anatomy of the fly of importance for our present object are the legs and feet and the alimentary apparatus. These will be sufficiently obvious from the diagrams (Figs. 1 and 2). The feet are covered with minute hairs, which are more numerous and finer than in the diagram, and extremely fine hairs are also placed upon the pads. A sticky substance is secreted by the surface of the pads, by means of which the fly grips. Each leg is like a minute paint brush, which is applied to the surface of whatever it rests upon, excrement or food-stuff, as opportunity offers.

The alimentary canal comprises a gullet, stomach, crop, intestine, and rectum (see Fig. 2). The gullet is prolonged forwards to a minute opening between the flaps of the proboscis, halfway down which it is joined by the salivary duct (S D). At the entrance to the stomach (S) it is bifurcated, and one limb of the bifurcation is extended backwards to the bilobed crop (C). By a valvular apparatus at the entrance to the stomach, the insect can direct the liquid driven by the pump in its trunk into either the stomach or crop. The proboscis is a highly elastic muscular organ with universal movement. At the end are two flaps

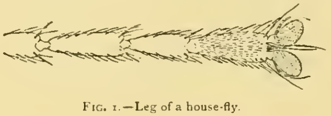

FIG. 1.—Leg of a house-fly.

or labella (only one of which is shown), which it can open out like the leaves of a book, and apply the medial surfaces to the material it feeds upon. From the middle line or hinge, minute chitinous channels pass outwards to the margin. At the base of the trunk a number of muscle fibres are attached to the gullet by the peristaltic contraction of which fluid is pumped up from the mouth and propelled into the stomach or crop. The structural arrangement of the channelled flaps of the trunk acts as a filter, through which solid objects larger than 1/4000th in. seldom pass. When feeding on a liquid, the fly applies the labella to the surface, and sucks the liquid through the

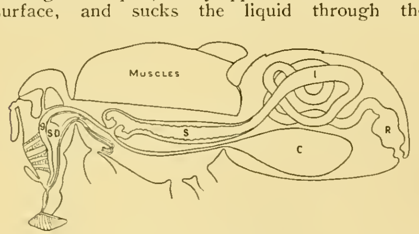

FIG. 2.—Alimentary system of a house-fly.

"strainer" first of all into the crop. When this is full, a further quantity is admitted into the stomach. In the case of solid material, such as sugar, the insect must first dissolve the material. This is done by pouring saliva upon it, or by regurgitating some of the contents of the crop.

A well-fed fly deposits fæces abundantly, and also the contents of its crop upon sugar and other solid objects.

It is clear, therefore, that there are *a priori* reasons for suspecting the fly of carrying bacterial infection. Born in a dunghill, it spends its days flitting between the sugar basin, milk pan, and any fæcal matter available. Its hairy, probably sticky, feet and the habit of regurgitating the contents of the crop and defæcating at frequent intervals, suggest it as an excellent inoculating agent for any bacteria it may pick up in the satisfaction of its catholic tastes. That it does, indeed, operate in this way has been abundantly demonstrated. Flies which have wandered over cultures of organisms and afterwards been allowed to walk upon gelatin plates leave a rich crop of germs in their footprints, which can be demonstrated by subsequent incubation.

Flies fed in the laboratory upon material containing easily identifiable pathogenic microbes have been shown to harbour them in their crops for days, and to deposit them in their fæces and the regurgitations from their crops. Internal carriage is probably more important than soiling of the exterior of the insect, as many pathogenic bacteria soon die from desiccation on the appendages of the insect.

In addition to these laboratory experiments, there are numerous recorded instances in which the pathogenic organisms of cholera, typhoid, phthisis, anthrax, and plague have been recovered from the interior or dejections of flies which have been captured in the immediate neighbourhood of cases of the disease, or, in the last two cases, of carcases of animals dead of the disease.

Although, however, flies may be discovered with the infection of a number of diseases in or upon them, and by their habits may not unlikely serve as agents in transferring infection, it by no means follows that they are the determining factor of epidemicity in the case of cholera, typhoid, dysentery, etc. In the case of fulminating epidemics of typhoid and cholera associated with an infected water supply, this is obviously not so.

It is in temporary encampments of troops or pilgrims, when the disposal of excreta must necessarily be of a primitive character, that the conditions obtain which are most favourable to the breeding of flies and the distribution of infection by them, if cholera or typhoid appear. Even in these circumstances it is difficult to assess the relative importance of fly carriage and other means of spread, but the conclusion that fly transmission is the principal means of spread of typhoid in military encampments and stations has been arrived at by a number of competent observers, amongst them the commission to inquire into the origin and spread of typhoid fever in the United States military camps during the Spanish war of 1898, and by a number of medical officers concerned with the severe outbreaks of enteric which occurred during the Boer war.

The sanitary arrangements of a military camp are not exactly those of the Ritz Hotel, and the prevalence of flies in late summer can scarcely be appreciated by those who have not had camp experience. The conditions are most favourable for transmission of disease by flies, and the circumstantial evidence against them is so strong as to have left no doubt in the minds of the American Commission that these insects play a large part in disseminating infection, for on page 28 of their general statement and conclusions we read:

"Flies undoubtedly served as carriers of infection."

An estimate of the fly population and its relation to admissions for enteric fever was made by Ainsworth in Poona, where enteric has a very definite season. A definite number of fly traps was set, and the daily catch taken as a measure of the fly population. The observations showed that the abundance of flies increased earlier than the admissions for enteric, and, speaking generally, the rise in fly population ante-dated the rise in enteric cases by about one month.

Taking into account the incubation period for the disease, this fact is in agreement with the view of a causal relation between cases and flies in Poona.

In considering the possible influence of flies in the spread of typhoid in a well-sewered city, it must be remembered that the opportunities for them to pick up the infection are vastly fewer than under the conditions of a military encampment, or even in rural surroundings. In large cities with modern sewerage, dejecta and urine from patients may be left available to flies, but the bulk goes promptly into the main drain, and similar observations to those above-mentioned have shown no close relationship, in point of time, between cases of typhoid and prevalence of flies in London, Washington, or Manchester.

As with typhoid, the case against flies as agents in the distribution of the infection of cholera is circumstantial, as other means of spread cannot be excluded. Take, for instance, the case of an accumulation of 300,000 pilgrims in Puri, India, in July, 1912, which was studied by Greig. The sanitary accommodation of the town was inadequate for such an accession to the population. Some of the pilgrims imported the infection of cholera, and an outbreak occurred. Flies in Puri "amounted almost to a plague," and a bacteriological examination of the legs and the contents of the alimentary tracts of flies caught in the neighbourhood of cholera cases demonstrated the presence of cholera vibrios.

Knowing the habits of flies, it is impossible to forgo the conclusion, arrived at by Greig, that some amount of distribution of the infection of cholera was due to their activity. But to what extent they were contributing could only be ascertained by the result of measures directed either to the diminution of their numbers, or to depriving them of access to infectious material.

Greig could not supervise the private latrines of the native inhabitants, but was able to carry out practical measures to prevent flies from visiting dejecta in the case of an outbreak of cholera amongst a limited population in the Puri jail. These were attended with immediate good results.

There are the same general reasons for assuming that fly transmission plays an important part in epidemics of summer diarrhœa of infants as in the case of typhoid and cholera. Anyone familiar with the domestic *ménage* of the average working man on a hot summer day, with the baby sick with diarrhœa, and other small children to care for, must realise that the opportunities afforded for flies to transport the infective agent from the dejecta of one child to the food supply of another are more than adequate.

Epidemic diarrhœa of children does not occur except during that season of the year when flies are abundant and active, and, as will be seen from the accompanying chart, the relation between fly population and diarrhœa cases is so

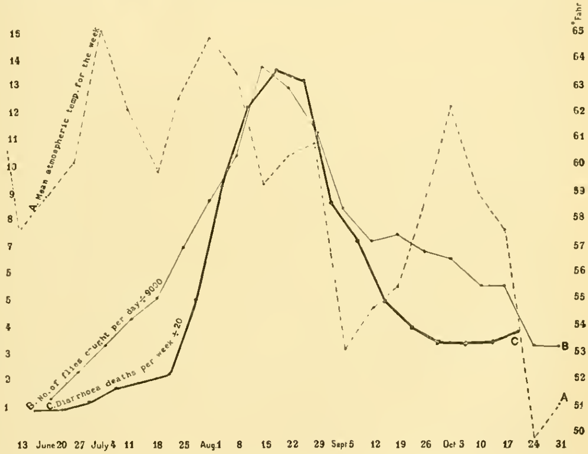

FIG. 3.—Dr. Hamer's observations on relation in point of time between prevalence of flies and diarrhœa mortality in London, 1908. (141 fly-collecting centres.) The deaths from diarrhœa have been antedated 10 days

striking as to suggest something more than a mere accidental dependence upon the same phenomena.

The chart is constructed from Dr. Hamer's observations on the numbers of flies caught daily in the same number of traps in 141 localities in London during 1908. An important point brought out by these observations is the dependence of both the number of flies and the epidemic upon the cumulative effect of previous warm weather—as, for instance, is indicated by the earth temperature four feet below the surface, a fact to which attention was directed by Ballard in 1889. Similar observations in Manchester, by Dr. Niven, in 1904 to 1906, showed the same relationship.

The reason why the number of flies should be dependent upon this factor is obviously that the generation time (cycle from egg to egg) is dependent on temperature, and requires three weeks or upwards in our climate. Months of warm weather are therefore required to produce any multitude of flies from the few surviving in the winter. Why the epidemic should exhibit this dependence is not explained, unless on the assumption that the fly population determines the number of cases of diarrhœa.

Without losing sight of the various other ways in which the specific infective agents of cholera, typhoid, epidemic diarrhœa, and dysenteries may be and are transported from the excreta of one individual to the mouths of others, the *prima facie* case against the house-fly is complete.

Further, in the case of infantile diarrhœa, the fly-carriage hypothesis offers a satisfactory interpretation of the extraordinary dependence of the epidemic upon the accumulated effect of temperature, and affords a ready explanation of the spread of the infection of cholera, typhoid, and diarrhœa to neighbouring persons who have no contact with the patient, in those cases in which contamination of a water or food supply may be excluded.

The direct proof of the extent of the danger due to flies is lacking, but the hypothesis has pragmatic value. It not only interprets facts otherwise awkwardly explained, but measures based upon it have been attended with beneficial results; in other words, it works.

THE RESURRECTION OF BABYLON.[1]

THOUGH scarcely a book to attract the general reader, Dr. Koldewey's account of the German excavations on the mounds which have for ages entombed the remains of Babylon the Great, is a work of considerable importance for all who are interested in the archæology of the Old Testament. This, as perhaps is not generally known in England, is still a growing science; and the worst thing that can be said of the German Expedition to Babylonia is that, after so many years of patient and persistent spadework on one of the most promising sites in the world, it has not yet succeeded in unearthing anything of higher historical or religious value than is recorded in the volume before us. Nothing extraordinary has hitherto been found; no great literary monument, no document of supreme religious moment, nothing that lends decisive help towards the settlement of any one of the unsolved problems of history or chronology. How much more fortunate in this respect were the pioneering labours of Layard and George Smith and Botta at Nineveh, of Rassam at Sippara, of De Sarzec at Tellô, of De Morgan and Scheil at Susa!

It is well for us that the Assyrian kings were so deeply interested in the literary monuments of Babylon. Had we depended for our knowledge of these on the remains of the Great City itself, we should (until the recent American discoveries at Nippur) have been left without any indication of the existence of the Babylonian legends of Creation and the Deluge; to say nothing of the many relics of the arts and sciences of Babylon which the library of Assurbanipal preserved for us.

The pathos of the position of the German explorers was that the site had been looted so often previously to their systematic investigations that scarcely anything of first-rate importance was left for the latest adventurers. The temples and palaces of Nebuchadrezzar's capital were probably swept bare of most of their portable treasures at a comparatively early period; and the ravages of people in search of building material, and the petty pilferings of Arabs and other stray visitors, had doubtless robbed the ruins of much that would have been priceless in the eyes of modern explorers. Even the beautiful enamelled bricks,

FIG. 1.—Enamelled wall length of the Ishtar Gate. From "The Excavations at Babylon."

with their strange mythological figures, are not altogether a novelty. Older specimens of the same kind of mural decoration were long ago reproduced by Perrot and Chipiez from Sargon's palace at Khorsabad ("History of Art in Chaldea and Assyria," II., plate xv.; see also plates xiii–xiv. Eng. Trans., London, 1884). But it is highly satisfactory to find such splendid examples as those of the Ishtar Gate still existing, *in situ*, and in such an excellent state of preservation (Fig. 1).

Whether anything of supreme value awaits disinterment at lower levels remains to be seen. Slabs of diorite or other hard stone, like the famous stela of Hammurabi, or the similarly written inscription of Nebuchadrezzar, which is (or was) one of the treasures of the library of the

[1] "The Excavations at Babylon." By R. Koldewey. Translated by Agnes S. Johns. Pp. xix+335. (London: Macmillan and Co., Ltd., 1914.) Price 21*s*. net.

East India House, might well have survived an age-long immersion in Euphratean mud. In any case, disappointing as, in such respects, results have hitherto proved to be, we entirely agree with Dr. Koldewey that it is most desirable that the work of excavating this historic site, begun so many years ago, should be carried to completion. Meanwhile, the special student will not fail to find many good things in this storehouse of facts and comments. It is now certain that ancient accounts greatly exaggerated the extent of ground actually covered by the city, the influence of which dominated the civilised world from the age of Hammurabi, the founder of its imperial greatness, to that of Nebuchadrezzar, who, if he did not find it of brick and leave it of marble, undoubtedly restored and enlarged its walls and temples and palaces on so grand a scale that the glories of Babylon the Great became a standing wonder of antiquity. The walls, however, have been found to range from upwards of fifty to more than sixty feet in thickness, and the mounds which concealed them rose to about four times the height of the ordinary *Tels* of buried Oriental cities: circumstances which sufficiently indicate the arduous nature of the task of excavation.

Dr. Koldewey's translations are, for the most part, good and accurate; but in EIH. VI. (not "7") 22–55, the passage in which Nebuchadrezzar or his court historian describes the building of the new eastern wall and the making of the moat, either he or his translator has misunderstood Winckler (KB., iii., 2, p. 23), who explains *IV M amat gagari*, "4000 cubits of ground," as referring to the length of the new wall, not to the distance from Imgur-Bel, and renders *itâti Bâbili nisis lâ dahê*, "an den Seiten von Babylon, in der Ferne, sodass sie nicht herankam," where "sie" also refers to the new wall.

We must also be excused if we demur to the transcription "Sirrush" and the explanation "a walking serpent" (p. 46). The çirrush, or rather, mush-rush, was one of the aqueous monsters created by Tiâmat, to help her in warring down the gods of light. It is something to learn what a MUSH-RUSH was like; and Dr. Koldewey has enabled us to identify it with a form already

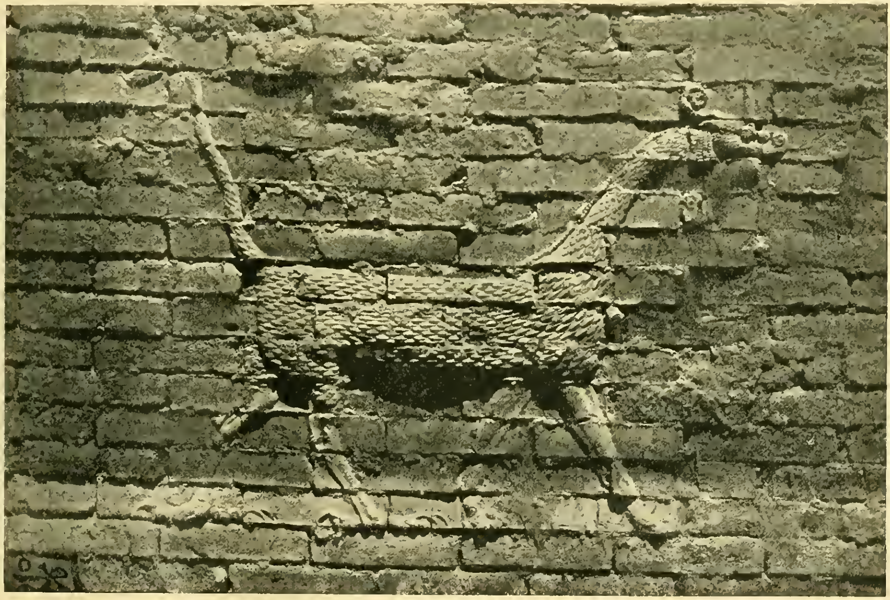

FIG. 2.—A Sirrush. From "The Excavations at Babylon."

familiar to us from other Babylonian monuments. It was, in fact, not so much a serpent (though the Sumerian MUSH includes that meaning) as a composite form with serpent head, scales, and tail, and four claw-footed legs—a sort of "laidly worm" or "fearsome dragon," and remarkably like a dinosaurus. The name may denote *fierce* (or *glittering*) *dragon* (Fig. 2).

Dr. Koldewey first visited Babylon in June, 1887, about the time when the present reviewer was working upon the text of the East India House inscription of Nebuchadrezzar (see Proceedings of the Society of Biblical Archæology, December, 1887). What a godsend would the present volume have been in those days, clearing up as it does by its thorough investigation of local conditions and the actual remains of the ancient buildings so many of the earlier translators' almost hopeless perplexities! One after another, the Procession Street of Merodach, the Sacred Way along which marched the annual solemnity of Babylon's tutelary god; E-MAGH, the temple of NIN-MAGH, "The Exalted Lady," several inscribed cylinders from which may be seen in the British Museum collection; the Gate of Nanâ-Ishtar, with its superb enamelled figures; the palace of Nabopolassar (Nabû-apla-uçur), which Nebuchadrezzar restored with great splendour; the location of E-SAG-ILA, the temple of Merodach, and chief sanctuary of Babylon; the world-famed walls, and various connected structures, were determined and in part exposed to view.

All this, though perhaps not exactly the kind of matter to stimulate the enthusiasm of one who reads merely to while away an idle hour, constitutes a highly important contribution towards an exact topography of Babylon, and to the right understanding of the inscriptions of the Neo-Babylonian period; while it enables classical students to bring to the test of ascertained facts the descriptions of Babylon which we find in Herodotus and subsequent Greek and Latin authors, extracts from whose pages are given in Koldewey's convenient appendix. It is to be hoped that current events in the East may prove no bar to the further prosecution of Dr. Koldewey's meritorious and, indeed, necessary enterprise—even if it happen by the fortune of war that the whole or part of the treasures recovered by his continued labours should find their way to London instead of Berlin.

It should be added that the author has been fortunate in his translator, the English of the book being generally accurate and readable—which is not always the case with translations from German originals.

C. J. BALL.

SCIENCE AND INVENTION.[1]

(1) MR. EDELMAN'S book commences with descriptions of a number of scientific experiments, illustrated by small but clear diagrams. Some of these experiments will be familiar to all those who have taken an experimental course in chemistry and physics, but freshness is given by including simple instances of technical applications of scientific principles. Thus, sections are devoted to "thermit," the electrolytic cleaning of tarnished silver by contact with aluminium in a solution of soda and salt, the preparation of colloidal solutions of platinum and gold, etc. The following description of a method of soldering aluminium may prove useful (p. 47):—

> Aluminium, 1 part; zinc, 4 parts. After the aluminium has been melted add the zinc, then a small quantity of fat. The mixture should be well stirred, after which it may be poured into stick moulds.
>
> To apply, scrape the article bright at place to be soldered. Use a little Venetian turpentine as a soldering fluid. A thin shaving of the solder may then be placed around the joint and melted with a blow torch.

It is impossible to mention the very large number of technical and scientific principles which are described and illustrated; it must suffice to say that these range from the production of Pharaoh's serpents, through electric motors and dynamos, to wireless telegraphy and X-rays. The last nine chapters are devoted to an analysis of the principles used in research and invention. The book is well got up, and forms interesting and instructive reading.

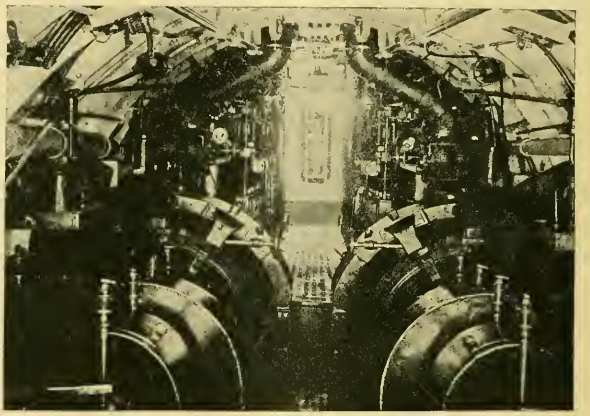

FIG. 1.—Engine room of submarine looking forward. From "Discoveries and Inventions of the Twentieth Century."

(2) Although the twentieth century is still young, Mr. Cressy has found nearly four hundred pages to be none too many in which to describe the progress of inventions made therein. The remarkable improvements which have been made in the details of most industries are clearly brought before the reader. The modern applications of water power, as exhibited in the water turbine and the Pelton wheel; the developments of the steam turbine; the Humphrey pump; improvements in gas, petrol, and oil engines, including the Diesel marine engine, and the "Gnome" engine for aeroplanes; these form a few of the developments described in the first few chapters. Electric lighting is next discussed, and some in-

[1] (1) "Experiments. A Volume for All who are Interested in Progress." By P. E. Edelman. Pp. 256. (Minneapolis, U.S.A.: Philip E. Edelman, 1914.) Price 1.50 dollars.
(2) "Discoveries and Inventions of the Twentieth Century." By E. Cressy. Pp. xvi+398. (London: G. Routledge and Sons, Ltd., 1914.) Price 7s. 6d. net.

stances in which electric heating is advisable are mentioned. Later, a brief but lucid account is given of the nature of steel, including the modern alloys of iron and manganese, chromium, nickel, and tungsten. A separate chapter is devoted to the electric furnace. An interesting and instructive chapter is devoted to the artificial production of cold, including liquefaction of gases and the methods used in cold storage. At the present time, when the advisability of increasing the productiveness of agricultural land is receiving attention, the chapters on "soil and crops" will be read with interest.

Railways, tramways, and motor-cars next receive consideration, and the wonderful developments of ship-building are ably dealt with. Great skill has been shown by the author in pointing out the scientific principles which have been utilised in each new technical advance. Thus, in connection with the speed of ships, Prof. Hele Shaw's experiments in fluid motion, and Froude's method of determining the power required to drive a full size ship from experiments on a small-scale model, are described and illustrated. Naturally enough, aerial and submarine navigation receive their due share of attention; the most important types of monoplanes, biplanes, dirigible balloons, and submarine ships are described, and an interesting section is devoted to the gyrostatic compass. Details of the construction and method of firing of the torpedo are also given. The illustrations showing the interior of a submarine (Figs. 1 and 2) will excite considerable interest.

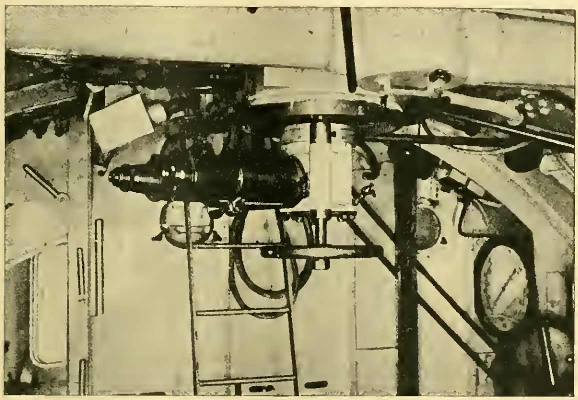

Fig. 2.—Telescope at lower end of periscope tube. From "Discoveries and Inventions of the Twentieth Century."

In reviewing this book, which contains an immense amount of material of the highest interest, it has been found impossible to do more than indicate the aim and scope of the work. Points of scientific interest are mentioned on almost every page, and the reader cannot but admire the painstaking erudition displayed by the author. Books of this character are apt to take the form of undigested summaries of inventions, only partially understood. This is not the case with the book now under review. The author could not hope, and has not attempted, to give exhaustive descriptions of the multifarious technical inventions with which he deals; but these are always described in a stimulating manner, and great accuracy is displayed throughout. The letterpress is illustrated with 281 figures and a coloured frontispiece.

Edwin Edser.

THE GOVERNMENT AND CHEMICAL RESEARCH.

The President and Council of the Royal Society and of the Chemical Society have recently had under consideration the state of chemical industry in this country as revealed by the effects of the war, and have prepared memorials to his Majesty's Government directing attention to the necessity for immediate action. On Thursday last a deputation was received by the President of the Board of Trade and the President of the Board of Education at the Board of Trade offices for the discussion of the questions raised in the two memorials. Mr. Runciman and Mr. Pease were accompanied by Dr. Addison, M.P., Sir H. Llewellyn Smith, Sir L. A. Selby-Bigge, Mr. Ogilvie, Dr. Heath, and Mr. Percy Ashley.

The deputation was introduced by Sir William Crookes, who explained the functions of the several societies represented, and it consisted of Prof. A. W. Crossley, Dr. H. J. H. Fenton, Dr. M. O. Forster, Prof. W. H. Perkin, Prof. W. J. Pope, Prof. A. Schuster, Prof. A. Smithells, Prof. J. F. Thorpe, and Mr. R. W. Harrison, representing the Royal Society; Dr. A. Scott, Prof. F. G. Donnan, Prof. P. F. Frankland, Prof. J. C. Philip, Sir W. A. Tilden, and Dr. S. Smiles, representing the Chemical Society; Mr. A. C. Chapman, President of the Society of Public Analysts, Dr. G. G. Henderson, President of the Society of Chemical Industry, and Prof. H. Jackson and Mr. E. W. Voelcker, representing the Institute of Chemistry. Sir H. E. Roscoe and Prof. R. Meldola were prevented from attending by ill-health.

Prof. W. H. Perkin, Sir W. A. Tilden, Prof. P. F. Frankland, Prof. W. J. Pope, and Dr. M. O. Forster spoke on behalf of the deputation. It was urged that the main causes of the comparatively backward state of many branches of chemical industry in this country are the general failure to realise that modern technical industry, to be successful, must be based on scientific research, and the want of intimate association between the manufacturers and the workers in science. The advisory committee which has been already appointed by the Board of Trade for the consideration of many emergency questions which have arisen, should be replaced by a permanent Standing Committee of the nature of an intelligence department serving the large and growing chemical industries of the country in the same way that the Commercial Intelligence Department serves merchants and traders. It was urged that the chemists of the country generally consider it imperative on national grounds that the development of the new organisation should be pushed forward with as little delay as possible; the expansion of the chemical industries of the country requires intimate co-operation between men of science and manufacturers, and, in view of the leeway which has to be made up, a considerable increase in the number of research workers is necessary in order to hasten progress and to insure the permanent retention of new manufactures after the war. The speakers insisted upon the need for a more intelligent appreciation of the significance of original scientific work by the Government, the urgency for increased facilities of communication between manufacturers and scientific chemical experts, and the fact that an intelligence department of the kind contemplated would, under Government auspices, form a clearing house for all the vast variety of scientific and technological chemical material which is at our disposal; such a department would form a link between the university or college, in which the chemical technologist must be trained, and the industries which would be of immense advantage to both teacher and student. The use which might have been made of the expert knowledge of such a body during the recent preliminaries to the foundation of British Dyes, Ltd., was also indicated.

Mr. Runciman, in reply to the deputation, pointed out that the Board of Trade fully appreciated the extent to which national progress is dependent upon the utilisation of the services of men of science, and the importance of provision for the thorough training of a very much larger number of industrial chemists than are at present available. He agreed with the views expressed as to the need of closer co-operation between manufacturers and scientific workers and teachers. The war had shown the weakness of our position in certain important respects, and he was in full sympathy with the general views expressed by the deputation. The actual proposals would receive careful and sympathetic consideration.

Mr. Pease informed the deputation that the particular problems to which it had directed attention had been present to the Board of Education for some time past, and that a scheme had been approved in principle by which substantial additional assistance would be given by the Government to scientific education and industrial research. He hoped that, though the funds immediately available might not be large, they would be sufficient to enable an organisation to be brought into being at an early date which would be capable of expansion afterwards. Mr. Pease further expressed his appreciation of the offer of assistance and advice by members of the societies represented at the deputation.

Sir William Crookes expressed the thanks of the members of the deputation for the sympathetic reception which they had met.

SIR WILLIAM R. GOWERS, F.R.S.

THE death of Sir William Gowers on May 4, at the age of seventy, deprives English medicine of one of its most illustrious ornaments. The state of his health—which suffered an almost complete eclipse by the death of his wife two years ago—had led to his retirement from active practice, so that the news of his death cannot have been quite unexpected. Yet it will be widely regretted, and the value of his work on the scientific side of medicine will perhaps be more completely realised than if his death had been delayed for some years.

William Richard Gowers was born on March 20, 1845. He was educated at Christchurch School, Oxford, and was for a time apprenticed to Dr. Simpson, a medical practitioner in Essex. He began his medical education at University College Hospital, London, and he had a brilliant career there, and at the University of London. He qualified M.R.C.S. 1867, took his M.B. degree in 1869, and his M.D. in 1870, winning the Gold Medal in Medicine. He became a Fellow of the Royal College of Physicians in 1879. He was also elected a Fellow of the Royal Society. He received the honour of knighthood in 1897.

Gowers's great work in medicine was in systematising the important class of nervous diseases, and in bringing into relation clinical facts with pathological changes. His early works were especially remarkable in this respect, and his clinical teaching—which was peculiarly stimulating to qualified medical men and senior students—always had this as its keynote. He would discuss fully the symptoms of what a patient complained, the clinical signs associated with these, and finally lay down definitely and clearly the changes in the nervous system which his experience had taught him were associated with these signs and symptoms.

It is not necessary here to enumerate the various medical works which he published, or to emphasise their importance. Several of them were translated into more than one European language. His chief work was the "Manual of Disease of the Nervous System," published in two volumes, the first in 1886 and the second in 1888.

Like many busy men he had, or made time for, hobbies. He was an artistic and skilful etcher, and had a great interest in, and an intimate knowledge of mosses, and also of ordinary wild flowers. He was also interested in archæology and architecture, and he himself investigated the remains of some of the old Suffolk churches, and described their character and reconstructed their history. He had early struggles and difficulties which sometimes made him seem a little austere, but as time went on his innate kindness asserted itself more and more, and his death will be deeply mourned, not only by those who benefited from his professional skill and knowledge, but by many who had experienced generous kindness at his hands.

NOTES.

AMONG the numerous portraits exhibited at the Royal Academy this year three may be specially mentioned. That of Sir Archibald Geikie, painted by Mr. R. G. Eves for presentation to the Royal Society, is a successful and welcome addition to the series of portraits of past-presidents of the society. The Hon. John Collier's portrait of Mr. C. V. Boys is not only excellent in itself, but also noteworthy for the skilful treatment of an experiment in thin films. A portrait of Dr. E. A. Wilson by Mr. H. G. Riviere, destined for Cheltenham College, is of melancholy interest as an appropriate memorial to the naturalist of the National Antarctic Expedition. A striking oil painting by Mr. John Cooke, forms a memento of a discussion on the Piltdown skull which was held in the conservator's room at the Royal College of Surgeons in June, 1913. Prof. Arthur Keith sits at a table covered with the remains of the skull, restored models, and specimens for comparison, while Prof. Elliot Smith stands behind on his right pointing to the disputed middle line of the cranium. Mr. Charles Dawson and Dr. Smith Woodward also stand behind on his left, and Sir Ray Lankester sits at the end of the table beneath them. Prof. A. S. Underwood and Mr. W. P. Pycraft are seated, one on either side of Prof. Keith, and the modeller of the restorations, Mr. F. O. Barlow, stands behind Prof. Smith. All the portraits are excellent, and the composition of the group is pleasing.

PROF. E. W. MARCHANT, of the University of Liverpool, has been elected chairman of the Liverpool Engineering Society for the coming year.

WE learn from the *Lancet* that Prof. R. Newstead, of the Liverpool School of Tropical Medicine, is in France, prosecuting entomological investigations from the point of view of military sanitation.

THE Pereira medal of the Pharmaceutical Society has been awarded to Miss Dora F. White, and the silver and bronze medals of the society to Mr. A. J. Somer and Mr. R. W. Bowles respectively.

WE learn from *Science* that the Draper medal was presented to Dr. Joel Stebbins, protessor of astronomy at the University of Illinois, at the annual dinner of the National Academy of Sciences, held on April 20.

MR. T. R. GREENOUGH and his mother have given, in memory of the late Alderman T. Greenough, a complete electrical and radiographic installation to the Leigh Infirmary. It is in three divisions, and its value is estimated at about 5000*l*.

THE Swarthmore lecture of the Society of Friends for the present year will be delivered at the Central Hall, Westminster, on Tuesday next, May 18, at 7.30 p.m., by Prof. Silvanus P. Thompson, who will speak on "The Quest for Truth." There will be no charge made for admission.

IN *Egyptian Illustration* for May Mr. W. G. Kemp announces his discovery of a partially fossilised human skull and associated remains in a cavern in the limestone of the Mokattam Hills, near Cairo. The specimens, which are considered to be prehistoric, are now being studied by Dr. Ferguson at the Cairo School of Medicine.

MR. G. MASSEE has retired from his position as head of the cryptogamic department in the herbarium at the Royal Botanic Gardens, Kew. Mr. Massee joined the Kew staff in 1893, in succession to Dr. M. C. Cooke, and he has rendered valuable service to agriculturists and horticulturists throughout the British Empire in all questions concerning plant pathology.

WE regret to learn of the death of Prof. Erich Harnack, director of the pharmacological institute of the University of Halle, and a brother of the well-known Adolf Harnack. The deceased, a native of the Baltic provinces, was a pupil of Schmiedeberg, in conjunction with whom he prepared, from choline, so-called synthetic muscarine, at one time believed to be identical with the poison of *Amanita muscaria*.

WE learn from the *Irish Naturalist* that the following naturalists in Ireland are among those who have been given commissions in the Army in connection with the present call to national service:—Prof. Gregg Wilson, professor of zoology, and Dr. A. R. Dwerryhouse, lecturer in geology, Queen's University, Belfast; Prof. H. A. Cummins, professor of botany and agriculture, University College, Cork; Mr. C. M. Selbie, of the National Museum, Dublin; Mr. G. P. Farran and Mr. A. B. Hillas, of the Fisheries Office; Mr. H. T. Kennedy and Mr. R. L. Valentine, of the Geological Survey.

THE *Pioneer Mail* for April 16 states that in spite of delays due to the European war, Sir Leonard Rogers's scheme for establishing a School of Tropical Medicine in Calcutta is progressing satisfactorily, and the time when the building will be ready for use is well in sight. The aim of the institution is to investigate specially the cause of tropical diseases and render the best possible relief on practical lines with the view of finding more accurate methods of diagnosis and improved treatment. The fund for building a hospital for tropical diseases now amounts to about 14,000*l*. (paid up), including a recent anonymous donation of 2700*l*. through Dr. K. C. Bose. Plans for the hospital are nearly ready, and the building is expected to be commenced very shortly.

THE third Wilbur Wright Memorial Lecture of the Aeronautical Society will be delivered by Prof. G. H. Bryan, on May 20, at the Royal Society of Arts, John Street, Adelphi. Gold medals of the society, awarded respectively to Prof. Bryan and to the late Mr. E. T. Busk, will be officially presented immediately before the lecture. The late Mr. Busk played a unique part in the extension to full-sized aeroplanes of the theoretical methods of calculating aeroplane stability due to Prof. Bryan, and lost his life by fire in the air while carrying out his experiments. Machines designed by the methods thus evolved form a large proportion of the valuable aerial equipment of the Royal Flying Corps. Tickets, of which the number is limited, may be obtained on application to the secretary, Aeronautical Society, 11 Adam Street, Adelphi, W.C.

Mr. C. S. Middlemiss, of the India Geological Survey, who was a native of Hull, and many years ago spent much time in investigating the geology of east Yorkshire, has made a valuable addition to the geological section of the Hull Museum. He has presented his entire collection, the specimens being all carefully labelled and catalogued, and most of them refer to east Yorkshire. Some years ago Mr. Middlemiss had an opportunity of examining the interesting sections in the Kellaways Rock at South Cave, which were made during the construction of the Hull and Barnsley Railway, and were described in the *Geological Magazine* at the time. The South Cave specimens, together with many others from the red and white chalk, etc., are included, and in addition there is a valuable series of rocks, with a catalogue giving full localities, etc. There is no doubt that Mr. Middlemiss's collection will be of great service to local geologists.

The British Fire Prevention Committee has done much useful war emergency work during the last nine months. The general honorary secretary, Mr. Ellis Marsland, has issued a statement which shows that the committee's special fire survey force of honorary surveyors has surveyed in detail about five hundred establishments taken over for war emergency work. The character and extent of these establishments varied, but often included extensive groups of buildings. The committee's warning service embraces the preparation and issue of public fire warnings disseminated in the form of posters, or as notices reproduced by technical societies, etc. More than 25,000 posters were issued to auxiliary hospitals at home, in France, in the Mediterranean, and in Egypt, as well as translations in French, Flemish, Urdu, and Panjabi. Refugees' homes and hostels in four hundred localities received about 22,000 warnings in English, French, and Flemish. The issue of farmers' warnings in connection with the epidemic of farm fires last autumn totalled more than 30,000. The number of warnings issued for premises occupied by troops exceeded 25,000. The committee's special fire service force, comprising ex-fire brigade officers and firemen, has rendered two hundred firemen with the necessary appliances readily available for mobilisation in sections within forty-eight hours. Fuller particulars of the various activities of the committee may be obtained from the office at 8 Waterloo Place, Pall Mall, London, S.W.

British zoology has suffered a distressing loss in the death of Mr. Charles H. Martin, of Abergavenny, who was killed in action on May 3, in the western battle front of the Allies, at the age of thirty-three. Mr. Martin was educated at Eton and Magdalen College, Oxford, took honours in zoology at Oxford, and devoted himself with enthusiasm to zoological research. He worked chiefly, and in recent times almost entirely, at Protozoa, and published important investigations on Acinetaria, on Trypanoplasma and allied forms, and on the cæcal parasites of fowls. Latterly he devoted himself to the study of the Protozoa of the soil, working in touch with the Rothamsted Experimental Station, and published valuable contributions to this subject, either alone or in collaboration with Mr. K. R. Lewin, of the Rothamsted Station. He was awarded the Rolleston memorial prize for his researches. For a time he was in charge of Messrs. Gurneys' laboratory at Sutton Broad, Norfolk, and afterwards assistant in the natural history department of the University of Glasgow for three years, but on his father's death he succeeded to his estate, and gave up all appointments. He continued, however, to pursue his zoological investigations with characteristic energy, in spite of the many distractions and occupations incidental to the life of a sportsman and a conscientious country squire, often carrying on researches at night after a strenuous and fatiguing day. A man of splendid physique, he joined the Officers' Training Corps early in his career, and obtained a commission in the 3rd Monmouthshire (Territorial) Regiment, of which he was an officer when he met his death. Possessed of great personal charm and of a most kindly, sincere, and generous temperament, his untimely but glorious death will be greatly deplored by all who had the privilege of being acquained with him personally, as well as by those who knew him only as one of the most promising of our younger zoologists.

In the Journal of the Royal Anthropological Institute for July–December, 1914, the Hon. John Abercromby discusses a large collection of pottery from the Canary Islands and the bearing of it upon the origin of the people inhabiting the archipelago. He arrives at the following conclusions. The archipelago was first colonised in the second, or Berber, stage of the Neolithic period by a people who spoke a Berber dialect. These colonists probably belonged to the short dolicho- and meso-cephalic stock of Hamitic type, or to the tall Cro-Magnon type. Both were of African origin, and may have arrived together or at short intervals. The short-headed people were presumably of European origin, but archæological considerations show that they may have reached the archipelago about the same time as the other two elements in the population, at any rate before the art of navigation had ceased to be known.

In a reprint from the Proceedings of the United States National Museum for April last, Mr. Oliver Hay describes remains of two extinct horses, a bison, and a musk ox, also extinct, and new to science, from the Pleistocene of North America. The author believes that it will be necessary to recognise at least two distinct species among the progenitors of our domesticated horses. One of the two supposed species is represented to-day by the large, narrow-faced horses; the other by the pony-like, broad-faced horses, especially the Celtic pony and the fjord horses of Norway.

AN interesting summary of the "Natural History of the Whale-shark" (*Rhincodon typica*), by Prof. E. W. Gudger, is given in the March number of *Zoologica*, the organ of the New York Zoological Society. Little is known of this fish, the largest of the sharks, and estimates of its length vary immensely, but it would seem that its maximum length is about 45 ft. Prof. Gudger's summary is based upon a specimen captured at Miami, Florida, during June, 1912. Unfortunately, however, he is able to write at first hand only of the stuffed skin of this fish, for the rest he has had to rely on photographs, and the account of Capt. Thompson, who harpooned it. He nevertheless brings together some valuable notes on its coloration, habits, and food, compiled from various sources.

IN "Notes on the Evidences of Age Afforded by the Growth Rings of Oyster Shells" (Fisheries, Ireland, Scientific Investigations, 1913, ii. [1914]), Miss A. L. Massy gives particulars of measurements and of the number of surface lamellæ of the shells of more than 600 oysters of known age and of various ages from eighteen months to six years. Summing up her observations as to the relation between age and the number of surface lamellæ, or growth rings, Miss Massy states that an oyster of eighteen months or two summers appears to possess at least two rings, but may have as many as five; one of three summers has at least two rings, but may have six. A four-year-old oyster may have only three rings, or may possess seven or eight. It would have added greatly to the interest of the paper if these surface rings had been compared with the number of rings shown in sections of the shell.

PUBLICATION DE CIRCONSTANCE, No. 69, of the International Council for the Study of the Sea is entitled "A Contribution to the Biology of the Mackerel: Investigations in Swedish Waters," by David Nilsson. The subjects dealt with are the relation of length to weight in the mackerel, age and growth, food, parasites, sex and maturity, eggs and larvæ, and variation. The material examined, which was collected off the west coast of Sweden, was unfortunately not very large; indeed, scarcely sufficient to justify many of the conclusions which the author attempts to draw from it. On the question of age and growth both the scales and the otoliths have been examined. In the mackerel, however, the appearances seen on both of these are very difficult of interpretation, and the figures given in the paper, which are reproductions (perhaps not very good ones) of photographs, are not very convincing. The author considers that mackerel of 120 to 210 mm. long in August, September, and October are derived from eggs spawned in the same year, although he shows that spawning in Swedish waters takes place principally in July. Much further research on a far more extensive scale is required before our knowledge of the life-history of the mackerel can be regarded as adequate and trustworthy.

IN his report on the survey operations for the year 1913–14 (New Zealand Department of Lands and Survey) Mr. E. H. Wilmot, who has recently taken up the duties of Surveyor-General, sets forth the work of the year and shows the steady progress which has been made. Work on the second-order triangulation seems to have been mainly preparatory for future field work, and to include the computation of observations previously made. The magnetographs at the observatory were kept continuously in operation, and the discussion of the field observations of the magnetic survey is well advanced. The observatory also co-operated with the staff of Captain Scott's Antarctic Expedition in pendulum observations, determination of times, transmission of time signals, etc., rendering thereby much valuable assistance to the expedition. An appendix treats briefly of the measurement of the Kaingaroa base, about 11·5 miles in length, for the second-order triangulation. The probable error of the measurements is small, but a complete discussion of the base and its relation to others in the network cannot yet be given.

THE two sections of *Science Abstracts* issued April 26 do not show any marked decrease in the number of scientific papers with which the publication has to deal in the interval between two issues. The Physics Section extends to forty-eight and the Engineering Section to forty pages. We notice in the former abstracts from the autumn and winter numbers of the *Annalen der Physik*, but there is nothing in the Engineering Section to correspond.

THE *Scientific American* for April 17 describes the American form of the metal-spraying "pistol" invented by a Swiss engineer, Mr. Schoop. A thin metal wire is fed at a suitable speed through the tube of a Bunsen burner into the flame, in which it is melted. At this point it is subjected to a rapid blast of air which blows it out of the mouth of the Bunsen in a stream of extremely fine particles. The apparatus is held in the hand very much like a pistol, and the jet may be directed on to any object which it is desired to cover with a thin film of the projected metal. The spray does not appear to damage the object on which it is deposited, and brass has been deposited on silk without its texture being injured.

THE "Appeal to Non-Producing Mathematicians," recently published by Mr. Paaswell in the Bulletin of the American Mathematical Society, and noted in NATURE, January 14, 1915 (vol. xciv., p. 541), has received a reply from Prof. C. N. Haskins in the April number of the Bulletin (vol. xxi., No. 7, p. 343). It will be remembered that Mr. Paaswell directed attention to certain outstanding mathematical problems of engineering, and comment was made in these columns on his omission of reference to aeroplane investigations. It would seem, from Prof. Haskins's comments, that engineers do not find it possible to add to their qualifications the training necessary to cope with such problems, and he suggests the desirability of mathematicians adding the necessary engineering to their mathematics. Unfortunately, however, when mathematical honourmen turn to engineering, they cease to go further in mathematics, as they find it pays better to qualify as engineers. The average mathematician who is not essentially by nature and genius devoted to pure mathematics, finds that it is more to his advantage, and is a far less arduous task, to qualify in physics, chemistry, or engineering, where he may find an outlet for his energies outside the teaching profession. Problems of the class contemplated by Mr. Paaswell depend essentially on a knowledge not so much of engineering as of *applied mathematics,* such as rigid dynamics, hydrodynamics, thermodynamics and conduction of heat, and elasticity, up to the standard of the old part ii. tripos, which is a less attractive sequel to part i. than the engineering tripos. Consequently applied mathematicians proper are few and far between, and a certain class of problems possessing no inherent difficulties is running to waste. Moreover, the few specialists interested in such work can only undertake it in the intervals between professional duties, often occupied with the teaching of engineering students of a very elementary standard.

Messrs. Dickinson and Osborne, of the U.S. Bureau of Standards describe in the April issue of the Journal of the Franklin Institute what they term an "aneroid calorimeter." It is an instrument in which equalisation of temperature is secured by means of the thermal conductivity of copper instead of by the convection of a stirred liquid. The calorimeter described, which consists of a thick walled cylindrical vessel of copper in the walls of which are embedded a coil of resistance wire to supply heat electrically, and a platinum resistance coil for use as a thermometer, has been found useful over a wide range of temperatures, and is applicable to a variety of problems. For use at low temperatures the calorimeter is mounted in a jacket surrounded by a bath of gasoline, the temperature of which can be controlled thermostatically to within a few thousandths of a degree at any temperature between $-55°$ and $+40°$ C., or can be changed rapidly in order to keep it the same as that of the calorimeter when heat is being supplied to the latter. A series of check experiments on the specific heat of water shows the order of reproducibility of results which can be obtained to be 1 part in 2000.

A note on radiation pyrometers and their characteristics, by G. K. Buyers and P. D. Foote has been communicated to the April number of the Journal of the Franklin Institute. It heralds the publication of a very complete paper which is to appear from the Bureau of Standards. Some twenty instruments have been examined, including all the ordinary types commonly met with in practice, such as the four due to Féry, and the Foster, Thwing, and Brown pyrometers. It has been established that the Stefan-Boltzmann law, $E=a(T^4-T_0^4)$, is not in general, except by accident, obeyed exactly by any of the pyrometers examined. The similar equation, $E=aT^4.T^{b-4}$ in which b is slightly different from 4 (usually neglecting the T_0 term) is, however, obeyed with sufficient exactness by all total radiation pyrometers. The main factors which influence the value of the exponent b are the geometry and mechanical construction of the instrument; the value of b for twenty thermo-electric pyrometers ranged from about 3·5 to 4·5. The same instrument of the Féry type may have a different exponent according to its use with or without the sectored diagram for increasing the temperature range.

A high-capacity wagon for the South African railways is illustrated in *Engineering* for May 7, together with another wagon of special design and 160,000 lb. capacity, built for transport of whales. These wagons have been constructed by the Leeds Forge Co., Ltd., and are excellent examples of steel rolling-stock. The whale wagon is intended to carry whales over a special 3 ft. 6 in. line a few miles in length from the point where they are brought ashore to the factory, where they are dealt with for the extraction of oil, etc., not far from Durban. The bodies are hauled on to and off the wagon by windlasses. The line is very uneven, and it has been necessary to design the wagon with six-wheeled bogies, so as to keep the axle-loads down to the required limits and ensure the necessary flexibility.

Screw pumps having blades like those of a steamer's propeller, mounted on a horizontal shaft, are a feature of several large pumping installations in the United States, particularly for drainage and flushing work, where large volumes of water must be handled promptly and rapidly. The latest and largest installation of screw pumps is at New Orleans, and is described in the *Engineer* for May 7. This installation is used in removing the storm-water drainage of the city and its surrounding district, lying between the Mississippi River and Lake Pontchartrain. Eleven screw pumps, 12 ft. in diameter, are now being built to supplement the present pumping equipment, so that the total pumping capacity will be 7,240,000,000 U.S. gallons daily. The rapid removal of storm-water by pumping has a marked influence upon the sanitary condition, since it enables the ground to dry out more rapidly, and thus reduces the unhealthy conditions which result from damp and water-soaked ground in a large city. The total annual rainfall in the district ranges from 62 to 75 in., most of the heavy rainfalls being due to severe but brief storms.

OUR ASTRONOMICAL COLUMN.

Meteors from Halley's Comet.—Like the Perseids and Leonids, the meteors connected with Halley's famous comet probably constitute a complete ring. They were first discovered by Lieut.-Col. Tupman while cruising in the Mediterranean in 1870, when the parent comet was near aphelion, and Prof. Alexander Herschel pointed out the significant resemblance between the cometary and meteoric orbits.

This year, in the early mornings of the first week in May, Mrs. Fiammetta Wilson, of Bexley Heath, observed, notwithstanding rather unfavourable weather, several splendid specimens of the Halleyan meteors. Two of these were also recorded by M. Felix de Roy, hon. secretary of the Société Astronomique d' Antwerp, but now resident at Thornton

Heath. One of these, observed on May 6, at 2h. 52m. a.m., was as brilliant as the planet Jupiter, and travelled over an extensive arc from E. to W. (Kent to Wiltshire). Its height according to Mr. Denning's computations, was from sixty-nine to fifty-nine miles, its luminous flight extended over eighty miles at a velocity of about forty miles per second. The radiant point was at $339^\circ - 2^\circ$. Another fine meteor from the same system was seen by Mrs. Wilson on May 6 at 3h. 23m. a.m., and a smaller one, also observed by M. de Roy, appeared on May 3 at 3h. 2m. a.m., with a height from forty-eight to forty miles. Radiant $335^\circ - 2^\circ$. These new materials are interesting as affording further corroboration of the identity of the comet and meteors.

Comet 1915*a* (Mellish).—The following ephemeris is a continuation of that given last week:—

	R.A. (true) h. m. s.	Dec. (true) ° ′	Mag.
May 14	19 9 32	−22 42·1	
16	14 29	25 19·2	5·9
18	20 2	28 15·4	
20	19 26 22	−31 32·7	5·6

The comet is rapidly moving southwards, and on May 18 will be found a little to the eastward of τ Sagittarii.

The Australian Solar Observatory.—The March number of the *Scientific Australian* contains a short communication by Mr. P. H. Baracchi on the demand for an Australian Solar Observatory. Mr. Baracchi enumerates the several steps that have been taken to secure such an observatory for Australia, and directs attention to the selected site known as Mount Strombo, the highest summit of a group of hills situated about 6·5 miles west of the centre of the Federal capital and about 2500 ft. above sea-level. For the purpose of testing the "seeing" at the site for the period of a year, Mr. Baracchi and his assistant, Dr. Baldwin, erected in 1911 a 9-in. refracting telescope on the site and built a 19-ft. dome to house it. The result of the observations showed that the local conditions fulfilled the most essential requirements for any class of delicate astronomical work. As yet nothing is very definitely known concerning the future of the observatory, but Mr. Baracchi states that "the Commonwealth authorities seem well disposed to expand the Mount Strombo Observatory, and make it a permanent astronomical institution, including a solar department, but no further steps have, as yet, been taken."

Photographing the Corona.—Writing in the May number of the *Observatory*, Mr. E. B. Knobel directs attention to the subject of whether the best means are employed in photographing the solar corona, and whether our knowledge of the structure of the corona has advanced since the introduction of the photographic dry plate. He is of the opinion that "no results have been secured comparable in value to the photographs of the corona in 1871, which were obtained with wet collodion plates. . . ." and that the time has arrived when the whole question should be investigated and the results of this investigation made use of on the next occasion of a total solar eclipse. In his communication he considers the merits of the three processes—daguerreotype, wet collodion, and dry plates. He refers to the difficulty in the daguerreotype process requiring much practice and experience, and to the principal drawback to its employment for the corona in that the image is only visible by reflected light, and that long exposures are necessary. He points out, however, the perfection of the resulting image. Mr. Knobel advocates strongly a serious attempt to revive the wet collodion process. He says: "There are no difficulties that cannot be surmounted. . . . All the procedure . . . requires practice and experience, and the assistant should have some familiarity with chemical operations. It ought not to be difficult to find a suitable man to train up for eclipse work among process-workers in collodion, as he would already be practised in some of the operations." It is hoped, as Mr. Knobel suggests, that some of the funds provided by the Joint Permanent Eclipse Committee may be utilised to defray the expense of the necessary training in what is almost a lost art, so that the process may be brought into use again for eclipse work.

Circulars of the Union Observatory, Johannesburg.—A batch of circulars of the Union Observatory, Johannesburg, has just come to hand dealing with a great number of varied observations. Circular No. 19 deals with the proper-motion stars south of declination -19°, and contains three tables of great interest. The first is a list of all stars for which the proper motion is known to exceed a fifth of a second of arc in either right ascension or declination. It includes also many double stars the proper motions of which exceed 0·1″, and a few stars of small proper motion. Table II. consists of those stars for which radial velocities have been published. The third table indicates groups of stars showing community of motion. The six groups given are the sun group, or group nearly stationary with regard to the sun, the 61 Cygnus, Taurus, π Mensa, α Centaurus, and δ Lepus groups. Circular No. 20, among other communications, gives an account of the discovery of variable stars, etc., with Pulfrich's blinkmicroscop, with remarks upon its use in astronomy. Circular No. 21 is devoted to observations made of the transit of Mercury in November last, a 9-in., two 6-in., and a 4-in. telescope being employed. In Circular No. 22 an orbit and observations of comet 1914*e* are given. This comet, as mentioned in this column last week, was discovered independently by several widely distributed observers. Observations of the Galilean satellites of the planet Jupiter made during the period April 8 to December 31, 1914, form the subject of Circular No. 23. These observations are in continuation of the series commenced in 1908. The present series has been compared with the times given in the American ephemeris, which are founded very closely on Damoiseau's tables, but the 1915 comparisons will be made with the Nautical Almanac, as Samson's tables have now been adopted.

SHELLFISH AND SEWAGE.

It is perhaps only by chance that the conclusion of the work of the Royal Commission on Sewage Disposal should almost coincide with the Shellfish Regulations issued by the Local Government Board. Nothing like the task performed by the Sewage Commission had ever been attempted by a similar body. It met throughout three reigns, during which time its *personnel* underwent notable changes. It interpreted liberally its "terms of reference," and conducted an inquiry which was most comprehensive in scope. It employed a scientific staff who carried out investigations of quite the best kind, and made reports which, for a long time to come, must be regarded as authoritative. It suggested legislation based on great knowledge of the conditions that were to be improved.

After all this it was with a kind of shock of surprise that those interested in the development of the inshore fisheries read the Shellfish Regulations of the Local Government Board, which were published on February 16, and came into force on March 1. For the last eight years the fisheries authorities have entreated the Board to legislate, and more than once Mr. John Burns assured them that a Bill would be drafted and laid before Parliament; it was believed that this would be necessary. The British Science Guild lent its authority in aid of the agitation. The fishing trade and the public health bodies were equally desirous that something might be done to remove the dangers that were inherent in the unrestricted exploitation of sewage-polluted shellfish beds and layings. It was felt that some comprehensive scheme of regulations, based on the well-thought-out recommendations of the Sewage Commission (and on the reports of the Board's own inspector, Dr. H. T. Bulstrode), was being prepared and awaited a favourable opportunity for consideration by Parliament.

In February last it was seen that the Board possessed power to legislate by Order in Council. Emergency legislation was in the air; and there were probably reasons traceable to the abnormal state of affairs in the country at present which stimulated the Board to action. Anyhow, the Regulations proceeded to establish a means of dealing with sewage-polluted shellfish on quite other lines than those suggested by the Sewage Commission or the fishery authorities. They set up a machinery for closing suspected layings which must invite criticism inasmuch as it can be put in motion without utilising scientific or technical skill. Briefly stated, the Regulations confer power on the local sanitary authorities to prohibit the exploitation of suspected shellfish beds or layings. If the medical officer of health of any local authority *attributes* disease of any kind in his district to the consumption of shellfish he may require the vendor of the food to state what was its place of origin. The disease need not be enteric fever, and it need not be traceable by any process of scientific investigation to the suspected shellfish. If the medical officer *suspects* (for that is what it comes to) that the consumption of shellfish from a certain place is the cause of disease he may ask the local sanitary authority in whose district this place is situated to take action. If the latter authority do not take action they can be compelled to do so by the Board.

Even then no investigation need necessarily be made. The local authority need only invite the fishermen and others interested in the industry to show cause that the shellfish which they place on the public markets are not the means of communicating disease. If they do not produce evidence of this nature the local authority may prohibit fishing on the suspected beds. It is true that the local authorities are invited to make investigations, and that it is suggested that they should base their conclusions on topographical and epidemiological evidence rather than on the results of bacteriological analyses. But many of the shellfish beds which are likely to come under suspicion may be situated in districts where the medical officer of health is a busy man with a private practice, and where the only other official to whom the investigation may be committed is perhaps an imperfectly trained sanitary inspector. No special technical training may be necessary for the consideration of "topographical and epidemiological" evidence, as it is for the conduct of a bacteriological investigation, but it is certain that evidence of the former nature is more easily misinterpreted, and is no less a matter for the expert.

It is not at all certain that this machinery will prove to be effective, for we may strongly suspect that the local authorities of the shellfish-producing districts will resent suspicion being cast on their local industries, and there is nothing to prevent them accepting the unanimous opinion of their local fishermen that the shellfish they market are to be regarded as blameless. This, however, is not our main point. Expert assistance for the investigation of the layings by the local sanitary authorities is easily procurable. There are the inspectors of the Local Government Board itself, as well as those of the Board of Agriculture and Fisheries, and some of the local fishery authorities have officers well qualified to make the necessary investigations. At all events, the sanitary authorities might well have been advised to follow the example of higher judicial bodies and obtain the assistance of assessors to help them in weighing the value of the opinions of the local fishermen. But one need scarcely say more about this; it is surely evident that the question as to whether an area of shellfish-producing foreshore is to be condemned, and a local industry destroyed, is a matter for the application of scientific investigation by men possessing special knowledge.

Then the suggestion conveyed in the covering letter of the Board, accompanying the issue of the Regulations, that stress is to be laid on the value of topographical and epidemiological, rather than bacteriological evidence, may also be criticised. There is no doubt that the Board were influenced by the opinion of the Sewage Commissioners, which rather deprecated the application of bacteriological analyses, *as a matter of routine practice*. In Dr. Bulstrode's last report no use was made of bacteriological methods; also there is, no doubt, much confusion as to "standards of impurity"; and there is no "norm" generally adopted in public health laboratories as to the precise methods of analyses. But much research upon the distribution in nature of intestinal bacteria is in progress, and we may be very sure that the extension of such investigation would soon enable us to utilise bacteriological methods with complete success—at least as an adjunct to whatever other investigations were employed. It is, in fact, unfortunate that the Regulations should have set up a machinery which can be made to work without the employment of scientific assistance, and with respect to a question upon which much research has already been made and much more suggested by the Royal Commission on Sewage Disposal. J. J.

LENGTH STANDARDS AND MEASUREMENTS.

IN his recent presidential address to the Philosophical Society of Washington,[1] Mr. L. A. Fischer, of the Bureau of Standards, gave an interesting historical account of standards of linear measure. He explained the intimate relation which existed between the American and the British official standard of length up to the year 1893. At present the yard is defined in the United States in terms of the metre, but the numerical ratio adopted agrees very closely with that legalised in this country. In fact, the American yard only differs from the British standard by about 0·0001 in. Until 1856 the United States official standard of the yard was for more than forty years a length of 36 in. on an 82-in. brass bar made by Troughton, which had been brought from London by Ferdinand Hassler, the first superintendent of the Coast and Geodetic Survey. Between 1856 and 1893 a bronze yard presented to the United States by the British Government in 1855 was recognised by the Office of Weights and Measures at Washington as the national standard.

The most important part of Mr. Fischer's address is that dealing with the measurement of base lines. During the last thirty years very radical changes have taken place in geodetical operations. End standards,

[1] Journal of the Washington Academy of Sciences, March 4, 1915, vol. v No. 5, pp. 145–159

"compensated for temperature," were in use when Mr. Fischer was first engaged on the Coast and Geodetic Survey. These gave place to 5-metre contact rods, consisting of a single bar of steel enclosed in a closely fitting wooden case, and covered with padded canvas. For use in the field they were mounted on tripods and placed end to end. In the hands of skilled observers it was possible with this type of bar to attain a degree of accuracy approaching 1 part in 2,000,000. In the elaborate apparatus devised by Dr. R. S. Woodward a line bar was supported when in use on a steel trough and covered with crushed ice, the trough being carried by two trucks travelling on a portable track. Micrometer-microscopes were mounted on supports fixed in the ground at carefully measured intervals approximately equal to the length of the bar. The operation of measuring was effected by bringing the bar under the first two microscopes and then setting the cross-wires of the micrometers on the lines of the bar; then without disturbing the reading of the forward micrometer the bar was displaced longitudinally until the line at its rear end was brought under the forward microscope, while at the same time an observer at the forward end set the micrometer on the line at that end, this process being repeated throughout the length of the base line. A kilometre base measured in this manner was estimated to have an accuracy of 1 part in 3,000,000.

Eimbeck's duplex base bars were next employed on the survey. These consisted of two concentric brass tubes in the inner of which a brass and a steel measuring bar were mounted. The inner tube could be rotated through 180° so as to equalise the temperature of the brass and steel components if one side of the apparatus should be more exposed to direct radiation. This method was in its turn superseded by the introduction of invar tapes. All primary bases of the United States Survey are now measured with invar tapes, tested preliminarily at the Bureau of Standards, and by this means base operations, while maintaining the high degree of precision which the work demands, admit of vastly greater rapidity in the field, with a consequent reduction in the expense involved.

PLIOCENE MAN.

THE discussion originated by the Rev. Osmund Fisher in NATURE of September 4, 1913 (vol. xcii., p. 6), has led to the systematic exploration, by a committee of the Dorset Field Club, of the Dewlish "elephant-trench," and the report on the excavations was read at the anniversary meeting on May 4.

This curious trench in the chalk yields bones of the Pliocene *Elephas meridionalis*, and Mr. Fisher suggested that it was artificial and dug for trapping the elephants. There can no longer be any doubt that the trench was of natural origin. The elaborate plans, elevations, and photographs exhibited by Mr. Charles Prideaux, who superintended the excavations, show clearly that a few feet below the surface the supposed trench divides into a chain of pipes or pot-holes in the chalk connected by a narrow joint. These become very narrow below; but one of them was traced to a depth of 36 ft. One or two of the smaller pipes still show traces of the lining of black clay commonly found in pipes caused by solution in the chalk; the larger ones were filled with chalky sand full of flints, and Tertiary material; many of the flints were beautifully polished. Flakes caused by sudden changes of temperature were also abundant.

Mr. Clement Reid discussed the geological evidence. He thought that it proved the existence of a fissure or joint transverse to the valley of the Devil's Brook. Along this joint a chain of pipes was formed by the action of percolating rain-water. Then the pipes nearest to the valley-bottom acted as "swallow-holes," into which the brook sank, the constant swirl of the water laden with calcareous sand giving the flints the wonderful polish now seen. In short, the Devil's Brook, then flowing at a level 90 ft. higher, was a "winter bourne," which at Dewlish, for part of the year, at any rate, was swallowed up and disappeared into these pot-holes. Such pot-holes are common in the Carboniferous Limestone, though rare in the Chalk. This chain of pot-holes acted as a natural pitfall, into which the elephants fell, or into which their bones were washed; thus far Osmund Fisher was right in calling it an "elephant-trap," though it probably had a natural origin. Mr. Reid saw no sign of human agency in the trench. The date of the deposit must still remain somewhat uncertain, for all the determinable bones belong to *E. meridionalis*, and this species, though mainly Pliocene, may have lived on into early Pleistocene times.

Mr. Reid Moir, in another report, described a number of the flints as showing undoubted human workmanship of eolithic type. Mr. Reginald Smith, however, after an examination of the same specimens, thinks that one or two of them may possibly be worked, the others he rejects.

A report by Mr. Dewey pointed out that a sample of calcareous sand from the trench proved under the microscope to consist mainly of minute rhombs of calcite, such as would be precipitated from a saturated solution. This he thought pointed to an arid climate.

SYSTEMATIC ZOOLOGY OF THE INVERTEBRATA.

AMONG recent systematic papers on the invertebrates, a noteworthy account of the parasitic worms collected on the British Antarctic (*Terra Nova*) Expedition, written by Dr. R. T. Leiper and Dr. E. L. Atkinson, has been published by the British Museum ("*Terra Nova* Zoology," vol. ii., No. 3). From the summary of results we learn that the Ross Expedition of 1841–4 brought back two species of Entozoa; the Scott (*Discovery*) Expedition of 1901–4 four species; the Bruce (*Scotia*) Expedition seventeen species; the French (*Pourquoi Pas?*) Expedition eighteen species; the *Terra Nova* twenty-eight species. These figures show how greatly zoological knowledge has been increased through our latest national Antarctic enterprise. Three of the worms now recorded from the far south had previously been known only from the Arctic regions. Two of these—a Filaria and an Echinorrhynchus—have whales as their hosts in both localities, but the third—a monostomid trematode, *Ogmogaster plicatum*, Creplin—is parasitic in rorquals in the north, and in the Crab-eating and Weddell's Seals in the south; a remarkable divergence in habit.

From home waters there is still much material to be gathered, and C. M. Selbie's important paper on the Decapoda Reptantia of the coasts of Ireland, part 1 (Fisheries, Ireland, Sci. Invest., 1914, i.), adds to the fauna of the Britannic marine area the family Eryonidæ, as represented by four species of Polycheles and four of Eryonicus. These were all taken in deep water off the west coast of Ireland, though the specimens of Eryonicus "lead a free-swimming life at a considerable distance from the bottom." The paper is illustrated by fifteen excellently drawn plates.

A very important paper on those interesting copepod fish-parasites, the Lernæopodidæ, has been published by C. B. Wilson in the *Proc. U.S. Nat. Museum* (vol. xlvii., pp. 565–729). Though dealing especially with species from North American waters, the author gives a revision of the whole family, thus affording a trustworthy work of reference for students of the group all over the world. The systematic part of the paper is preceded by a useful introduction to the anatomy and metamorphosis of the parasites, and is illustrated in thirty-two clear plates of diagnostic drawings.

The zoological results of the Abor Expedition (N.E. India) continue to appear in the Records of the Indian Museum. The lately issued part 6 of vol. viii. contains papers on land planarians by Prof. R. H. Whitehouse, terrestrial Isopoda by W. E. Collinge, and Onychophora by Stanley Kemp. The last-named deserve more than passing notice, for the discovery of a Peripatid "at the foot of the eastern Himalaya" is one of the most important faunistic results of recent years; no member of the class had hitherto been found at all as far north as this. The specimens were found under stones in a comparatively small area at an elevation of 1320 ft. From a consideration of the structure of the species, Mr. Kemp considers it allied to the Malayan Eoperipatus, but on account of the total absence of eyes (although the optic ganglia are present), and other distinctive characters, establishes a new genus (Typhloperipatus) for its reception. The unpaired oviduct in the female and the ejaculatory duct (also unpaired) in the male are remarkably long. The eggs are richly yolked, and embryos at various stages were found in the uterus. From the appearance of the embryos and young it is concluded that reproduction takes place only during the wet season.

G. H. C.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Messrs. F. T. Brooks, Emmanuel College, and K. H. Compton, Gonville and Caius College, have been appointed demonstrators of botany, and Mr. T. S. P. Strangeways, St. John's College, has been reappointed demonstrator of physiology. The council recommends to the Senate that the Vice-Chancellor be authorised to countersign and seal certificates of attendance to Belgian students attending the courses of instruction organised by Belgian professors now lecturing in Cambridge.

The Financial Board has presented a report to the Senate in which the financial position and prospects of the University are reviewed. The income of the University chest for 1913 and 1914 was 53,400*l.* and 46,800*l.* respectively, and is estimated at 26,600*l.* for 1915; the corresponding figures representing the receipts of the common University fund are 22,510*l.*, 23,800*l.*, and 15,780*l.* Details are given in the report of the manner in which the board proposes to meet the large deficiency disclosed in the estimates by the temporary suspension of vacant teaching and research posts, of salaries to officials now in the national service, and of contributions to pension and building sinking fund accounts. One of the most substantial items of expenditure under the control of the Financial Board is that of grants to the departmental funds of the scientific departments of the University; these amounted to 5580*l.* in 1914. The accounts of these departments, although controlled by the Board, are not incorporated in those of the University chest or the common University fund, but the board estimates that in 1915 the receipts from fees of the scientific departments of the University will fall some 16,000*l.* to 18,000*l.* below those of 1914. It is evidently not desired that the University contribution towards the upkeep of the science laboratories in the University should be diminished; it is obvious, however, that even in normal times the chest and the common fund could do little to support natural science in Cambridge if the annual revenue of the science laboratories were suddenly diminished by 16,000*l.* to 18,000*l.* The *Cambridge Review* records the number of undergraduates in residence this term as 1097, as against 3181 during the Easter term of 1914.

LONDON.—Lord Rosebery presided at the presentation of graduates on May 5. The annual report of the principal (Sir Henry Miers), his seventh and last report in view of his appointment as Vice-Chancellor of Manchester University, referred to the special work resulting from the war, particularly the training of 1300 officers and educational provision for two hundred refugee students. In his retrospect of his period of office, the principal referred to the report of the Royal Commission, the incorporation of King's College and King's College for Women in the University, the Universities' Congress, the transfer of Bedford College to Regent's Park, the new buildings at the Imperial College and University College, the development of the professoriate, the increase of internal students from 3580 to 4950, and in the number of external candidates, and many benefactions for teaching and research. He looked forward to the time when the University would have a dignified home bearing its own name, and would be adequately endowed; and expressed his complete faith in its power to fulfil all its duties, both local and imperial. Lord Rosebery, in an eloquent address, hoped that as one result of the war, a new spirit of co-operation would enable the University to work out its own salvation. He had never believed that there was anything incompatible between the local and imperial aspects of the work of the University.

The London County Council is prepared to award for the session 1915–16 a limited number of free places at the Imperial College of Science and Technology, South Kensington, S.W. The free places will be awarded on consideration of the past records of the candidates, the recommendations of their teachers, the course of study which they intend to follow, and generally upon their fitness for advanced study in science as applied to industry. Candidates will not be required to undergo a written examination. It is possible that the free places may be extended to two or more years. Particulars may be obtained from the education officer, L.C.C. Education Offices, Victoria Embankment, W.C., and application forms must be returned not later than Saturday, May 22.

SHEFFIELD.—Dr. J. Sholto C. Douglas, lecturer on pathology in the University of Manchester, has been appointed to the Joseph Hunter chair of pathology, in succession to Prof. Dean.

FOUR lectures on the progress of public health in Egypt will be delivered at Gresham College, E.C., on May 18–21, by Prof. F. M. Sandwith, Gresham professor of physic. The lectures are free to the public, and will begin each evening at six o'clock

WE learn from *Science* that grants for two new buildings to meet the needs of the University of Ohio and for additional tracts of farm land west of the Olentangy have been voted through the finance committee of the lower branch of the State legislature. These extensions would involve an expenditure of 68,000*l.* A domestic science building to cost 30,000*l.* and a shop building for manual training to cost 24,000*l.* are provided. Ninety acres of land would be purchased west of the Olentangy River at a probable cost of 14,000*l.*

A SUMMER School of Mining and Engineering for the South Wales coalfield is to be held in August next at the Technical College, Swansea. The courses of instruction will be seven in number, comprising a surveyor's course (to meet the requirements of the

Coal Mines Act, 1911), one in engineering, one in metallurgy, one for architects and builders, one for teachers (dealing with geology, physics, and chemistry), one on the electrification of collieries, and one on gas detection and analysis and by-product recovery. Further particulars can be obtained from the chief education official, County Hall, Cardiff.

THE number of foreign students in German universities, according to the *Nieuwe Courant*, was 1438 during the last winter semester, as against 4715 in the previous summer. The decline is primarily due to the removal of about 2600 students belonging to hostile countries. The students from Austria-Hungary numbered 547, as against 814 last summer; the corresponding decline was:—For Switzerland from 312 to 146; for Rumania 146 to 111; for Bulgaria 131 to 105; for Holland there was an increase from 37 to 44. During the war foreign students have shown a strong preference for Berlin; the chief decline in their numbers being at Königsberg, Göttingen, Marburg, Munich, Strassburg, Freiburg, and Heidelberg.

SEVERAL gifts in aid of higher education are announced in the issue of *Science* for April 23. Harvard University receives 20,000*l*. by the will of the late Mr. James J. Myers, of Cambridge, Mass., and further bequests amounting to 14,600*l*., to be devoted to cancer research at the Harvard Medical School, are announced. By the will of Mrs. L. L. Ogden Whaling, of Cincinnati, Miami University receives 54,000*l*. The residue of the estate is to be divided between Miami University and the Cincinnati Museum Association, and it is said that each institution may receive 40,000*l*. The Addison Brown collection of plants offered to Amherst College by Mrs. Brown in memory of her husband has now come into possession of the college. Containing many thousands of specimens collected in the United States, Mexico, Porto Rico, the Hawaiian Islands, and elsewhere, it is the largest accession ever received by the department.

THE Imperial Department of Agriculture for the West Indies has issued revised courses of reading and examinations in practical agriculture. Reading courses have for some years been established under the direction of the department for the purpose of enabling overseers on estates, and others engaged in agriculture, to acquire by reading knowledge they can apply in their everyday work. Examinations are held periodically at various centres in the West Indies for persons who have previous been registered as students in reading courses. Registration in reading courses entitles students to certain publications of the department which are recommended for reading. The certificates awarded by the department at the examinations are intended to be a guarantee of a sound general knowledge of the fundamental principles underlying the practice of agriculture, and also a practical knowledge of at least two crops and their products, such as sugar, cacao, cotton, limes, rice, coco-nuts, and bananas.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 6.—Sir Alfred Kempe, vice-president and treasurer, in the chair.—G. W. **Walker**: Some problems illustrating the forms of nebulæ. The paper is concerned with the form of the surfaces of equal density when a quantity of gaseous material at uniform temperature, and following Boyle's law as regards pressure and density, is at rest under its own gravitation. The differential equation for these surfaces is not linear. In the two-dimensional case Pockels obtained the solution in terms of two arbitrary functions of complex variables. In the paper the solution is put in a form which must give real positive density anywhere. Three cases only are considered which illustrate respectively a ring nebula, a pear-shaped nebula, and a nebula with two equal nuclei. Some consequences of motion of the material are considered.—Hon. R. J. **Strutt**: Observations on the resonance radiation of sodium vapour. (1) The centres emitting resonance radiation of sodium vapour excited by the D lines are not persistent enough to be carried along when the vapour is distilled away from the place of excitation. This result is extraordinary, because it contrasts absolutely with the behaviour of sodium vapour excited electrically. It also contrasts absolutely with the behaviour of mercury vapour, whether excited optically (2536 resonance radiation) or electrically. (2) The resonance radiation of sodium cannot be seen through even a very dilute layer of sodium vapour placed in front of it—a layer quite transparent to white light. This explains why the spot of superficial resonance produced on the wall of a glass bulb can only be seen from in front, when the light passes to the eye without traversing sodium vapour. From the back it cannot be seen, as Dunoyer has observed. (3) The resonance radiation of sodium vapour is changed in intensity when the vapour is placed in a magnetic field. If the exciting flame is weakly salted, the radiation diminishes with increasing field strength. If the exciting flame is strongly salted, the radiation increases to a maximum and then diminishes again. (4) A change in intensity of resonance radiation can also be observed when the exciting flame is placed in the magnetic field. In this case a weak flame gives diminished radiation in the field, while a strong flame gives increased radiation in the field. (5) All the facts summarised under (3) and (4) can be explained qualitatively and quantitatively, so far as the available data will go, by taking into account the known Zeeman resolution of the D lines, and the observed width and structure of these lines as emitted by the flames used. The latter data were obtained by observation with a concave grating of high resolution.—Hertha **Ayrton**: Local differences of pressure near an obstacle in oscillating water. When the water is approaching the mean level there is a diminution of pressure, or partial vacuum, created in the lee of the obstacle. When the water is departing from the mean level the diminution of pressure continues high up on the lee side, but over the lower part there is a pressure in the opposite direction to that of the main stream. The jet in the first part of a swing is due to the local current created by the local difference of pressure; the vortex in the second part of the swing is due to the conjunction of the main stream with the opposing local current set up by the local pressure difference.

Geological Society, April 14.—Dr. A. Smith Woodward, president, in the chair.—S. H. **Warren**: Further observations upon the Late Glacial, or Ponder's End, stage of the Lea Valley. With notes on the Mollusca by A. S. **Kennard** and B. B. **Woodward**. The paper is supplementary to one previously published, and describes additional sections which increase the range of the deposits. They have now been traced for a distance of $6\frac{1}{2}$ miles along the valley and $2\frac{1}{4}$ miles across it. The section at Hedge Lane, Lower Edmonton, shows several thick, and for the most part undisturbed, Arctic plant-beds, which occur in a deep Drift-filled channel. The relative levels and stratigraphy point to the conclusion that the Hedge Lane deposits belong to a slightly earlier stage of the Low-Terrace River-drift than the deposits of Ponder's End. Broadly speaking, they undoubtedly belong to the same group. It is suggested that it would be a convenience if the

East Anglian word "platymore" were adopted for the underlying eroded floor of country-rock beneath a later accumulation of drift. The importance of this "platymore" surface in the correlation of Drift deposits has been increasingly recognised during recent years. The view that the lower river-terraces are later than the higher river-terraces is supported. Further evidence is also brought forward in support of the view that the Arctic deposits form an integral part of the Low-Terrace Drift. One section appears to suggest that the climate became nearly as temperate as that of the present day before the mammoth and woolly rhinoceros became extinct.

April 28.—Dr. A. Smith Woodward, president, in the chair.—Prof. G. A. J. **Cole**: A composite gneiss near Barna in the County of Galway. The great mass of granite west of Galway town is seen on its northern margin to be intrusive in a metamorphosed series of Dalradian quartzites, limestones, and mica-schists, and has received a foliation which is parallel with the bedding of this series; this foliation is ascribed by the author to the partial absorption of sheets of the bedded series into its mass. Traces of similar intermingling occur in Townparks (Galway town) and west of Barna. At Furbogh Bridge, the granite contains pink crystals of orthoclase, at times 10 cm. long in the direction of the vertical axis, and these have become stranded, as it were, among the foliation-planes of dark green biotite-schist, into which they were carried by an intimate intermingling of the granite with the schist into which it flowed. Quartz and smaller felspar-crystals from the granite abound in the resulting composite gneiss, and the general effect is comparable with that of igneous intermixtures described from County Down and Skye. In the Galway instance, however, there is no sign of general fusion of the invaded rock, which retains its original foliation and controls the structure of the composite mass.—Prof. S. H. **Reynolds**: Further work on the igneous rocks associated with the Carboniferous Limestone of the Bristol district. The paper gives an account of the additional information, concerning the Carboniferous volcanic rocks of north Somerset, which has become available, largely through digging trial-holes, since the publication in the Q.J.G.S. for 1904 (vol. lx.) of a paper by Prof. Lloyd Morgan and the author on the subject. The rocks occur at five localities:—(1) Goblin Combe; (2) Uphill; (3) Limeridge Wood, Tickenham; (4) Spring Cove and Milton Hill, Weston-super-Mare; and (5) Woodspring or Middle Hope. At Goblin Combe, as the result of digging nearly forty trial-holes, it was ascertained that the igneous rocks form two discontinuous, somewhat crescentic masses, each consisting of olivine-basalt overlain by a considerable thickness of calcareous tuff. At Uphill, the evidence obtained was insufficient to determine whether the basalt is a sill or a lava-flow. At Limeridge Wood, Tickenham, where only débris of basalt had previously been recorded, the presence of an oval mass measuring about 60 by 25 yards was proved by digging trial-holes, and the fact that it is completely surrounded by limestone indicates its intrusive character. Several additional exposures are described on Milton Hill, where the lava forms a band about 150 ft. thick. The lava at Middle Hope or Woodspring is shown to form an irregular and discontinuous mass.

Royal Meteorological Society, April 21.—Capt. H. G. Lyons, president, in the chair.—H. Helm **Clayton**: A study of the moving waves of weather in South America. It is the custom in most meteorological services for the forecaster to make a mental estimate of the changes to be anticipated during the succeeding twenty-four or forty-eight hours. In order to improve on this method and to raise forecasting from an art to a science, the author believes it is essential to replace estimates by quantitative measurements of expected changes and to make quantitative forecasts. He gave an interesting example of such a method as applied to one of the Argentine weather maps. —E. H. **Chapman**: Correlation between changes in barometric height at stations in the British Isles. This was an attempt to discover the relationships existing between the changes in the barometric height at one place and another during the same and also different intervals of time. The conclusion arrived at is that the best information for foretelling barometric changes at any station is from a station south-west of it, the statistical measure of the accuracy with which such a change can be foretold being expressed in a correlation coefficient.

Manchester.

Literary and Philosophical Society, April 13.—Mr. F. Nicholson, president, in the chair.—H. **Day**: Some points bearing on the relationship of the fishes and the amphibia. The author deals with three specimens of the so-called parasphenoid bone in *Rhadinichthys monensis* from the Manchester Museum collection. The three specimens together give an excellent idea of both dorsal and ventral surfaces of the bone, so that an accurate description can be given, thus providing material for a determination of the relations and homology of this bone in the Crossopterygian fishes and in the primitive Reptilia and Amphibia. It was shown that in all these groups the bone is really compound, consisting of parasphenoid and basisphenoid combined, and also that the bone is remarkably constant in its form and relations. The remarkable constancy in form was contrasted with the entirely different form of parasphenoid which prevails in fossil and living Dipnoi, and was brought forward as a strong argument in favour of a development of the Tetrapoda from a Crossopterygian Ganoid stock rather than from the Dipnoi. Further, it was pointed out that in all cases this bone takes part in the suspension of the upper jaw, a process of the metapterygoid region of the palato-quadrate uniting with the basipterygoid process of the basisphenoid region of this compound para-basi-sphenoid bone. This "pedicular" connection thus constitutes a form of autostyly common to the Crossopterygii and the primitive Amphibia and Reptilia, but totally different from the autostyly found in Dipnoi, which latter type is never found in the Tetrapoda. Hence the common pedicular autostyly forms another argument in favour of a Crossopterygian derivation of the Tetrapoda as opposed to the Dipnoian derivation.

Paris.

Academy of Sciences, May 3.—M. Ed. Perrier in the chair.—Gaston **Darboux**: The representation on a plane of the surface of the fourth order with double conic.—G. **Bigourdan**: The comparison of the scintillation and the instrumental undulations of celestial images under various influences. Supplementing an earlier communication the effects of magnetic disturbances, aurora borealis, barometric depressions, neighbourhood of clouds, azimuth, and twilight are discussed, the observations of various observers on these points being quoted.—M. de **Sparre**: The trajectory of projectiles thrown from aeroplanes or balloons.—Pierre **Delbet**: A prothetic apparatus with co-ordinated movements for use after amputation of the thigh. The apparatus described facilitates walking and conceals the deformity.—J. Kampé de **Fériet**: A generalisation of the series of Lagrange and of Laplace.—Pierre **Humbert**: A figure of equilibrium of fluids in rotation.—E. **Vaillant**: The laws of flow in drops through capillary orifices.—Léon **Bloch**: Optical resonance in the magnetic field.—A. **Leduc**: The determination of the ratio γ by means of the velocity of sound. A discussion of the values of the ratio of the two specific heats of gases and vapours obtained from experimental determinations of the velocity of sound. The author concludes that the values of γ thus obtained are generally inexact.—N. **Arabu**: Studies on the tertiary formations of the basin of the Sea of Marmora.—Henry **Hubert**: The distribution of rain in western Africa.—Henri **Coupin**: The morphogenic action of increased salinity on the marine bacteria. Increasing the salt percentage in the culture media of marine bacilli increases the length of the organisms and in some instances transforms them into true Spirillæ.—Robert **Sorel**: Wounds received in battle and the sun cure. A list of cases cured in the Alexandra Hospital at Monte-Carlo by sun treatment.—Maxime **Ménard**: The radioscopic localisation of foreign bodies by the method of Hirtz.

CALCUTTA.

Asiatic Society of Bengal, April 7.—P. **Brown**: A preliminary note on the prehistoric cave paintings at Raigarh. These were originally discovered on the rock-surface of a shallow cave in the State of Raigarh, Central Provinces, by Mr. C. W. Anderson, of the B.N. Railway, in 1910. This note is the result of a visit to the caves in March, 1915, by the author and Mr. C. W. Anderson. Certain geological evidences were obtained on the occasion, such as agate implements, etc., which have been submitted to the Geological Survey for investigation. The cave containing the paintings is apparently only the ruin of a much larger excavation. At some remote age the entire front must have fallen in, thus hermetically sealing up the cave and preserving the drawings. At a much more recent date the débris which had thus closed up the opening broke away and slipped another stage down the cliff, exposing the remains of the paintings to view. The paintings are mainly hunting scenes, and in some instances bear a remarkable resemblance to the cave paintings at Cojul in Spain, which are said to be 50,000 years old. In the technique there is also a striking similarity to some of the "cross lined" pottery of prehistoric Egypt. The paintings are evidently of very great antiquity, probably older by thousands of years than any other paintings yet discovered in India.—J. **Evershed**: Sun-spots and prominences.—W. **Burns** and S. H. **Prayag**: Grafting the mango-inflorescence. Starting from the observation that the inflorescence of *Mangifera indica*, L., often becomes partly or wholly vegetative, a phenomenon already studied by Burkill and Bose, the authors give an account of experiments on the artificial production of mixed inflorescences by grafting an inflorescence either on a vegetative branch or on another inflorescence, the grafted inflorescence either dying after the ripening of the fruit which it bears or sometimes persisting and producing vegetative axillary branches.—M. O. Parthasarathy **Iyengar**: Observations on the defoliation of some Madras trees. The author takes as his starting point the observation that, in Madras, trees do not remain in a leafless condition during the period of drought, but produce fresh leaves during the latter period, and he concludes that, in the case of Madras trees, the leaf-fall is not due to the failure of water-supply, but possibly due to the necessity of a replacement of the old by fresh, physiologically more efficient leaves, the greater efficiency of the latter being due to their cuticle being less permeable to water, to their stomatal mechanism being more perfect, to their being less charged with excretionary matter and less clogged by dust, and to greater vitality. The fall of the older leaves may also be caused by successful competition of the growing young leaves for supply of materials. The author also directs attention to the fact that prolonged wet weather may cause trees to shed their leaves. He deals in greater detail with a group of trees—called by him the Odina group—which remain in a leafless condition for a considerable length of time, and which flower while in the leafless condition. Defoliation due to salt-laden sea-breezes is referred to, and a number of special cases are considered in greater detail.—P. F. **Fyson**: Note on the flora of the South Indian Highlands. The region considered comprises those parts of the Nilgiri and Palney Hills which rise above the 6500-ft. level. Forty-five per cent. of the 430 indigenous phanerogamic species are endemic in South India and Ceylon, 17 per cent. are shared with the Khasia Hills, 12 per cent. occur also in the temperate Himalayas, and 9 per cent. are Chinese and Japanese.—W. F. **Smeeth**: The geological history of southern India. A general account of the geology of Mysore.—H. C. **Das-Gupta**: Palæontological notes from Hazara. In this paper the author has described a few fossils obtained from the Triassic, Jurassic, Gieumal, and Tertiary beds of Hazara, and these fossils include one new species of Corbula (*C. middlemissii*), and another new species of Nautilus (*N. hazaraenois*).—H. V. **Nanjundayya**: Some aspects of ethnographic work.

SCIENCE AND THE STATE.

IN the *Chemical News* of April 30 there is a very moderate article emphasising what has been frequently preached in vain: the necessity of a close connection between the public Services and men of science. It is argued that the present is a special opportunity of again advocating the necessity of intimate co-ordination of effort; the societies have ever been willing to render gratuitous service; the Royal Society, for example, has for long put at the disposal of the Government the knowledge and advice of experts in all branches of science. The writer of the article, however, directs attention to the comparative scarcity of young men trained in research, and points out that it is by no means easy for a young graduate to obtain employment otherwise than by teaching. To rectify this state of affairs, he suggests the foundation of research institutes, where such young men could find employment (remunerative, it is to be presumed). These institutes should, it is remarked, be directed by men of eminence in their own branches, free from the irksome duty of teaching. The writer of the article further points out that while the average quality of German research is not high, still its quantity is great; and that British inventiveness is relatively higher. It is questionable whether his statement holds that the result of the German methods of scientific education has been the production of men of resource, men who are able to act promptly and on their own initiative in emergency; this power he believes that we British lack in the present crisis. I do not agree; it is not that power in which we are deficient, but the faculty of organisation, where each man is willing to do only the share which is allotted to him. That is the essential characteristic of the German; he lacks originality, but is content to form a cog in a system of wheels directed from above. Nor are the brains of this human machine original; they have learned how to appropriate and render commercial the ideas of inventors, chiefly those of the non-Germanic nations.

The deputations to Mr. Runciman and Mr. Pease of members of the Royal and the Chemical Societies, and of the Societies of Chemical Industry and Analysts, reported on in NATURE of May 13 (p. 295), urged the appointment of a Standing Committee, serving the purpose of an intelligence department, and also helping the large and growing chemical industries of the country in the same way that the Commercial Intelligence Department serves merchants and traders. It was pointed out that the expansion of the chemical industries of the country requires co-operation between science and manufacturers, and that an increase in the number of research workers is desirable. The speakers also insisted on the need of a more intelligent appreciation of the significance of original scientific work by the Government. To these remarks Mr. Runciman and Mr. Pease made sympathetic replies.

On the evening of the same day on which the report appeared in NATURE, Mr. Pease announced in the House the intention of the Government to create an Advisory Council on Industrial Research—a committee of experts who would be able to consult with other expert committees working in different directions, and associated with leaders of industry. "He was now considering names."

Now, we do not doubt the good will of the members of the Cabinet, but we distrust their judgment in this matter. The handling of the dye scheme was, to say the least of it, very unfortunate. There are two German works, one the Mersey works, a branch of the "Badische," and one at Ellesmere Port, a branch of the German works at Höchst, which might have been associated forcibly with this combine with advantage to the country; moreover, the total lack of chemical talent on the directorate does not argue for its success, as the public has testified by failing to subscribe the issue. The two "eminent chemists" who advised the Government on the dye scheme doubtless do not thank the member of the Cabinet for their unsought publicity. These and other similar instances lead us to mistrust the judgment of Mr. Pease and his colleagues on questions involving science.

There is certainly room for a chemical council, and I had already prepared a draft scheme about two months ago, which has been submitted to, and has had the general approval of, several of our leading industrial chemists. Perhaps it might help were an outline of the scheme to be given here. It is headed "A Draft Scheme of a Chemical Council of State." The clauses are as follow:—

1. The dependence of the welfare of a country on its chemists is obvious. Chemistry lies at the basis of practically all manufactures. Continental nations and the United States have long acknowledged this.

2. Great Britain is behind no nation in the eminence of its chemists. But inducements are lacking to persuade young men to accept minor

positions. Chemical research, as indeed all research, is of two kinds; capital discoveries are made by some, and in this Great Britain probably leads. But the patient development of known ground requires men of a different calibre—men of more ordinary attainments; such men are lacking in numbers in Great Britain.

3. Men of the first rank exist both in the universities and in industry. It is of these that the Chemical Council should consist. About twenty men of this class could easily be named, of the highest reputation and of great experience. Among them every one of the numerous branches of chemistry could be covered; one or more of them would be competent to give expert opinion on every subject which falls within the purview of chemistry.

4. The manufacturing chemists in Great Britain are, generally speaking, not combined. It is true that the alkali-makers work on a mutual understanding; so do the ironmasters. But chemical products are so varied that it may be truly said that industrial chemists work in isolation from each other. It is also generally true that there is little contact between industrial and scientific chemistry. The teachers and students in universities and colleges know little of what passes in the world of manufacture, nor do industrial chemists, as a rule, consult the heads of scientific laboratories. This, again, does not obtain abroad.

5. A Chemical Council for the United Kingdom or for the Empire should comprise both classes of men: scientific investigators and those who apply scientific discoveries to industry. It should contain about twenty-four members, of whom one-third should be technical chemists, one-third scientific investigators, and one-third analytical and consulting chemists.

6. Its duties should be:—

(*a*) To ascertain from every chemical factory in the kingdom (1) the nature of its raw material; (2) the nature and amount of its finished products; (3) the nature of its by-products and what becomes of them. Also to learn by inquiry of the purchasers and users of chemical products—(1) what articles they obtain from home manufacturers; (2) what articles they purchase from abroad; and (3) the causes which induce them to encourage foreign rather than home industries.

(*b*) To establish connection with the chemical laboratories of universities and colleges, and to bring chemical researchers into contact with manufacturers, so that the latter should indicate to the former what problems await solution; and the former should keep the latter posted in any discoveries which appear to promise to be of technical value.

(*c*) To advise the Government on questions involving a skilled knowledge of chemistry and its applications.

7. It would not be desirable to enlist the services of the members of such a committee free of remuneration; a small annual retainer would, however, be sufficient to create a feeling of responsibility. It would, of course, be necessary for the Council to employ agents, who must also be skilled chemists, to carry out such work as visiting factories and interviewing the heads of departments both of factories and colleges; also some clerks and typewriters would be essential.

8. It would make for efficiency if a certain proportion of the members of such a committee were to offer themselves for retirement annually, as do the directors of a company. It would be open to the remaining members to recommend their continuance in office or their replacement by fresh blood. If the Council consisted of twenty-four, eight members might retire each year, with the possibility of re-election.

9. This Council would resemble to some extent a Royal Commission, but it should be appointed for a term of years, say ten, with the possibility of continuance as a permanent body should its work be successful. It must be remembered that the progress of science and its applications has no end.

10. The Committee should report once a year at least, or even at shorter intervals, to the Crown. It would appear advisable not to attach it to any Government department, but to associate it with the Board of Trade, the Board of Agriculture and Fisheries, the Local Government Board, the Board of Education, and also with the Government laboratories.

11. As it is clearly of advantage that such a committee should be non-political, it would be well if it were appointed by and were directly responsible to the Crown.

To whom is the nomination of the first members of such a committee to be entrusted? For on that will depend its success or its failure. I suggest that the President of the Royal Society, himself a most distinguished chemist, should be asked to nominate from the Fellows four persons, two scientific chemists and two technical chemists; and that they, under his chairmanship, should select the names of twenty other persons, themselves constituting four members of the Council. It is unlikely that Sir William Crookes could be prevailed on to add to his numerous onerous duties by himself serving on the Council; but he would probably consent to act as chairman of the electoral committee.

It is earnestly to be hoped that members of the Government will agree to adopt some such scheme. To embark without expert—real expert—advice on nominating the members of such a Council would be to expose it to risks equal to that attending the dye scheme, and would make it impossible to achieve the objects which they appear to have at heart. Let us hope that they will, in this case at least, trust the expert.

Lastly, it is earnestly to be hoped that Mr. Pease's good intentions will not take the form of the institution of a number of Government scholarships. It is grossly unfair to induce young men by scholarships to embark on a career which has little if no outlook; and that has hitherto largely been the case. The status of chemists in Government employment, for example, is not such as to induce any young man who can choose any other profession to devote himself to the career of an official chemist. Compared with other civil servants, he is underpaid and overworked. And although certain manufacturers, to their credit, maintain excellent laboratories, in which a young man has scope to show his ability and may meet with a suitable reward, yet these are the exception. It is to increasing their number and organising their resources that the efforts of the Chemical Council should be devoted.

The suggestion of the foundation of chemical institutes will not meet the case. Those at Dahlem, near Berlin, I am informed at first hand, are not appreciated by the young chemists who work in them; they do not lead to permanent positions. The same cause has resulted in the comparative failure of our Davy-Faraday Institution; and it would be futile to embark on an ambitious scheme for training research chemists without first making sure of their having a reasonable chance of earning a living when they leave.

WILLIAM RAMSAY.

A GREAT PLANT COLLECTOR.

Journal kept by David Douglas during his Travels in North America, 1823–1827. Pp. 364. (London: W. Wesley and Son, 1914.) Price 21*s*. net.

DAVID DOUGLAS, whose journals after lying neglected for nearly ninety years have recently been printed and published by the Royal Horticultural Society, was born near Scone, in Perthshire, in the year 1798. He was apprenticed as a gardener in the Earl of Mansfield's gardens at Scone. When he was about twenty years of age he went to the botanic garden at Glasgow, where at that time the elder Hooker held the position of professor of botany. He became Hooker's assistant and companion during his famous botanical tours in the western Highlands, and showed such a love and enthusiasm for plants that when the Royal Horticultural Society, in quest of a suitable man for a botanical expedition to North America, applied to Hooker, the latter at once recommended Douglas. Douglas accordingly visited the eastern United States and Canada in 1823. His journal describing this trip has but a mild interest, much of the ground he traversed having been already well trodden. He fulfilled his task, however, so much to the satisfaction of the Royal Horticultural Society that, in 1824, he was again dispatched to North America, this time to the western side. By reason of the number of plants he discovered and introduced this journey proved an epoch-making one, both in botany and horticulture. Douglas left Gravesend in July, 1824, and, going by way of the Straits of Magellan, reached the mouth of the Columbia River the following April. After two years' work in Oregon and California he returned by the overland route to York Factory, south of Hudson's Bay, and reached England in October, 1827. He made a second journey to the same regions in 1829, but of this the present volume gives no account.

Douglas stands undoubtedly in the very first rank of plant collectors, having as his compeers such men only as Masson, Allan Cunningham, William Lobb, Robert Fortune, and Wilson. The journals show that he possessed to a high degree those peculiar and diverse qualities that go to make a first-class plant collector—physical courage and endurance, contempt of hardships, a love and knowledge of botany, together with a certain business aptitude and adaptability to new surroundings. He enjoyed the advantage of a practically virgin field for his labours, for scarcely any botanical exploration had been done in this region since Vancouver's voyage of survey some thirty years before, when Archibald Menzies—Vancouver's surgeon and botanist—had made a few excursions near the coast. And not only was his field a virgin one; it comprised the finest sylva of temperate regions, one might even say, of the entire world.

These journals were written in simple style, often apparently after the day's journey was done, with no attempt at literary embellishment and agreeably free from any bombast or undue self-consciousness, such as has been too often characteristic of self-educated men of Douglas's class. It is not often even that Douglas indulges in a reflection on the marvels of nature, new and wonderful as they must have appeared to him. Much of what he records is little more than what has happened on previous days, and is going to happen on succeeding ones. Yet in spite of a certain monotony, the narrative possesses that charm and interest which mark even the plainest story of the pioneer. Douglas was apparently but seldom in danger from Indians or animals, although, with regard to the former, the situation became strained on more than one occasion. Grizzly bears, too, provide an occasional excitement, and we have a glimpse (p. 217) of one of Douglas's companions hurriedly climbing an oak, with the claws of an angry grizzly so close behind that his coat and trousers were torn to tatters. But, on the whole, it was storm and rain, cold, swollen rivers, excessive fatigue, and an insecure food supply that made up the chief hardships of his wanderings. The botanical interest of his writings is not so great as it would have been had the plants he met with and enumerates been identified. There is not so much to interest one in a paragraph like "(467) *Poa* sp.; annual; small, creeping; on the sandy banks of rivers, plentiful," as there would be if we knew the particular grass to which he was referring.

One of the most interesting items in the narrative is the collector's quest for a pine of extraordinary dimensions of which from time to time he heard accounts. His final success in exciting circumstances is recorded on page 230:—

"About an hour's walk from my camp I was met by an Indian, who on discovering me strung his bow . . . and stood ready on the defence. As I was convinced this was prompted by fear, I laid my gun at my feet and waved my hand for him to come to me, which he did with great caution. With my pencil I made a rough sketch of the cone and pine I wanted and showed him it, when he instantly pointed to the hills about fifteen or twenty miles to the south. As I wanted to go in that direction he, seemingly with much good will, went with me. At midday I reached my long-wished pine, and lost no time in examining and endeavouring to collect specimens and seeds. Lest I should never see my friends to tell them verbally of this most beautiful and immense tree, I now state the dimensions of the largest one I could find blown down by the wind: Three feet from the ground, 57 feet 9 inches in circumference; 134 feet from the ground, 17 feet 5 inches; length, 215 feet."

The editor gives no indication of what this tree proved to be, but from the description we have no doubt that Douglas here describes the first discovery of that most wonderful of pines, *Pinus Lambertiana*. He was not permitted to get away from the spot unmolested, for in bringing down the cones with shots from his gun the reports brought some armed and painted Indians on the scene, and it was only after some hazardous moments and a combination of palaver and display of pugnacity that Douglas escaped with but three cones and a few twigs.

Where a plant is mentioned by Douglas under a name which is not now accepted, the editor has given its modern equivalent in a footnote. This, of course, is helpful in many instances, but where the collector was palpably in error the fact might have been pointed out. Douglas was in a new country, but he often erroneously assumed that a plant he found on the western side of America was identical with one he already knew on the eastern. A novice is thereby led to believe that *Abies balsamea, Pinus Strobus, Tsuga canadensis, Amelanchier canadensis, Picea rubra,* and several more eastern trees are to be found in Oregon or California.

We are given a portrait of Douglas (showing a mild but Napoleonic cast of countenance), but in reading the book one feels very much the need of a chart giving an indication of his itinerary. Some of his place names are not discoverable in the atlas. Considering the book is published at the not ungenerous price of one guinea net, we think this addition might reasonably have been made. In a series of appendices are given a brief memoir of Douglas, an account of some ascents of the mountains in the Sandwich Islands, a list of the plants he introduced, and an account of his early and tragic death at the age of thirty-six in the Sandwich Islands, where he fell into one of the pit-traps made to catch wild cattle, in which an infuriated animal was already entrapped.

APPLIED CATALYSIS.

The Hydrogenation of Oils, Catalyzers, and Catalysis, and the Generation of Hydrogen. By C. Ellis. Pp. x+340. (London: Constable and Co., Ltd., 1914.) Price 16*s*. net.

THE catalytic reduction of unsaturated carbon compounds by the direct action of hydrogen in the presence of a finely divided metal may be said to have been discovered by v. Wilde in 1874, when he succeeded in transforming ethylene into ethane by passing the unsaturated hydrocarbon mixed with hydrogen over platinum-black. Although this reaction was found to be of considerable service in synthetic chemistry, it remained without special significance until Sabatier and Senderens started their epoch-making researches in 1897. These chemists found that finely divided metals other than platinum, namely, iron, cobalt, copper, and especially nickel, could be used with marked success as catalysts in reactions of this type, and the catalogue of Poulenc Frères, of Paris, bears witness to the practical success which has attended their work.

It is stated that the nickel most suitable for the purpose is obtained by reducing the oxide by hydrogen at a temperature of between 270° and 300°, but no one who has worked on this subject can have failed to experience the extraordinary differences in the activity of the metal produced under various experimental conditions, and it is therefore not surprising that no great technical use has been found for the process until within comparatively recent years.

The fact that the liquid or unsaturated fats of the olein type are unsuited for the purposes of soap-making, as well as for the production of edible fats, has caused numerous experiments to be made with the object of converting these substances, either wholly or partially, into the saturated or hard fats of the stearin series. As early as 1875 Goldschmidt showed that oleic acid could be reduced to stearic acid by phosphorus and hydriodic acid at a high temperature, and, indeed, this process, or a modification of it, was applied on the industrial scale at about this time, but the method was not successful, and it was not until W. Normann, in 1903, took out a patent for a "process for converting unsaturated fatty acids or their glycerides into saturated compounds" that the Sabatier and Senderens' method was applied to the saturation of unsaturated fats and the tremendous possibilities of the process from an industrial point of view became evident.

The patent of Normann was obviously bad, and it was rendered invalid in 1913, as the result of an action between Joseph Crosfield and Sons, Ltd., and Techno-chemical Laboratories, Ltd.

In the book under review, the first two chapters are devoted to a description of all the various processes which have been used for the purpose of effecting hydrogenation, and it is in this portion that the author seems to have erred on the side of over-elaboration. The point had evidently occurred to him, because, in his introduction he states that "The observations and opinions of many minds have been brought together. Some of these views obviously are sound, others are open to grave doubt, and still others are of a contradictory or polemical nature. Whether or not in the treatment of this material to carry through a vein of critical comment was a problem which confronted the author." That he decided not to introduce this vein of criticism and to give the value of his experience in discriminating between the various processes is, we think, a matter which will be regretted by the average reader. As it is, one almost feels inclined to say that some of the methods described could scarcely have been expected to yield satisfactory results even by their discoverers, and the reader who is not an expert will arrive at the conclusion that there are some fifty different ways by which hydrogenation may be accomplished, and that all of them are of equal importance. To the expert, however, who is able to sift grain from chaff, this section will be of the greatest service.

The same criticism applies to the next section of the book, which deals with the various kinds of catalysers which have been used. This section occupies two chapters, and is succeeded by an admirable account of nickel carbonyl, followed, in chapter vi., by an interesting account of the work of Paal and others on the use of the rare metals in the colloidal state as catalysts. Chapter viii. deals with the analytical constants of hydrogenated oils, and the two succeeding chapters contain a description of the methods by which these oils may be converted either into edible fats or into soap. The last nine chapters of the book, some hundred pages in all, deal with the various methods which have been devised for the preparation of hydrogen. This section is treated in a most exhaustive manner, and the influence of impurities in the hydrogen, acting either as poisons to the catalysts or as substances injurious to the oils, are discussed. The book ends with an appendix containing an account of the recent litigation over the Normann patent.

This excellent treatise is well illustrated by some 145 photographs and drawings both of scientific apparatus and of plant. The admirable manner in which the author has emphasised the scientific basis of the technical processes which he has described causes it to be a noteworthy addition to our literature on specialised organic chemistry.

J. F. T.

A TEXT-BOOK OF EFFICIENCY.

Fundamental Sources of Efficiency. By Dr. F. Durell. Pp. 368. (Philadelphia and London: J. B. Lippincott Company, 1914.) Price 10*s*. 6*d*. net.

TO many it once came as a shock to hear that the great Mach laid stress on the economy of thought in science. It seemed as though science were brought into too close analogy with much more mundane kinds of human activity. But in this book the study of almost every conceivable kind of activity, including scientific activity, is made from the abstract point of view of efficiency. "An efficient process is one in which the available results exceed the expenditure" (p. 4); and the work is an attempt to analyse the various forms and sources of efficiency into a few elemental principles. "While the book has been cast in a form adapted to general reading, groups of exercises have been inserted which, it is hoped, will add to its value if it is used as a text-book in any institution where the principles of efficiency are taught."

Surely it is only in America that we could have a professor of efficiency. From the preface we also learn that, since the importance of investigating the elements which constitute fitness, that is, efficiency, becomes evident as soon as the principle of the survival of the fittest is recognised, the leading ideas of the book were suggested by the reading of Herbert Spencer. Many important details have been obtained from the publications of the Efficiency Society and the works of various modern writers.

The most primitive and, in a sense, fundamental source of efficiency is the act of re-use or repetition, and human progress in general is marked by an increasing amount and by higher forms of re-use (p. 31). A superior efficiency to more or less haphazard re-use is attained by the "unit and multiplier principle" treated in chapter iii.: "A *unit* is any entity used manifoldly in space or time or in any relation. The *multiplier* expresses the number of manifold uses made of a unit" (p. 50). This principle may be extended so as to form a still more general agent of efficiency, that of the "group," and this is dealt with in chapter iv. The group is so fundamental in its nature that the other primal sources of efficiency may be regarded as various methods of using the group. Groups may be used not only singly, but also in combination, with a corresponding increase of efficiency (chapter v.). It is often a source of efficiency to substitute for a given system of groups a series of groups or "orders" of the system (chapter vi.). The use of an object or objects external to a given domain as a means of obtaining results by forming new and large groups is the source investigated in chapter vii.

Chapter viii. deals with sources obtained by the perceptions of diversities and of uniformities. After a study (chapter ix.) of the aims and ends of efficiency processes, chapter x. contains a good treatment of symbolism as an agent of efficiency, and here pp. 174–175, 177, 185, 187 (*cf.* p. 359) seem especially noteworthy. The other chapters are on the principle of directive action, the study of speed and rhythmic methods as means to efficiency, the principle of "dialectic" or unexpected discovery, the study of limitations of processes, the removal of waste and error, and the combinations of efficients. Chapter xviii. deals with applications to psychology, education, sociology, business, art, ethics, and religion. Finally, there are appendices on "The Categories and a General Philosophy of Life" and a "Historical Survey."

The book is rather obscurely written, but contains very much valuable illustrative material.

ϕ.

OUR BOOKSHELF.

Elementary Human Biology. By J. E. Peabody and Dr. A. E. Hunt. Pp. xii + 194. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1915.) Price 4*s*.

UNDER this somewhat curious title the two authors, American schoolmasters, have produced a manual which deals with elementary hygiene. It is evidently written for children, for the pronunciation and derivation of comparatively simple words, such as involuntary and ventilation, are given. It, however, manifests a curious lack of perspective, for while it contains simple exercises which teach young pupils the reasons for rules of health, such as cleaning the teeth, masticating the food, and washing the skin, it also deals with elaborate details for comparing bacteriologically with Petri dishes the air of a room after sweeping it with a broom, and after the use of a vacuum cleaner. One home exercise which with unconscious humour is marked optional consists in chewing popped corn and noting that it becomes sweet during the process. The conditions of American life are so often different from those in this country, for instance, in the matters of heating and ventilating houses, that we doubt whether the present book will profitably replace the many excellent text-books on hygiene we already possess here; the same may be said in relation to subjects such as profitable housekeeping and cooking. Even if the English child or his parent overcomes the difficulty of converting dollars into shillings, we doubt whether they will be much enlightened by such words as skillet, round steak, and string beans.

A few of the many errors noted are: that milk-sugar is changed into grape-sugar by heating it with Fehling's solution; that the saliva forms dextrose from starch; that nerve impulses travel 100 ft. per second; that Nissl granules in nerve cells appear as a result of fatigue; that the epiglottis closes as a lid on the larynx during swallowing; that peptone is the end-product in digestive proteolysis; that Sylvester's method for artificial respiration is the best. Children, it is true, require teaching to be simple, but they deserve that it should be accurate. W. D. H.

Inorganic Plant Poisons and Stimulants. By Dr. W. E. Brenchley. Pp. ix + 110. (Cambridge: At the University Press, 1914.) Price 5*s*. net.

MISS BRENCHLEY has set herself a difficult task in attempting to deal with problems such as are indicated in the somewhat ambitious title of her book, and we confess to a feeling akin to disappointment after a perusal of the volume. The work is good as far as it goes, but the treatment is less suggestive, and the grip less firm than we had been led to anticipate.

The effects of the salts of five elements, viz., copper, zinc, arsenic, boron, and manganese upon plant growth have been studied, and the surprisingly deleterious results which follow on the addition of minute traces of some of them to plants grown as water cultures are described, and are also illustrated by excellent photographs. The conclusion is reached that no stimulation of growth follows the addition of even the smallest amounts of salts of copper, zinc, or arsenic, whilst some improvement does occur when salts of boron or manganese are employed. This is of interest when the somewhat widespread notion of the beneficial action of traces of copper salts, in some instances, at any rate, is recalled. Naturally, however, one must accept with caution conclusions based on the results of water-culture experiments in any endeavour to extend them to plants growing under ordinary soil conditions. This is the more necessary when one reflects how differently plants may behave in pot culture and in the field, and that even in the field itself it is not possible always to predict results at all accurately when the soil, aspect, drainage, and other factors as well are all subject to variation. We need a far more intimate knowledge of the physical conditions, as well as of the chemical processes that are in part, and often largely, governed by those conditions in the soil, before we shall be in a position even to formulate these fundamental questions, a satisfactory answer to which must form the basis on which our real knowledge of the plant, in this connection, will have to be built up. Miss Brenchley is fully aware of the difficulties which surround the whole subject, and her summing up of the whole position is admirable in its caution.

Index to Periodicals. Compiled by various authorities and arranged by A. C. Piper. Vol. i., April—September, 1914. Pp. xxxii + 192. (London: Stanley Paul and Co., for *The Librarian and Book World.*) Price 21s. net.

The general editor of this classified and annotated index to the original articles contained in some of the principal weekly, monthly, and quarterly periodicals, Mr. A. J. Philip, rather disarms criticism by recounting in the preface the difficulties due to the war under which the index has been prepared. The idea of such an index of the important signed articles in periodical literature was excellent, and had it been possible to carry it out with some completeness, the result would have been widely welcomed.

It is difficult to understand on what plan the 109 periodicals indexed have been chosen. The preface says that foreign periodicals have been omitted, yet the names of a few appear in the list of those indexed. The *Journals* of the Royal Anthropological Institute, the Royal Microscopical Society, the Royal Sanitary Institute, and the Royal Statistical Society have been dealt with, but the publications of the Royal Society, the Royal Astronomical Society, the Royal Meteorological Society, the Chemical Society, the various engineering institutions, and scores of others of equal importance are ignored. Similarly in education, attention is confined apparently to the *Educational Times*, the *Journal of Education*, and the *Parents' Review*, while no mention is made of the *Preparatory Schools Review*, the *School World*, the *Schoolmaster*, and a host of others. The *Classical Review* is indexed, but the periodicals concerned with modern languages, English studies, nature study, and so on, seem to have been forgotten.

While appreciating the enterprising beginning which has been made, it may be hoped that in the next volume the compilers will cast their nets more widely, and so secure a more representative production.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The National Organisation of Scientific Effort.

For readers of Nature one of the most striking features of the war is that the German Government should be approved and supported by its prominent men of science, in spite of the fact that it uses methods of warfare which we regard as being outside the pale of humanity and common civilisation. It seems inconceivable that anything like it should happen in this country. If the British military authorities had transgressed against the written and unwritten laws of humanity as Germany has done, we feel sure that our men of science would have found a voice in condemnation of the Government. In this country it is no unusual thing for men of science to find a voice in condemnation of the Government, both for what it does and for what it leaves undone. Such condemnation used, in fact, to be, in peace time, a staple article of scientific public-speaking, the like of which one did not find in Germany. One never heard there even in private conversation the kind of criticism of Government action or inaction which in this country is reiterated commonplace.

The difference in practice may be attributed to the fact that in Germany scientific effort is organised by Government, which stands to scientific work in the relation of creator, provider and guardian, on its own terms. In Germany, Government is the providence of science; and to rail against Government, even when its ways are dark and mysterious, is not to be thought of. The attitude of the man of science in Germany towards his Government recalls Cowper's hymn. Changing the grammatical gender to avoid irreverence:—

> Blind unbelief is sure to err
> And scan Its work in vain,
> It is Its own interpreter
> And It will make it plain.

We have nothing like it in this country, and this reflection prompts the question: What is the corresponding organisation in this country? For organisation there must be, whether it be simple or elaborate, effective or ineffective, intentional or haphazard.

Our organisation is, in fact, haphazard, a matter of history and tradition; and, on examination, it will be found to be at least moderately efficient as regards persons, but woefully inadequate as regards subjects.

The difference is well pointed by an incident at a dinner in connection with a scientific meeting a few years ago. The speaking, after dinner, had become rather informal, and one of the foreign representatives urged the desirability of a professorship in, say, seismology—the particular subject is unimportant—and, in reply, the chairman said that he had recognised the need for a long time, and was uncertain whether the best way of approaching its satisfaction was to appeal directly to the universities, or to begin with the schools and so create a demand which the universities would find it to their interest to meet. The German representative on leaving the dining-room remarked: "But, of course, *your Government* must create a professorship." The only reply to that is that it is not our way.

Then what is our way? To what authority in this country does one appeal for the promotion of the study of any scientific subject which is felt to be in want of support?

There is the Royal Society, which is known to be a remarkably powerful body for discriminating between the merits of the scientific workers in this country. Some years ago one of its presidents devoted a series of presidential addresses to the claims of science in education; but to ask the Royal Society to put machinery in motion to supply the need for university professorships in certain subjects would be simply to court a rebuff, and for an obvious reason. It is understood that the Royal Society, though it is, for some purposes, a representative body, does not regard itself as the proper body to take the initiative in approaching the Government for the support of a new scientific project. The proper course is supposed to be for those who are interested in the project to approach the Government themselves, and for the Government to refer the matter to the Royal Society as a kind of jury. By that mode of procedure the promoters, without the official support of the representatives of science, have first to convince the Government that their project comes within its province, a task that in itself is enough to damp the ardour of many enthusiasts.

If the Royal Society is shy of approaching the Government, it would be still more shy of approaching directly an academic corporate body. That is not to be thought of. Besides, it is itself academic enough to know the answer without going through the formality of making the inquiry.

Nor is it likely that an avenue to the purse of the private benefactor could be found through the corporate action of the Royal Society, although without such action any appeal is prejudiced from the start. It can scarcely be doubted that if the Royal Society would from time to time set out the gaps in the professorial ranks of the universities on account of subjects of deep human and scientific interest which have no exponents in the academic life of this country (and so, by conscious or unconscious imitation, of the British Empire), the appeal would carry conviction to some of those who are willing to consider a worthy outlet for part of their wealth. The contention that the British Empire is not rich, or at least not rich enough to staff its universities properly, will not really bear examination; and yet the very dignity of the Royal Society seems too great for it to undertake the duty of appealing for funds for separate subjects that need support.

So we are back again at the usual refuge for science in distress: the Government. The front door is closed, as we have seen, but we can try the back.

Let us concentrate our attention on the "research" aspect of the question and appeal for support to the "Government grant for scientific research" which is administered with a free hand by a committee appointed by the Royal Society. It is common knowledge that the committee acts ostensibly on the principle that for research in this country all that the Government needs to provide is a number of small doles to enthusiastic workers who find themselves deficient in apparatus and materials. The sums necessary for the maintenance and remuneration of these workers have to be provided by other means—into which the Government Grant Committee is careful not to inquire.

But with the neglected subjects to which we have been referring, research has to be initiated and workers found and paid: the Government Grant Committee draws the line there. It is a very unfortunate conclusion, because any appeal to Government for research from anybody but the Royal Society can be, and indeed is, rightly estopped by a reference to the provision which already exists for scientific research, and which is not officially known to be inadequate.

Here again the Royal Society shows itself admirably efficient in discriminating between the merits of the persons who apply for the doles, but it has practically nothing to say to the appeal for subjects left entirely in the cold.

Is it unjust to sum up the situation with regard to the subject-aspect of our national organisation of scientific effort by saying that it is in this unfortunate position: that on the one hand nothing can be done without the Royal Society, and on the other hand, with all respect and admiration, nothing can be done through the Royal Society?

Yet things are done from time to time; ways out of the dilemma have been found; our existing organisation must have other aspects. Parenthetically it is a matter for wonder how the subject of mineralogy came by the provision which it now enjoys at the older universities. One has the feeling that if it had not been endowed long ago it would never be endowed now. It seems even further from the important consideration of the "main chance" which appeals to the universities than some other subjects which have still no academic status.

Looking back at the history of the other subjects which may be included in the title of out-of-door physics, we find that the British Association for the Advancement of Science stands out as the specialised organ of our national organisation for giving things a start. One knows the mode of procedure quite well. Certain prominent men of science (who when they are back in London will be the Royal Society) meet in some provincial town, discuss the matter, appoint a committee, and make a grant out of the members' pounds for out-of-pocket expenses. The subject prospers by the unpaid work of some indefatigable member of the committee; after some years an appeal is made to Government. The British Association conducts the appeal, which is thereby guaranteed respectful consideration; and its reception by the Royal Society jury is also guaranteed by the *personnel* of the committee; there is no element of danger in the reference, and so the plan is brought to some sort of fruition.

To the operation of the British Association can be traced the origin of what provision there is (outside the Royal Observatories, the Hydrographic Department of the Navy, and one division of the Meteorological Office) for meteorology, terrestrial magnetism, solar physics, seismology and the so-called "Standardisation" of instruments, now represented by the National Physical Laboratory. For each of these one or more committees of the British Association could be named, one of which dates as far back as 1842, early days even for the British Association. There are, no doubt, many other enterprises in other branches of science which have a similar history.

So the organisation of scientific effort on our side which corresponds with the Government organisation of Germany may be expressed by this precept for anyone who has a project for scientific work: "You first attend a meeting of the British Association and get a strong committee appointed; then you work for a number of years without pay, but with a mind conscious that you will thereby acquire merit with the Royal Society, the great discriminator; then if you have not money enough to pay for apparatus you can appeal to the Government Grant Committee with an assured prospect of success; then when you find it necessary for somebody to be paid, you can move the Council of the British Association to approach the Government for the money. The Government will then take the opinion of the Royal Society, and that will be quite all right, because your own committee will be in force there; and then, if you are moderately fortunate, Government will give you half of what you ask as a 'grant in aid,' and for the rest you must look out for yourself."

We are therefore by no means devoid of organisation; what we have is almost venerably historic and very elaborate; but it is long and tortuous and sadly inefficient for the following obvious reasons:—

First, that in spite of our pride in private effort, and our prejudice in its favour as being vastly superior to anything that Government can do, our process leads ultimately to Government and nowhere else. It gives no footing in the universities or in any other body, corporate or incorporate, whose members control the temporary destinies of the British Association. Of course, at the end of the chapter the Government could approach the universities, but with the present relations between Government and the universities this is a perilous thing for a Government to do. It was done in one instance lately; and there is "a smile on the face of the tiger."

Secondly, it leads to accepting Government money in the form of what is called a "grant in aid," which means public money with public responsibility, but no official prestige and no official purpose. The grant is made as a concession to somebody's enthusiasm; the responsibility for success rests with the unfortunate enthusiast, and the limitation of ways and means rests with somebody else. One of the common forms of our scientific attitude is that Government support chills and discourages private effort. The scientific societies are fond of adopting it because it leaves them in a sort of control of things; and, of course, Government "as at present advised" is not likely to demur. But what attracts and stimulates private effort is really efficiency, whether public or private; it is frequently the case that support by Government lacks that stimulating quality simply because it represents not a purpose, but a concession. The situation recalls a remark once heard at a college dinner-table, when a country clergyman thus expressed himself concerning the Nonconformist discontent about education: "I cannot see what these dissenters have to complain of; we *tolerate* them." So with our national organisation of scientific effort: it ends in toleration by the Government, and the "establishment" looks on with a sort of bewildered wonder at our insatiable discontent.

Among the changes which will follow the war, whatever the issue may be, the reorganisation of scientific effort must find a place. All the after-dinner speeches about the parsimony of the Treasury, and all the complaints in *Science Progress* and at the meetings of the British Science Guild, punctuated by what has been brought to light since the war began, mean at least that.

We may learn from our enemies and let the Government take over the control of our scientific effort, or, appalled by the result in the case of Germany, and sharing the feeling of Prof. Brants and the Dutch for whom he speaks in the March number of the *Nineteenth Century and After*, we may have the courage to be ourselves and manage things in our own way. The future will show; only we must have a way which is recognisable and recognised. Behind the Government, whether in association with a special Minister or not, there must be a powerful advisory committee with facilities for initiation as well as discrimination, a sort of Privy Council for Science with public responsibilities, to whom the public as well as the Government can appeal.

Before that can be established the Royal Society must settle what its function is to be. At present it claims to discriminate in its corporate capacity, and leaves to its individual members the duties of initiation. The British Science Guild has sought to remedy this state of affairs, and is prepared to take the initiative in an organised way. But it is evident that, if the Royal Society is to exercise the power of discrimination, the two bodies must be in reality the same persons, as in the case of the initiative of the British Association, or the scientific body politic will be divided against itself; therefore the first question to be settled is whether the Royal Society's claim to the power of discrimination is to be confirmed and supplemented by the faculty of initiative, or whether both faculties are to be vested in a recognised and responsible body of Government advisers.

The Royal Society is by no means an ideal institution for the purpose, and it was not created for such work; its full body of four hundred and fifty members is too numerous to carry the responsibility, and its Council of twenty-one too small, too much selected for the purpose of personal discrimination, too transitory, too full of work of other kinds, too much unpaid, and not sufficiently representative of the subjects with which a national organisation must deal in the long run because they are not adequately represented at the universities.

The point is obviously a difficulty; but in the long last it can only be settled in one way, and the sooner the Royal Society takes the field with a proposal for an initiating and discriminating advisory body other than its own Council the sooner will it be possible to take a definite step in the direction of the national organisation of scientific effort. F.R.S.

Osmotics.

In connection with the recent discussion, at the Faraday Society, on osmotic and vapour pressures, it seems worth while to state that a long and laborious series of vapour pressure measurements which Mr. Hartley and I have undertaken is nearly completed, and I hope will be published shortly.

The results so far go to show that by taking $RT=22\cdot3909$ (in litres and atmospheres, and with $O=16$), which is the value for nitrogen and close to that derived from water vapour at 30° C., a very good agreement is obtained between the direct and indirect values of the osmotic pressure of cane-sugar at 0° C., and incidentally of calcium ferrocyanide.

I also take the opportunity of mentioning that if p be the osmotic pressure, V and v the volume of solution and volume of water containing one gram-molecule of cane-sugar, respectively—both being measured when compressed to the osmotic pressure—then $p(v-bv/V)=RT$ is found to give a fair fit to the results both at 0° C. and at 30° C.

A closer approximation is obtained with

$$(p-a/v^2)(v-v/Vb)=RT,$$

in which case the same constants give the values of p for both 0° C. and 30° C.

I also find that a somewhat less good fit is obtained from $(p+a/v^2)(v-vb/V)=RT$; this last equation, however, has the advantage that it gives a value of V when $dp/dV=0$, which, assuming that this point is the limit of supersaturation, we know is about right; that is, V is greater than the molecular volume of cane-sugar in the solution, and less than its value in a saturated solution, *i.e.*, a solution containing about 960 grams per litre at 30° C.

I would reserve the discussion of the meaning of these equations and others, which I have also obtained, until our final results are published.

BERKELEY.

Foxcombe, near Oxford, May 15.

A Bibliography of Fishes.

THE time is ripe—and has, indeed, long been ripe—for the publication of a carefully prepared bibliography of fishes, to cover the entire range of the subject: fishes fossil as well as living, and fishes from many points of view, such as anatomy, physiology, embryology, pathology, parasitology, distribution, taxonomy, everything, in short, excepting matters which deal with clerical details of the fisheries. Such a compilation, it is clear, means much for this branch of zoology, for the literature of the fishes is vast, widely scattered, and ill-digested. In fact, I believe that there is scarcely an investigator to-day who has not been obliged, needlessly, to give weeks or months of his time to searching for references.

The importance of such a bibliography was brought home to me about 1890; at that time I began the work of collecting references to be used in my studies, and as years passed I was able to build up a card-catalogue giving author and subject, which proved indispensable. Later my catalogue became known to correspondents, who in turn found it of use in their studies; and they, for their part, were generous in contributing references, and thus added notably to its value. It next, through the kindness of the Smithsonian Institution, absorbed the bibliography which Prof. Goode undertook to publish, and which his death left unfinished. Thus the value of the work became greater year by year. About 1910 the American Museum of Natural History allowed me secretarial help in the direction of editing the catalogue for publication. And thereafter, for about a year and a half this secretarial work was carefully carried on under the supervision of my colleague, Dr. Louis Hussakof, and since 1914 by Dr. C. R. Eastman, of the American Museum.

The scope of the undertaking may be understood when one considers that nearly 50,000 references are brought together. These have been gathered from all sources, notably from all accessible bibliographies, serial publications, and book catalogues. Finally, the effort was made to complete the lists of titles by bibliographies secured in so far as possible from authors themselves. To this end circulars were sent out to several hundred writers on ichthyology, many of whom responded cordially.

There still remain, however, a number of individual writers who have not contributed the titles of their publications. I have, accordingly, been led to publish the present note in the hope that any who have not already sent to Dr. Eastman or myself their bibliographies, may be reminded that we are especially anxious to make the work as complete as possible. We urge that their lists be sent in without delay, for the work is undergoing its final revision, and the first volume is shortly to go to press. This is the "author's" volume, which will consist of about 1000 pages, and include under the names of writers a serial list of their publications. The second, or "subject" volume, will be a classified index of the titles in vol. i. Here one has access to special papers in the various branches; for example, in anatomy, distribution, embryology.

BASHFORD DEAN.

American Museum of Natural History, New York.

The Use of the Term "Pinacoid" in Crystallography.

CAN any of your readers help me as to the original definition of the familiar term "pinacoid"? I suspect that it was introduced by C. F. Naumann about 1830; it was derived from πίναξ, a slab, and appears from the first to have included two parallel planes. Naumann, for instance ("Anfangsgründe der Krystallographie," 1841, p. 126), uses "basal pinacoid" for the pair of planes parallel to the two lateral crystallographic axes. But he restricts the use of pinacoid to the three possible pairs in a crystal that cut only one of the three axes, and (p. 19) defines a pinacoid as including "two parallel planes which are parallel either with the base or one of the other co-ordinate planes."

In 1856 we find Tennant and Mitchell ("Mineralogy and Crystallography") using pinacoid for a single plane of any of these pairs, and this, which is clearly a mistake, has been followed by writers of very recent date. Story-Maskelyne ("Crystallography," 1895, p. 20) agrees with Naumann, calling the single plane a "pinacoid plane." This latter fact has not been observed by the authors of the Oxford Dictionary. P. Groth ("Physikalische Krystallographie") in 1876 and 1885 employed the term in Naumann's way; but in his third edition of 1895 he introduced the term "pedion" (p. 337) for any single plane, and defined a pinacoid (p. 340) as consisting of any two parallel planes.

This extension of the term pinacoid from Naumann's original usage has been adopted by Lewis, Liebisch, Miers, and Tutton in their authoritative works. The pinacoids parallel to the three co-ordinate planes are thus left without a distinctive title, and in my own small "Outlines of Mineralogy" (1913) I have styled them "principal pinacoids." If the history of the matter is as I have traced it, it would seem better if Groth had invented a new term, side by side with pedion, rather than, as was so often done by Rosenbusch in the nomenclature of rocks, employed a well-established term in a new signification.

A Mistaken Butterfly.

A FEW summers ago I noticed a fine cabbage butterfly executing a number of gyrations in front of a milliner's shop in New Bond Street, and making every effort to get through the plate-glass window. Immediately inside the window was a lady's hat (or bonnet, I am not sure of the distinction), ornamented by an enormous artificial scarlet poppy. It was quite clear that the object of the butterfly's attention was the poppy. Apparently he was guided by sight, and not by smell.

ETHNOGRAPHIC STUDIES IN MELANESIA.[1]

THE two volumes of "The History of Melanesian Society," by Dr. Rivers, represent two methods of the study of mankind, the ethnographical and the ethnological. The first volume is devoted to an ethnographical study of a considerable portion of southern and central Melanesia and of various Polynesian islands; the account of Tikopia is of especial interest, as, although situated in Melanesia, it is inhabited by Polynesians, who have scarcely been affected by external influences. Most of the data were collected under the auspices of the Percy Sladen Trust. In the second volume the author breaks new ground in ethnology, as he synthesises and gives explanations of an even wider array of facts than those accumulated in the first volume.

Those who are acquainted with the previous writings of Dr. Rivers are well aware that, whether recording new facts or correcting and expanding information acquired by others, he has always paid great attention to method; indeed, he has perhaps done more than anyone else in this country to establish ethnology on scientific methods. It is interesting to note that until he began writing the theoretical discussion in the second volume, he was a firm adherent of the current English school, being almost exclusively interested in the evolution of belief, custom, and institution, and paying little attention to the complexity of the several cultures. He came to see, however, that Melanesian culture was more complex than had at first appeared, and that it was necessary to dissect out, so to speak, the associated elements in each of the component cultures.

Graebner was the first to study this problem systematically, but he approached it from the point of view of the museum curator without experience as a field ethnologist. Dr. Rivers states that the chief aim of his book "has been to show how social institutions and customs have arisen as the result of the interaction between peoples, the resulting compound resembling that produced by a chemical mixture in that it requires a process of analysis to discover its composition. To Graebner, on the other hand, the process of blending of cultures resembles rather a physical mixture in which the component elements exist side by side readily distinguishable from one another. . . . . He assumes that social institutions and religious practices can be carried about the world and transplanted into new homes as easily, and with as little modification, as weapons and implements. . . . Such an assumption is impossible to anyone who appreciates the far more vital and essential character of the less material elements of culture" (ii., p. 585).

By means of the genealogical method Dr. Rivers has discovered several remarkable forms of marriage in Melanesia, or has deduced forms which have existed previously. For example, cross-cousin marriage (*i.e.*, between the children of a brother and those of his sister) occurs in widely separated parts of Melanesia, and wherever found is accompanied by features of the systems of relationship which are clearly the direct result of this form of marriage; these features are found in places where cross-cousin marriage does not now take place, but they must certainly be survivals of it. The same applies to marriage with the wife of the mother's brother. The extraordinary system of the island of Pentecost owes its special features to two anomalous forms of marriage which either still exist or have been practised on the island, viz., marriage with the wife of a mother's brother, and with the granddaughter of the brother. For the latter, there

is a clear tradition of its occurrence in the past, and it is said still to be practised. This form of marriage also takes place among the Dieri of Australia, who recognise that relatives belonging to generations twice removed from one another are naturally husband and wife (ii., p. 47). Dr. Rivers will be interested to learn that Sarat Chandra Roy, in his forthcoming book on the Oraons of Chota Nagpur, will produce evidence to show that there are "reasons for inferring the former existence amongst the Oraons (before clan exogamy was instituted) of a system of marriage or union between persons related to each other as grandparent (or grand-uncle or grand-aunt) and grandchild (or grand-nephew or grand-niece)." These archaic social institutions may be preserved in nomenclature like flies in amber. Dr. Rivers argues that the anomalous forms of marriage imply a dual organisation with matrilineal descent, and he is driven to assume a state of society in which the elders had acquired so predominant a position that they were able to monopolise all the young women. He also points out that, according to this view, cross-cousin marriage arose as a modification of the marriage with the wife of the mother's brother.

FIG. 2.—Canoe and canoe-shed, Tikopia. From "The History of Melanesian Society."

Dr. Rivers has made a special study of the secret societies of Melanesia, and he works out an elaborate argument to show that the secret ceremonial is derived from rites brought by an immigrant people, relatively few in number, who were solely of the male sex, or accompanied by very few women of their own race. By considering the distribution and the customs and objects associated with betel-chewing and kava-drinking, he shows that these comestibles mark two main migrations into Melanesia, which previously was inhabited by a people with a dual organisation. Various methods of the disposal of the dead indicate racial complexity, and a study of each mode combined with associated data leads to a finer analysis. His conclusions may be summarised as follows:—

The introduction of betel-chewing was relatively late and restricted and may have taken place from Indonesia after the invasion of the Hindus. With it were associated marriage with the wife of the father's brother, the special sanctity of the skull, and the plank-built canoe.

The effect of the kava-using peoples was more extensive in time and space; they had neither clan organisation nor exogamy, some preserved the body, and respect was paid to the head or skull. Contact with the earlier populations resulted in wife purchase and the development of secret societies. They introduced the cult of the dead and the institutions of taboo, totemism, and chieftainship, an outrigger canoe, money, the slit drum or gong, the conch trumpet, megalithic monuments, and the fowl, pig, and dog. There may have been two immigrations of peoples who made monuments of stone. (1) Those who erected the more dolmen-like structures, probably had aquatic totems, and interred their dead in the extended position; (2) and later, those whose stone structures tended to take the form of pyramids, who had bird totems, practised a cult of the sun, and cremated their dead.

These immigrants found a people divided into two exogamous groups, with matrilineal descent, and three special forms of marriage (with daughter's daughter, wife of mother's brother, and wife of father's father), they had rectilinear decorative designs, and employed the bullroarer. The dual organisation seems to have been formed by fusion rather than by fission, judging from the frequent survival of hostility between the two moieties, their mythology, character, and possibly even slight traces of differences in physique. Whatever the previous social condition of each moiety, a fusion of two races under certain conditions might produce matrilineal descent. The dual organisation would thus imply a dual origin, of which the immigrant people spoke an Austronesian language (as did the kava and betel peoples), interred their dead in a sitting position, feared the dead, believed in spirits, practised circumcision, introduced the bow and arrow, and an outrigger canoe. The Baining of New Britain may represent, though, of course, in a modified form, the aboriginal elements of the dual people; they are devoid of any fear of the dead, and their small stature suggests that the pre-dual people may have been pygmies.

Dr. Rivers has produced a work which will have far-reaching results, it being not merely a storehouse of facts, but a demonstration of method, and conclusions are arrived at which will be sure to provoke discussion. Whatever may be the final results of such discussions, this book will probably take rank as a landmark in the study of ethnology. A. C. HADDON.

TYPHUS FEVER.

TYPHUS fever, which has just appeared in some of the prisoners' camps in Germany and is rife in Serbia, has been one of the great epidemic diseases of the world. Hirsch remarked:—"The history of typhus is written in those dark pages of the world's story which tell of the grievous visitations of mankind by war, famine, and misery of every kind."

The name is of no great antiquity, for it was applied to a malady or group of maladies first by Sauvages in 1759. Until then, from the time of Hippocrates downwards, it had been employed to designate a confused state of intellect, with a tendency to stupor. It was, in fact, not until 1850 that typhus fever was finally differentiated from typhoid or enteric fever by the researches of Jenner. One of the older synonyms for the disease was *jail fever*, and in the sixteenth century, at the first three of the famous "Black Assizes," judges, sheriffs, and jurymen were stricken with it as the result of infection from prisoners brought for trial. Another name formerly given to it is *Morbus castrensis* or "military fever," on account of the ravages occasioned by it among soldiers and camp followers from the time of the Thirty Years' War and the English Civil War down to the siege of Sebastopol. Owing to the character of the eruption, typhus fever has sometimes been termed "spotted fever" (to be distinguished from cerebro-spinal fever, also known as spotted fever), and the German name is *flecktyphus,* also *typhus exanthematicus,* to distinguish it from *typhus abdominalis*, typhoid or enteric fever. The French name is similarly *typhus exanthématique.* Brill's disease, met with in New York, and Tabadillo of Mexico, seem to be manifestations of it. Few countries have suffered more than Ireland, and the disease has lingered in the outer Hebrides, but of late years has been practically unknown in England, and is seen but rarely in Scotland.

The invasion of typhus is, in the majority of cases, like pneumonia, sudden and severe after an incubation period of about twelve days. On the fourth or fifth day the eruption appears, first measly in character, but appearing on the wrists, trunk, and thighs, and afterwards becoming hæmorrhagic. The patient then suffers from severe fever with its usual concomitants, passing into extreme prostration. The nervous system suffers severely, and there is great muscular restlessness and tremor, excitement and delirium. In favourable cases the attack ends comparatively suddenly about the fourteenth day.

There are, of course, considerable variations in the course of the disease in individual cases; it is always to be regarded as a serious affection, and the average death-rate for all ages under favourable conditions is 15–19 per cent.; no age is exempt. An attack of typhus affords marked protection, and second attacks are as rare as those of small-pox. No special treatment for it has yet been discovered.

The ætiology of the disease is still uncertain: no specific micro-organism has been discovered, but it is probably protozoan in nature.

Typhus is markedly infectious, and the infectivity is greater the larger the number of cases which are aggregated together. The mode of spread for a long time was uncertain, and until recently it was regarded as being conveyed by the emanations from the patient. A few years ago, in the epidemic which occurred in Aberdeen, Prof. Matthew Hay made the pregnant suggestion, on epidemiological grounds, that the disease might be conveyed by fleas. Further investigations have conclusively proved that it is conveyed by the body-louse, possibly by the head-louse also. This important fact explains how it is that typhus is so prone to appear in times of stress, war, and famine—when misery prevails and personal cleanliness is difficult or impossible to maintain.

Prevention of the spread of the disease largely resolves itself, therefore, into extermination of lice, and much attention is now being directed to the means which may attain this end. R. T. H.

AN ADVISORY COUNCIL ON INDUSTRIAL RESEARCH.

THE proposed formation of an Advisory Council concerned with industrial and scientific research was announced by Mr. J. A. Pease, President of the Board of Education, to the deputation of which we gave an account last week. The scheme was described by Mr. Pease in Committee of the House of Commons on May 13 in connection with the Education Estimates; and the debate which followed upon it was one of the most important from a scientific point of view that has been heard in the House for a long time.

The general question of the relation of science to the State, and the particular work which a suitably constituted Advisory Council could undertake, are dealt with elsewhere in this issue of NATURE by Sir William Ramsay. We need scarcely remind our readers that the need for increased provision for research in pure and applied science has been urged in these columns for many years by leaders in the scientific world concerned not only with the advancement of natural knowledge, but also with the promotion of national prosperity. For the past ten years the British Science Guild has been continuously endeavouring, with little encouragement, to secure public and official recognition of scientific research and organisation as essential factors of industrial progress. It has shown over and over again that whereas in Germany the State fosters all work and institutions engaged in scientific work and advanced technology, and in the United States private benefactions increase the endowments for such purposes at the rate of about 5,000,000*l*. annually, in the United Kingdom neither the State nor the generosity of individuals makes provision for research on a scale at a l comparable with what is done in the two countries which are our chief competitors in the industrial world.

The war has brought to the forefront the national necessities to which Sir Norman Lockyer directed attention in his presidential address to the British Association at Southport in 1903, and throughout its existence the British Science Gui'd has persistently endeavoured to stimulate action which would encourage the expansion, and promote the use, of the scientific forces of the Empire. At last both men of science and members of Parliament have awakened to a sense of the importance of these matters; and, as we reported last week, representatives of the Royal Society and the Chemical Society have urged upon the Government the need for intimate interest by the State in scientific research and its relation to manufactures. We congratulate these and other societies upon the support thus given to the efforts of the British Science Guild to organise scientific work in the interests of national welfare.

Political leaders have expressed, from time to time, their sympathetic interest in scientific investigation and their belief in its influence upon industrial development, but until now little attempt has been made to give practical value to their profession. The unanimity with which the scheme put forward by Mr. Pease was supported in the House of Commons shows that all parties are prepared to make adequate provision for scientific work and its organisation in the interests of industry when a definite policy is proposed. We reprint below, from the official report of the debate on May 13 (Parliamentary Debates, vol. lxxi., No. 52) the main parts of speeches referring to the Advisory Council.

Mr. Pease: The war has brought home to us and to our notice that we have been far too dependent for very many processes and many materials upon the foreigner, and we have realised that it is essential, if we are going to maintain our position in the world, to make better use of our scientifically trained workers, that we must increase the number of those workers, and that we must endeavour to secure that industry is closely associated with our scientific workers, and promote a proper system of encouragement of research workers, especially in our universities. The fault in the past, no doubt, has been partly due to the remissness on the part of the Government in failing to create careers for scientific men. It has also, I think, been due partly to the universities, who have not realised how important it is that pure science ought to be utilised with applied science and brought into close contact with manufacturing interests. I think it was also partly due to the fact that the manufacturers themselves under-valued the importance of scie ce in connection with their particular industries. It was partly due, too, to the fact that the ratepayers have been too niggardly in making provision in connection with their technical institutions and colleges.

I ought, perhaps, to give a few illustrations to the House in order to show that by expenditure in the first instance of a comparatively small sum of money, which ought to develop into very substantial sums of money in the future, much can be done by research workers, and by properly scientifically trained individuals in regard to many of those processes for which hitherto we have been dependent upon other countries. We relied upon Germany for hard porcelain tubes used in pyrometers which are required for measuring high temperature. On a supply of these pyrometers depends the manufacture of needles required for the sewing of boots and providing the footgear of our troops. I am glad to say that, owing to the research work that has taken place recently, we are now able to produce as good porcelain as that previously produced for this purpose in Germany, and we are able, therefore, to produce the necessary needles for this purpose. It may astonish the House when I tell them that, whereas four firms in Germany employ 1000 chemists in connection with their dye works, in the whole of our industries there are only 1500 chemists employed. There are in Germany more than 3000 students, even at the present time, so far as I can learn, studying research work in connection with their university life, whilst in this country I do not think we have more than 350 students engaged in such research work. Let me give another illustration of the success which may be secured by research work. Our successes over our enemy in aviation are very largely due to the investigations made into automatic stability by a young man who went through an elementary school, fought his way up to the Imperial College, and went through a course at the National Physical Laboratory, and invented and introduced the B.E. biplane—at any rate, from his investigations the B.E. biplane was developed. We have hitherto done very little to encourage these brilliant young men taking up a scientific career.

The average salary given to a junior teacher of science is, I am told, only about 150*l*. a year. With a meagre salary of that kind it is not to be expected that individuals are going to endeavour to enter a career which is so badly rewarded. Let me give the Committee just one other illustration of what research may do. Lyddite was made at the commencement of the war out of phenol. The price went up at once from 6*d*. to 5*s*., and owing to laboratory experiments conducted by Prof. Green at Leeds he was able to reduce the cost to 1*s*., as lyddite can now be made from benzol. That was entirely attributable to the research work of one man. If those things can successfully be done in times of war, I know how many things can be done in times of peace. I have been associated myself with the production of a large number of by-products from coal, and it was even necessary to go to Germany for the bricks and plant in order to erect a certain oven in this country. I satisfied myself that it is possible that these materials can be produced, and ought to be produced, at home, if only we had a sufficient number of research workers and trained men of science turning to practical value their scientific training.

I could go on and develop this subject. I see opposite a representative from Ireland who asked me a question in regard to technical optics, and there is a great deal of work to be done in this country with reference to that subject. A professor told me the other day that it had only just been found out why they were making so many failures. A greenish hue came into the glass they were producing, and in consequence they were unable to produce the necessary lenses. By research work it was found that this was due to barium oxide being contaminated with iron, and they had to go to another source in order to obtain the glass free from this impurity. And so I might go on and give case after case where by research and a little expenditure on the scientific training of able men we would be able as a country to succeed just in the same way as the Germans have succeeded in recent years. My fear is that after the war we shall have to contend with a fiercer competition than we have had to contend with even in recent years, and it will be conducted by our enemy with less scrupulous methods. The Government agree with me that something ought to be done at once, and we must make more use of the workers in our country and prepare for an increased supply of them, and bring our universities and technical institutions into closer association with industry, and also bring our leaders of industry into closer association with skilled workers. Steps must be taken at once. Adequate supplies require prolonged endeavour. The task immediately before us may be advanced at once by the appointment of an Advisory Council on Industrial Research. I want a Committee of experts who will themselves be able to consult other expert committees working in different directions. They, in turn, must be associated with leaders of industry. We shall want advisers representing various industries in the country who not only possess certain knowledge in connection with pure science, but will be able to turn to the best account the knowledge they have acquired in the application of that knowledge to industry. We shall work in close co-operation with the Board of Trade, who are seconding the efforts of my old board. Such a body as an Advisory Council of very distinguished men upon whom we shall rely for advice, ought to be at work, and I hope it will be at work within the next few weeks. I am now considering the names, although I am not in a position to name them at the moment.

So soon as we get a Committee of that kind nominated they will at once begin their work. The solution of several problems will be placed before them in connection with the glass industry, the making of hard porcelain, technical optics; and it will be one of their duties to secure selected workers who have passed through graduated courses suitable for doing research work in laboratories in the solution of a certain number of definite problems. They will have to advise me as to how money should be immediately spent, and how it should be subsequently spent when we are able to obtain rather larger grants from the Treasury than we shall have at our disposal during the current year. They will have to advise as to the way money should be spent in training and research work generally, and how money should be spent and distributed amongst specialised departments, such as the Imperial College of Science at South Kensington. What I am anxious to secure is the use of the best scientific brains in connection with this enormous problem which is of such vital importance to the country. I hope to place on the Estimates for the current year a sum between 25,000*l.* and 30,000*l.*, but the demand for money for this work will enormously increase as time goes on, and I want to inform the House that whilst we are beginning with this comparatively small sum we think it will develop, and if the scheme is to succeed I believe it must depend upon State help in the years to come, and State help must steadily progress.

As I have been longer in my present post than any of my predecessors, I may be allowed to say that in my judgment two things are essential in the interests of this country if we are to maintain our position and succeed in the future and remain in the proud position, industrially and commercially, in which we are now situated. First, that after the war, and even during the war, an effort should be made to retain longer at school those who are able to benefit by further education. Too many now leave school at the ages of twelve, thirteen, and fourteen, and there is an enormous wastage of ability in the country owing to the non-education of the children after that age. Secondly, the nation should create careers for men who are capable in the scientific world of benefiting that problem. If we had these two things I believe we should maintain our position, and without them I am afraid we shall be discouraged. Therefore, so far as I am able, I wish to appeal to all those men throughout the country who are devoting their lives to the cause of education to do what they can to encourage, not only the longer education of abler children in the secondary schools, but also to make the scheme which I have outlined here this evening very briefly a success in connection with training scientific workers who will be a real advantage to the industries of this country in years to come.

SIR PHILIP MAGNUS: I have no doubt whatever that the scheme for co-ordinating more successfully the science of industry will be welcomed by all scientific men in this country. I should not like it to be thought for one moment that our universities and our technical institutions have failed to turn out a sufficient number of scientifically trained men to be able to carry on research work in connection with our industries almost to the same extent that it has been done in other countries. Where we have to some extent, and to a large extent, failed in this country is in the appreciation of manufacturers and employers of the value and importance of such scientific training, and if the conclusions at which the President has arrived, and if the facts connected with this war will bring home to our manufacturers and employers the great advantage which they can obtain by liberally supporting scientific men in connection with their work, then the Right Hon. gentleman will not have spoken in vain this evening.

There is nothing in which we have been more deficient in this country than in scientific organisation, and, if I may say so, in the organisation of our science, and to this I hope that any such council as he has proposed will diligently apply itself. We have a great number of institutions doing excellent work, but the work of one often overlaps that of another. We want very carefully to see that each institution does that work which it is best fitted to do, and that manufacturers shall have no difficulty whatever in obtaining through any technical or scientific institution the particular class of scientific man which will be helpful in the industry in which they are employed. Take London, for instance. We have already the Imperial College of Science and Technology, on the organisation committee of which I was a member. We have also the Imperial Institute, in which a certain amount of research work is being done of a very high quality in connection with our colleges. We have also, not very far removed, the National Physical Laboratory, where research work is being done, but where more research work might be done if larger funds were available for the purpose. In Berlin there is what is called the Reichsanstalt. That is a research institute which combines the work of our national institute and the National Physical Laboratory, and that institute is placed in close juxtaposition with its Imperial Institute of Science and Technology, which goes by the name of Charlottenburg.

The President of the Board of Education has referred to the fact that it is very difficult to obtain men who will be attracted to the profession of technologists at a salary of 150*l.* a year. I was sorry that he did not remember that the Government itself has advertised for very highly skilled technical chemists at Woolwich at that same salary. I complained of that years ago, but I was told that there was quite a sufficient number of highly skilled chemists only too glad to accept the position at that small sum. I hope that the Government will be the first to take to heart the lesson which the Right Hon. gentleman has given. There is only one other word I want to say at the present time. I heard with great satisfaction that it is proposed in the scheme to which the President referred that the Board of Trade shall be associated with the Board of Education. I attach great importance to that, because we do not want in this work merely theoretical scientific men. We want men who are imbued with the commercial spirit, and it is desirable that in any body who are to direct instruction by giving suggestions you should combine those who have an intimate knowledge of the trade requirements with those who at the same time are developing the scientific instruction itself. Personally, in the thirty-five years during which I have been associated in, it may be, a feeble endeavour to bring science to some extent to bear upon industry, I have always been most careful to see that the commercial requirements of those engaged in the trade are carefully considered by those who have the task of organising the schemes of instruction. I am glad to see that same policy is likely to be carried out by the President of the Board of Education acting in conjunction with the President of the Board of Trade.

SIR JAMES YOXALL: I think that the Right Hon. gentleman even to-night attached more importance to the highly technical education which has been procurable in Germany under the German system of education than was just. The impression I have been able to form after years of study has been that it is probable that during the last twenty or twenty-five years as many capable men of science, highly skilled chemists and physicists, have been produced by the educational system of this country as has been produced in Germany. My impression is that probably in number, and certainly in quality, even our somewhat unorganised and uncoordinated British system has produced quite sufficient men to provide the industries of this country with sufficient guides, leaders, and captains. The fault has been not with them, or with the schools, colleges, and universities, but, no doubt, with the manufacturers and employers of this country, who have been blind to the opportunities which this material has presented to their hands. Even now, when my Right Hon. friend has created his excellent Advisory Committee, and has used his new grant and has developed further this admirable attempt on the part of the Government to provide for what may happen with regard to industry after the war, little will be the result so long as it is rooted in the minds of employers and capitalists that rule of thumb is better than rule of brain. I would suggest to my Right Hon. friend that he might consider, as a development of what he has submitted to-night, the running of this great concern which he has in view on a commercial basis, so that if manufacturers and capitalists will not take up this work, the State itself should take it up, and provide and sell to the manufacturers the results of researches which otherwise they would not obtain.

MR. ANDERSON: Perhaps the most important matter raised by the President to-night was that of establishing an Advisory Council to deal with matters relating to science and industry, and to bring science into closer touch with industry. That is a very important statement. Personally, I believe that it is along these progressive lines, and not by adopting reactionary policies, that the nation is going to hold its own in regard to industry and trade. We have not in the past spent anything like the amount of money we should have spent in regard to scientific research and technical training. We ought to equip ourselves to the fullest extent along these lines, and it is by doing so rather than by adopting backward policies that we are going to make headway in the future. You ought to try to bring science and industry into closer touch with each other and to make science the great servant of industry, to make it a more practical matter rather than merely be taken up with abstract questions, and you ought to avail yourselves to the fullest extent of the practical knowledge and experience of the working people who are now employed in the factories, in the mills, in the workshops, and so on, and I believe in regard to that, that your Advisory Committee ought to have representatives of labour so as to show that you are going to bring the practical knowledge and experience of the workpeople into account in this matter, and I believe it will be important from the point of view of the success and welfare of your scheme.

MR. LYNCH: Whatever we think of the material aspects of Germany, we really have in her history one of the most extraordinary examples in the whole history of the world of a nation gradually rising to great material power on a foundation of high scientific education. The rise of Germany does not date, as some have said, merely from the great victories in 1870, but from a much earlier epoch when a German with a less salary than the then President of the Board of Education held that office for only two years, and yet within those two years left such a stamp on the education of Germany that it has remained ever since, and has been the real source of the education of the nation—Wilhelm von Humboldt.

Let us consider now one of the questions referred to by the President of the Board of Education to-night, technical education. When we speak of technical education in this country we are too apt to think of trifling details, such as wood carving and filigree work, or such as crewel-work or crocheting impossible parrots on the background of some fancy cloth. In Germany technical education has a very different and a much higher meaning, and having had the advantage of studying in the University of Berlin myself, I can say that one of the most abiding impressions of my whole life was the extraordinary revelation I had there, not merely of the devotion to science itself, but of the manner in which that widened out the whole horizon and prospect of the nation's view, and the way in which science was seen to be the vital influence in great enterprises and wonderful industries. I would not labour this question to-night, but those who have leisure might refer to an article by Sir William Ramsay, first published in NATURE in November, 1914, but to which my attention was called in the French paper *La Revue Scientifique*. The French recognise the value of that article, and in France I think it got wider publicity than in this country. Sir William Ramsay analyses the causes of the greatness of Germany in the industrial world, and he finds several very interesting points which he tabulates. The first is that in a great German industry the board of directors are not a set of ornamental magnates with a peer thrown in to give respectability or publicity, but are a board of specialists on that subject which is the basis of the industry, keen and hard-working men. Secondly, that there is another agency definitely appointed with the definite active functions to watch out for new inventions in other countries. I could enter into this question very deeply, and I could show that right throughout the range of industry there are cases where the real central idea of that industry has not originated in Germany, but in France, England, or America. I believe if I were to ask which is the nation most fertile in ideas and most inventive, from my own brief experience I would be inclined to place the French in inventive genius above even the Americans. The Germans are always looking out and asking the question, "In what way can we utilise new inventions for the benefit of our own industry?" That forms No. 2 of the points of Sir William Ramsay.

The third is that there is another agency always asking the question as to the cheaper production of the material, not in a passive way, but in an active way; in making inquiries and making voyages to other countries, examining what is done there and exploiting the brains of other men, often covering up the source. That is what the Germans call war. Then comes in the question of protection by the Government. There is a point where the Government could actively intervene to foster industry. Another point not less important is the protection of patents. In many cases Germans have gone so far as to steal the patent from other countries and protect themselves by patents from the other country recovering its ideas. Then there is the propaganda of the excellence of their own products, sending men throughout the world, speaking many languages, active missionaries of the active progress and greatness of Germany. I will cite several industries. The German spirit of organisation is so great that in the most unexpected fields it is exhibited. I remember one of the most prominent mathematicians, M. Picard, of the Institute, who said that though perhaps there had been great names in the history of French mathematics equal to those of the Germans, such as M. Poincaré, who I am proud to have called my friend, who recently died; yet the Germans had pushed their organisation so far that even in that field, so abstruse, they had perfected an organisation for that study.

Take the question of aniline dyes, of which we have heard so much, and which has been the subject of consideration in this House. It is always said in this House, and in the public prints and text-books, that the story of aniline dyes is that a British chemist, Dr. Perkin, discovered and invented a new dye, and that was stolen by the Germans. The matter does not rest in such a passive way at all. Perkin was not, I believe, the first man to produce coloured material from the by-products of coal tar. That was done by Runge some years before. In 1856 Perkin produced his first aniline dye, mauve, and that was considered a great achievement in this country. Already the Germans were beginning that extraordinary organisation of which they are the masters. They seized hold of this, saw its possibilities, and set to work in all the laboratories of that great kingdom, particularly Prussia, and soon produced a whole succession of aniline dyes. They opened up new possibilities, and in this way founded their industry in a perfectly legitimate manner. So that the lack in this country was first a want of appreciation of the value of that discovery, and then the want of active organisation to make use of the discovery when found.

Or take, again, the case of glass, also raised by the President of the Board of Education. The manufacture of glass, of course, has gone on from time immemorial. As a matter of fact, one of the oldest glass manufactories in the world was in what at that time was a Roman colony, Cologne. The most interesting development of the glass industry, however, was, perhaps, the manufacture of optical glass. It arose in this way: A German physicist of great ability, Abbe, noticed that a great deal of the finest microscopical work was robbed of its value by the difficulty of obtaining good optical glass, and so he turned directly away from his own study, sacrificed himself in a certain measure—that is to say, sacrificed his scientific ambitions—upon the altar of the industry of the Fatherland, and devoted his great talents to the study of glass in itself. Being a man of scientific endowment, he speedily discovered what those who had been engaged in the industry before without scientific knowledge might not have discovered in a hundred years in reference to the manufacture of glass. Then came another point which has been raised earlier in the debate. After having reached a certain point, he found that it would be difficult for him to proceed without being sustained financially. He then appealed to the State. The German State was intelligent enough to foster his researches in every possible way, to pay him not merely for his chemical research, but for his endeavour to build up a great industry. So there you have a striking example of the alliance of science with industry, and of State aid supporting both, one which we might very well take to heart. The result was the building up of an industry which imposed itself upon the whole world, and is one of the legitimate glories of Germany to-day. Every medical student who wishes to do his work well is forced to buy a German microscope.

Compare that with the condition of things in this country. I have come down to this House myself in those days when I was more hopeful and I had a real respect for the Government, and I have pleaded for 10,000*l*. for great research work, research work which would have enabled one of the very few men in this country who stand out in the eyes of the whole world as a great figure in modern science, to do most useful work, and I was received with a certain polite indifference and shunted off. I say that, so far from asking 10,000*l*. for research work, I should have been entitled to ask for 10,000,000*l*.—that is to say, if I could ask with sufficient authority—to stimulate in every possible direction the great industries of this country. I go so far as to say that eventually the whole civilisation of this world, and not merely of England itself, must turn on the axis of science, and as we advance we must give proportionately greater and greater importance to this great development of scientific life. When I was a student some years ago of some of these questions, of which I have only given one or two examples out of hundreds which I could expound to the House, I made this extraordinary discovery, that in tracing out the development of science I was really in my own mind proceeding with the development of Humboldt's cosmos. That is to say, that science is the roof of civilisation, and our civilisation is superior to that of the Greeks only in one particular, and that one particular is the advance in positive science. As a result of the advance of positive science our modern civilisation has reached that great expansion which we now recognise.

Then the President spoke about the number of chemists in this country, and said that the number of research students in chemistry is only 350, and yet this country is competing in the commercial world with Germany! I have looked into the organisation in Germany, and I find this astonishing fact: That, in the great chemical works in Germany, for every fifteen men employed in any category whatever there is one highly trained specialist and chemist, and that this industry is so important that there is one highly trained specialist in chemistry for every forty-five employés in any category, right throughout the whole range of industry. When we reach facts like these, are we astonished at the pacific invasion of Germany in every country in the world which, had they been sage enough, would in fifty years have given them a mastery of the world without the cruel and brutal and abominable war which has caused such suffering? But knowing the enormous disparity between one trained chemist for every forty-five employés in all industries, and a total of 350 research students in this country, how are these defects to be remedied? Partly by giving encouragement to students of science. That is important, but it is not all. I asked a question in this House about the pay of students of chemistry. I find that the War Office itself, which is advertising for students of chemistry, some of them men with degrees, all of them required to do analytical work of a really very difficult kind, such as, after a man obtains his degree in chemistry, would require some special training for at least six months to do the work with the requisite degree of fineness, offered to these men a salary of—1000*l.*? There would be nothing preposterous in that. Some of these men are quite qualified to become professors in the great capitals in the Dominions. Was it 500*l.*? It was 100*l.* With what conditions attached? Those men technically were placed on the same footing as ordinary workmen, and they could have been required, had the regulation been enforced, to join in a queue every Saturday to take their 2*l.* at the pay office.

To-day an advance has been notified by the Under-Secretary for War. They are paid 150*l.* Even that is scarcely enough to stimulate men to follow in the path of scientific research. I do not believe that any man who has the true scientific spirit—I appeal to my hon. friend to back me up there—is ever attracted by the mere sake of gain. There is something of the scientific spirit which is almost incompatible with making money. When I read the lives of the great workers of the past I feel indignation even now. Take, for instance, the record of Faraday. The great man, who stands out among the few whose names will be remembered for a thousand years, even after the records of our own Parliament have passed away, as one of the great pioneers of human civilisation; toiled all his life at the stipend of the valet of a peer, and that, remember, in a country where a man's social status and his work, as he calls it, is judged very largely from the amount of salary that he earns.

There will be a revolution when the war is over; a peaceful revolution, if you will, which will be felt right throughout the world, enlarging our education particularly in regard to our technical schools. We do not want the history of the world in text-books given to children at their most susceptible age, which divide history into reigns of kings and queens, most of them utterly worthless, as if the whole philosophy of the world turned on the sanguinary and wretched and often unintelligible accounts of wars and battles. I hope the time will come when we shall have a clearer and saner view of the whole scope and importance of education. It will be more important for the child to know the date at which Oersted discovered the reaction between electricity and magnetism than even to know the date of the battle of Waterloo. There is in science a real spiritual influence—that it to say, the most alluring and fascinating of all the problems which can attract the mind in the gradual unfolding of the meaning of this world itself in which we live. I would like the President of the Board of Education to take his courage in his hands as did Wilhelm von Humboldt in other days; and if he feels himself not strong enough to do this work solus, let him call in the aid of those enthusiastic in the development of science, and the help of those committees of which he has spoken, to carry out their recommendations, not in the half-hearted way in which matters have sometimes been presented in this House, but with something like the missionary zeal of a new evangel. I am certain that when this war is over if the education of this country remains in the condition in which it now is, you may bolster up your military power, you may build *Dreadnought* after *Dreadnought,* but this country will sink. But if this country is to save itself, to regenerate itself, and to proceed on a new path of high development, then the most vital of all problems is that of education.

MR. KING: On this Vote we have had a chorus of approval in favour of greatly increased expenditure on scientific education. I wish to join in that chorus. You cannot have a nation able to benefit by the scientific research and technical instruction and the various facilities for scientific advance which have been foreshadowed to-night unless you have a good foundation in elementary education. If you begin on the same night to cut and curtail elementary education, you are doing an evil turn to advanced research in scientific education. I wish very heartily to congratulate the representatives of the Board of Education upon having shown what is to my mind the first evidence we have had that statesmanlike foresight exists on the Treasury Bench at the present time. We have had plenty of energetic pushing on of the war, but in grasping the issues of what are to come after, and to prepare for the inevitable changes and difficulties and problems which will immediately arise at the end of the war, this is the first inkling we have had that those considerations are present to the mind of the Government. I congratulate the President of the Board of Education and the Parliamentary Secretary to the Board of Education on the scheme they have put forward. I from time to time directed attention, by means of questions and in other ways, to our great deficiency in scientific and technical education, especially with regard to research. Anybody who knows anything about Germany knows the enormous amount of money and the great numbers of men of the highest ability and training and standing engaged in purely scientific research and inquiry.

Everybody who thinks of it and who studies the question must know that Germany's position in the world to-day is due not to the real genius of the people so much as to organisation combined with education, and especially scientific education. I am very pleased that at this time there is an opportunity for an educational advance. I congratulate the members on the Treasury Bench upon their courage and persistence, for I believe it must have needed something of that kind to get this scheme through the Cabinet. I congratulate them on the prospect of having an early Supplementary Estimate. It is true it is only 25,000*l.* I think it ought to be ten times as much, but I have no doubt it is an estimate that will grow. I should like to recall to the members of the Committee the historical references, to my mind of great significance, which we had from the hon. member for West Clare (Mr. Lynch). It was in the year 1809, only two years after the Peace of Tilsit, that Prussia started the University of Berlin. Prussia had been robbed of half its territory by the Peace of Tilsit, which also imposed upon it an enormous indemnity. It had also to support a huge French army of occupation until the indemnity was paid. Yet in that very time Stein and Wilhelm von Humboldt founded the University of Berlin, which has become for its equipment and influence in scientific matters by far the greatest University in the world. They also established at the same time, when the taxes were simply overwhelmingly crushing, the elementary-school system of Prussia, which remains to the present day. I say that a nation that could so appreciate in its hour of ruin the value of education is a lesson to us which we ought to take to heart.

MR. RAWLINSON: I was very glad to hear the President's announcement of the creation of an Advisory Council to deal with this matter, and I need scarcely say that though I have not been able to consult them upon the point, the University of Cambridge, I am sure, will give most unstinted support to the scheme, such as it is. Whether it will be a success or not will depend upon matters which we cannot discuss to-night. It will depend largely upon the men and upon the methods by which the work is carried out. No one doubts that there is a need for it at the present time. The Right Hon. gentleman has enumerated some of the things in connection with which we have discovered the need, and he could have made a much longer list—things which are vitally important for the carrying on of the war. This country has had brought home to it the recklessness of any island country being dependent for its supplies to a large extent upon places outside its bounds. That is one of the lessons we shall learn from the war. It must be remembered that scientific men have been connected with agriculture and industry in this country before. They were connected with it in the best possible way; they were present while the work was being done. But in one case after the other the Germans bought up those firms and practically carried the industries away to Germany. We must not have that occur again. It is not merely a question of scientific research; it is much more a question of policy. So far as the scientific side is concerned, I think that even the President of the Board of Education was scarcely sufficiently optimistic when speaking of the enormous supply of men in the universities who are perfectly qualified and ready to take part in the industrial side of science. A large number are already doing so, and a very much larger number are perfectly ready and willing to take part and assist in the science of industries of any kind.

DR. ADDISON: There are many things which we must attend to without any delay, and it is for this reason that the Committee for Research will be set up quite soon. A great deal has been done by private effort in respect of research, and notwithstanding all that my hon. friend the Member for West Clare (Mr. Lynch) has pointed out, quite properly, in this connection, I think that the research which has been associated with British men of science has often been the most original of any in the whole world. We have not organised and developed it as we ought to have, but the British researcher is often freer in his outlook and greater in his conceptions, I think, than almost any other. At all events, he certainly stands far above the average German researcher, who tends more to apply the ideas which have been suggested by others, but from all that my hon. friend pointed out we have got to recognise that we cannot afford nowadays to leave all this to private effort. A great deal can be done by careful organisation and by seeing that the men turned out from our universities and technological institutions are equipped with that training which will make them acceptable in industry, and make them more likely to find a good market and a good career for themselves. Going around our institutions you will find certain departments where the professors will tell you that they cannot supply the men quickly enough to the manufacturers, while in other departments it is quite the reverse. The Royal Society has lately, very patriotically, been assisting chemical research in respect of drugs. This was one of the matters in which we felt ourselves behindhand at the beginning of the war. However, I think that my Right Hon. friend may be satisfied with the full assent of the House in all quarters in getting ahead with this great scheme, which, while we hear so much of the mobilisation of our industries with respect to the production of munitions of war, will quickly, for the first time in this country, show that we are going to some extent, at all events, to create a machine which will enable us to mobilise brains and science in the service of industry and national progress.

NOTES.

THE annual visitation of the Royal Observatory at Greenwich will be held on Saturday, June 5.

SIR WILLIAM CROOKES and Prof. R. Meldola have been elected honorary members of the Society of Public Analysts.

WE learn with regret of the death, on May 8, of Dr. P. Zeeman, since 1902 professor of geometry and theoretical mechanics in the University of Leyden.

PROFS. MAURICE CAULLERY (Paris), Charles Henri Marie Flahault (Montpellier), and Jacques Loeb (Chicago) have been elected foreign members of the Linnean Society.

THE London County Council has decided to commemorate the residence of Lord Lister in London by placing a memorial tablet on the house, 12 Park Crescent, Marylebone Road.

WE regret to announce the death on May 13, in his eighty-ninth year, of Dr. M. W. Crofton, F.R.S., formerly professor of mathematics at Queen's College, Galway, and also, later, professor of mathematics and mechanics at the Royal Military Academy, Woolwich.

SIR DAVID BRUCE will this year deliver the Croonian lectures at the Royal College of Physicians of London on June 17, 22, 24, and 29. His subject will be "Trypanosomes causing Disease in Man and Domestic Animals in Central Africa."

AT the annual meeting of the Iron and Steel Institute last week, the Bessemer gold medal of the institute for 1915 was, in the unavoidable absence of the French Ambassador, handed to M. de Fleuriau, councillor of the French Embassy, for transmission to M. Pierre Martin, for his invention of the open-hearth system of steel manufacture.

THE regents of the American College of Surgeons announce the appointment of Dr. J. G. Bowman as director of the college. The college was founded in 1913, and is an organisation of the surgeons of the United States and of Canada, having for its purpose the advancement of the art and science of surgery. The address of the executive offices is 30 North Michigan Avenue, Chicago.

THE trustees of Columbia University, in the city of New York, have awarded the Barnard gold medal to Prof. W. H. Bragg, Cavendish professor of physics in the University of Leeds, and his son, Mr. W. L. Bragg, fellow of Trinity College, Cambridge, and a member of the college staff, at present holding a commission in the Leicestershire R.H.A. (T.F.), for their work on X-rays and crystals. The medal is awarded every five years for "meritorious service to science," on the recommendation of the National Academy of Sciences of the United States. The previous recipients have been Lord Rayleigh and Sir William Ramsay, Prof. von Röntgen, Prof. Henri Becquerel, and Sir Ernest Rutherford.

A PARTIALLY restored skeleton of a small ancestral camel, *Stenomylus hitchcocki,* from the Lower Miocene of Nebraska, U.S.A., has just been added to the exhibited collection in the geological department of the British Museum (Natural History). The specimen was obtained from Prof. F. B. Loomis, of Amherst College, Mass., who discovered the remains of a herd of these small animals which had been suddenly destroyed and buried by some local accident. As a camel, Stenomylus is remarkable for its extremely slender build, which would render it as agile as a gazelle. It also has molar teeth with unusually deep crowns, so that it would be able to feed on hard and dry grasses. It was therefore more completely adapted for life on open plains and uplands than the other camels which abounded in North America in Oligocene and Miocene times.

THE death is announced in *Science* of Mr. E. W. Morse, formerly instructor in natural history at the Bussey Institution of Harvard University, whose name is associated with his contributions to the history of domesticated animals. Mr. Morse more recently acted as a specialist in animal husbandry in the U.S. Department of Agriculture. In addition to his official duties as an associate editor of the *Experiment Station Record*, and later as an expert in the U.S. Dairy Division, Mr. Morse was instrumental in putting the foundations of animal breeding and feeding on firmer bases. He was an active member of the Biological Society of Washington, the American Society of Animal Nutrition, and the Boston Society of Natural History, and a regular contributor to several standard year-books and encyclopædias.

THE issue of *Science* for May 7 announces the completion of the rebuilding of the Gray Herbarium in connection with Harvard University. The work of enlargement and rebuilding was begun in 1909, and has been carried out a section at a time as the generosity of many benefactors made extension possible. The herbarium dates from 1864, when the late Mr. Nathaniel Thayer gave a building to house the botanical collections which Asa Gray had presented to the University. The primary ideals followed in rebuilding have been those of safety, permanence, and convenience of arrangement, but the elevation of the new structure gives the impression of dignified simplicity and great solidity. During the whole period of reconstruction the herbarium and its library have been open as usual for consultation.

ENGINEERS in many parts of the world will notice with regret that the name of Dr. Fred Stark Pearson appears in the list of those lost in the *Lusitania*. We are indebted to the *Engineer* for May 14 for the following particulars of Dr. Pearson's career. He was widely known on account of the construction of many notable reservoirs for water supply in sub-tropical countries, his first great work of the kind being undertaken in the Republic of Mexico. He became a director of the Puebla Tramway, Light and Power Company, owning five different properties in the Republic of Mexico, and from his long and intimate association with these enterprises he became acquainted with other industrial openings in Latin-America. Gradually he took up interests in concessions, and lent his great talents to the development of many similar enterprises in Mexico, Argentina, Brazil, Paraguay, and Texas. Perhaps Dr. Pearson's most notable enterprise was in connection with the design for, and the construction of, the great hydro-electric station at Necaxa, Mexico, and the construction of a transmission line to a distributing station erected at the city of Mexico, situated some ninety-five miles distant. The success achieved by Dr. Pearson in connection with these Mexican enterprises led to his association with similar projects in different parts of the world, and to his becoming what he at first never intended to be—a company promoter and professional director. In addition to his membership of the American institutions, he was a member of the Institution of Civil Engineers.

By the death of Lieutenant Thomas Wright, who was killed while reconnoitring at night on Sunday, May 2, the staff of the faculty of science at King's College, London, has lost one of its most promising younger men. Mr. Wright studied chemistry under Prof. J. M. Thomson and Prof. Herbert Jackson from 1908 to 1912, completing his course with the associateship of the Institute of Chemistry and first-class honours at the B.Sc. examination. Soon after graduation he was appointed demonstrator in chemistry, and during his short tenure of this post he displayed the greatest energy in teaching science students of all faculties and many races. He came of yeoman stock, and his practical and intimate knowledge of agriculture added to the value of his chemical studies, and although he was not spared to complete any original research, he had already given proofs of an ability, power of observation, and keen insight which would have been of great value at the present time, when the nation so sorely needs numbers of such young men of science. In 1914 Mr. Wright gained an Anglo-German scholarship on the Cassel Foundation, the only one awarded outside Oxford or Cambridge. He was to have proceeded to Germany for further study and research, but the outbreak of war found him under arms as a trooper in King Edward's Horse. He received a commission in the Berkshire Regiment in December, 1914, and was sent out to France in the early spring. As an officer he displayed the same ability, zeal, and initiative which had characterised his all too brief career at King's College. His death means a serious actual loss to his college and potentially to science also, while all who knew him mourn that such a promising life should have passed into silence.

IN *Man* for May, Mr. K. A. C. Cresswell supplements from another field the very interesting paper by Prof. J. L. Myres on the causes of rise and fall in the population of the ancient world (*Eugenics Review*, vol. vii., p. 15), which was practically confined to one field, the Mediterranean. He now extends the survey to Mesopotamia, Persia, and Central Asia. He dwells on the importance of irrigation in the agriculture of these regions, and on the fact that there is historical evidence to show that ages of warfare caused the decay of the canal and karez systems of water supply. He is therefore led to the conclusion that the chief cause of the great fluctuations of the population in these regions has been the collapse of the irrigation system, and that but for this neither war nor misgovernment would have sufficed to bring it about, although Ellsworth Huntington has shown that general desiccation has been a factor. Increase of conserved rainfall follows extension of irrigation, and it is suggested that, the chlorophyll reaction being endothermic, there must be a perceptible lowering of the temperature over large tracts of cultivation. If this is the case, it may possibly have an appreciable effect on condensation.

MESSRS. C. G. SELIGMANN and F. G. Parsons describe, in the Journal of the Royal Anthropological Institute for July–December, 1914, a skeleton found in 1903 at Gough's Cave, Cheddar. It is that of a young adult male whose stature was about 5 ft. 4½ in. It was found in association with implements of the late Palæolithic or Magdalenian period. The cranium shows a fairly close resemblance to that of the River Bed type from whom, in the present state of knowledge, the writers believe the Neolithic people to be descended. There are marked contrasts between the Cheddar skull and two of the Aurignacian age with which the writers are familiar, and though the face and the cranium, except that the latter is long, differ rather markedly from those of the Saxons, the cranium alone could not be distinguished from that of a medieval Englishman. The face and orbits are, however, very different. The conclusion arrived at is that the similarity of the Cheddar and English medieval skulls is not so much a sign of racial affinity, as an indication that among the latter a cranium closely resembling that of the River Bed type had been produced incidentally by numerous crosses.

THE Royal Zoological Society of Dublin is to be congratulated, inasmuch as it possesses the only living gorilla in Europe. But, according to the *Irish Naturalist* for May, their captive has been suffering from a tumour on the right side of the neck and face. A microscopic examination of the pus obtained therefrom showed that the growth was due to actinomycosis. This much having been discovered, it became possible to determine on a suitable course of treatment, which we are glad to note gives promise of success. Having regard to the rarity of gorillas in captivity, and the importance of the results of a study of their habits, it is devoutly to be hoped that a complete cure will be effected.

EXPERIMENTS in acclimatisation should never be undertaken save when they promise to yield some definite and worthy end. But what appears to be a quite harmless venture has been made on Lambay Island, Co. Dublin, where, according to the *Irish Naturalist* for May, more than two thousand reptiles and amphibians have been turned out. For economic reasons Dr. Scharff, the director of the Dublin Museum, now suggests an addition to this number in the diamond-backed terrapin (*Malacoclemmys terrapin*). This species he considers might do well in the harbour, since it lives in North America in salt marshes, feeding on molluscs and crabs. In this event a lucrative "fishery" might in course of time be established, since in America terrapin stew—and champagne sauce—is held in high regard.

Two very interesting articles bearing on the problems of sexual selection will be found in the May number of *Wild Life*. The first, which is all too short, is by Mr. H. B. Macpherson, who describes the "tournament" of the blackcock, illustrating his remarks by some admirable photographs. The second is from the pen of Mr. Edmund Selous, and describes the early breeding habits of the shag. Anything Mr. Selous writes about the courtship of birds is sure to be interesting, and this account of the shag is no exception to the rule. His notes seem to show that, as with the Phalaropes, and some other species, the sexual *rôle* is reversed in the matter of courtship, the advances being made by the female. This being so, the assurance that polyandry prevails with this species is not surprising, though the evidence produced to favour this view is by no means convincing.

THE characteristics of molybdenite are discussed in a short but interesting article in the *Scientific Australian* for March. Since the outbreak of the war the price of this mineral has advanced from 60*l*. to 725*l*. per ton. Happily for us, more than half of the molybdenite ore of the world is obtained in Australia. Though principally used for hardening steel—armour plate containing about 20 per cent. of molybdenite—it is also used for the preservation of certain explosives and as a substitute for tungsten, while the salts of molybdenum furnish a blue pigment used in colouring porcelain and in the dyeing of silk and woollen goods. The normal method of washing the ore proving very wasteful, the experiment of oil flotation is being tried, and promises to effect a great saving. Experiments by the United States Bureau of Mines in smelting molybdenite ores electrically are also being made, and these have shown that ferro-molybdenum, low in carbon, can be made directly from molybdenite in the electric furnace, with excess of lime as a desulphurising agent, and that the sulphur can be readily slagged off as calcium sulphide.

THE appalling rate at which the extermination of the native fauna of Australia is proceeding is tersely told by Mr. W. H. Le Souef in the *Scientific Australian* for March. The ravages of foxes and feral cats, introduced by settlers, is answerable for much of the mischief that has been done. The fox, he remarks, "will in course of time overrun the whole of Australia—it is half over already—and in consequence all ground game . . . will suffer severely." The loss to Australia cannot well be computed in cash, as, besides native game, the fox destroys young lambs, turkeys, geese, ducks, and other domestic poultry. The introduction of the rabbit has proved no less disastrous. The realisation that these agents of destruction need never have been introduced makes the consequences the more deplorable. The inevitable removal of timber and scrub, the drainage of swamps, and the erection of miles of wire fences have proved even more speedy and complete factors of elimination. Wire fences alone have accounted for the deaths of thousands of emus and kangaroos, which are now prevented from making their customary migrations in search of water, and consequently die maddened with thirst. Mr. Le Souef pleads for an increase in the number of sanctuaries, and we trust his appeal will not fall on deaf ears.
