ORIGINAL LECTURES.

ON GENERAL AND LOCAL CHEMICAL DISORDERS ARISING FROM PEROXIDATION,

AND ON THE MECHANICAL DERANGEMENTS THEY PRODUCE.

By H. BENCE JONES, M.D., F.R.S.

Part III.—Lecture IX.

On Bright's Disease.

The ordinary oxidation which takes place in each texture of the body gives heat and motion sufficient to carry on the ordinary nutrition of the structure: but the smallest increase of oxidation set up by direct extra-vascular or indirect intra-vascular motion through the nerves is followed by altered heat, motion, and nutrition.

The effect of slow, but continued peroxidation may be watched in the skin or in the eye continually; and within the body mechanical alterations show no less clearly what such increased chemical changes can effect. The slightest long-continued mechanical pressure produces not only thickened cuticle, but altered nutrition of the skin itself; or a slight cut may cause a thickening which may last for months or years after the slight inflammation which united the surfaces has passed away. So in the cornea the most chronic inflammation from some slight mechanical cause will leave a thickening which may be perceptible for years. Or if you look within, you may see the most chronic gout, rheumatism, or scrofulous inflammation, when long continued, slowly cause such an amount of thickening in the joints and other parts that the utmost mechanical impediment to motion may ultimately result.

Of all textures the cellular texture is the one in which substances pass most immediately from and to the blood, and in which alterations of oxidation and nutrition are most liable to occur.

In the kidney this cellular tissue constitutes the interstitial structure and the capsule. It is much less developed than in other organs, and it is so related to the vessels and tubes that altered action can hardly be limited to this structure alone.

Still, for clearness, I shall treat of its thickening and cell growth under the head of interstitial nephritis. Dr. Dickinson includes this inflammation in his parenchymatous nephritis; but Virchow has defined parenchyma as "the proper structure" of the kidney, including the tubes, with their epithelium and capillary system; so that, though I shall use Dr. Dickinson's observations, I shall not adopt his nomenclature. In the *Med.-Chir. Trans.*, vol. 43, p. 235, Dr. Dickinson says:—"It is common to meet with kidneys as to which there is a doubt whether they are healthy or not. The capsule is a little thickened, and it is more adherent than it should be. When removed the surface presents a confused, muddy appearance; and it may be noticed that a thin layer of capsule is adhering to the kidney. As yet there is no distinct granulation, though the tendency may be indicated by one or two curved depressions, or by a little general roughness. On examining such a kidney in section, we shall find all the central parts quite healthy, save that closely attached to the inner capsular film; we shall see certain narrow projections insinuating themselves between the tubes. If we observe the position of an external depression or cicatrix, we shall find that from this passes inwards a process of fibrous-looking material, which is seen to involve in its interior the contracted remains of tubes it had embedded in its passage. It looks as if an effusion, small in amount, had commenced in the surface and worked its way inwards among the ducts, numbers of them thus becoming completely surrounded. After a time contraction follows in the wake of the exudation, and the tubes imbedded are reduced to mere microscopic threads. At the same time another result of the contractile tendency appears. The points at which the processes originate become depressed, and when these are numerous and tolerably regularly distributed the result is superficial granulation."

A slight increase of the ordinary oxidation in the cellular tissue leads to increased flow of blood, to increased production of cells and fibrillæ, and when the chemical action is considerable to suppuration. After a time the increased pressure from the effusion and thickening causes diminished supply of blood, and hence imperfect nutrition and oxidation, contraction, and even fatty deposit are seen in the interstitial texture, and ultimately the nutrition and secretion of the kidneys is visibly affected. The kidney becomes smaller than natural, the capsule very adherent, the surface rough and uneven, the stellated veins distinct, the substance hard; frequently the capsules of the malpighian tufts and the basement membrane of the tubes ultimately are involved in the thickening. Interstitial nephritis and cirrhosis of the liver are similar diseases affecting similar structures. In both the mechanical pressure that is produced stops the chemical function and the nutrition of the organ in which it occurs.

Causes of Interstitial Nephritis.

Every substance that enters the stomach passes into the blood and surrounding textures according to its diffusibility. It is carried by the blood everywhere, and again, according to its diffusibility, it passes into every structure of every organ and into every surface by which it can be thrown out.

In its passage in, during its stay, and in its passage out, it acts according to its chemical affinities for the gases, liquids, and solids with which it comes in contact, and the effects produced vary according to the chemical actions that take place.

If the ordinary substances that daily go in are represented by oxygen, water, salt, bread, meat, and stimulants, none of these except the oxygen have the degree of chemical action which so-called stimulants possess. Setting aside tea and coffee, our stimulants are essentially alcohol; and it is the long-continued strong chemical action of this substance on oxygen and on the different textures at the temperature of ninety-eight degrees, that gives rise to that increased motion and increased thickening, followed by contraction and sub-oxidation, which constitutes cirrhosis of the liver and kidney.

Let me for a moment follow a dose of alcohol through the system. It passes through the stomach, and in going through is to a small extent oxidised. The greater part escapes, and enters the circulation, acting there on the oxygen, fibrin, albumen, and blood globules to a small degree. In a few minutes a part passes, still being oxidised, into every secretion, as, for example, into the lungs, kidneys, liver; whilst another part passes into every other texture; and on each substance in each texture the alcohol produces its chemical action, still continually undergoing oxidation, so that in a few hours one part has entirely escaped, and another part has been entirely oxidised in the blood and textures. What has the alcohol during this time done? It has acted chemically on oxygen and on the textures with which it has been in contact. The first action has little to do with the strength of the alcohol. Weak or strong, it combines with oxygen; increased oxidation, increased circulation, increased secretion, increased effusion of lymph, altered nutrition result. The second action depends on the strength of the alcohol. Strong alcohol acts chemically on albumen, fibrin, cellular tissue, etc. It has a powerful attraction for water, and it shrivels up cellular tissue, hardens fibrin, and precipitates albumen by its chemical properties.

To no organs of the body is more alcohol taken than to the kidneys and liver, and in no organs are the mechanical results of its chemical actions more manifest and the consequences of the altered structure more apparent; and the increased oxidation, the increased flow of blood, the altered nutrition are identical in kind with the first actions of inflammation; and when the series of actions are repeated over and over again for years, the result is the same as might have been produced in a shorter time by an ordinary inflammation when no alcohol whatever had been taken.

Dr. Christison states that three-fourths of all the cases of Bright's disease which he saw were produced by the habitual long-continued abuse of drink. Very great occasional excess did not act so strongly as long-continued smaller excess.

No doubt the alcohol acts on the vessels and ducts; but not so powerfully as on the interstitial texture, with which we are at present occupied.

On the Symptoms and Consequences of Interstitial Nephritis.

If the disease could be limited to the interstitial texture, and to that alone, it is possible that no appearance of albumen in the urine might occur. No fibrinous casts might be seen. The kidney might gradually, by its contraction, cease to secrete urinous matter, and uræmia would be the final result. But the affection spreads to the vessels and tubes, and then the pressure in the tufts is altered and albumen is effused, the production of epithelium is increased, and some fibrinous casts appear in the urine.

Usually the specific weight of the urine becomes less and less, and generally this weight may be taken to be directly proportional to the amount of cortical structure that exists;

so that when the specific weight of the urine is least the cortical structure is least also. Even when hardly any cortical structure is left, an excess of water of the lowest specific gravity may be thrown out, most probably from increased circulation in the mammary part of the kidney.

As long as this excessive flow continues no dropsy occurs, and hence throughout the whole course of the disease no dropsy may occur. The altered blood and the altered lymph may give rise to all kinds of hæmorrhages, thickenings, and effusions, and chemical actions on the nerves and muscles, which may be summed up in the word poisoning, and which I have already brought before you when speaking of uræmia.

At any period during the progress of the disease more acute inflammation may suddenly come on, and in the cellular tissue, more readily even than in the tubes, pus-cells are readily formed, suppuration extends throughout the altered cortical structure, and rapidly that assemblage of low feverish general symptoms which now appears to us to be so inaccurately designated as a typhoid state, is produced.

With regard to treatment, medicine avails little for stopping the effect of alcoholic poison or for removing the thickening of the interstitial structure. No appreciable alteration of structure occurs until the alcohol has acted for months; but as each day produces its infinitesimal effect some good may be done by recognising the disease early and by stopping as far as possible the further action of the poison. Usually the second nature cannot be changed, and the treatment consists then only in alleviating symptoms and in warding off complications as they arise.

Of all the symptoms that of general debility is the one which will most frequently present itself to you, and of all the complications uræmia is the one which is most serious.

The loss of general mechanical power consequent on wrong chemistry of the blood and lymph begins from the very commencement of the disease, and lasts until its final close.

One of the first effects in the blood is the insufficient production of blood globules, on which the passage of oxygen into the blood depends. The gradual diminution of albumen in the blood is a very much more remote cause of symptoms, and as long as food can be taken this admits of an easy remedy; whilst the reproduction of blood globules requires a far more complex chemistry, and necessitates an increased supply of iron for the formation of hematosine.

The accumulation of descending substances in the blood, and still more in the lymph which surrounds and permeates each particle of every structure, must begin from the moment that the kidney begins to perform the function of oxidation and excretion imperfectly. Still it is evident from the experiments in which one kidney is removed and no poisoning occurs that even half the structure may be destroyed by disease without the occurrence of bad symptoms. This is a large margin for safety, but as soon as it is removed the lymph begins to cause wrong chemistry in the textures. Products of downward change from urea upwards keep circulating in the blood and lymph, and these substances produce their chemical actions everywhere. Thus on each mucous and other membrane urea exudes, and in the mouth even it is converted into carbonate of ammonia, and this, with some urinous smelling substance, gives the foul breath that is so frequently observed. The same substances effused in the stomach give rise to sickness, and in the bowels often to diarrhœa. The higher uric acid compounds in the joints produce chronic gout, and the excess of kreatin in the muscles may stop the changes in the syntonin, whilst the still higher compounds as yet uninsulated may in the nerves and brain produce irritant or narcotic symptoms from the slightest cramp or subsultus to the most profound coma. That there is in every case some distinct local action is clear from the amendment or arrest of the symptoms which is occasionally observed. The sickness and the diarrhœa may be stopped, the convulsions may cease, the coma may disappear.

Let us look at the removal of the poisonous substances a little closer. The vomiting and diarrhœa are not to be checked by strong remedies when the ammoniacal and urinous odour tells you of the accumulation of poisons within. You must, whilst endeavouring to obviate the extreme prostration which these actions cause, remember that more serious muscular and nervous actions are at hand, and that except by acting on the skin, you have no other gate through which the poisonous substances can pass out. Warm baths and hot air baths give no immediate relief like vomiting and purging. I have been asked by a patient for an emetic when he was within a few moments of his death from exhaustion. Almost whilst speaking to me another violently relaxed action of the bowels came on, and from the effects of this he died.

By the stomach, by the bowels, and by the skin, all poisonous substances can be thrown out of the blood and lymph, and, according to circumstances, by this or that road a passage must be obtained.

Irritative actions of the nervous system seem to mark a less degree of affection of the nerves than narcotic actions, and cramps, subsultus, and epileptiform convulsions pass away or yield to treatment far oftener than oppression and coma.

To any of you who have witnessed the stoppage of convulsions in Bright's disease by the inhalation of chloroform, the thought must have occurred that the chloroform must have so acted directly on the nerve as to render it incapable of being irritated by the urinous poison. A volatile coma, so to say, is produced. Perhaps the local action of the urinous poison is checked by the substance on which it was acting being altered in composition by the chloroform. But when the urinous poisons are causing both convulsions and coma, then this fixed coma is more dangerous than the convulsions; and all your efforts must be directed to stop the local action on the nerves, and whilst doing your utmost to evacuate the poison, you must try, by counter-irritation, to determine by blisters the largest possible effusion of serum and lymph as near as possible to the spot where the wrong action is taking place.

(To be continued.)

ORIGINAL COMMUNICATIONS.

ON

EXCISION OF ENLARGED SPLEEN, WITH A CASE IN WHICH THE OPERATION WAS PERFORMED.

By T. SPENCER WELLS, F.R.C.S.,
Surgeon to Her Majesty's Household, and to the Samaritan Hospital.

The idea of removing an enlarged spleen first occurred to me at a meeting of the Pathological Society in 1862. Mr. Nunn exhibited a spleen which weighed thirteen pounds and a-half, and appeared to have been the only cause of the death of the patient. My remarks upon the specimen are recorded in the *Medical Times and Gazette*, December 13, 1862. I asked, "Whether (as the patient was apparently being killed by the splenic tumour, and by nothing else) the question of removal by Surgical operation had been considered. The spleen could be removed very easily in dogs and other animals; they seemed to remain perfectly well without a spleen, and there certainly could not be more difficulty in removing a large spleen from the human body than a large ovarian tumour." I added, that if I "met with a case where the patient was evidently being killed by a large spleen, where all remedies had proved useless, and where the dying person was willing to run the risk on the chance of saving his life, I would certainly be disposed to remove the tumour."

At that time I did not know that the operation had ever been performed; but very soon afterwards Dr. Simon, of Rostock, sent me a very elaborate treatise on the extirpation of the human spleen, published in 1857 (a). From this work I learned that Quittenbaum, of Rostock, in 1826, and Küchler, of Darmstadt, in 1855, had each excised an enlarged spleen. These appear to be the only two authentic cases on record. A case is attributed to a Neapolitan Surgeon, named Zaccarelli, who is said to have operated, in 1549, upon a Greek woman, 24 years old, whose abdomen was enormously distended, yet the spleen, after removal, only weighed thirty-two ounces. The report of the case is so meagre and unsatisfactory that almost every writer who has commented on it has rejected it as untrustworthy. Simon suggests that the tumour was probably ovarian, and that it was the cyst, after the contents had been evacuated, which weighed thirty-two ounces. But the cases of Quittenbaum and Küchler are undoubtedly authentic.

Quittenbaum's patient was a married woman, 22 years old, who had been married fifteen months, had menstruated regularly before marriage, had never had ague, but after a severe cold felt acute pain in the left side; the catamenia were suppressed, and the abdomen gradually enlarged for nine months. She was thought to be pregnant; but time passing on, Quittenbaum detected an enlarged spleen, ascites, and anasarca of the

(a) "Die Extirpation der Milz am Menschen." Giessen, 1857.

legs. He removed the spleen by an incision ten inches long in the linea alba, extending from the ensiform process to three inches above the symphisis pubis. Nine pints of ascitic fluid escaped, and the spleen, which was quite free, was removed after a silk ligature had been carried round the vessels. There was very little bleeding. The intestines which had escaped *were anointed with warm olive oil!* before they were returned. The wound was then closed by sutures, and the ends of the ligature on the splenic vessels were brought out through the middle of the wound. The patient only lived six hours. After death the ligature was found quite firm. It included a small piece of the pancreas. The liver was small and hard, in all probability in a state of cirrhosis. The case was one in which the operation certainly ought not to have been performed. The extent of the ascites and anasarca should have taught the Surgeon that failure was almost certain. The spleen weighed five pounds. In Küchler's case the spleen weighed three pounds. The patient was a man, 36 years old, who, fourteen years before, had suffered for nine months from ague, and soon afterwards from enlarged spleen. The incision was only four inches long, and extended from the costal cartilage along the outer border of the left rectus abdominis. The spleen was non-adherent, and was easily turned on its edge and pressed through the opening. A little serum escaped—the first evidence of commencing ascites—seven vessels were tied, and the spleen cut away. The wound was united by sutures, and the ends of the ligatures on the splenic vessels were brought out as in Quittenbaum's case. The patient rallied well, but two hours after the operation died quite suddenly. At the examination of the body the liver was found to be cirrhosed. The cause of death was the escape of twenty-two ounces of blood into the peritoneal cavity from a small branch of the splenic artery which had not been tied. In both these cases the enlargement of the spleen was complicated by cirrhosis of the liver. In the first case, the patient was so nearly moribund that no severe operation ought to have been attempted. In the second, the tumour was not so large nor the sufferings caused by it so great as to warrant a dangerous operation, while the dependence of the enlarged spleen upon ague ought to have suggested a course of Medical treatment before resorting to operation. Still, the possibility of removing a large spleen without difficulty was proved, and my determination to operate if I should meet with a suitable case was strengthened.

In the autumn of 1863 I was consulted by a lady who had a tumour—evidently a spleen enlarged to three or four times its natural size—between the left false ribs and the umbilicus. There had been no attack of ague. The face was very pallid, and there was a considerable excess of white corpuscles in the blood. Bromide of potassium and quinine were each given freely without effect. The spleen rapidly enlarged. Dr. Jenner and Sir Ranald Martin consulted with me in the spring of 1864; but the state of the blood set aside any serious consideration of the question of operation. The patient died in March, 1865, and Mr. Michell Clarke, of Clifton, examined the body at my request, with the express object of ascertaining what would have been the mechanical difficulties encountered if the large spleen had been removed. He reported that "it was very easily drawn through a long incision in the linea alba, and the vessels having been tied in three or four bundles, it was detached. There was not the slightest adhesion to any organ, nor to any other part." In the early part of this year I have seen other cases of enlarged spleen with Dr. Budd, Dr. Boulton, of Horncastle, and Dr. Gill, of Bow. But these were dependent upon malarious influence, have been subjected to Medical treatment, and the patients were not so seriously affected by the tumour as to make a dangerous operation advisable.

At length I was consulted by a patient, who was evidently dying from a large spleen, and who, so far as I could discern, had no other disease. She was a married woman, 34 years of age, who had been married at the age of 19. She had three children, the youngest of whom was born eleven years ago. She had never miscarried. The catamenia had been regular, but very scanty for the last five years. Leucorrhœa was constant. She had always been very weak after her confinements, but had never had any serious disease. Her father and mother were both insane, and she had lost a brother and two sisters with phthisis. She had been as well as usual till the latter part of 1864, when she began to feel ill and weak, and continued to do so; but it was not till last April that any swelling in the abdomen was noticed. It was first observed beneath the left false ribs, and grew downwards, and to the right. At my first visit on October 12, 1865, I found the spleen extending as high as the seventh rib, and so low in the pelvis that it could be felt by the vagina in front of the uterus. The notch was distinctly perceptible a little above the umbilicus. On the right side below the umbilicus it extended within three inches of the anterior superior spine of the ilium. On the left side the posterior border was felt quite free and well defined in the loin. It was impossible to ascertain by palpation or percussion where the enlarged spleen and left lobe of the liver met, nor could any enlargement of the liver be detected. Some dilated superficial veins ran over the tumour and left side of thorax to the left axilla. There was no œdema of the legs, nor any sign of dropsical effusion nor glandular enlargement. The complexion was rather pallid, but the lips, gums, and conjunctivæ were of a good colour; indeed, rather florid. She had been confined to her bed for nearly a month, owing to the pain in the abdomen and general uneasiness; but the appetite was tolerably good. There was a tendency to constipation. I explained the nature of the disease to the husband, and said that nothing but an operation, which had never been done in England, and only twice abroad unsuccessfully, offered a hope of saving life; and I prescribed bromide of potassium once a-day and quinine once a-day. I saw her again in a fortnight. She had been unable to take the quinine, as it caused headache, but had taken the bromide. The tumour had increased a little; otherwise, there was no change. Iron was ordered, and I saw her again a fortnight later, November 11. The catamenia had appeared twice within the month. Her nights had been more disturbed by pain; she had a little cough, but air entered both lungs freely. The heart was pushed a little upwards, and to the right. The urine was acid, deposited urates, and was free from albumen. The spleen was rapidly increasing in size, and I proposed a consultation with Dr. Jenner, who saw the patient with me on November 14. He observed a soft anæmic cardiac murmur, and a small tumour just above the umbilicus, to the right of the notch in the spleen, which we supposed either to be a splenculus or a part of the pancreas. The blood was carefully examined, and a slight excess of white corpuscles was observed, but not greater than is often seen in pale persons.

Dr. Jenner expressed his opinion that the patient could not live long if left to Medical treatment only, but that excision of the spleen did give the "*shadow of a chance*" of saving life. The patient and her husband considered the matter, and I performed the operation, by their desire, on November 20. Mr. Clover administered chloroform, and I was assisted by Drs. Bowen, Ritchie, and Wright. I made an incision along the outer border of the left rectus abdominis, which extended five inches above and two below the umbilicus. Two arteries were tied before the peritoneum was opened. In opening the peritoneum rather a large artery was cut across in a piece of omentum, which was loosely adherent between the surface of the spleen and the abdominal wall. The vessel was tied. The adhering portion of omentum was separated, and by putting in my hand and turning the lower edge of the spleen first through the opening the whole of it was easily removed. The intestines were prevented from escaping by Dr. Wright, who kept the edges of the opening carefully together behind the spleen, which was held only by the vessels and the gastro-splenic omentum. I was beginning to twist the spleen round to bring the vessels into a sort of cord preparatory to applying a ligature, when the splenic vein, which was as large as a small finger, gave way, and blood ran freely from the spleen; but none was allowed to enter the abdomen, and I at once enclosed the vessels in a large clamp, and cut away the spleen. Before tying the vessels temporarily secured by the clamp, I passed eight silk sutures to keep the edges of the incision well together. The peritoneum was thus protected and the viscera retained while I was dealing with the vessels. These were tied in two bundles above the clamp, which was then loosened, and two arteries and a vein were also separately tied before it was finally removed. On taking it off, I found that a part of one end of the pancreas, as large as the end of a thumb, had been bruised by it. All the ligatures, except those on vessels in the abdominal wall, were cut off close and returned with the included tissues. The sutures were then tied, and the abdomen was well supported by plaster, pads of lint, and a bandage.

Mr. Clover told me that the patient was thirty-five minutes under the influence of chloroform, that she had borne it with less evidence of shock than he had often observed during ovariotomy, and that her pulse throughout was between 80 and 90.

The spleen is now in the museum of the Royal College of

Surgeons. It weighed on removal 6 lbs. 5 oz. avoirdupoise; but nine ounces of blood drained out of it, leaving the weight 5 lbs. 12 oz. It measured 11 inches in length, 8 in breadth, and between 3 and 4 in thickness.

For the following notes of the progress of the patient after operation I am indebted to Drs. Bowen and Ritchie, who watched her alternately or together with the most anxious care, night and day, until we were all hopeful that she was recovering:—

"During the first twelve hours the pulse varied from 84 to 88, and was very weak, in spite of the administration of brandy by the mouth, and brandy and beef-tea by the rectum. Pain was by no means a prominent symptom. The stomach was very irritable, but the kidneys secreted abundantly. At least sixteen ounces of brandy were given during the first twelve hours. The surface of the body was kept warm. Thirst was complained of, and relieved by sucking ice.

"Twelve hours after the operation the pulse rose to 100, and the right radial pulse was observed to have a smaller volume than the left. The patient became restless. Stimulants were required as much as before. There was some bilious vomiting, and nothing could be retained in the stomach. During the whole of the first day after operation the pulse remained at 100, the skin continued warm and moist, the urine was abundant, and free from albumen. Early in the day the patient was fed by the rectum, but towards evening she retained in the stomach some milk and soda-water. She slept from time to time. About 10 o'clock there was a slight fæcal motion. There was no tympanites, and flatus passed readily both by mouth and rectum.

"In the morning of the second day (November 22) the rectum had become very irritable; small doses of brandy-and-water were given by the mouth. She sucked ice greedily. About 7 o'clock there was violent spasm of the diaphragm, causing her to cry out with pain. This was relieved by hot brandy-and-water. The pulse gradually rose to 112; the skin was hot and dry, and there was a troublesome wheezing in the chest, with spitting up of mucus. In the afternoon abdominal pain was complained of, which was relieved by ten drops of laudanum given by the mouth.

"The patient slept quietly from 9 p.m. of the 22nd to 3.30 a.m. of the 23rd (the third day after operation), only waking up at intervals to take food and brandy. At 3.30 there was a violent rigor, commencing suddenly with a feeling of cold in the back. The rigor lasted only a few minutes, but reaction did not take place for half an hour, and was followed by profuse perspiration. During the day the patient was able to take milk and soda-water; but at 4 o'clock in the afternoon a second rigor, in every respect similar to the former one, took place. The rest of the evening the pulse remained at 120 to 130, and the urine continued to be secreted in large quantity, notwithstanding the violent perspiration.

"On the morning of the fourth day six grains of quinine were given before the expected attack. There was no rigor, and the patient slept well. In the morning the pulse was only 96. During the day egg beaten up and mixed with milk was given, and relished. In the afternoon Mr. Wells removed the stitches, and found the wound was perfectly united. Some more quinine was ordered and given, but as it produced buzzing in the head it was discontinued.

"During the fifth day the patient was remarkably well. She was able to enjoy the milk and rusk. Pulse continued about 108, rising at night to 120. Some fluid fæces were passed. The patient also continued wonderfully well during the sixth day. Urine in abundance was secreted, and the bowels acted naturally in the morning. Milk given freely. In the afternoon the bowels began to be irritable, and port wine, with ten drops of laudanum, was injected into the rectum. A good deal of flatus passed. At night she was very cheerful and comfortable, and there was some colour in the cheeks. About ten at night she ate some beaten eggs, milk, and rusks with appetite, and slept; but about one on the morning of the seventh day she awoke, complained of cold and of a pain in the back, which she had felt at each of the previous rigors. The bowels acted very freely. The pulse was very feeble and rose to 150, and the respiration to 44. The patient said she was sure she was going to die; she rapidly became weaker and weaker, although brandy was given freely both by mouth and rectum, and she died in about four hours after the sudden change,—158 hours after the operation."

The body was examined, twelve hours after death, by Dr. Bowen, assisted by Dr. Ritchie and by me. Decomposition had advanced with unusual rapidity. Fluid blood and air bubbled from the superficial veins as they were opened. The wound was perfectly united, but the cutaneous edges were separated without difficulty. The peritoneal edges adhered much more firmly. Two ligatures on superficial vessels came away with a very slight pull. A few drops of pus were observed in the track of one of the ligatures. There were no signs of general peritonitis; scarcely any serum, and not a trace of blood being found in the abdomen. Redness and effusion of lymph were entirely limited to the seat of operation. The ligatures on the blood-vessels were found with difficulty, being overlapped by the pancreas, which was large. The liver was also large. The kidneys were healthy. Both pleural cavities and the cavity of the pericardium contained a large quantity of dark red serum. The lungs were healthy, although there were old pleural adhesions at each apex. The heart was large and flabby, and contained soft clots, which extended along the pulmonary artery to the second divisions. This was the only clot found in the body, the blood elsewhere being thin and fluid, and air bubbling out wherever a vein was opened.

The heart, liver, and pancreas were given to Dr. Richardson for examination, as well as some of the fluid from the pleural cavities, and the blood which had flowed from the spleen directly after removed.

The cases of Quittenbaum and Küchler had taught that a large spleen could be easily removed; but, as one patient only lived two hours and the other only six hours, it was doubtful whether a human being would recover from the immediate effects of the operation. The case now recorded does at least make this addition to our knowledge.

It also proves that neither hæmorrhage nor peritonitis necessarily follow the operation. Some alteration in the blood, which becomes fluid, and permits of a rapid exudation of serum into the pleural or other serous cavities, may perhaps prove in other cases, as in this, to be the chief danger to be dreaded.

The principal difference between the operative proceedings of Quittenbaum and Küchler and my own was, in the removal of the ends of the ligatures which secured the splenic blood vessels. In their cases the ends of the ligatures were left and brought out through the wound. I had found a similar mode of dealing with the ligatures which secure the pedicle in ovariotomy to be so very unsuccessful, the threads acting as setons and setting up peritonitis, that I determined (if the clamp made much pull upon the stomach) to cut off the ends of the ligatures, and return them with the included tissues—a proceeding which has led to very good results in ovariotomy. In dogs, two or three turns of the spleen, twisting the blood vessels, are often enough to stop bleeding without any ligature; but, although this may answer with a spleen of natural size in a dog, it could not be thought of, except as a preparative for the ligature, in the case of a large spleen in man. But my trial shows that it would be better not to attempt it, for the splenic vein burst before one turn was completed. If I were to operate again, I would tie the vessels in separate bundles as they enter the spleen, and then cut away the organ.

The parallel between the operation for the removal of an enlarged spleen and an enlarged ovary ends with the operation itself. The successful removal of one ovary is frequently followed by the most perfect health of the woman, who may bear children of both sexes. Whether a human being would enjoy good health without a spleen is a question still waiting for a satisfactory answer. Experiments on other animals may be objected to, although the impunity with which the organ may be removed, and the good health of the animal for years after does seem to imply that the offices it performs cannot be of very great importance, and may be performed by the lymphatic glands or some other organs. Dr. Wilks says that the spleen may be "shrunken into so small a compass, and surrounded by so thickened a capsule, that its enlargement seems impossible, and its appearance would suggest that the functions of such a withered organ had altogether ceased. Yet, if so, there are no symptoms to indicate its loss."—*Guy's Hospital Reports*, Third Series, vol. xi., page 41.

Many cases have been recorded which prove that after partial or total removal of the spleen by accident life may be prolonged, but there is little satisfactory information as to the length of life or state of health of the individuals.

In one remarkable case, a woman 30 years of age, who had fever in January, 1711, had swelling and pain in the left side of the abdomen, followed by swelling of the left foot and

leg, and in February by a fetid discharge from the uterus. For the next four months she became thinner, and fluctuation was detected in the abdominal swelling. Ferrerius then made a puncture three fingers breadth below the umbilicus to the left side, from which a discharge of fetid pus was kept up for many days. A second and larger opening, higher up, near the umbilicus, then occurred spontaneously, and the matter was discharged through both. The patient became much emaciated, when the Surgeon saw a blueish body at the upper opening and removed it without much trouble. It was eight fingers in length, two in thickness, and the same in breadth. It was examined by Fantoni and found to be the spleen. The patient began to improve at once, but for several days a portion of her food passed through the opening near the umbilicus, as if the abscess about the spleen had been complicated by a gastric or intestinal fistula. But the wound healed, the patient recovered her strength, had a good colour, the catamenia returned regularly, she became pregnant and bore a healthy child; but from this time the abdomen began to swell again, and during a year different parts of the body, especially the head, were attacked.

This is one of the most complete accounts we have as to the state of health after loss of the spleen. It is quoted by Hecker and Simon from Fantoni's *Opuscula Medica*, published at Geneva in 1738. Cases in which, after penetrating wounds of the abdomen, the whole of the spleen or portions of it have been removed are on record, but I have only been able to meet with two well-authenticated cases where the *whole* spleen was removed. The first was in 1678, by Mathia. It is related by Crüger and quoted by Simon. A watchman, 23 years old, was stabbed. The spleen protruded. The vessels were tied and the spleen cut away three days afterwards. There was free bleeding, but it was stopped by a styptic powder, and the man was well in three weeks. The divided vessels formed a lump of the size of a hazel nut, and adhered to the cicatrix. The man returned to his duties, and was seen in good health six years and a-half after the accident.

The second case occurred in 1815, and is recorded by Lenhossek (Hecker's *Annalen*, Berlin, 1828). A youth of 19 was wounded in the abdomen. The spleen protruded, and, as it was becoming gangrenous, it was cut away after tying the vessels. The wound healed, and in 1818 the man was quite well.

Cases of partial excision of the spleen are much more numerous, but I shall only refer to one recorded by Berthet, in 1844, where a man lived and enjoyed good health for thirteen years after a wound followed by hernia and extirpation of a large portion of the spleen. He died of acute pneumonia, and after death only a small piece of spleen was found, the size of a hazel nut, which was adhering to the stomach. The case is quoted by Gray and Simon from the *Archives Générales de Médicine*, 1844. These cases of partial excision are of far less physiological importance than cases of total excision; for Dr. Crisp has shown that if a portion of the spleen be left it may grow, and the organ may be more or less completely reproduced. This, Dr. Wilks observes, is "quite in harmony with the simple hypertrophy of the spleen; for if an organ of a given size can grow to several times its normal standard, there appears no reason why a small portion remaining after an operation should not again grow to the original dimensions."—*Op. cit.*, page 40. This remark prepared me to leave a portion of the spleen in my patient, if I found it possible to do so, or the splenculus, if, as we thought probable, it had existed. Possibly it might be advisable to act on this principle in a case where it could be done safely.

If it be asked, "In what cases may an enlarged spleen be excised?" the conclusion would seem to be, that they can be only very few. If a large spleen were wounded, or ruptured, or caused obstruction of intestine, the operation might be the only means of saving life. But, in the absence of some such accident immediately endangering life, it is not often that a patient *has* a large spleen and has *not* some co-existing disease of liver, kidneys, or lymphatic glands, which would either prevent the success of the operation, or would destroy the patient soon after the recovery from its immediate effects. Where no such disease co-exists, then probably the ill-effects of the large spleen are either too slight to warrant a dangerous operation, or the general condition of the patient is too bad to give any reasonable prospect of recovery. This is especially true with regard to that form of enlarged spleen which follows ague. Either it is amenable to treatment—or, if the patient be ill enough to induce the Surgeon to think of an operation, the general health is so broken up, and the blood is so altered, that a simple cut or ulcer may lead to dangerous bleeding, and *à fortiori* a serious operation would most likely be fatal. The relation which the enlarged spleen after ague bears to the accompanying leukæmia, hydræmia, or melanæmia, is a problem which has still to be solved; and, even in the leukæmia which occurs independently of ague, it is still a matter of doubt whether the enlargement of the spleen or the alteration in the blood bear always the same relation of cause and effect. But, as it has been proved experimentally that the blood which issues from the spleen by the splenic vein does contain a much greater number of white corpuscles than the blood in the general circulation, and it is known that in simple hypertrophy of the spleen there is a great increase in the proportion of white to red corpuscles in the blood throughout the body, it would seem to be a fair presumption that removal of the spleen, by cutting off the supply of the white corpuscles which are in excess, might save the life of persons who would otherwise die of leukæmia.

CONDITIONS UNDER WHICH CHOLERA APPEARS IN ITS HOME.

By Dr. JOHN MACPHERSON.

Having spent more than twenty years in that portion of India where cholera is endemic—in fact, in its hot-bed, Lower Bengal and Calcutta—I have had the disease constantly before me. The first death of a friend, was that of the chief officer of the ship in which I had arrived, of cholera; the first Hospital case seen was a European child struck down by the disease, and crying feebly for water, and the last cases treated before leaving India were two children with a threatened attack.

But while thus able to write of familiarity with the disease, it is not in my power to say what is its treatment. If there be any special one, I have failed to discover it. There are very few modes of treatment that I have not, at one time or other, tried, or seen tried,—some of them attended for a time with marked success, which was, however, pretty generally followed by as marked failure. It cannot honestly be said that all the experience of our Professional brethren during the former epidemics in Europe led to much practical result in helping us to a better treatment; nor is there much of novelty in any of the curative measures that have been lately indicated, whether in the public prints or in the Professional journals. One main cause of disappointment with the effects of remedies in this disease is,—that the success of every mode of treatment varies according to both the intensity and the stage of the particular case to which it is applied, according to the nature of the particular epidemic, and also the period of it. Thus, I have often been gratified by the seeming good effects of remedies in the decline of an epidemic, and then in the onset of the next one found them of no avail.

But as it is not the object of these notes to discuss the treatment of the disease, it need only be said in passing, that much may be done to check its invasion; that much also may be done when the disease is fairly established, but that at that stage, although there are a few rules generally applicable, the treatment must be adapted to the particular circumstances of the case.

Although, then, I have no novelty to propound regarding the treatment of the disease, and, in fact, nothing on any point that is really new to any one having extensive experience of it, yet at this time, when the progress of the disease is being carefully studied in Europe,—when the assemblage of a Congress is proposed, and the idea has been broached of attempting to strangle the disease in its cradle—it may be well to call attention to some of the generally-acknowledged facts concerning it, to ascertain some of the conditions under which it occurs in its own home. This it is proposed to do succinctly, without referring to any theoretical views regarding its nature or mode of propagation, or to its manifestations in other parts of the world, or even of India, as far as possible avoiding facts of partial application, and illustrating the subject from my own experience, which was mainly confined to the Lower Provinces of Bengal.

Cholera Epidemics Influenced by Season of Year.—It may be well to say that Jessore, in which district cholera is considered to have made its first appearance, is in the Delta of the Ganges,

about eighty miles from Calcutta, and having much the same climate as that place—indeed, the climate and the soil of Lower Bengal are wonderfully uniform. Also, to make what follows more intelligible, that the year in Calcutta may be divided into four hot months—half February, March, April, May, half June; hot and wet four months—half June, July, August, September, half October; and cold months—half October, November, December, January, half February. These half months unfortunately cannot be represented in returns; or, perhaps, the simplest division is into dry and wet—the dry ones being November, December, January, February, March, April, May; and the wet ones, June, July, August, September, October.

Cholera is always present in Calcutta. There is not a month of the year in which deaths do not occur from it, both European and native. It is the cause of one-third of the total deaths, which vary from 11,000 to 16,000 per annum. The native population of Calcutta within the town proper is roughly calculated at about 400,000. The deaths from cholera have been—in the period from 1840 to 1850, 46,697 natives; in the period of 1850 to 1860, 45,823. The smallest mortality during the whole of the twenty years was in the month of July, 1843, when the deaths amounted only to 46.

Although, however, cholera is never absent from Calcutta, it has its seasons of maximum and minimum prevalence very strongly marked. It is found that, taking round numbers, of the 92,000 deaths above referred to, 65,000 occurred in the seven dry months, and only 17,000 in the five rainy ones, and that in twenty Aprils there were 16,193 deaths, in twenty Augusts only 2586.(a) These rules of prevalence apply to the course of the disease in both Europeans and natives. It was observed on the first outbreak of the disease that, though it appeared to die out by the end of October, yet it broke out again with renewed virulence before the end of next February; and, indeed, the first cholera noticed in the Jessore district in 1817 was in the month of May. This, therefore, appears to be a steady habit of the disease from its very commencement. Again, attempting the division into cold, hot, and wet months, we find in round numbers that about twice as many die in the cold as in the wet months, and that more than four times as many die in the hot as in the wet months.

Among both natives and Europeans, there is always a slight increase in the return of cholera cases in the months of February and October—the months when the hot and the cold seasons commence. While, however, both Europeans and natives suffer most during the hot weather, natives differ from Europeans in suffering to a greater extent in the cold months than the latter do. The Europeans usually have much less of it at that season, unless they are placed in particularly unfavourable circumstances. For instance, there was always some cholera among the unfortunate invalided soldiers passing through Calcutta in the cold weather, caring little for themselves and little cared for, or among drunken sailors staggering about the bazaars; and I remember an outbreak in Her Majesty's 18th following some Christmas festivities. But owing to the peculiarity, which we shall presently have to mention, of cholera mainly attacking the floating, not the resident Calcutta European population, we have no data that enable us to speak as positively about them as about the natives.

While its epidemics appear to follow the laws above mentioned, yet cholera is at all times to be met with in Europeans as well as natives. I shall give a few examples of the sporadic cases among the former, these sporadic cases occurring most commonly at the season of the greatest prevalence of the disease.

Sporadic Cases.—The first case of the season may very likely show itself in February, just as the season begins to get hot. You will probably have but a single case in a house, perhaps, two children, or rarely a man and his wife, attacked at the same time. It is generally difficult to find fault with anything local to the house, or to discover in what the particular house differs from others of its class (although some think differently on this subject, and almost always do discover what is wanted—a palpable cause). Thus of first-class houses in the best situations that I have known for a series of years, I recollect one in which a lady died just fourteen years ago at the epidemic season. There has been no death by cholera in it since. The house next it was certainly free from cholera for twelve years, when there was the solitary death of an infant also at the epidemic season. In another house, standing in the centre of a park, free from jungle and away from all drains, a lady at the same season of the year suddenly fell a victim. Of course it was accounted for by her having tired herself shopping in Calcutta. The house had always been healthy before, and continues to be so. In another instance, while the hot winds were blowing as strong as they ever do in Calcutta, a retired Medical subordinate officer living in the Hospital quarters was seized. He had taken an aperient that he was accustomed to use, and to this he ascribed the attack, of which he died. He had not been inside the Hospital for many weeks, and there was no cholera in Hospital; but on the day of his seizure a woman in a very airy ward, a patient for ophthalmia, was seized with cholera and recovered. In neither case did the disease spread. I give these as average cases, showing that even during the epidemic season the disease does not usually spread in good houses, or when there is no congregation of people. The same applies to natives; perhaps one or two servants (they are far more numerous, of course, than the Europeans) would die in the outhouses of the mansions just spoken of every two years or so, seldom more, and the disease would not spread.

Climatic Influences.—It seems hopeless to attempt to ascribe the epidemic or sporadic occurrence of the disease to any meteorological changes or to local conditions more special than the general laws of climate operating on a crowded, undrained city in the tropics. What appeared to apply in one case was absent in another, or the conditions were reversed. So much, however, I may venture to say that the hot winds do not blow cholera away; that the heavy fall of rain for a couple of hours has often stopped an outbreak—at all events, for a time; and that I always looked forward with pleasure to the coming of the rains, if it were only for the certainty that they would relieve me of much of the anxiety always attending the treatment of cholera. Still, if we are only to state what is beyond all doubt and not open to cavil, we must for the present be satisfied with the one general law in Bengal, that cholera is far more prevalent among all classes in the dry than in the wet months, and that the change from the cold to the hot season, and from the wet season to the cold, both seem to favour its development.

Who most Liable to be Attacked.—Having ascertained at what periods of the year cholera prevails most, we turn next to consider whom it is most likely to attack; and as our last figures were derived from Mr. H. M. Macpherson's valuable inquiry into the mortality of Calcutta, and figures derived chiefly from the native population, so also the main fact now to be announced is from the same source, but the figures are necessarily got from European returns. Mr. Macpherson has analysed the deaths by cholera among Europeans in Calcutta, and ascertained that 76 per cent. of the deaths occur in the floating population and only 24 per cent. in the fixed population; but as, to the standing shame of Government, we have no census even of the fixed European population that is in the slightest degree reliable, these facts are deprived of half their value. Cholera is most likely to attack—

1. New arrivals, or those who have lately come from sea. The great majority of deaths occur among sailors whose ships have just come in, but this I shall have to allude to hereafter. A new regiment is very fortunate indeed if it passes through Calcutta without losing some men. It would be easy to multiply examples; for instance, H.M. 96th Regiment, which arrived from New South Wales in April, had not landed thirty-six hours before cholera of a virulent type broke out. Every Professional man in Calcutta must have met with many cases of cholera in private life among those recently arrived. Some of the most striking cases of this kind have happened in young women and children.

2. Those who are travelling are specially liable to be attacked. New arrivals might perhaps be considered to come under this head, but they are even more liable to suffer, than people who have been some time in the country or natives, when they are moving about. It is notorious that among Europeans more cholera occurs in hotels and lodging places than elsewhere. Many of these houses are no doubt defective in sanitary arrangements, but I believe that the fact is attributable more to something in the condition of the travellers than to the state

(a) The average temperature of April may be taken at 84·6°; average range at 14·7°. The average fall of rain, 1·13 inches. The average temperature of August is 82·9°; average range, 5·2°; average fall of rain, 14·4 inches. December and January, the two coldest months, have nearly the same temperature. The average temperature is 67°; range of temperature, 17°; rain fall, 17 inches.

of the houses they resort to. I have seen persons from the provinces die in Calcutta in the airiest and loftiest private houses. Under this head come travellers dying at staging bungalows; the readiness with which, in certain districts, both European and native troops get cholera on the line of march. It is well known how pilgrims on their way through Lower Bengal and Orissa strew the road to Juggernaut with their bones. Natives travelling are just as likely to suffer as Europeans.

3. Those who are overcrowded suffer most. There is something in the massing of people together that favours the development of disease. This is especially true of cholera. Just as in 1785, long before the disease became fixed in Lower Bengal, an epidemic of cholera broke out at the great fair of Hurdwar, so, according to my friend Mr. Stewart Clarke, a fresh outbreak takes place nearly every year. The more closely packed a regiment is, the more likely is it to suffer severely from cholera, just as separating the men is one of the first steps towards stopping an outbreak. It would be easy to multiply instances of this in crowded barracks, in gaols, and in ships, or among ill-housed railway labourers; but I shall merely refer to a very frightful attack of the disease at Dum Dum in September, a month when, as we have seen, the disease does not usually prevail. In this instance the disease was mainly attributable to over-crowding and the various evils engendered thereby, for the men who were in roomy barracks escaped. It is, however, not to be forgotten that an outbreak, though on a much smaller scale, occurred at the same time at a station only ten miles off, where the accommodation was ample. Instances of the effects of overcrowding both in the European and native population must be familiar to every Medical man in Calcutta. I shall presently give the details of what appears to me a very instructive case that occurred in my own practice.

4. It might be presumed that those who are weakened by any cause would be likely to suffer from cholera. This is the case; at least in Hospitals, instances of it are common. Many cases of dysentery, a few of fever, and one or two of phthisis swept off by it are fresh in my memory. The prisoners in unhealthy gaols readily become victims to it. Excessive action of the bowels from purgative medicine, or any disorder of the digestion or bowels from excess in eating or drinking, would come under this head, as instanced in H.M. 18th suffering at Christmas time. And here it may be remarked that most violent cases of vomiting, purging, and cramps simulating cholera have been clearly traced sometimes to eating bad shell fish and sometimes to copper poisoning from the cooking utensils. But though irregularities in diet may sometimes be fairly blamed, it should be remembered that patients or their friends are so anxious to have some cause for an attack assigned, and Medical men are so often as it were compelled to assign a reason for their satisfaction, that irregularities of diet are often discovered that never existed, and it would be hard to say what article of diet has not at times in Calcutta got the credit of having produced cholera. Those who are most alarmed are most likely to be seized. But no strength of constitution, no regularity of life, no supposed acclimatisation, no excellence of a dwelling-house, no previous attack of it, no age, no sea gives security against this pestilence.

Cholera seizures appear to be most frequent in the early morning, but there are no statistics on the subject.

(To be continued.)

UNIVERSITY OF CAMBRIDGE. — SCHOLARSHIP FOR NATURAL SCIENCE.—There will be an examination on Oct. 9, at Sydney College, in Natural Science (electricity, chemistry, geology, anatomy), and two scholarships of the value of £40 a year each will be awarded. There will also be an examination, at the same time, in classics and mathematics for other scholarships of the same value. The examinations are open to all students, provided they have not commenced residence at the University. Further information to be obtained from the Rev. J. C. Ellis, tutor of the College.

PRESENTATION TO DR. USSHER.—Dr. Ussher was on Friday evening, December 29, presented with a handsome salver, bearing the following inscription:—"Presented to Dr. Ussher as an offering of regard and esteem from grateful patients." The gift, which was electro-plate, was purchased by some of the members of the Wandsworth Provident Dispensary, to which institution Dr. Ussher has been Resident Medical Officer for three years. This feeling recognition of his services was the spontaneous act of very poor persons, and not that of his committee.

REPORTS OF HOSPITAL PRACTICE
IN
MEDICINE AND SURGERY.

THE LONDON HOSPITAL.

RESUME OF A WEEK'S ADMISSIONS,

BEING THE SUBSTANCE OF A CLINICAL LECTURE DELIVERED DECEMBER 20, 1865.

(Cases under the care of Mr. HUTCHINSON.)

[Reported by Mr. WARREN TAY.]

GENTLEMEN,—The following is a list of our admissions during the week which ended yesterday:—

Strangulated hernia (femoral)	1
Fracture of base of skull	1
,, humerus (comminuted)	1
,, ,, into elbow-joint	1
,, ,, femora and pelvis	1
,, neck of femur (impacted)	1
,, ribs	6
,, tibia and fibula	5
,, ,, (only)	1
,, fibula (only)	2
,, patella (transverse and comminuted)	1
,, inferior maxilla	1
,, toes (compound)	1
,, metacarpus and phalanges (compound)	1
Retention of urine	1
Orchitis	1
Scalds	3
,, of throat	1
Burns	4
Ruptured eyeball	1
Erysipelas	2
Concussion of brain	1
Laceration of scalp	3
,, knee	1
Inflamed leg	3
,, bursa patella	2
Contused abdomen	1
Contusions	5
Stricture of urethra	1
Ulcers	2
Eczema	1
Scabies (pustular with ecthyma)	1
Rheumatic disease of hip-joint	1
Carcinoma of breast	1

The total number of admissions was 59, but in complicated injuries one or two cases have been mentioned twice.

The week has, on the whole, been rather a heavy one. Many of the cases have been severe; we have already had five deaths, and three other patients are in a critical condition. Amongst the more interesting of our cases we may select the following:—

On Thursday a boy was admitted, having been knocked down in the street and possibly run over. He had a fracture in the upper part of his left humerus, with great displacement. He was in collapse when admitted, but conscious and without paralysis. I directed your attention to the fact that both his upper eyelids were purple from extravasated blood, and that he was also bleeding a little from the nose, and remarked that as there was no external bruising about his eyes to account for the ecchymosis, as the ecchymosis was on both sides, and his lower lids were quite free from it, we might regard this symptom as almost pathognomonic of fracture of the base of the skull in its anterior fossa. The plates of bone at this part—those constituting the roofs of the orbits—are very thin, and are very easily broken, and when they do break hæmorrhage into the cellular tissue of the orbit is a very frequent consequence. More usually the blood first shows itself beneath the ocular conjunctiva; but sometimes it is limited to the lids. In this instance there was not on either side any ecchymosis beneath the conjunctiva; but, as I have said, both upper lids were distended and livid with extravasation. The boy had no bleeding from either ear, and his symptoms were those of the collapse stage of concussion of the brain. He complained of pain, and resisted our attempts at examination. The treatment consisted simply in keeping him warm, so as to favour his rallying. I

ought to have stated that there was no laceration of his scalp, and that the chief bruise was on his left temple, indicating perhaps that he had been struck there. He could both hear and see. He passed the rest of the day and the following night in great restlessness; he tossed about in bed, and undid the bandages which had been put on his arm.

On the following day we found him still very pale, and with a cool surface. He would take his food, but was very unwilling to be disturbed. He complained much when I examined his arm, and begged me "not to pull it so much." We now found that he could scarcely see with the right eye, and that his right pupil, which on the previous day had been of the same size as the other, was widely dilated and fixed. We made this examination as to his sight about three o'clock in the afternoon, and he was then quite able to answer questions as to what he could see, etc. About eight the nurse gave him some bread and milk, and he took it well. At half-past eight the House-Surgeon found him insensible and apparently dying. His breathing was now difficult and irregular, but there was no stertor; his pulse was rapid, upwards of 170. Within a few minutes, and whilst Mr. Dawson was with him, he died.

You will see that beyond the symptoms which usually attend cases of severe concussion of the brain (accompanied as they frequently are by more or less of contusion also), we had had had none excepting the dilatation of the right pupil. The boy had been conscious up to within about half an hour of his death; he had had a rapid pulse and great restlessness throughout; he had had no observable paralysis.

A week ago, at a clinical lecture, I had the opportunity of illustrating one cause of unilateral dilatation of pupil after injury to the head. A man had died in whom this symptom was present, and in whom we found a large clot of blood between the dura mater and the bone pressing forwards upon the sphenoidal fissure, and no doubt compressing the trunk of the third nerve. In our present case, singularly enough, the cause of this symptom proves to be the same. As we had diagnosed, there is a fracture across the anterior part of the base of the skull, in some parts, taking the line of the junction of the lesser wings of the sphenoid to the orbital plates of the frontal bone. This fracture on the left side has crossed the trunk of the meningeal artery, and a large clot of blood is found between the dura mater and the bone extending downwards into the sphenoidal fossa. I have not dissected it, wishing not to spoil the specimen, but from the position of the clot there can be little doubt that the third nerve is compressed, and thus the dilatation of the pupil is explained. These two cases, so exactly parallel, seem to supply us with a new and very valuable symptom indicative of effusions of blood in this situation. Regarding the case now with the light which the autopsy has thrown on it, we can have little hesitation in assuming that the cause of death was compression of the brain. The quantity of blood found is quite sufficient to account for death. It would seem probable that a second hæmorrhage had occurred immediately preceding his death; and the state of the clot, one half much softer than the other, seems to favour this view. I drew the attention of those who were present at the autopsy to the fact that the brain substance was exceedingly pale, remarking that in all probability the manner in which compression proves fatal is by squeezing the blood out of the brain substance. This case adds another to a considerable series which we have recently had showing that the orthodox symptoms of compression of the brain, absolute insensibility, stertor, slow, laboured pulse, and hot surface, are not by any means always met with. In the early stage of this case we had before us probably symptoms which were a mixed result of a slight degree of compression together with a very considerable degree of concussion. The blow by which the base of the skull was fractured must of course have severely concussed the brain; indeed, we had evidence of this in the existence of a few small patches of ecchymosis into the brain substance, beneath the anterior lobes. These were in themselves trivial, but become important as proof of the severe shake which had been received. I think you will agree with me in holding that we were not to blame for not having diagnosed the presence of blood in the situation where we found it. The symptoms were so altogether different from those supposed to be usual in compression, and so closely similar to those of severe concussion, that it was impossible to establish a differential diagnosis; nor can we, perhaps, boast of having learnt much which may aid us in the diagnosis of future cases, with the one exception of having discovered the meaning of the one dilated pupil. This point we will store up carefully for future use.

Our next case is one of femoral hernia; the patient, a woman; a hernia not so large as an egg, strangulation tight, of fifty-three hours' duration, and the symptoms severe. The taxis had been fairly tried before her admission, and I tried it again, under chloroform, before proceeding to the operation. Finding that the hernia did not yield in the least, I at once adopted the latter measure. After notching Gimbernat's ligament, and then dividing some tight bands below it, I succeeded in effecting reduction without having opened either the sac or the fascia propria. As the hernia had been strangulated a considerable time, and the strangulation was tight, I was quite prepared for the occurrence of that form of peritonitis which is consequent on the return of damaged intestine into the peritoneal cavity, but I thought, on the whole, it was better to run this risk than to add the danger of direct traumatic peritonitis by opening the sac.(a)

On the morning following the operation I found the patient in a satisfactory state, having no sickness whatever, but with a little tenderness of the abdomen immediately above the hernia. We therefore applied some leeches and ordered calomel and opium every three hours. On the next day she was better and almost free from pain.

On the third day we struck off the pills and ordered her a mutton-chop, as she seemed quite out of danger. During the next night, however, she had an attack of diarrhœa, and passed motions which were slimy and contained blood. She was now feeble, her surface being very cool. I ordered her some brandy and a suppository of opium every four hours. To-day, six after the operation, she is quite comfortable, and I think we may consider her out of danger.

We have had several severe cases of fractured ribs. In two of these the danger has consisted not so much in the accident itself, as in the fact that the patients had previously suffered from chronic bronchitis and emphysema. One of these, a man aged 41, has died. It is very unusual for us to lose a case of simple fracture of the ribs. This man had a barrel-chest and a very clear percussion note over all parts in front, indicating the existence of extensive emphysema, and we had the history that he had often been laid up with attacks of bronchitis. He had fracture of only one rib (the ninth), and there was no laceration of the pleura or lung. He came to us two days after his accident, because his breathing was getting worse. He was very dusky in the face, and breathed with great difficulty. We discussed the point as to whether it was a case in which venesection would be likely to relieve; but the history of old bronchitis deterred me from it. We kept him well elevated in bed, and contented ourselves with giving him small doses of antimony. His symptoms of bronchitis, however, increased; and he died on the fifth day after admission, and the seventh from his accident. We found the lungs most extensively emphysematous, but their posterior lobes were congested, and on the left side there was positive pneumonia, the lung tissue being solid, soddened, and much softened. It is worthy of note that this occurred on the side opposite to that on which the rib was broken. On both sides there were a few fibres of recent lymph on the pleural surfaces. I do not think that we need regret not having used the lancet.

We have another case now under care with almost precisely similar symptoms and history, and in this case I shall not venture to bleed. In these cases of broken ribs, with previously existing damage to the lungs, it becomes an important question whether the chest ought to be bandaged or not. I do not know that we can have any better rule on this point than the patient's own feelings and the progress of the case. If he says that he has less pain with it on, keep it on; if, however, his breathing shall be steadily getting worse, I think then that it would be wise to remove the bandage for a time and note the result.

We will next take a case of contusion of the abdomen, in which the diagnosis of rupture of the liver was made. Henry R., aged 27, was admitted about midday, December 18, having received a violent blow on the right side of the lower part of the chest from a bar of wood. He was in a state of collapse, and had vomited immediately after the accident. He was very pale, and his pulse was very weak. There was a bruise to the right of the epigastrium over the false ribs, and there was one spot that seemed very soft, as if there was a deficiency of the abdominal wall. No fracture of ribs was detected. He continued very sick, but rallied somewhat from the severe collapse. He passed water which did not contain blood. He died on the evening of the next day. I should have mentioned

(a) See clinical lecture on the "Causes of Death after Hernia Operations" in the "London Hospital Reports," vol. 2.

that a short time before death emphysema in the cellular tissue of the chest and abdomen was noticed.

At the post-mortem this afternoon we found a rupture of all the muscles of the abdominal wall and of the parietal layer of the peritoneum sufficient to admit three fingers. The skin was not involved. There was no fracture of ribs. There was a large quantity of bile in the abdominal cavity, and diffuse peritonitis, the intestines being everywhere glued together. The intestines were most carefully examined, but no rupture was found. No rupture of the liver or gall-bladder was found before removal, but afterwards we discovered a hole in the common duct, which, I believe, was not made in taking out the liver, and it accounts for the quantity of bile found extravasated. There was a considerable amount of dark blood about the right kidney, but no torn vessel was seen. I should have mentioned that at the time of admission a swelling over the epigastrium was noticed, and attributed to the ecchymosis in the abdominal wall; this was fully confirmed by our examination.

There was one interesting peculiarity that remains to be noticed—namely, that at first we could not find the left kidney. By tracing up the ureter we came to the diminutive one which I now show you. Part of it seems quite atrophied and replaced by cellular tissue, the other part shows evident kidney structure, though very small. The right kidney, as you see, is congested, but otherwise healthy, and not of particularly large size. The pelvis of the left kidney is much dilated, and suggested that he had formerly had a calculus imbedded there. A large sound was introduced into his bladder, and neither a calculus nor any stricture of the urethra was detected.

His death was evidently caused by intense peritonitis, set up by the extravasation of the bile, the emphysema of the cellular tissue being probably produced by decomposition.

The case of fracture of the patella bears out what I have often brought before your notice, that we mostly get a combination of muscular action and direct violence in the production of a transverse fracture of the patella; not muscular action alone. The patient while walking in the street slipped forwards and struck his knee violently on the flat pavement, at the same time having his quadriceps extensor in full action. A transverse fracture resulted, with much effusion into the joint, and the lower fragment is broken into at least two pieces. We are treating it in the usual way, a broad, straight splint being applied behind the knee, and the fragments being brought together by means of strips of plaster passing obliquely from above the upper and below the lower one to the splint. The leg has not been elevated on an inclined plane. Owing to the effusion, we do not aim at a very close approximation at present.

The fracture of the inferior maxilla is situated just to the right of the symphysis. Excepting that there was rather more displacement, and the right division more moveable than usual, I do not know that it differs from the majority of cases we have here. It is satisfactorily treated with a gutta-percha splint and four-tailed bandage.

Of the four cases of burn, I will only notice one, a poor fellow who received such severe injury to his head, face, chest, arms, and lower extremities that he died in about twenty-four hours. When admitted he was in extreme collapse, sensible, but greatly excited, and very soon severe rigors came on. They were so severe that most who saw him thought he could not rally from them. He did, however, do so to a certain extent and for a short time, then became comatose and died. He was a maker of fireworks, and it appears that some gunpowder became ignited and exploded. He jumped out of a window, but two of his comrades were killed on the spot. Another patient, a child, suffering from a severe burn, is in a critical state.

Amongst the committee cases we will only mention the case of carcinoma of the breast and that of stricture of the urethra. The subject of the former, a woman, aged 70, you have just seen in the operating theatre. Though the disease had progressed rapidly, and the patient was old, I agreed with Mr. Little that it would be well to remove the growth, as there was a tendency to ulceration, and we might hope to relieve her of the pain consequent on cancerous ulceration.

The subject of the next case, a very tight stricture of the urethra, was a man, aged 41, who had been liable to symptoms of stricture for about three years. Two days before admission Mr. Webb, of Poplar, introduced a No. 2 catheter. On Thursday last I failed to pass a No. 3, but the day before yesterday I succeeded with a No. 2. I then introduced Mr. Holt's dilator, and dilated the stricture gradually to an extent probably equivalent to a No. 10 catheter; this was about three o'clock. I ordered him half a drachm of laudanum to be taken immediately. He did not have it for two or three hours afterwards, and then felt so comfortable that he was loth to take it. About 7.30 he was seized with a violent rigor, lasting for some time. Some brandy was given him, and he somewhat rallied.

The next morning when the House-Surgeon saw him he examined his perineum carefully, but could detect no extravasation of urine, neither could I when I saw him later on in the afternoon, but I was then very much alarmed by the state of extreme collapse in which I found him. He was almost pulseless, pale, and his surface cold; he had passed some urine which was coloured with blood. I have often remarked to you that rigors in connexion with any affection of the urethra are not usually of much consequence. It seems to be a peculiarity of that part that any interference with it may cause a rigor, but then usually the rigor is a single one and the patient soon rallies, but in this case we had our patient in extreme collapse twenty-six hours after the operation.

The one treatment let me impress on you for these rigors and the collapse which follows them consists in the administration of repeated doses of hot brandy and water. I increased the quantity ordered by the House-Surgeon and this morning I found our patient better, and again still better this afternoon, though he is as yet in a somewhat critical state. Although the occurrence of collapse which this case examplifies is usually quite transitory, yet the Surgeon cannot afford to neglect it, for now and then, unless the proper measures be adopted, the patient will die in it. After any operation on the urethra the patient ought, therefore, to be carefully watched.

OUR REPORT ON FRACTURES AND DISLOCATIONS.

As an addition to our reports upon cases as they occur in the practice of the different London Hospitals, we propose to lay before our readers a series of papers or reports on the "Treatment of Fractures and Dislocations," remarking on any differences of treatment in special cases which may come under our notice. Not that the various methods applied differ to any great extent in any Hospitals, or under any Surgeon, but some useful hints in some particular cases may often prove of great service where emergency, or the want of the appliances usually adopted, renders one method more favourable than another. It is our intention, therefore, to take the bones of the upper and then of the lower extremities, the fractures and dislocations to which they may be subjected, *seriatim*, and make some remarks upon their treatment and reduction, noticing the *reasons*, surgically and anatomically, upon which this or that peculiar method is based. No physiological order of arrangement will be adopted, for our intention is that of commenting as we proceed upon the actual methods employed in the various Hospitals. We shall probably commence with the more common, and keep the rarer forms in reserve for the completion of our series. Especial notice will be taken of these accidents in children, as those who have had experience in this particular recognise their difficulties and importance.

To those of our readers whose residence in the country renders access to a Hospital impracticable, we trust these papers may be of service, and any suggestions which might occur to them, or to any of our friends, we should consider of the greatest assistance.

We also sincerely trust that every help may be rendered us by the House-Surgeons, or those in office at the various Hospitals we visit, with a view of helping us in our task.

Statistics of the union or non-union of the various fractures treated is obviously impossible, as in many cases patients will leave Hospitals before, in the judgment of the Medical officer, they are fit to do so, and desire to get about too soon after the fracture has united; but this hardly comes under our province, which is merely to report upon the treatment of the fractures and dislocations, as pursued in the Hospitals.

We should esteem it the greatest assistance if we could have the co-operation of those in office at the County Hospitals, especially manufacturing towns, where such accidents are of more frequent occurrence, at least in proportion, than in the metropolis.

THE SOCIETÉ IMPÉRIALE DE CHIRURGIE DE PARIS.—M. Giraldès has been elected President, and M. Follin Vice-President for the ensuing year. MM. Guyon and Dolbeau are the new secretaries.

Medical Times and Gazette.

SATURDAY, JANUARY 6.

ANNUS MEDICUS, 1865.

The two most prominent events of the Medical year just closed have been the invasion of England by the Rinderpest, and the first droppings of a cholera epidemic.

The first cases of the "Cattle Plague" occurred in the month of June, in an Islington dairy, among some cows which had been purchased about a week previously in the Metropolitan Cattle Market. By the end of July more than a hundred cows in that dairy had died of the disease, or been killed on account of it; it had spread to other London dairies, and it had appeared at several places in the country. Authorities differed as to what the disease really was, some believing it to be the Rinderpest, or Steppe-murrain of Russia, while others declared that it was identical with the typhoid or enteric fever of man. Continuing to spread rapidly, and exciting considerable alarm by its intensely fatal character, a Royal Commission, composed of men of high scientific and social standing, was appointed on October 6 "to investigate its origin and nature, to ascertain as far as possible the mode of treatment best adapted for the cure of the affected animals, and the regulations which may, with the greatest advantage, be made with a view of preventing the spread of the said disorder, and to avert any future outbreak of it."

Early in November the Commission published a very valuable preliminary report. In this it was proved that the disease is undoubtedly the Rinderpest; that it belongs to the class of specific contagious fevers; that its "contagious matter is subtle, volatile, and prolific in an unexampled degree," and that it is extraordinarily fatal. That no means of cure, nor any markedly successful method of supporting an animal through the attack, had yet been discovered, but that the experience of foreign countries had shown that by slaughtering all diseased animals, and by resolutely and perfectly isolating all centres of contagion, the spread of the malady might be absolutely put a stop to. Six out of the seven scientific members of the Commission, with the Right Hon. R. Lowe, dealing logically with the evidence before them, recognised the conclusion that the prohibition, for a time, of all movement of living cattle through the kingdom would be a certain means of preventing and eradicating the disease, and they boldly recommended its adoption as the only measure equal to the occasion. The remaining scientific member, with three others—whom we may distinguish as representing the agricultural and landed interests,—while they agreed with their colleagues in their opinions as to the nature and character of the disease, and believed in the efficiency of the means recommended by them, quailed before the difficulties and inconveniences that would attend its adoption, and recommended measures similar in principle, but less stringent and efficacious. They were guided by what seemed expedient rather than by what seemed necessary. The remaining member of the Commission, Mr. M'Clean, the President of the Institute of Civil Engineers, thought that a great deal too much was made of the danger, and that the existing Orders in Council would, if properly carried out, fully suffice to arrest the evil.

The report also presented a graphic picture of the fearful and wide-spread destruction the plague had formerly caused in this country and in foreign lands, and showed how uniformly all measures short of the complete stoppage of the movement of cattle had failed to arrest its progress.

Government had not the courage to act decisively, and the progress of the plague continued. When the report was issued, at the end of October, there were about 200 infected spots; by the end of November these had increased to 4000, the disease had caused the loss of some 30,000 head of cattle, and 5000 fresh cases occurred weekly.

The farmers, and the people of England in general, have faced the evil with calmness and courage, but the "organs of public opinion"—as the daily journals love to be called—in too many instances set them anything but a good example; and the "leading journal,"—so-called—excited by the presence of cattle plague and by threatenings of cholera, justified its right to that title by displaying a mixture of childish unreasonableness, petulance, and agitation such as might have led to a perfect panic. It refused to recognise patent facts; it rejected angrily the possibility of the importation of the disease; it maundered over theories of "spontaneous origin;" it derided and scorned the advice and experience of distinguished Veterinary Surgeons and men of science, and opened its columns to any and every babbler and quack who would write to it; and, losing apparently all sense of dignity and calmness—actuated, we suppose, by the same emotions as lead ignorant and excited multitudes in times of pestilence to accuse the Doctors, or any other prominent class, of poisoning the public sources of water—this great and infallible entity distinguished itself by a furious philippic against the impotence and backwardness of Medical science, and the ignorance and gross darkness of the Doctors. No old lady of Billingsgate could have scolded with greater virulence and volubility, or with more complete ignorance of what she was talking about. The inexorable logic of facts was, however, too strong for even the *Times;* it gradually altered its tone, and at last came to speak of the measures recommended by the majority of the Royal Commission as the only measures worthy of adoption. "Our great agriculturists"—thus it wrote early in December—"have to fall back on common sense . . . . inquiry as to treatment, etc., is not to rest. . . . . As to transport, everything is to be done to reduce it to that in dead meat." Its leading articles on the subject were written, as time went on, in a much higher and truer spirit, and it published communications of a really scientific and valuable character, foremost among which is the able letter by which the honoured President of the Royal College of Physicians gives the support of his name and position to the Royal Commission recommendations; though the journal has not been able yet to acknowledge honestly and simply that the disease is only known to spread by contagion, and that, in the fact of there being no known *cure* for it, it is only like small-pox, measles, and other contagious eruptive fevers; and its columns are still open to letters recommending such absurd "remedies" as the hanging of a bunch of onions round an affected animal's neck.

It is not often that an English Government is timid and irresolute in the actual presence of calamity, but in this instance our Government seems stricken with most inexplicable feebleness and hesitation. It is perfectly well known that this plague is frightfully fatal, and frightfully contagious; that it spreads only by contagion; that the contagion must be carried from or by a diseased animal; that if this carriage of contagion is stopped the disease must die out;

that to be successful this stoppage must be complete and absolute; and that the main and principal source of contagion is the movement of cattle from place to place; and that if this movement is altogether and everywhere stopped the pestilence will be arrested. The Royal Commission recommended that "some high officer of Government" should be invested "with the power of suspending for a limited time the movement of cattle from one place in Great Britain to another, for extending or shortening such period, and for renewing the prohibition as often as circumstances may render necessary;" the farmers have almost unanimously demanded from Government the adoption of "stringent and uniform measures" of the character recommended by the Commission; and the press now supports this demand; and still Government hesitates, and only issues Orders in Council, such as were uselessly issued when the same pestilence ravaged the country in 1745. The last Order, dated December 16, empowered "local authorities" to prevent, if they see fit, all movement of cattle in their respective districts; but we know how "local authorities" may differ, and how they have failed before. Suppose that in every place in the land but one they stopped the movement of cattle, that one exception would again infect the whole country. The case demands, if ever a case did demand it, "uniform and stringent measures," proceeding from one central authority.

We have said that the Royal Commission recommended such measures, for while every hour has shown the wisdom of their recommendation, it may be now regarded as being nearly unanimous. Mr. M'Clean's opinion may be entirely put on one side, for subsequent events have shown its utter fallacy; and Mr. Read, one of the expediency-minority, when present with a deputation to Sir George Grey a few days ago, said "that he had not altered his opinion, but that circumstances had changed; and that what he had considered impracticable at one time might be made practicable now."

Meanwhile, while Government thus hesitates, the pestilence spreads with fearful rapidity. According to the official statistics for the week ending December 23, the disease had appeared during that week in 434 fresh places, and 6256 fresh cases had occurred, of which 574 were killed, 4123 died, and 960 recovered. The total statistics for Great Britain were 8442 centres of disease, and 63,593 cattle attacked, of which 13,137 were killed, 34,861 died, 5803 recovered, and 9792 were still suffering from the disease.

It is worthy of note that homœopathy, which declared itself fully able to cope with the disease, has been fully and fairly tried in Norfolk, and utterly failed; out of sixty-six animals on whom that "system" was tried sixty were dead, and the remaining six "by no means recovered" at the date of the the last report of the experiments.

It seems almost certain, however, that out of all this great evil and loss, one great good will result—viz., that the Rinderpest epidemic will free our cities and towns from live-meat markets and slaughter-houses, for it can hardly be supposed that these will ever again be permitted if they are suppressed for any length of time, and it is unnecessary to point out how great would be the sanitary gain therefrom.

Epidemic cholera broke out early in May among the vast concourse of Mussulman pilgrims aggregated at Mecca; shortly after it appeared at Alexandria, next at Cairo, and early in June at Ancona. On July 1 it was imported into Constantinople also, by a Turkish vessel from Alexandria. From these points it spread to several places having with them the freest intercourse, and communication by water. It attacked Malta, Gibraltar, some places in Spain and Portugal, Naples, Marseilles, and Toulon, and then Paris, and on September 22 a case occurred at Southampton. The epidemic did not spread much in Southampton, and quite ceased there by the end of October. The only other place in England at which it appeared was Epping. Mr. Groombridge arrived at his residence in Thoyden, a sub-district of Epping, on September 26. He had been staying at Weymouth, and on his way home passed through Southampton. On September 27 he was attacked by cholera. Within a very short time eleven cases of the disease occurred in his house and some adjoining cottages, eight of the cases proving fatal, but there the plague was stayed; and by the middle of November the Registrar-General's Returns were free from all report of cholera. It did not visit either of the above-mentioned places, however, without taking a toll of victims from our own Profession. At Southampton Mr. Francis Cooper, Officer of Health for the Borough, and at Epping the elder Mr. McNab, both died of the disease, attacked by it in the earnest and fearless discharge of their duties to their suffering fellow-men. But though cholera has ceased in England for the present, it is but too probable that it will, as on former occasions, return next year, and then, as formerly, instead of counting its victims by tens, it will count them by thousands. Meanwhile, the approach of it has given a fresh impetus to sanitary work, and infused some new vigour into boards of health and parish vestries. If we have not yet learnt how to cure cholera, we have learnt well what kind of places it most loves to visit and to riot in; we know that overcrowding, filth, bad drainage, and tainted water-supply as certainly make a cholera-haunt as they do a fever-nest; and so, though infinitely too little is being done, yet is there some increased effort being made to set our houses in order, not to welcome and foster, but to repel or starve epidemic cholera. France has already suffered this year far more than we have; and the Emperor of the French has not only taken the subject of cholera epidemics into "his royal consideration," but has inquired and thought about it for himself, and, looking at the apparent origin and the course of this and some other epidemics, he, with a happy audacity worthy of genius in power, has proposed to the various foreign courts to hold at Constantinople an International Scientific and Diplomatic Conference on Cholera, in order "to attack the disease at its fountain-head." The Conference is "to investigate the primary causes of cholera; to determine its principal points of departure; to study its characteristics and its march; lastly, to propose practical means for confining the disease and stifling it at its origin." All the powers addressed have, we believe, given in their adhesion to the Conference. The calling together of such a meeting—the first Congress on the subject of disease—is a truly grand idea, and does infinite honour to the Third Napoleon. By thus leading the thrones and powers in a war on disease, he will win for himself and the second Empire a far truer and more lasting glory than Napoleon the First gained out of all his victories and conquests.

It is indisputable that more than one cholera epidemic has appeared to originate in pilgrim gatherings at Mecca, and that "the present organisation of the sanitary service in the East" demands extensive "reforms;" but can any one avoid suspecting that, had the annihilation of distance by the modern powers of locomotion been somewhat more advanced, His Majesty of the French would have proposed one of our Indian capitals as the seat of the Conference instead of Constantinople? All that is said or hinted at in the communications from the French Government concerning barbarism, filth, and superstitious practices in Arabia applies with increased force to India. We must hope that the covert rebuke to us conveyed in the French proposition may rouse our Government into adopting active sanitary measures in our Indian Empire. The incredible filthiness of Indian cities and villages is known well enough to the powers that be, and most startling exposures have been lately made of the condition of the "City of Palaces" and the other seats of Government. Some of the details were even too revolting for publication; but very little has yet been done to remedy the evil. Here and there, however, the authorities are acting vigorously, as at Bombay, where the duties of Officer of Health have been entrusted to a most able and energetic Surgeon of the

*

Bombay Army, Dr. Gillum Hewlett, and an army of labourers —from 1500 to 2000 men—have been placed under his orders.

Typhus fever has been very prevalent in parts of the metropolis throughout the year, and it will most probably continue largely to swell the Registrar-General's weekly return of deaths; for so long as railway companies are permitted to bring their lines through the most densely populated parts of London, and to carry out wholesale evictions of the inhabitants, without making any new provision of house-accommodation, so long must the poor crowd together like cattle in a railway-truck; and such over-crowding will most surely generate and propagate typhus.

In the early part of the year much alarm was excited by reports that a mysterious and extremely fatal epidemic had broken out at St. Petersburg and about the Lower Vistula, and was advancing towards this country. Answers to inquiries made through the Foreign Office showed that there was undoubtedly a very unusual mortality in those places, and Government sent out Physicians to St. Petersburg and Dantzic. From their reports, and accounts published by various foreign Physicians, it proved that the former city was suffering from a severe epidemic of relapsing fever, and that the epidemic prevailing about the Lower Vistula was acute cerebro-spinal meningitis.

Besides the Commission on the Cattle Plague, a Royal Commission on Venereal Disease in the Army has been diligently sitting and taking evidence, but has not yet issued any report. It is understood, outside, that they will report in favour of a periodical examination of soldiers, as well as of prostitutes. It is said that such a proposal will be exceedingly distasteful to the Army Medical Officers, who speak of it as being "humiliating" to them. Very much, of course, will depend on the manner in which such a duty is to be carried out, but we cannot see why it should necessarily be a "humiliation" to our military brethren to carry out measures calculated to prevent disease. Were Surgeons to refuse duties because they are distasteful or repulsive their usefulness would be sadly curtailed.

The Commission is expected to include in their report the much-mooted question of syphilisation, the courteous and enthusiastic promoter of that system of cure, Professor Boeck, having been before them for examination. The Professor has for some months been residing in London, at a great sacrifice to himself, in order to give English Surgeons the opportunity of becoming acquainted with syphilisation as he practises it, and the beds of the Lock Hospital were with laudable liberality placed at his disposal for the purpose.

A "Committee" has been appointed, and sat at the Admiralty, "to inquire into the condition of the army and navy Medical officers, as respects their rank, pay, etc." We do not know how the Committee was appointed, nor what are the differences between a "Committee" and a "Commission;" and the necessity for either Committee or Commission is not very apparent to the outside world. Through deputations, memorials, and other communications from the Colleges of Physicians and Surgeons and the British Medical Association, both Horse Guards and Admiralty are already perfectly acquainted with the causes that have brought their Medical services to the very verge of a dead-lock, and with the required remedies; and for further guidance they have only to go to the minutes and recommendations of the late Lord Herbert on the subject. But no doubt their mightinesses are far above using information derived from these civil sources; it might seem like acknowledging that such meddlers in things beyond them had had truth and justice on their side, and it might encourage similar troublesome pertinacity. Whatever the Horse Guards and the Admiralty do must be based on knowledge gathered by themselves, and arise out of their own spontaneous and generous liberality. Well, we must try to take thankfully whatever good such gods provide us, and not criticise too narrowly the manner and spirit of the gift. It is a matter of congratulation, at any rate, that the authorities are at last convinced that they must do something to revive the spirit and recruit the ranks of the two services.

Of the national Parliament, the most noteworthy facts are the dissolution of the old one and the election of a new one. "*Le Roi est mort; vive le Roi!*" At the general election several members of our Profession were candidates for the honour of the M.P. Sir Charles Locock endeavoured to deliver the Protestants of the Isle of Wight from the danger of being represented by a Roman Catholic, but for once in his life was unsuccessful. Mr. Mitchel Henry offered to the electors of Woodstock the freedom of advanced Liberalism instead of the chains of Conservatism, but they were too bigotted to listen to his charming. Mr. Alfred Smee also failed at Rochester; but Dr. Brady was re-elected by his old constituents, and Mr. Clement, an eminent and popular provincial Surgeon, was returned without opposition for Shrewsbury; so that Medicine has one additional, and a very able and fitting, representative in the new House of Commons. It is, however, much to be regretted that the other three Medical candidates were not also successful, for until the Profession is more powerfully represented and better able to make its voice heard in the national councils, its rights and interests will be pooh-poohed or passed over as they were in the last Parliament. The way in which the claims of Naval Medical Officers to a share in the distribution of good-service pensions were set aside in the Greenwich Hospital Bill was a well-marked specimen of the treatment our Profession has always received from Government. Its claims were sneered at, laughed at, or met by evasion or—prevarication, we should say, were the word parliamentary—according to the temperament of the Government official who had to reply to them. And thus will it continue to be unless influence, such as Medical men throughout the kingdom can wield if they will, is used to put pressure on the Government, especially, judging from past experience, so long as the Government is what is called a "liberal Government."

Our own little Parliament, the General Medical Council, met very early, and talked very fluently. At the dinner of the Fellows of the College of Surgeons the very able and efficient President of the Medical College was "happy to say that they were gradually settling down;" the length of time they have required for this, some seven years, does not say much for their gravity; light bodies float long.

The Council were called together early in the year in order that an amended Medical Act might be obtained from Parliament during its then present session. The attempt to do so failed, the Home Secretary declining to introduce the proposed Act to amend the Medical Acts; and not a few thought the failure fortunate. The most important part of the proposed Amendment Act was a clause to make registration compulsory.

The Council refused to admit to registration the new degree of Bachelor of Surgery of the University of London; a proceeding which, considering the high character of the degrees of that body, caused not a little surprise. More efficient arrangements were made for the registration of Medical students, which have not, however, prevented licensing boards from continuing to vex students with a multiplicity of registrations. A fixed period of forty-eight months from the date of registration to the final examination was agreed on as the duration of Medical study; and arrangements were made for the supervision of the examinations of the various licensing boards.

Mr. Cesar Hawkins is now a member of the Medical Council as the representative of the Royal College of Surgeons, in place of Mr. Arnott, who has retired from the labours and well-earned dignities and honours of the Profession to the repose and pleasures of a country life. May he long enjoy them!

At the election into the Council of the College of Surgeons nine candidates stood for the three vacancies caused by the resignation of Mr. Arnott, and the retirement, by rotation, of Messrs. Quain and Shaw. Mr. Quain was returned, as the head of the poll, by such a majority has must have been to him a very gratifying proof of personal regard and confidence on the part of the Profession. Mr. Paget, and Mr. Turner, of Manchester, were the other successful candidates; one more Country Fellow thus obtaining a seat at the Council Board.

Some beginnings have been made in the improvement of the management of workhouses, and especially in the construction, arrangements, and management of the workhouse infirmaries. The inquiries into the shocking cases of Timothy Daly and Gibson have done much to compel a change for the better by setting before the public, with painful distinctness and urgency, the enormous difficulties with which the Medical Officer of a workhouse has to contend; the extent to which he is overworked and underpaid; the wretched places his patients are herded together in; the insufficiency and miserable unfitness of the means and appliances at his command, and the no-system of nursing. There is some ground for trusting that these infirmaries will in future be arranged and managed more like hospitals, and that the infirm and sick will be given the advantages—the necessities rather—of a more liberal dietary and of skilled nurses.

The larger and more liberal arrangements forced from the guardians of London parishes for the relief of the houseless poor deserves to be noted here, not only as a remedy of a crying evil, but also because the temporary refuge thus given from want and exposure saves numbers from occupying beds in our Hospitals and Infirmaries.

There have not, happily, been any trials at common law worthy of special notice as concerning the Profession, though as usual there have been some illustrations of the hardships and dangers attending the treatment of lunatics.

The trial and execution of Dr. Pritchard for poisoning his mother-in-law and his wife was a terrible proof of the fact that the belonging to the most humane and self-denying of Professions may not always keep a weak and wicked man from giving way to his worst passions, and employing his knowledge and skill to destroy instead of to save life.

The death-roll for the year was a remarkable one, at home and abroad; the two most prominent names on it were those of our veteran Premier, Lord Palmerston, an eminently sagacious and English statesman, and of the King of the Belgians, formerly so closely allied with the hopes and interests of this empire, and of late a most valued and trustworthy councillor and friend of our Queen. And in our own Profession many men of mark and note have gone to join the many. Among them were Dr. Jones Quain, Mr. Grainger, Dr. F. W. Mackenzie, Dr. E. E. Day, Dr. H. H. Southey, Dr. R. Ferguson, Sir John Richardson; Messrs. J. P. Garlick, C. W. Crowdy, F. Cooke, M'Nab, and D. Saunders; Mr. T. J. Pettigrew, Dr. Hugh Falconer, Dr. Daniel, the African traveller; Mr. King, of Eltham; Mr. Tegart, Dr. Herbert Barker, Dr. J. A. Easton, and Dr. Hutton, of Dublin; and latest and most melancholy of all, Dr. C. G. Ritchie, taken in the flush of youth, when his life seemed full of hope and promise. Abroad, too, some great men have gone to their rest; as Valentine Mott in America, Gratiolet and Malgaigne in Paris, and Remak in Germany.

To turn to a brighter subject, we may note some of the honours bestowed on the Profession. Dr. A. Taylor and Inspector-General Hilditch have been knighted, and William Fergusson has been elevated to a baronetcy, "on account of his distinguished eminence and merit as a Surgeon." The whole Profession has felt gratified by the honour thus done to English Surgery.

For ourselves, we have endeavoured at all times, and in every way, to uphold and promote the best interests of the Profession, and faithfully, honestly, and impartially to perform our duties as journalists. We have not hesitated to blame whenever blame seemed justly due, and we have diligently laboured to present a faithful record of the intellectual life and progress of the Profession. Besides records of Hospital practice, and reports of the proceedings of the Medical Societies, we have been able to present to our readers communications from such men as Laycock, Pirrie, Spencer Wells, Lionel S. Beale, Chapman, Keith, Allingham, Lawson Tait, Hine, Gant, J. W. Ogle, J. Y. Simpson, Dr. Murray of Newcastle, Haynes Walton, Dr. Boeck, C. G. Ritchie, and Furneaux Jordan. Further, we have had special satisfaction in being the means of making public Dr. Harley's valuable and practical lectures on "Urine and the Urinary Organs," and lectures of great interest and weight by Dr. L. S. Beale, Dr. West, Dr. Bence Jones, Mr. Paget, Dr. Pavy, Dr. Handfield Jones, and Professor Lyon Playfair. "The Medical History of England" has been continued, and its able author has also contributed a series of papers on the "History of Cholera." In a succession of leading articles, entitled "Modern Dermatology," "Modern Chemistry," and "Rough Notes on Syphilis," we have also made our readers fully acquainted with the modern doctrines and practice of those important subjects.

We have every reason to believe that our labours have been acceptable to the Profession; and, while heartily thanking all our valued coadjutors for their assistance, we assure our readers that no effort will be spared by us to make the journal as worthy of their support in the future.

THE ACUPRESSURE CONTROVERSY.

We print elsewhere a correspondence between Professors Syme and Simpson and the Editor of the *British Medical Journal* which, we fear, will not give posterity a very exalted notion of Professional courtesy at the present day. Professor Simpson is well known to be a man of great originality and inventive powers. Having made known many new medicines for internal use, and many new forms of treating uterine disease, and having discovered the anæsthetic which European experience has shown to be the best, he has also set to work to explain the causes of that mortality after operations which robs the Surgeon of the results of his most brilliant efforts, just as puerperal fever robs the Accoucheur of his most interesting patients. Having established the identity of Surgical fever with puerperal fever, and shown that each springs from similar causes, he attacks them in detail; and finding that the ligature employed to stop hæmorrhage keeps wounds open, encourages suppuration and ulceration, on however small a scale, not to mention the protracted agony it sometimes causes (as in Lord Nelson's case) he sets to work and invents a method of sealing arteries which shall be as safe as the ligature for its immediate purpose, and capable of being removed when no longer necessary, so that the wound need not be kept open whilst waiting for separation by sloughing. All this, one would think, was well meant, to say the least—some would say meritorious;—and allowing that further experience is required to test its efficacy in *all* cases, yet it has been tried in a sufficient number by Professors Pirrie and Watson, and Mr. Dix (whose plan is a modification, perhaps an improvement), to render it at least a thing not to be rejected rashly. But it is in vain for Professor Simpson to raise his voice. He is an *obstetrician!* and what right has an obstetrician to meddle with arteries? Then his pamphlet was summarily "executed," not by the hangman, but by a brother Professor, before a class of students, in the one-thousand-eight-hundred-and-sixty-fifth year of the Christian era, within the city which men call Edinburgh, but gods, the modern Athens. This "execution," which the whole civilised world deplored as unworthy of the man and the times, has actually been alleged by Professor Syme as a reason why Professor Simpson

deserves no civil answer! It is much to be regretted that the Editor of the *British Medical Journal* should have allowed such a letter as Professor Syme's to appear in the *Journal* of that Association.

IS THE CATTLE PLAGUE SMALL-POX?

During the last three weeks there has been great excitement on the question of the identity or otherwise of the cattle plague with the small-pox. Strange to say, small-pox is at a premium! A patient ill with this loathsome malady, who would of late have been shunned as a plague, is now eagerly sought after for the sake of the *matter;* and cows and calves are being subjected to inoculation and vaccination daily. Early in the last century the occurrence of eruptions on the skin of animals ill of the cattle plague was noticed by Ramazzini and other observers. Neither have these phenomena been overlooked in the present epidemic—witness Mr. Gamgee's observations, and the Report of the Norwich pathologists, and that of Dr. Smart, of Edinburgh.(a) If the Rinderpest be small-pox, it will be a singular fact in the history of pathology that observers so experienced should not have been struck with the resemblance to that exanthem, but absolutely should have affirmed that it resembles scarlatina! And this not once only, or in one place, but by different observers at different places! The opinion, however, that it is small-pox is held by such men as Drs. Quain, Richardson, and Murchison, and Professor Simmonds; whilst it is denied by Professor John Gamgee and Dr. Sanderson. The matter clearly demands investigation; and during this, for our own part, we take the liberty of suspending our judgment.

In treating of this matter, the first thing to arrive at is a definition of small-pox, and this may be got in one of two ways. We may define small-pox by its visible characters, or by the physiological effects of its poison, just as a toxicologist might depose to the presence of poison by the *post-mortem* appearances in its victims, or by the effects it produced on animals subjected to experiment with it.

Following this formal division of the subject, let us ask what are the essential characteristics of small-pox, using the word generically, to include that of animals as well as of man? The absolute divergence of opinion on the part of the ablest pathologists, as to whether the visible, tangible, measurable lesions of the Rinderpest come within the category of small-pox, give a sufficient answer to the former question. As to true, well-developed small-pox, as with scarlet fever, gout, cancer, typhoid, and every other malady under the sun, there can be no mistake. But with these diseases in an ill-developed, irregular condition, their nature is often matter of inference.

As to the *behaviour* of the poison, that must be ascertained by a combination of observation and experiment combined. Hitherto writers on this matter have suggested negative experiments only—for example, that cattle shall be vaccinated and variolated, and then be exposed to the Rinderpest. A truer method would be to take cattle which have had the Rinderpest and recovered, or which have been well exposed to it and have not taken it, and ascertaining whether they can take variola or vaccine. One affirmative experiment of the latter kind would settle the question.

Experiments will soon be forthcoming. Meanwhile it would be a great pity if the question were made a party or personal one. We should all rejoice at a positive solution of this problem, and especially at one which showed a way to escape a great national calamity.

(a) "*The Character of the Disease*, as deduced from the morbid appearances which it presents, bears no resemblance to the ulcerative typhoid fever of man. As regards human typhus, the analogy likewise fails. The morbid conditions are undoubtedly peculiar. In so far as any resemblance to human disease exists, it points to a condition of the internal lining membrane analogous to that of the skin in acute scarlatina, and the disease might not inaptly be termed an internal or mucous scarlatina. The general congestive but non-inflammatory state of the mucous membranes, the epithelial desquamation from the mucous surface, the increased temperature of the animal in the early stage of the disease, and the incubation period and critical days, are facts which all tend to support this view; while the condition of the kidneys and the invariable presence of albumen and blood cells in the urine lend additional confirmation to it."—"Reports to Lord Provost," etc. Edinburgh: Maclachlan and Stewart. 1866. Price 3s. 6d.

THE SICKNESS OF THE TROOPS AT HONG-KONG.

Our readers will, no doubt, have remembered a leading article in the *Times* referring to the great sickness and mortality among our troops in China, the defective arrangements—or rather, the want of all arrangement and ordinary precaution—in the accommodation of the troops, and the absence of the senior Medical Officer during a time of unusual pressure. With some portion of the public, at any rate, these evils have been placed at the "Doctor's door," and the shortcomings of other departments have been debited to that of the Medical. Now, we believe from all we can gather, that the hands of the Army Medical Department are quite clean of this matter. The deficiency of accommodation was pointed out to the authorities by the Medical men, who remonstrated against a second regiment being sent to Hong-Kong, and predicted what the results would be. There can be no doubt that the senior Medical Officer was at Japan with the General-Commanding, but, we presume, he was there upon duty, and he returned as soon as he knew of the prevalence of serious disease among the troops at China.

THE WEEK.

HISTORIES OF MEDICAL SCHOOLS.

In the year 1862 our journal contained histories of most of the chief Medical Schools in London, in the English provinces, and in Scotland and Ireland. The history of each School was entrusted to some gentleman who had been an old pupil and partisan—or who, to use students' language, was a "regular *Guy's* man" (or whatever other School might be treated of). These articles were anonymous, but not editorial; it is understood that each writer was to have in turn the privilege of saying all he chose to say in favour of his own *Alma Mater*. The accounts we gave of most of the Schools excited a good deal of interest, and we have often and often been asked why any were omitted. Amongst the latter were University and King's Colleges—Schools the foundation of which marked a very palpable era in the history of the Medical Profession. To-day we have the pleasure of publishing an account of University College from an accomplished writer and distinguished pupil of that School, and we shall soon follow it with a history of King's College. Articles such as these keep alive many a genial anecdote, and enable many a hard-working man to live his younger days over again.

PATHOLOGICAL SOCIETY.

The meeting of the Pathological Society on January 2 was an important one for many reasons. It was the annual meeting for the election of officers. These proceedings were more formal than usual, and were most noticeable as a hindrance to a discussion in which the members were much interested. Dr. Quain brought before the Society a Veterinary Surgeon, Mr. Hancock, of Uxbridge, who had inoculated the back of his hand whilst dissecting a cow which had died of the Rinderpest. Dr. Quain read a report of the case, and urged that it tended strikingly to show the relationship of the Rinderpest to variola. The nature of the eruption, he considered, was characteristic, and had been considered to be vaccine by a Surgeon at Uxbridge who saw Mr. Hancock's hand soon after the eruption appeared, and also by Mr. Ceely, of Aylesbury. Dr. Quain then showed several drawings to illustrate the resemblance of the eruption to that of cow-pox. The case excited great interest, and after Mr. Hancock had left, Dr.

Quain made further observations on the subject. He said the question of the resemblance of the cattle plague to small-pox was not a new one. It had been raised by Ramazzini in 1711, and by Dr. Layard in 1758. But he thought the case of Mr. Hancock was the only case in which anything like satisfactory proof had been given. In the newspapers there had been plenty of statements to the effect that the Rinderpest was variola, but they were mere surmises. There were, however, other arguments. It had been observed that some cows had a remarkable immunity from infection, and it had been ascertained that in some instances the animals had had vaccine disease in early life. Dr. Quain concluded his statement by remarking on the great importance of this question to the community. If the Rinderpest really was variola, vaccination would put a stop to the epidemic. Dr. Sanderson next spoke. He thought not only that the eruption in Rinderpest was not a vesicle, but that it could not even be mistaken for one. On this Dr. Sanderson spoke very emphatically. Whatever relation there might be betwixt the cattle plague and small-pox in human beings, there was, he held, no evidence of resemblance to be founded on the eruption of the two, as they were quite unlike. Moreover, the eruption in Rinderpest was not like the eruption in the small-pox of sheep. Mr. Gamgee said there were two points to which he wished specially to draw their attention. First, the cutaneous eruptions of the cattle plague were not overlooked by him, even at the commencement of the present outbreak; and not only did he specially notice it, but Continental observers and writers have commented on the observations of Rammazzini, Vicq d'Azyr, and others in relation to the appearances occasionally noticed. Dr. Murchison had, indeed, referred to one specimen which he saw at the Albert Veterinary College, and in which the tuberculated eruption was very remarkable, with well circumscribed nodules, flattened and even depressed in their centres. But there is a marked difference, as Dr. Sanderson had mentioned, between the Rinderpest eruption and a variolous one. The changes occurring on the skin, or, more correctly speaking, in the epidermis, were changes similar to those in which the epithelium of the mucous membrane was involved. Not only on the general surface of the membrane, but in their glands, as distinctly seen in the fourth stomach, the cells undergo granular degeneration, masses of nuclei are formed, and there is a detachment and desquamation of the entire epithelial structure. There was nothing analogous to this in small-pox. He had seen the whole small intestine deprived of its epithelium, which could be traced in flocculi or caps of the villi in the intestinal contents. There was a similar separation of the epidermis, which he noticed and described last August. But the cutaneous eruption bears no relation to the severity of the disease. It is not, as in all known variolous fevers, the index of the progress and severity of the complaint, but rather the reverse. It is seen to be most severe, most confluent, in mild cases, and has been witnessed more in Holland than in England during the past few months. The eruption often heals as the disease becomes aggravated and the animal dies. The second point to which he wished to call attention was the frequency with which eruptions occur from handling animals affected with various diseases or dissecting animals after death. He held in his hand the first volume of the *Veterinary Review*, in which there was a drawing, and of an ecthymatous eruption on his own arm, contracted by passing the arm into the vagina in a cow in a case of protracted labour. Although his case was widely different from the one before them that evening, there were reports of eruptions occurring with the same periodicity as variolous forms. It was not new to him, for one, and indeed for several, individuals to contract pustules very similar to the one on Mr. Hancock's arm, and from animals which he had had under treatment for cutaneous and other diseases. It was, indeed, necessary to be very cautious in drawing inferences from a post-mortem inoculation, which he held in this case could not be regarded with anything like positive assurance as one of communication of the Rinderpest poison to man. He trusted that such a case might not divert them into vain trials of another method of dealing with the plague short of the true plan which ought to be adopted in this distressing calamity. Dr. Murchison admitted that the eruptions of Rinderpest and of human small-pox were not identical in appearance, but he thought their differences were most probably caused by the differences in the structure of the skins. Besides, Dr. Murchison added that the resemblance of the diseases (if we may still call them two) was to be found, he believed, in their general history, and not in the eruption only. He drew attention to the fact that in India it was admitted that cattle suffered from small-pox, and that it was very fatal. Moreover, experiments in India had shown that matter from cows thus suffering produced in the human subject sometimes vaccine disease, and sometimes small-pox. Dr. Sanderson drew attention to the fact that he had stated not only that the eruption in Rinderpest did not resemble that of small-pox in the human subject, but that it did not even resemble that of small-pox in sheep.

FROM ABROAD.—DEATH FROM CHLOROFORM AT BERLIN—THE CATTLE PLAGUE IN THE PARIS JARDIN — OUTBREAK OF TRICHINOSIS AT HEDERSLEBEN.

At a recent meeting of the Berlin Medical Society, Dr. Hüter related a case of death from chloroform which occurred in the Surgical Polyklinik. A boy 4½ years of age, who some time since had an attack of scarlatina followed by œdema of the extremities and albuminuria, was brought on account of retention of urine, none having been passed, according to his mother's account, for two days. Slight œdema still existed, and the child looked pale and ill. On examination there was found to be distension of the bladder, but the boy was so restless while it was made that it was deemed prudent to administer chloroform before passing the catheter. This was given by an assistant accustomed to its exhibition, a napkin being moistened with a small quantity—this being, in fact, less than children of this age usually require, and not to be compared to that employed in operations. The abdomen was examined again, and a catheter was passed into the bladder, from two to three minutes at most having elapsed since it was determined to employ chloroform. At this moment, however, the lips were observed to become blue and the jugulars distended, while the pulse and respiratory movements ceased. A deep inspiration was caused by passing the finger down to the epiglottis, but this could not be renewed, a second one, however occurring upon opening a vein of the neck and discharging an ounce or two of blood to relieve the turgor. Tracheotomy was now resorted to (a third inspiration occurring during its performance) and artificial respiration performed, the diaphragm being at the same time stimulated by the induction apparatus, and the face kept sprinkled with cold water. Electricity was also applied in the region of the heart, and this was followed by acupuncture of the organ by means of two long needles. The heart's action, which had ceased to be audible, was seen by the regular and isochronous movements of the needles to become temporarily revived. These, however, soon ceased. All these means were most energetically applied by able assistants, and Dr. Hüter does not see that in a similar case that he could do otherwise, excepting, perhaps, that he would resort to acupuncture of the heart at an earlier period. No account of the autopsy is furnished. He does not think that so exceptional a case of death from chloroform should influence our general employment of this agent —this, indeed, being the first instance on record of a child under five years of age dying from the effects of chloroform. Deaths under chloroform may be ranged in three categories,—those in which this agent really exerts no essential effect, the

patient dying not through, but during, the narcosis, in consequence of some other circumstance accompanying or preceding the operation; those cases in which the narcosis only operates mediately—*e.g.*, through the flow of blood into the anæsthised glottis during operations on the throat; and those cases in which the narcosis is the direct cause of death. It was so in the present case, although the patient had inhaled so little of a chloroform the entire purity of which has been ascertained.

In a communication to the Academy of Medicine, M. Leblanc read a memoir in which he shows that the cattle plague, termed by him, in common with all the French writers, "the typhus of horned cattle," is not confined to these animals, and may be propagated to other species. The following is the summary of the facts he observed at the Paris Jardin d'Acclimatation:—

"On November 15 two Indian gazelles, contaminated by the typhus virus in England, were introduced amidst a collection of 135 animals of very varied race and species – ruminants, pachyderms, rodents, and carnivora. Of these 135 animals 34 were attacked with more or less severe typhus, and all were sacrificed except one, without any treatment having been put into force. Two dogs and two peccaries were also killed which were not ill. One only of the animals affected, a male auroch, survived. Those attacked were 12 oxen, 9 goats, 5 antelopes, 3 stags, 2 kids, and 2 wild boars. The disease was propagated with extraordinary rapidity, and from December 14 there remained no diseased animal. The promptitude of the slaughtering of the animals affected certainly contributed to the arrest of the extension of the scourge. It results from these facts that various species of animals, appertaining to different genera and families of the class mammalia, may be attacked by this disease. The ovine species does not seem very apt to contract it, for not a single sheep of the twenty-five inhabiting the infected locality was attacked."

An eye-witness gives, in a recent number of the *Deutshe Klinik*, an interesting account of a severe epidemic of *trichinosis* which occurred at Hedersleben, in Prussian Saxony—a place containing about 2000 inhabitants. A butcher having slaughtered two pigs, most of the consumers, among whom were many factory hands, ate the chopped flesh in a raw condition; and soon afterwards many persons at the factory were seized with a similar illness. One of the Doctors of the town immediately suspected trichinæ, but others called in consultation declared the affection to be cholerine. However, as out of 37 cases 20 soon died one after the other, the autopsies amply proved that the disease really arose from trichinæ; and three weeks after the first case the whole number had amounted to 300, with 40 deaths. (According to another account, there were 100 deaths.) This does not represent the whole numbers, for several persons, alarmed by the cholera panic, left the town, and of these several have died at the places they repaired to. At the autopsies, even three weeks after the outbreak, numerous "parent trichinæ" were found in the intestinal mucous membrane, the great bulk of the animals being in the intramuscular structure. The number of children affected, going down even to the third year, was remarkably great, yet they all recovered. As on other occasions, some of the patients, through exhibiting all the characteristic symptoms, denied having eaten pig's flesh, while some admitted only to have partaken of the fat. The immediate cause of death seemed to be paralysis of the inspiratory muscles; the most alarming symptoms, besides the loss of motion, were the profuse sweating and complete sleeplessness. There was delirium only in one case, and the convalescence resembled that of typhus. It seems that in examinations which have been recently made of beetroot, which forms the principal food of pigs, numerous animalcules have been found, but these are said to present quite different characters to those of the trichinæ.

Royal College of Surgeons.—The next primary and Pass Examinations for the Diploma of Membership will take place on Saturday the 13th and 20th respectively.

UNIVERSITY COLLEGE AND HOSPITAL.

(*From a Correspondent.*)

For us as Medical journalists, University College means University College Medical School. We are not anxious to step out of our vocation by expressing the faintest opinion as to the political principles on which the College in Gower-street was instituted. Its story, as far as it invites the attention of the Medical reader, may be traced without allowing political bias to affect the narrative. It may be that the success of the College as an institution for general education has fallen somewhat short of the expectations and hopes entertained by its founders, but the position it has taken as a Medical school has always been far above mediocrity, whilst for a long period it bid fair to outstrip all its rivals. Although its history does not date back fifty years, it has enrolled amongst its professors in the Medical faculty, some of the greatest names in science, whilst a large proportion of the foremost men of the day as Medical teachers, writers, and Practitioners in Great Britain and the colonies have been amongst its *alumni*.

We suppose that most readers are familiar with the situation and appearance of the College and Hospital. The former has always been in an unfinished condition. The wings, intended to give completeness to the handsome but somewhat pretentious front, have as yet existed only on paper, and the mutilated ends of the building contrast oddly with the magnificence of the central dome and portico. The College stretches north and south, and is divided by the central dome into two halves, of which the northern is devoted to the Medical school, whilst the southern is the "Arts end." In front is a large open space, intersected by gravel walks and grass plots after the most approved academic pattern. The Hospital is separated from the College by the road. It is a plain building, but very well adapted to its purpose, and were it not that it is too closely surrounded by houses on the north, west, and south, and that it lacks a sufficient open space for the exercise and recreation of convalescent patients, its external appearance and proportions would insure it a favourable criticism; as it is it gives one the idea of a good useful Hospital, situated in a densely populated, but neither squalid nor unhealthy quarter —a building that has already done good service and that is destined to do a great deal more as years roll on—yet an appendage to the College, erected where it is rather for the sake of the students than of the patients.

Although, as we have said, University College has not existed more than forty years, it has a history. Our personal acquaintance with it does not date back much more than half that period, but we have seen many changes and events there which have more than a local or narrow interest. We remember well the time when, coming up to London a raw country lad, we looked with awe at the portico, the theatres, and the dissecting-room, and with triple awe at the Professors seated in formal phalanx at the introductory lecture. At that time the Master of the Mint was the Professor of Chemistry, Liston and Samuel Cooper shared the Surgical Chair, Richard Quain taught Anatomy, Dr. C. J. B. Williams lectured on Medicine, Dr. Walshe on Pathological Anatomy, Lindley on Botany, and Anthony Todd Thomson on Materia Medica. Each of these professorships has now another incumbent. Some of them have changed hands more than once since 184-. Liston, Cooper, Lindley, and Anthony Todd Thomson are dead, and the rest have retired after long and successful services. Other stars have arisen in their places, but, excepting the mediæval Hospitals, there are few British Schools of Medicine which can show a more noble roll of past worthies than can University College—modern as it is.

A truce at present to personal reminiscences. On the 1st of October, 1828, the Medical Department of University College was opened by Mr. Charles Bell, the Professor of Physiology and Surgery, who delivered an introductory address in the

largest theatre of the institution, built to hold 800 persons, which was filled to overflowing on the occasion. So says a contemporary journal, and *certes* a great Medical school could not have been opened under better auspices. We have no doubt that the distinguished physiologist was listened to with breathless attention, and applauded vociferously. Bell's connexion with the College was not, however, of long duration. The team does not seem to have pulled together very amicably at first; at least, a good many changes occurred in the earlier years, and one or two squabbles were talked about and even written about out-of-doors. Bell retired early in the Session of 1830-31, and Dr. Southwood Smith temporarily supplied his place in the Chair of Physiology. He went back to the Middlesex, was knighted, and chosen Professor of Anatomy to the Royal College of Surgeons. But the University School cannot afford to forget that it was opened by a man who, amongst British Physiologists, ranks only second to Harvey.

The College at first bore the name of the London University, and it was originally intended that a charter should be obtained for the purpose of enabling it to grant degrees. When the University of London was instituted and endowed by the Whig Government in 1836 the name was altered to University College, but no little confusion was caused to the public by the alteration, and few uninitiated people knew the difference between the two institutions.

Besides Charles Bell, the following composed the Medical Faculty during the session 1828-29:—Mr. G. S. Pattison taught Anatomy; Dr. Conolly, the Nature and Treatment of Disease; Dr. D. D. Davies, Midwifery; Dr. A. T. Thomson, Materia Medica; Dr. Edward Turner, Chemistry; Mr. T. R. Bennett, Practical Anatomy; Dr. Watson, Clinical Medicine; Prof. Grant, Comparative Anatomy; Prof. Smith, Medical Jurisprudence; and John Lindley, Botany. The students obtained their Hospital practice at the Middlesex Hospital, and Dr. Watson and Mr. Bell delivered clinical lectures in the University on the cases which occurred in the Hospital. The number of students entered on the College books was 193, and on looking down the prize list for the year we find the name of Edwin John Quekett third in honours in Anatomy and obtaining the first silver medal in Chemistry. Mr. Quekett was afterwards known as an original observer in Microscopical Botany and the Lecturer on Botany at the London Hospital, where he educated his more celebrated brother, the late Conservator of the Hunterian Museum. He died at the age of thirty-eight. To have given the first impetus to such a career was alone a tolerable share of success for the first year.

In this journal we have never been great advocates of the prize system. We regard its extensive introduction into the system of Medical education as by no means an unmixed good. Early honours have sapped the vital powers of many an active brain, and left it irritable and partially exhausted for life.

But certainly there are some robust natures, some elastic intellects with whom forcing seems to agree. All high wranglers do not become useless members of society nor forgotten in science, and when on looking down the prize and honour list of University College, during the first twelve years of its career, we find the names of Quekett, George Viner Ellis, William Baly, of Lynn Regis, Norfolk, George Newport, of Canterbury, John Taylor, of Huddersfield, Thomas Bevil Peacock, Thomas Morton, J. Philip Potter, Erichsen, W. B. Carpenter, William Jenner, E. A. Parkes, Durancé George, Edwin Lankester, Frederick John Mouat, and Richard Quain, junior, we are bound to confess that there must have been a race of young giants in those days who stood the training admirably, and came out of it with powers of thought and observation and work strengthened by the trial. All horses are not for the racecourse, and we want hackneys and carriage horses; but abolish the turf and the strain of thoroughbreds would soon get impoverished and disappear.

Other changes besides Bell's retirement took place in the Session 1830-31. Dr. Conolly resigned, and was succeeded by a Physician whose name is identified with the early career of the Institution. Dr. Elliotson soon obtained in the Chair of Medicine the zenith of popularity and a European fame. His genius and acquirements can now be appreciated by a study of his lectures. But by his old pupils he is still remembered as perhaps the most popular teacher of his time. How attractive his teaching was is proved by the fact that the number of students in the class of Medicine increased from 90 to 197 during his tenure of the Professorship. It little becomes us here to speak of one who is still amongst us. The causes which led to his resignation in 1838 were widely discussed at the time, and although he retired as the apostle of an exploded fallacy, he left behind him a name as a practical Physician and teacher which will last when Mesmerism and phrenology are finally consigned to the limbo of alchemy and astrology. In the same Session Professor Pattison retired from the Chair of Anatomy. His retirement, we believe, was compulsory, and the curious in squabbles may read the story in the dusty volumes of the *Lancet* at the College of Surgeons. Professor Bennett died, and in the following Session we find Dr. Jones Quain occupying the Chair of Anatomy, and Mr. Richard Quain superintending the department of Practical Anatomy.

The Session 1831-32 saw the Army veteran and the most learned Surgeon of the age, Samuel Cooper, inducted into the Chair of Surgery. Our recollections of Mr. Cooper date a good many years later than the time of which we are writing. Well do we remember him—bald and white haired, somewhat infirm, but still in a green old age, intelligence and kindness sharing his face as he walks slowly into evening lecture, sits down, crosses his legs, and, without note or book, begins a discourse full of practical maxims, illustrated by all the rich experience of the battle-field and Hospital, and all the varied stores of learning which went to compose the Surgical Dictionary. What a favourite he was with the students! There was a tradition in our day—we do not vouch for the truth of it—that after he had been somewhat roughly attacked on one occasion by the redoubtable Editor of the *Lancet*, the men had unhorsed his carriage, and, taking the place of the horses, dragged him to his own door!

On May 22, 1833, the first stone of the Hospital was laid by the Duke of Somerset, and it was opened on November 1, 1834. In Elliotson's address at the close of the Session, he says that already 2464 patients had been treated in it, and 116 students had taken tickets for Hospital attendance. The success of the new Hospital was doubtless due to many causes. There was the fame and reputation of the staff—the *prestige* of the College and the attractions of novelty. But apart from all these, the founders of University College Hospital had established a principle which made the whole body of Medical students their debtors. By throwing open the whole of the Dresserships, Clinical Clerkships, and House-Surgeoncies to be competed for by the most deserving students without the payment of special fees, they had given the key of the surest path to practical knowledge to hundreds of young men whose want of pecuniary resources would have cut them off from attaining it at the older institutions. Nowadays things are altered: the University College principle is adopted everywhere, or with very few exceptions; but we must not forget the honour due to the inaugurators of a great reform. The appointment of House-Surgeons by the French system of *concours* was another happy innovation well adapted to attract able, ambitious young men. It will be readily allowed that these were not amongst the least powerful of the causes which for a time carried the College ahead of all competitors. Already the tide was setting in, for in the Session of 1835-36 there were 424 students entered on the books.

Two great names were added to the list of the Faculty of Medicine during the session 1835-36. Dr. Carswell, after-

wards Sir Robert, delivered his first course of pathological anatomy in the summer session of the latter year, and Robert Liston was appointed Professor of Clinical Surgery. Every one who has visited the College has been shown the unequalled series of pathological drawings with which Carswell enriched the institution. With the wax models by the Tusons, father and son, they form an almost unrivalled collection. Except, perhaps, in the hands of Sir Charles Bell, art had never been rendered so subservient to pathology as in Carswell's drawings; and in becoming possessed of them the College received a treasure, a faithful transcript of nature, of which the value can never diminish. The name of Liston, ἄναξ ἀνδρῶν, would alone stamp dignity on the history of any school. No doubt he is still fresh in the memory of most of our readers; but for those who are entering their Professional career we may attempt a description of the greatest Surgical genius of modern times. Of gigantic form and proportions, a noble, upright bearing, handsome, large featured, with a grand head of the dolicho-cephalic type; bald, a sharp, scrutinising grey eye, forehead well proportioned, but not unduly predominating; a wonderfully determined mouth and brow usually wearing a stern expression, but which could break into the most winning smile; hands that would have served a son of Anak, but thoroughly well proportioned, powerful as a gorilla's but flexible and delicate of touch as Paganini's; he was one of the few men who not only are sufficiently marked to set their personal identity above the risk of being mistaken, but who are so unlike all others that they do not even suggest a resemblance. Liston was Liston, not only in person, but in dress, gait, bearing, voice, manner; there was a grand simplicity about the man which was like no one else. Even to the plain black riband of his watch, he scorned ornamentation. See him at 7.50 on a frosty morning in spring coming to lecture on Operative Surgery, in red neckcloth, shooting coat, and gaiters, after a sharp walk round the park, or at two in the afternoon stepping from his dark brown chariot, with the tall bays, at the Hospital door in spotless linen, loose black silk neckerchief, plaid trousers, with half-a-dozen Surgical instruments concealed up his capacious coat sleeve, there was no occasion to ask, "Which is Liston?" How the students used to rush after him up the Hospital stairs, or on field days swarm into the operating theatre! Watch him at lithotomy—see how carefully he examines his instruments, looks to the tying up of the patient and other preliminary details! He passes the sound and then sits down, whilst every voice is hushed in the crowded theatre and every eye directed on the bald head and those marvellous hands! A decided cut, one or two lesser ones, and in a moment the huge left forefinger is in the bladder, and the forceps is following it, whilst a deep-voiced "Steady, steady," reassures the groaning patient. With wonderful adroitness the stone is seized and extracted, and a short tube introduced into the wound, and the great operator looks round as calm and unexcited as if he had been carving at the dinner table. We have seen splendid lithotomies in London and elsewhere, but we never saw anything which came up, in simplicity, rapidity, or certainty, to Liston's operation.

"Facta non verba" might have been Liston's motto. He never was a fluent lecturer. His sentences were short, broken up, abrupt, colloquial; but they were *remembered*—a higher virtue than belongs to the efforts of many a voluble orator.

That he did many wonderful Surgical feats is as mere a truism as that Napoleon fought many wonderful battles. But we recollect one which is of some historical interest. One day it was noised abroad that Liston was going to remove a ball from the head of the thigh bone of an old foreigner which had been imbedded for a great number of years, and had resisted the operating skill of Dupuytren and other Continental Surgeons. The theatre was accordingly crowded, and after a time a greyheaded, thin old man, in a red nightcap, was assisted into the area by the Hospital porters. We heard that he was a Pole, and that his name was Bem, and that the ball had been received in a duel fought some twenty years before. The operation began—there was no chloroform in those days, but not a murmur escaped from the patient. After the preliminary incisions, which extended deep down through the muscles of the thigh, some minutes were occupied in bone cutting and gouging, and then Liston looked up with the ball in his hand. It had been lodged deep in the bone in the neighbourhood of the great trochanter. We fancy we can see now the flicker of triumph that came over Liston's usually impassive face. Hæmorrhage is stopped, the flaps replaced, and some water dressing placed on the wound; and as the old man is carried out he takes off his red nightcap and waves it to the students, who give him a cheer that must have startled the patients in the adjoining wards. Not many seasons after all Europe had heard of the storming of Hermanstadt, and that the best troops of Russia and Austria were in rapid retreat before the victorious national legions of Hungary led by General Bem.

Love of athletic exercise was a strong passion in Liston. To ride a restive horse or hunt a rough country were to him delight. A little danger only added zest to the pleasure. He did not always escape unscathed, and it was supposed that his fatal illness was precipitated by the exertion of taming an unmanageable horse. He met with more than one serious accident whilst hunting, and on one occasion fractured his pelvis. But his Surgical instinct never forsook him. He used to relate in his lectures that when he came to himself after fracturing his pelvis his first thought was to ascertain that his bladder was uninjured. In his last illness it was he himself who suggested the true cause of the dysphagia and hæmoptysis that accompanied it. The writer recollects to this day with devout gratitude one of Liston's hunting stories. He was undergoing the ordeal at the College of Surgeons, where Liston at the time was an examiner. One of the Court, who shared a table with Liston, was posing the candidate very unmercifully about some particular fracture of the lower extremity, when Liston broke in, and related that he had met with the same accident, and, rising, showed how he had managed to limp about during its cure. The good-natured diversion had the most happy effect. The conversation, which before had taken something of the complexion of a cross-examination at the Old Bailey, became a pleasant chat, and everything went smoothly until the President's bell rang.

Many stories are told of Liston's enormous muscular strength; we recollect an instance of its exercise which created some amusement at the time amongst the students. It used to be a favourite trick with many of the men to climb over the railings which surrounded the area of the operating theatre after operations were over, and thus make a short cut into the corridor outside. This had at last become a nuisance, and was accordingly forbidden by the Hospital authorities. One day, however, a luckless youngster, of not very tall stature, made a bolt over the railing before Liston had left the theatre. In a twinkling of an eye the hapless wight was suspended in the air by his coat collar and quietly deposited on the other side of the railing, amidst a roar of laughter from the bystanders. Liston was the favourite of the students generally; but his House Surgeons and assistants almost worshipped him, and he became warmly attached to many of them. Few things affected him more than the death of Philip Potter, who was Junior Demonstrator of Anatomy, and had as a student achieved a brilliant reputation both in the College and at the University of London. Potter died from dissecting wound. His bust now stands in the lobby of the library of University College, close to that of his great master. He was as handsome as Apollo Belvidere, a first-rate anatomist and Surgeon, and as gentle and kindly natured as a

knight of romance. Not long after Potter's death Liston's House Surgeon and one or two more of the senior students were dining with him. After dinner the party drew round the fire. Liston sat for some time moody and silent. At last he rose, and, filling a bumper of claret, said to his guests, "Do as I do"—"Poor Potter!" He drank the wine and dashed the glass on the floor. It was never to be profaned by a less solemn use.

But we must return to University College. It has always been the good fortune of that institution to secure the services of one of the best men of the time in the Chair of Chemistry. The first Professor was Dr. Turner, the author of the most popular text book of the time, and an exceedingly able teacher. Old pupils of Turner's still speak of the wonderful clearness with which he could impart a knowledge of those elementary principles which most students find it the most difficult part of the business to grasp. Of course organic chemistry was then in its infancy, and the "Doctrines of Modern Chemistry," with which the readers of the *Medical Times and Gazette* may be charitably supposed to be now familiar, were sleeping unborn in the pregnant womb of philosophy. But in teaching the old-fashioned "KO SO_3" no one was more successful than Turner. He died in 1837, and was succeeded by Mr. Thomas Graham, of Glasgow, the future Master of the Mint, and acknowledged one of the most philosophical chemists of the day. The great attraction in Professor Graham's lectures was the beauty, perfection, and certainty of the experiments by which they were illustrated. They never failed, and more than compensated for the Professor's moderate pretensions as an orator. On his retirement he was succeeded by Fownes, the benefactor of Medical students by his admirable Manual, and of University College by the bequest of a valuable chemical library. The premature death of Professor Fownes again left the Chair vacant; but fortune again proved auspicious, and a worthy successor to the chair of Turner, Graham, and Fownes was found in Professor Williamson. The facilities offered in the Birkbeck Laboratory for the study of chemistry render University College one of the best training places in Europe, not merely for the students who study chemistry as a branch of Medical science, but for men who are to make it the business of their lives.

The Session 1838-39 was an eventful one in the history of the College and Hospital. Professor Elliotson resigned in consequence of the discharge of one of his mesmeric patients by the Hospital authorities. The students were divided into two parties: one favouring the Professor, the other siding with his opponents, and several stormy meetings took place. Dr. Copland was selected to continue the course which Dr. Eliotson had left unfinished. His first lecture was delivered amidst a storm and counterstorm of hisses and cheers that would have silenced a man of less cool head and less determined will. Like one of the Scandinavian heroes from whom he is descended, with burly form and unblenching brow he stood confronting the hurricane. In vain did Dr. Sharpey interpose and enforce the claims for learning and ability of the new lecturer. The *fraeas* lasted until the termination of the hour, but was never repeated. Dr. Copland persevered, and conducted the course to a successful termination. Dr. C. J. B. Williams succeeded to the Chair. The appointment was hotly contested. Among the candidates were Dr. Marshall Hall and Dr. Craigie. Dr. Williams held the Chair and the office of Physician to the Hospital until his large practice rendered their further tenure impossible, and he was replaced by Professor Walshe, who had succeeded Dr. Carswell, on his appointment as Physician to the King of the Belgians, in the Chair of Pathological Anatomy. Dr. Walshe retired from the College and Hospital a few Sessions back, and Dr. Jenner now ably performs the duties of Professor of Medicine.

The next events which it behoves us to notice are the changes which followed the death of Mr. Liston, which took place in December, 1847. This was the heaviest blow that the College had received in its whole career. Mr. Cooper's health was failing, and he had obtained the assistance of his son-in-law, Mr. Morton, a very talented Surgeon and amiable man, who was already Assistant-Surgeon to the Hospital, in the delivery of the lectures. The authorities of the College, however, rightly thought that Liston's successor should be one who had already achieved a high reputation. They were determined to have the very best man they could obtain. They accordingly made overtures to the Surgical Autocrat of the North. Mr. Syme acceded, and came up to London, and was elected Professor of Clinical Surgery and Surgeon to the Hospital. His tenure, however, only lasted a few months. After the undisputed sway he had enjoyed in Edinburgh, the rivalry of London Professional life was probably distasteful to him, and he set his countrymen the almost unprecedented example of returning to Scotland. Mr. Cooper, naturally, perhaps, hurt at a supposed neglect of his son-in-law's claims, also tendered his resignation, and he shortly afterwards died. The Chair of Surgery was then filled by the able Surgeon Mr. Arnott, who quitted the Middlesex Hospital at the invitation of the Senate. He, however, retired in 1850, and Mr. Erichsen, an old pupil of the College, who had already obtained a high reputation at the Westminster Hospital, was elected to the Professorship, which he still holds.

About the time of Mr. Arnott's retirement Mr. Quain resigned the chair of Anatomy to Mr. Ellis, retaining only the office of Special Professor of Clinical Surgery to the Hospital. Many years before—in 1836—Dr. Jones Quain had vacated the Professorship of Anatomy and Physiology, and the Council were fortunate enough to obtain the services of the greatest physiological teacher of the age—Dr. Sharpey. When Dr. Sharpey began to lecture, minute anatomy, in its modern sense, was unknown in England. He was the first teacher who demonstrated to an English audience the wonders which Henle, Schleiden, and Schwann had brought to light in Germany by microscopical research. His classical article on Cilia had stamped him as an original observer in the same field, and the Professorship gave him the opportunity of utilising the results of his wide and varied acquaintance with biological science. It is not within our province to speak much of the living, but our sketch would be imperfect did we not refer to the lustre thrown over the whole College by its present Professor of Physiology.

In 1849 the College and Hospital sustained another loss by the death of Dr. Anthony Todd Thomson. Dr. Thomson was a perfect cyclopædia of Medical knowledge, a diligent and painstaking lecturer, and a successful Physician. Before his death his health and powers had been failing, but in the zenith of his energies he had contributed greatly to the success of the College. Originally a general Practitioner at Chelsea, he had by his writings elevated Materia Medica into a science, and in this country pioneered the path which has been so successfully followed by Christison, Pereira, and Garrod. He was very kind to the students of his class—inviting them in batches to his house, where he entertained them with Scottish breakfasts and good talk. In the Hospital, skin diseases which nobody else could cure vanished before his well-remembered "*Pergat in usu medicamentorum.*" No man knew better than he the value of remedies or applied them with more skill. He was succeeded in the chair of Forensic Medicine by Dr. Carpenter, and in that of Materia Medica by Dr. Garrod, whilst Dr. Parkes filled the vacancy caused by his death at the Hospital. All were men who had done honour to the College in which they had been educated by earning first-rate reputations as scientific writers and observers. Dr. Carpenter was succeeded on his retirement by Dr. Harley, who had previously been commissioned to give lectures in the College on the microscope and its applications to Medical science, and Dr. Garrod by Dr. Sidney Ringer, a distinguished pupil of the school. The readers of the *Medical Times and Gazette* need not to be reminded of the debt which Medical science owes to Dr. Harley.

We have said little hitherto of the means, appliances, and advantages for Medical education possessed by the College. First and foremost is the noble dissecting-room, 98 feet long by 38 feet wide, well ventilated and lighted from above, so that a dozen students might work round a subject without overshadowing each other. Then there is the Birkbeck Chemical Laboratory, fitted with every requisite for carrying on at one time the education in Practical Chemistry of a large number. The Museum and Laboratory for Materia Medica, the Laboratory for Practical Physiology and Histology, furnished with a series of microscopes, the old Museum for Comparative Anatomy, rich in Invertebrata, all deserve notice. Carswell's collection of coloured pathological drawings, about 700 in number, with a systematic catalogue and histories of the cases, arranged by the collector himself, has already been alluded to. But besides all these, the College possesses a Museum of Healthy and Morbid Anatomy which might be the envy of many an older institution. It was founded on the basis laid by Sir Charles Bell, and contains many of his preparations and drawings, with their original catalogues. The wax models and the series of brains east in

wax, from dissections made by Professor Sharpey; the skeleton of Harvey Birch, which the poor misshapen acrobat left to Liston, and which is described in the Medico-Chirurgical *Transactions* by Professor Ellis; the splendid set of preparations illustrating utero-gestation made by Dr. Davis; a valuable collection exhibiting the anatomy and diseases of the arteries; an extensive series of calculi, including, besides many others, halves of all those removed by Liston—are amongst the treasures it contains. Capital Medical and general libraries, with every facility for quiet study, are open to the students. Neither is the outer man forgotten. They have an excellent dining- and common-room, a fives'-court, and a well-furnished room for a reading-club, to which students are admitted by ballot. The College, also, is rich in treasures of art. The glorious Flaxman collection, the Murvelt portrait of Harvey bequeathed by Mr. Field, the statue of Locke in the general library, prove that utilitarianism is not the only goddess worshipped within its precincts.

The Hospital contains ten wards and 136 beds. There are six large wards, each 63 feet long, 24½ wide, and 14½ high. Twenty beds in each gives 1100 cubic feet for each patient, and 11½ feet from foot to foot of each bed, but the number of patients in the wards has never, we believe, been so great. Of the ten wards, four are Surgical and six Medical. There is a small ward, containing three beds, for obstetric patients, an ophthalmic ward for six patients, and two beds are allotted to skin disease. As we have before hinted, University College Hospital is, *par excellence*, a Clinical Hospital, and, although comparatively small, it affords the student a thoroughly well-worked field for the study of disease.

But we must bring our sketch to a close. We know how imperfect it is, and should have been glad to have paid our slight tribute to the memories of Lindley, the great practical botanist of his time and country; of Jones Quain, the accomplished anatomist; of John Taylor, Professor of Clinical Medicine, whose crucial observations first shook the popular belief in the value of mercury in pericarditis, and of several others who have passed away; and amongst the living, to the eloquent and venerable Professor of Comparative Anatomy, who, with Drs. Watson and Conolly, are the sole survivors of the original Faculty. We should have liked, also, to have dwelt on the career of many of the students of the College who have carved, or are carving, for themselves niches in the Temple of Fame. Of such men as George Newport, the entomologist and comparative anatomist; Stocks and Griffiths, the Indian botanists; Herbert Barker, of Bedford; or, to come nearer home, of Professor Ellis, Henry Thompson, Humphry Sandwith, of Kars, Cadge, of Norwich, and many more. But time and space fail us. As we close our manuscript, our thoughts wander back to many pleasant memories and associations which we owe University College. Fondly and gratefully we take leave of Alma Mater. That our feeling will be shared by all who have had the advantage of studying within her walls we feel certain. She has nobly fulfilled her mission as a Medical School, and if future success is to be predicted from past history, centuries hence will see her then, as now, in the van of the great educational institutions of England,—

> "To lead her sons to all the Castalies,
> And feed them with the milk of every Muse."

RINDERPEST NOT SMALL POX.

(*From a Provincial Physician.*)

In attentively considering this subject, it at once strikes us as remarkable that this disease should have appeared in our country at a time when the human small pox is disappearing, or has disappeared, from amongst us; and that whilst variola has been raging on all sides for some two or three years past, it has now for several months almost ceased its ravages; so that, in fact, just as the epidemic constitution of the atmosphere has become unfavourable to the continuance and existence of small pox in man, it has (on this supposition) become so favourable to its development in cattle, that an epidemic of the utmost virulence has appeared amongst them, spreading and destroying, as if it were flourishing under the most favourable possible influences.

Again, we must not overlook the fact that a disease known by the name of, and believed to be true, small-pox is already known in sheep; a disease, too, in which very strong analogies with the human variola unquestionably exist, but which does not appear to be communicable to the ox tribe by inoculation. On the other hand, the Rinderpest of sheep is most readily and freely conveyed to them. So, too, the cattle plague is very readily communicated to sheep, as well as to other ruminants, such as goats and deer, both by inoculation and by making them breathe infected air; the result being the development in them not of variola ovina, but of a disease identical in all its leading features with that of the ox, from which it was derived. If, then, the disease called variola ovina be true small-pox in sheep, and if this cannot be conveyed to oxen, whilst the Rinderpest of sheep can be so conveyed, and if, again, the cattle plague can be communicated back again to sheep, where it developes not small-pox but its exact bovine analogue, we may well pause before coming to any conclusion as to the identity, or even intimate alliance, of the two affections.

Another very strongly marked point of divergence between the two diseases as appearing in man and beasts is, that in the small-pox of man the eruption is, as it were, *the* disease; in animals, on the contrary, it is its least marked feature—so much so, indeed, that it is only quite recently that the eruption has attracted any attention at all. If it is varioloid, therefore, in beasts, it must be a suppressed eruptive disease—a *variola* almost *sine variolis*. In sheep, on the contrary, as in man, the eruption is the marked feature of the pox; the fever is evidently symptomatic of the eruption; and the eruption itself presents many and close analogies with that of human variola.

It has been said that the texture of the skin of bovine animals is such as to prevent the development of ordinary variolous eruption upon it. We ask, is there any proof of this? In sheep the eruption appears without difficulty, and runs through its various stages of papules, vesicles, and pustules, not only without apparent hindrance, but the latter become even larger and, if possible, more fully matured than in man; yet sheep and oxen belong to the same ruminant class, and, consequently, have the same class of integument. Moreover, in oxen nothing like a true variolous eruption appears on the nostrils, eyelids, or other spots where the skin is thinner, and where, consequently, we might expect a struggling eruption to develop itself in its more distinct and proper character.

Let us look also to the eruption itself. It will be found that this, in its whole course and duration, differs most widely from that of true variola. Thus, in man, the eruption of small-pox in its first appearance is both peculiar and distinctive. The papules come out in a crop; they are dense, often feeling like small shot in the skin, and giving the integument a very peculiar, finely-nodulated feeling. In Rinderpest oxen the eruption is always comparatively scanty. When first discoverable, it consists of very small, fine, and by no means hard or dense papules; and as it developes, forms minute acuminated vesicles, which present little or no analogy to variola, and none to vaccinia; which more nearly resemble minute vesicles of eczema than anything else, and which run through their course far more rapidly than human or cow pox, quickly becoming or drying up into small semi-purulent acuminated pustules.

In the small-pox of sheep the vesicles and pustules are large and flat, and occasionally umbilicated, thus showing exactly the contrary condition to that found in Rinderpest animals. In man the eruption of small-pox specially affects the face, and its appearance here gives the type to the disease; in oxen the eruption, when it appears at all upon the face, consists of a few small vesicles, chiefly upon the nose, which quickly run their course, leaving only little white spots or scars behind, instead of passing the prolonged stages of maturation and desiccation seen in man.

In many other respects this disease in oxen presents the widest differences from the variola either of man or sheep. Setting aside the congestions seen in the tracheal and intestinal mucous membranes, and which may present a certain analogy to those seen in virulent small-pox, nothing that has ever been noticed in the latter disease has shown any approach to a resemblance to the remarkable purplish-red discolorations which are invariably found in Rinderpest in the mouth, the ilio-cæcal valve, around the vaginal orifice, and elsewhere. These discolorations may be, and doubtless are, in some way due to the changes effected in the constitution of the blood, but they are nevertheless more peculiar, more constant in their seat, and more truly characteristic of the disease than the eruption or even the intestinal congestions.

The purple patch upon the edge of the ilio-cæcal valve has in our experience been so definite in appearance and situation and so constantly present as almost to constitute a diagnostic sign of the disorder; and, moreover, almost sufficiently definite to justify the idea of its being a portion of a distinct intestinal exanthem or rash, rather than an accidentally-placed bit of inflammatory congestion; subject, indeed, to laws, which, from its nature and type, are fixed and definite, rather than to the ordinary and variable course of typhoid inflammation or congestion. In this respect there is an undoubted analogy to the faucine blush of scarlet fever. But this analogy is by no means perfect, except perhaps as to its specific nature, for whereas the redness of a scarlatinal throat disappears in a few days—with the cutaneous rash, in fact—this discoloration in the mucous membranes of Rinderpest animals lasts for a far more lengthened period, and we have recently seen this very purple patch remaining in great intensity and distinctness upon the edge of the ilio-cæcal valve of a cow which, having survived an attack of the disease six weeks, and being nearly convalescent, was killed for economical reasons, the congestion of the mucous membrane of the stomach and bowels having all but disappeared, and left only a dirty, muddy, yellow discoloration behind.

All observers have agreed in describing the smell emitted from the diseased oxen as most peculiar and offensive; and, indeed, it is so peculiar as in our opinion to form another point of separation between this disease and variola. The variolous smell is most peculiar, sickening, and characteristic; so is the Rinderpest smell peculiar and characteristic; but it has not the sickening odour of human variola, and it is in our opinion perfectly different in character from it. Moreover, the smell of variola is emitted in greatest intensity by the skin, that of Rinderpest by the abdominal viscera of the carcass, and by the breath of the animal when alive.

One more point remains to be noticed. In human variola, except in the most virulent and malignant types, no such ecchymoses beneath the skin and mucous membranes are met with as are constantly found in Rinderpest; or if by chance petechiæ, vibices, etc., do occur, they are generally accompanied by true hæmorrhages from the nose, mouth, etc., or by other signs of a defibrinised or a plastic state of the blood.

In Rinderpest they are nearly always found; but at the same time the blood is firmly coagulable, and apparently hyperfibrinised, the hæmorrhages which do take place being confined to a very slight escape of blood in the urine, or to the discharge of a small quantity mixed with the mucus of the dysenteric stools.

We have said enough, we think, to show with what difficulties this subject of cattle plague is still surrounded. For several months the attention of some of our best pathologists and acutest observers has been directed to it, yet its very nature is still undecided, and except in a negative sense no progress whatever has been made in a therapeutical point of view. Were it to be determined that the disease is either true bovine small-pox or its equivalent, we might hope that the problem of preventing its ravages was about to be solved. It may, indeed, be that in spite of the great, the marked—we had almost said the intrinsic, differences between the manifestations of this disease in oxen and variola as seen in the kindred race, the sheep, and in man, the bovine constitution may be found to create and explain them all by its modifying influences (and so important is this point that it must be cleared up at once by the only accurate test of experiment); yet without venturing to express a positive opinion upon the point, we cannot help feeling that the differences are so great as to damp the hopes which such an idea at once suggests, and to make us fear that we have rather in Rinderpest a disease allied to small pox it may be in its nature, like it in many most remarkable features, yet withal essentially distinct from it, *sui generis*, and specific.

Dr. Romberg.—A testimonial was presented to this distinguished Physician on the occasion of his reaching his 70th birthday by a deputation composed of the *élite* of the Berlin Professors and Practitioners, and headed by Langenbeck, Virchow, Von Graefe, and other celebrities. In his reply he observed one of the warmest desires of his life was to secure the love of his pupils and the friendly esteem of his colleagues. These could not be attained by science and knowledge without the aid of integrity of character, and it was for this reason that he felt so much honoured by the demonstration.

REVIEWS.

Narrative of an Expedition to the Zambesi and its Tributaries, and of the Discovery of the Lakes Shinva and Nyassa, 1858—64. By David and Charles Livingstone. With map and illustrations. London: John Murray. 1865. Pp. 608.

It would be out of place in a Medical journal to attempt a regular analysis of this very interesting volume. The heroic Dr. Livingstone, who has devoted his life—we may say, who has given one dearer to him than his own life—to the exploration of Eastern Africa, with the purpose of making known its geographical features, of ascertaining its produce, developing its commerce, studying the character of the native races, and imbuing them with the light of Christianity; and besides, of putting down the infamous slave trade, which is carried on under the auspices of the Portuguese;—he, we say, tells us in this volume of his adventures between March 10, 1858, when he left England, and June, 1864, when he arrived at Bombay on his way home. The Doctor headed a missionary and scientific expedition, of which Mr. Charles Livingstone, Dr. Kirk, and Mr. R. Thornton were members. He speaks generously of their co-operation, and leads us to hope soon for an account from Dr. Kirk's pen, of the botanical and other natural history specimens which they met with. His tone throughout is bold and uncompromising; he can see no excuses, nor admit the possibility of failure. Readers of the *Medical Times and Gazette* are aware of the disastrous results of the Oxford and Cambridge Mission to Central Africa; how Bishop Mackenzie lost his life; how the missionary party were cut up by fever and famine, and the scheme abandoned, at least for a time.

Much of this disaster is ascribed by Dr. Livingstone, and apparently with great justice, to want of experience in the missionaries; to want of knowledge how an European—a tender exotic—could maintain life in Central Africa. It is true that to attain great ends lives ought not to be weighed in the scale; but if experience has anything to teach, ought not the missionaries to have learned it before starting?

Neither, however, the mishaps of missionaries nor the villainies of slave hunters can be treated of in these columns; but we may notice a few passages which we have marked as bearing on Medical topics.

Fever is the curse of the country, and is met with at every step. The mouths of the Zambesi River are, like those of the Nile, channels through an enormous delta of sand. Some members of the expedition were obliged to remain three months on a small island a few miles up in this delta. "Here some had their first introduction to African life, African fever. Those alone were safe who were actively employed."—P. 23. A few miles higher up Dr. Livingstone was requested to take the Portuguese Governor, who was very ill of fever, across to Shupanga."—P. 27. His Excellency was a disciple of Raspail, and insisted on taking nothing but a little camphor; so he became comatose, and whilst thus helpless his chief officer dosed him with quinine, so that by the next morning he was "cinchonised and better."—P. 28. At Shupanga, "in 1826, poor Kirkpatrick, of Captain Owen's Surveying Expedition, died of fever; and here, in 1862, died of the same fatal disease, the beloved wife of Dr. Livingstone."—P. 31. A little higher, the expedition came to Senna—a dull, sleepy place; of which, says the Doctor, "one is sure to take fever in Senna on the second day if by chance one escapes it on the first."—P. 35. For some time the expedition had its head quarters at Tette, about 250 miles up the river. "There," says the Doctor, "a good deal of fever comes in with March and April; in March, if considerable intervals take place between the rainy days; and in April always, for then large surfaces of weed and decaying vegetation are exposed to the hot sun. In general, an attack does not continue long, but it pulls one down quickly, though when the fever is checked the strength is as quickly restored. It had long been observed that those who were stationed for any length of time in one spot, and lived sedentary lives, suffered more from fever than others who moved about and had both mind and body occupied." "We observed that we were often all affected at the same time, as if from malaria. This was particularly the case during a north wind; it was at first confidently believed that a daily dose of quinine would prevent the attack. For a number of months all our men except two took quinine regularly every morning. The fever sometimes attacked the believers in quinine, while the unbelievers in its prophylactic powers escaped. Whether we took it daily, or

omitted it altogether for months, made no difference; the fever was impartial, and seized on us in the days of quinine as regularly and as surely as when it remained undisturbed in the medicine chest; and we finally abandoned the use of it as a prophylactic altogether. The best preventive against fever is plenty of interesting work to do, and abundance of wholesome food to eat. To a man well housed and clothed who enjoys these advantages the fever at Tette will not prove a more formidable enemy than a common cold; but let one of these be wanting, let him be indolent, or guilty of excesses in eating or drinking, or have poor, scanty fare, and the fever will probably become a more serious matter." Although not a preventive, "quinine was found invaluable in the cure of the complaint as soon as pains in the back, sore bones, headaches, yawning, quick and sometimes intermitting pulse, noticeable pulsation of the jugulars, with suffused eyes, hot skin, and foul tongue began." P. 72.

The Doctor gives a curious picture of the mental effects of the fever poison on certain persons—despair, apathy, and irritability are not to be wondered at; but something like hallucination seemed to be one of the earliest symptoms. The line of treatment which seems to have been pretty successful was first the administration of pills, to which the Doctor gives the name "rousers"—composed of six to eight grains of resin of jalap, the same of rhubarb, and three each of calomel and quinine—then quinine to cinchonism. The only cases in which he was completely baffled were those in which obstinate vomiting occurred. He made full trial of "Dr. Warburgh's fever drops," and found them useless. "In the shivering stage it caused warmth, but did not cure. One old man seemed cured, but died a day or two afterwards."

In March, 1859, when the main body went on a prolonged trip, they found on their return that the quartermaster who had been left in charge of the ship, was dangerously ill with fever. Dr. Livingstone gave him twenty grains of calomel with excellent effect, and speaks of its virtues in causing an abundant flow of bile. On the whole subject of the relation of different modes of treatment to each other—the antiphlogistic, the calomel, and the quinine—the facts related by Dr. Livingstone confirm the views of Surgeon-Major Hare, as given in the *Medical Times and Gazette* of last year. They thoroughly vindicate the character of Medicine as a beneficent art, advancing by slow experiment, age after age;—and they show that the doctrines and practice laid down by Dr. James Johnson, and other writers of his time, on Tropical Diseases, were not false, though they were only partially true. "Wisdom is justified of her children;" and the longer we live, the more truth and reason we find in the practice of our predecessors, making allowance for the light they enjoyed. Bleeding does good, calomel does good, and quinine does good; each under certain limitations. There is no such thing as an *absolute* remedy.

Dr. Livingstone says that in a similar case, a blister put on the pit of the stomach, may bring out serum black as porter, from being impregnated with bile.

There are many remarks scattered through the book, with regard to causes, which show that Dr. Livingstone does not believe that stink *per se* will cause fever. For example, on their way home, they were compelled to halt at an offensive spot, where the water was black as ink, and the air filled with sulphuretted hydrogen. Paint and metal were all turned black, but it was found by the Doctor and averred by the natives that this stench caused no fever. There are two curious sources of it mentioned; one is a plant called *Pedœvia fetida*, of extremely foul smell, the effluvia of which cause headache and fever. The other is *coal*—though the deleterious emanations from coal are not here noticed for the first time. "Fever broke out," says Dr. Livingstone, "on board the *Pioneer*, at the mouth of the Rovuma, as we thought from being anchored close to a creek coming out of the mangroves; and it remained in her till we completely isolated the engine-room from the rest of the ship. *The coal-dust rotting sent out strong effluvia, and kept up the disease* for more than a twelvemonth."—P. 350.

Not to linger further on the fever, we may say that Dr. Livingstone's book is full of points which would interest Medical men. He mentions the wonderful tenacity of life of some animals, and how a waterbuck would run after part of its heart had been blown out by one of Jacob's shells. His accounts of old diseased buffaloes banished from the herd to die in solitude are curious. Mr. Annandale may learn that diseases of the fingers and toes are not unknown even amongst these children of nature, and that corns and distorted toes are met with where no bootmaker ever was seen. P. 313. The true leprosy was met with in the person of a chief, and seems not to be uncommon; and it is worth notice that Dr. Livingstone and Dr. Kirk, while dressing the leprous chief's sores, were attacked with something so like the early symptoms in their own fingers, that they were glad to use a liberal allowance of caustic to save themselves. The observations on the habits of crocodiles, and on the flavour of their flesh and eggs, on the flesh of the eland and other wild animals (Dr. Livingstone does not like eland), on the use of filtered and distilled water, on moon-blindness, snakes, and mosquitoes (some *midges* are used as food), are all worthy attention, and may entice the busiest Practitioner to read this book whilst he reposes from his day's fatigues.

Photographs (Coloured from Life) of the Diseases of the Skin. By Alex. Balmanno Squire, M.B. Lond., Surgeon to the West London Dispensary for Diseases of the Skin, Lecturer at St. Mary's Hospital Medical School. Twelve Parts. London: John Churchill and Sons. 1865.

The excellence of these photographs of skin diseases has already been noticed in the articles on "Modern Dermatology" which appeared a short time ago in this journal; but we cannot forbear from saying a word or two more in their praise, now that the number proposed to be published has been completed. In the "advertisement" to his work, Dr. Squire says: "The great difficulty hitherto experienced in producing illustrations adequately portraying the various diseases of the skin induced me to try if greater accuracy and more life-like representation might not be obtained by means of photographs of the disease coloured from life by one of our best artists. . . . It soon became evident that excellent results were to be obtained by this means, and that they might be rendered more widely available by publication." The author well merits a high compliment on the admirable manner in which he has carried out his project, and on the good service he has thus rendered to the Profession. The student of skin diseases cannot have a better guide and counsellor in his endeavours to obtain a precise acquaintance with, and knowledge of, the classes of skin diseases than is afforded by these photographs and the well and clearly-written, though concise, descriptions, histories, and notes on treatment that accompany them. All the illustrations are good, far more truthful and "life-like" than any representations of skin diseases previously published, but some are specially admirable: such as No. 2, Impetigo Figurata; No. 3, Lichen Inveteratus; No. 8, Papular Syphilide; and No. 9, Nævus Vascularis. We hope that Dr. Squire will feel encouraged to continue his labours and to give us from time to time similar excellent portraits of the diseases of the skin.

GENERAL CORRESPONDENCE.

FURTHER CORRESPONDENCE REGARDING ACUPRESSURE BETWEEN PROFESSORS SIMPSON AND SYME.

Letter from Professor J. Y. Simpson.

[To the Editor of the Medical Times and Gazette.]

Sir,—I shall feel obliged by your inserting in the *Medical Times and Gazette* the following further correspondence regarding acupressure.

In order that you may understand the correspondence, let me premise that my former letter to you (see *Medical Times and Gazette*, December 16th, 1865, p. 667) was a copy of another sent to the Editor of the *British Medical Journal*, with this sole difference: that the arrival of the post hour prevented the last two or three paragraphs from being transcribed. Both copies were sent off by the same post. You kindly inserted the letter, but I was treated with very different courtesy by the Editor of the *British Medical Journal*. After two days' delay he wrote me that absolutely he would not admit my reply to Mr. Syme into his *Journal* unless I permitted the removal from it of many strong personal allusions, and left in the scientific points only—forgetting, as he did, that the initial letter of Mr. Syme, which he had at once admitted, consisted of strong personal allusions only, and had not one scientific point in it. Not having any desire that he should write my letters, I telegraphed him to insert the letter

as a paid advertisement. He answered that it was too late that number; and I received back the manuscript. Early in the following week I sent the letter back to be printed, and paid for as an advertisement. He then wrote that he would not admit it either as an advertisement or as a communication. But, to my surprise, he nevertheless printed it in the columns of his *Journal* on Saturday last. He added to it, however, a little Editorial note, the great inexactitude of which will appear from the following letter, which was sent to him early last week, but which he has had the injustice to delay the admission of into his columns, and possibly intends to exclude altogether.

I am, &c.,
Edinburgh, Jan. 2, 1866. J. Y. Simpson.

No. I.—Letter of Professor Simpson to the Editor of the "British Medical Journal," in answer to the Editor's Criticism on his Letter in the "Medical Times and Gazette" of December 16.

"Sir,—In an editorial note appended by you to a letter of mine in last week's *Journal* you observe,—'Professor Simpson's letter would have appeared in the *Journal* of last week had it not, as originally forwarded to us, contained some very strong personal allusions which we declined to publish.'

"This note is calculated, however unintentionally, to mislead, in my opinion, very gravely the members of the British Medical Association.

"My letter is printed exactly as sent to you with three trivial alterations only—namely, (1.) You have omitted the single word "vituperative" as applied by me to Mr. Syme's ungenerous language regarding Dr. McKinlay. (2.) You have omitted in the same paragraph a simple critical remark to the effect that it was, perhaps, not right in you to open your columns to Mr. Syme's censurable observations upon that excellent Surgeon" (see the paragraph printed in full in my copy of the letter in the *Medical Times and Gazette* for December 16, p. 668); "and (3) you have omitted, simply because it was not sent to you in the last copy, a sentence suggesting a doubt whether it was right in Mr. Syme by his letter to mislead the English brethren of the Association so much upon such a Scottish question as the spread of acupressure in Scotland. This sentence was in fact unnecessary, as the idea stands in my letter in another form.

"After refusing to publish my letter as sent to you, either as a communication, or, latterly, as a paid advertisement, you printed it—somewhat to my surprise. The primary letter which you inserted from Mr. Syme in your *Journal* of December 2 contained little, or, indeed, nothing whatsoever, but strong personal allusions against accupressure and its abettors; and having once—in my opinion, indiscreetly—admitted that communication, you were bound, I think, to admit an answer to it. You must excuse me if I add that your strong resistance to the publication of such an answer has appeared to me as extraordinary and unjust as your annotation on my letter.

"Yours, &c.
"Edinburgh, December 26, 1865. "J. Y. Simpson."

No. II.—Letter from Professor Syme to Professor Simpson's Letter in "Medical Times and Gazette" of December 16. *To the Editor of the "British Medical Journal."*

"Sir,—Your obstetric correspondent can hardly expect that, after the *public execution* of his obnoxious pamphlet, any amount of personal abuse or Professional misrepresentation proceeding from him should be deemed worthy of my notice.

"I am, &c., "(Signed)
"Edinburgh, December 26, 1865. "James Syme."

No. III.—Answer by Professor Simpson to Professor Syme's Letter. To the Editor of the "British Medical Journal."

"Sir,—All who are acquainted with Mr. Syme's peculiar mode of speaking and writing will at once perceive in his last note to you a virtual acknowledgment on his part that he had not succeeded in detecting a single flaw in the facts or arguments adduced by me regarding the recent history, etc., of acupressure; or, otherwise, he would at once have rejoiced to expose any such error in my statements.

"Assuredly I should not have again taken up my pen to trouble either himself or you with the matter had it not been that Mr. Syme has, in his last note, introduced a new element into the discussion, raising in it a question, not in Surgery, but in ethics.

"Some twelve months ago, when discoursing to his class on the subject of acupressure, Mr. Syme finished his remarks by fiercely tearing in pieces with his fingers a pamphlet of mine on the subject. (See *Medical Times and Gazette* for March 4, 1865, p. 236.)

"When lately called upon to write to you regarding Mr. Syme's bitter opposition to accupressure, I purposely abstained from alluding to this very petty but very discreditable piece of mediæval vandalism—believing, as I did, that Mr. Syme could only have acted so deplorably under an ebullition of passion; and hence under circumstances which, in all charity, ought to be forgotten and forgiven.

"But in his note to you of last week Mr. Syme gives entirely a new aspect to this misconduct of his, as he now proudly speaks of his unhappy violence as being the "*public execution*" of an "obnoxious pamphlet," which saved him from further reply to me. In other words, he seemed to hold that in any controversy regarding Surgical facts and practice the tearing in pieces, before a class of students, of the paper on which the opinions of your opponent are written or printed, gives you forthwith the double right (1) of subsequently publishing on the matter any misrepresentations which you please, and (2) of refusing to allow of the correction of these gratuitous misrepresentations by others.

"Without stopping to show how painfully and carelessly Mr. Syme here contradicts himself—forgetful, as he apparently is, of having already written and re-written on the subject to different public journals *since* this alleged "public execution"—let me add that Mr. Syme seems strangely callous and unaware of the humiliating and wretched position in which he gratuitously places himself before the Profession by such a self-conviction and self-adulation as he has now been guilty of uttering in your paper.

"Though thus curiously blind to the character of his own avowed conduct, I feel sure that if Mr. Syme will honestly inquire in regard to the matter among either his Professional or non-Professional friends, here or elsewhere, he will find among them one universal feeling of deep regret, both at his formerly assuming the character of a public executioner in the sense he speaks of, and latterly in his glorying in the shame of being so. It is well known in Edinburgh that even his staunchest adherent and defender, Dr. John Brown (who was present at the original pamphlet scene), has, to his honour, frankly confessed that he witnessed the tearing portion of the transaction with grief and sorrow that his old teacher should so misconduct himself.

"You, Mr. Editor, as a friend and supporter of Mr. Syme's, must have felt like all his other friends in this respect, for at the time you kept all notice of Mr. Syme's unhappy proceedings cautiously excluded from your pages. And, for one, I do think it was the very reverse of kind in you to Mr. Syme to allow him at last to denounce and expose himself so grievously regarding the transaction in your *Journal*. For, after all, the public execution which he has performed is a public execution upon his own character, and not upon acupressure, which lives and spreads steadily, in spite of all his vain opposition to it, and is, on the whole, promoted, I believe, rather than retarded, by that opposition. The only other gentleman in Great Britain who at present enjoys the character of a public executioner—Mr. Calcraft, of London—would, I fear, looking to the certainty of *his* 'ligature,' consider the Scottish aspirant to the same honours as rather an unsuccessful operator.

"I am, &c. "J. Y. Simpson.
"Edinburgh, January 2, 1866."

ON THE SMALL POX AND RINDERPEST POISONS.

Letter from Dr. B. W. Richardson.

[To the Editor of the Medical Times and Gazette.]

Sir,—In reply to the queries which you have done me the honour to ask of me, I would state:—

1. That the view of Dr. Murchison, to the effect that the cattle plague may be derived from small pox poison, is quite consistent with the theory of the mode of origin of the disease-producing poisons which I have ventured to place before the Profession. Dr. Murchison's views, if proved to be correct, would, in fact, be demonstrative, as by experiment, of the catalysis theory.

2. Dr. Murchison's views are enunciated with such masterly skill and judgment that one can hardly hope for less than the realisation of their correctness. The result of experiments will soon settle the question. If animals that have been subjected to simple vaccinia, or human small pox, will not take the Rinderpest on inoculation with the poison of Rinderpest, the correctness of the view is virtually confirmed.

3. Presuming that experiments made in this direction do not, however, succeed, we need not give up research in despair. If the original poison be not that of small pox, it is a poison as near at hand, and is to be found if properly looked for. It may be the secretion of farey or of glanders; or merely secretion in a decomposing state derived originally from the mucous surface of an animal subjected to local disease.

I have been so much absorbed in the study of two questions—one relating to the restoration of muscular action after some forms of death, and the other in relation to the nature of the animal poisons—that since the cattle plague has been present I have not, in fact, been able to pay any special attention to it. But I shall be happy, if you think it worth the while, to point out to your readers what would be the most promising experimental methods of research in determining the precise nature of the poison of Rinderpest, its action, and its antidote. I am, &c.,

B. W. Richardson.

12, Hinde-street, W., Jan. 3, 1866.

IS CATTLE PLAGUE SMALL-POX?

Letter from Dr. T. Sarvis.

[To the Editor of the Medical Times and Gazette.]

Sir,—The opinion that the cattle plague is small-pox is gaining credence with many intellectual men. Why this should be I know not (for the symptoms are quite different) unless it be that in the hides of animals having died of, or been slaughtered for, the cattle plague there are depressions which appear like pits left upon the skin after a violent attack of small-pox.

Having seen a great many cases of cattle plague, both in my own district and in the Metropolitan Cattle Market, the latest case being that of a cow bought at the market a fortnight ago, which was attacked on Saturday last and died yesterday, I cannot think that the disease is small-pox, for in the cattle plague we have no pustular eruption. It is true we have "ulcers," so called, of the tongue, but they are of an irregular shape; "ulcerations" also occur in other parts of the mucous membranes, but they are also irregular in form. I have never seen in any case a pustule proper. There is one symptom which is like typhoid—a rash that appears on the skin, especially over the udder, which is darker than that seen in the typhoid fever of man, but not so dark as the mulberry spot of typhus. These spots appear as if the epithelial surface of the skin were partly eroded; hence the depressions discovered during the process of tanning, which have mainly led to the inference that the cattle plague is small-pox. I believe the production of these pits to be post-mortem.

I am, &c., Thomas Sarvis, M.D.,

Medical Officer of Health for Bethnal-green.

135, Bethnal-green-road, Jan. 3, 1866.

REPORTS OF SOCIETIES.

THE PATHOLOGICAL SOCIETY.

Tuesday, December 5.

Dr. Peacock, President.

(Continued from vol. ii., 1865, page 696.)

Dr. Cayley showed a specimen of

ABSCESS OF THE CEREBELLUM.

A man, 40 years of age, a patient under the care of Dr. Goodfellow, in the Middlesex Hospital, had had purulent discharge from the ear from childhood. Recently he had suffered pain at the top of the head, and at the back of it. The pain came on in paroxysms. There were no signs of paralysis, and mental power was good. He died suddenly in an attack of pain. There were no convulsions. An abscess was discovered in the cerebellum, and a large cavity in the position of the mastoid cells, and the membrana tympani was perforated. There was, however, no continued disease from the ear to the abscess.

Dr. Dickinson exhibited specimens from

THREE CASES OF ANGINA PECTORIS, ALL DEPENDING ON OCCLUSION OF THE OPENINGS OF THE CORONARY ARTERIES, BY ATHEROMA OF THE AORTA.

Case 1.—The first case was that of a gentleman, a patient of Dr. Dudfield, of Kensington, at whose post-mortem Dr. Dickinson was asked to assist. The patient, 45 years of age, had had symptoms of disease of the heart for eight years, well-marked fits of angina for three years before his death. In an attack within a day or two of his death, Dr. Dudfield described him as presenting a ghastly appearance, pale, with upraised arms, and glazed eyes. He complained of a horrible sense of constriction in the chest, with pain, numbness, and coldness of the left arm. He died at last rather gradually. At the examination of the body, the stomach was found to be dilated; but there was nothing to account for the symptoms, excepting the state of the heart. This was rather increased in size. The aortic valves and root of the aorta were much altered by atheromatous deposit. This was soft, and lay under the lining membrane of this vessel, especially about the origin of the coronary arteries. By the encroachment of this material, the left coronary artery had become completely obstructed, so that its position could only be found by tracing up the vessel from the outside. The right was much narrowed, but still remained pervious. The coats of both these vessels were free from atheroma; but the left artery had become much shrunk, while the right retained its full proportions. The ventricles were both contracted; the tissues displayed a slight general amount of fatty change.

Case 2.—The second case was that of a muscular, spare man, 42 years of age, a gamekeeper. He was a patient at St. George's Hospital under Dr. Fuller. For the last two years of his life he had had much epigastric pain, attributed to dyspepsia. While in the Hospital, he had several attacks of angina pectoris in its ordinary form, in one of which he expired while under the eye of his Physician, who was at that time going round. This attack, like many before, had come on immediately after food. At the post-mortem examination some points of extravasated blood were found on the surface of the heart. The left ventricle was quite uncontracted; the valves were natural. There was much soft atheroma on the root of the aorta, which had so encroached upon the openings of the coronary arteries that neither of them would admit the head of a common probe. The vessels in their course were natural. The heart was slightly increased in size, weighing 13½ ounces; it had a trace of fatty degeneration about it, but not enough to be considered morbid.

Case 3.—The third case is that of a soldier who had been discharged from the army in consequence of some cardiac affection. He was 35 years old. He was brought into the Hospital dead. An agitated young woman came with the body, and from her account it appeared that the two had been passing some time together in the park; the time was evening. While in her company, as she said, sitting down, he fell dead. From the fact that the glans penis was found to be covered with spermatozoa, it was presumed that either at the time of death or very shortly before he had been engaged in sexual intercourse. Most likely, like Attila, he had died in the act, the excitement having produced a paroxysm of the disease from which he had before suffered. The heart, as in the preceding cases, was slightly enlarged (14 oz.). The left ventricle was quite uncontracted. The valves were all natural. There was the same soft atheroma under the lining membrane of the base of the aorta, as has been described in the other cases. By it the right coronary artery had been so completely occluded at its mouth that no opening whatever remained, and its place could only be found by dissection from the outside. The lining membrane of the aorta appeared continuous over the orifice. The opening of the other artery was much narrowed by the same means. The coats of the vessels were natural. There was no fatty change in the muscles of the heart. The stomach contained much gas and undigested food. The symptoms known as "angina pectoris" have furnished pathologists with ground for speculation ever since Heberden drew attention to the disorder and gave it its name. Atheroma of the coronary arteries has been assigned as a cause for it, and Laennec has described atheroma of the aorta as a more frequent cause. He does not, however, allude to the state of the coronary openings. From these cases it would appear that obstruction of these little vessels at their mouths may be no uncommon cause of the disorder, and it is such that it may often escape notice. The atheroma is soft and smooth, and if not especially looked for its effect upon the little openings might be disregarded. Angina pectoris has been described as neuralgia of the heart, and that it is an affection of the nerves of that organ there can be no doubt. In connexion with this, we cannot but observe the relation of the coronary arteries to the nervous structures of the ventricles. The

vessels pass just beneath the pericardium, closely entwined by the nerves; and judging by their obvious arrangement and situation, would seem to have more to do with the nerves than with the muscular fibre. They are of course too large to be needed by the nerves alone, but it may be presumed that they chiefly supply the nerves and more superficial structures of the organ, since in these cases, though they were in great part closed, and from the chronic nature of the disease must have been so for some time, yet there was no atrophy of the muscular structure. How, then, is the muscle of the heart nourished? Probably in great part by imbibition from the cavities, in the same manner as are the walls of the great vessels.

Dr. Gibb exhibited a

FIBRINOUS CAST OF THE TRACHEA AND BRONCHI

of a child, 5 years old, who was admitted on the third day of croup into the Westminster Hospital, and upon whom tracheotomy was performed the night of admission. The child went on well up to the third day, when the tube of the canula became blocked up by portions of loose fibrine, which nearly suffocated him—indeed, he was almost gone, were it not for the perseverance of Mr. Hawken, the House-Physician, who removed the canula, and extracted a complete fibrinous cast of the trachea and larger bronchial tubes. The child at once rallied, but, unfortunately, died from pneumonia on the ninth day of the operation.

Dr. Gibb also showed

A TAPE-WORM EXPELLED WITH ITS HEAD,

from a Hospital patient treated with the oil of male fern. The practice he is the habit of following with general success is to administer a dose of castor oil at night, followed by the fern oil at 7 the next morning, and another dose of castor oil three or four hours after, the patient meanwhile fasting. The passage of the head of the worm is of course the great thing desired in the treatment of tænia, when the cure is considered complete.

Mr. Curling exhibited a specimen of

COLLOID DISEASE OF THE LOWER PART OF THE COLON, PRODUCING OBSTRUCTION, WHICH WAS RELIEVED BY OPENING THE COLON IN THE LEFT LOIN.

The patient, a female, aged 68, was suffering from pains in the abdomen of great severity, arising from the efforts to overcome obstruction in the bowel. The pains were entirely relieved by colotomy, but the patient sank exhausted eleven days afterwards. The terminal portion of the colon was affected to the extent of three inches, with colloid infiltration of its walls, producing great thickening and diminution of the cavity of the bowel. There was a large cystic tumour of the right ovary, containing dark grumous fluid, with colloid deposits in its walls. Mr. Curling stated that this was the oldest patient upon whom he had performed the operation.

Mr. Curling showed a drawing of a

TESTIS IN PERINEO

in a child a month old, in which he had recently attempted by operation to place the organ in its normal position in the scrotum, and had succeeded in securing it in the upper part. Mr. Curling stated that it was useless to operate later, after the scrotum had become atrophied, and he showed an engraving of this malposition in the adult, in which the corresponding side of the scrotum was quite defective.

Dr. Ogle showed a specimen of a

LARGE MASS OF CALCAREOUS DEPOSIT FOUND ATTACHED TO THE DURA MATER AND IMBEDDED IN THE CEREBRAL SUBSTANCE.

The patient was a woman, aged 40, who had been considered to be a very lazy woman, sleeping a great deal, and neglecting her children and household duties. She was said by some to have been a drunkard, as she was dyspeptic and frequently complained of headache. No paralysis existed. She was found dead in bed. On post-mortem examination, a mass (of about the size of a bantam's egg) of calcareous matter, formed of different separate fragments of different sizes, was found attached to the inner surface of the dura mater, covering the right cerebral hemisphere and occupying the substance of the superficial part of the brain, portions of which in the neighbourhood were softened. At one part in the neighbourhood was a small abscess. The calcareous matter was found by Dr. Davy to consist of 60 per cent. of phosphate of lime and magnesia, the rest being animal matter, showing in parts under the microscope a fibrous structure. The specimen was given to Dr. Ogle by Dr. Ward, of Twickenham.

Dr. Ogle also showed

CARCINOMATOUS MASS CONTAINING CYSTS CONNECTED WITH THE LUMBAR GLANDS WEIGHING BETWEEN SIXTEEN AND SEVENTEEN POUNDS.

The patient, a man, aged about 40, of good family history, had been in good health until the beginning of the present year, when he began to experience great pain in the loins. This was followed by swelling of the abdomen, and he became an inmate of the Windsor Infirmary, when great distension of the belly was found and a large, hard, solid mass discovered in the right side of the abdomen. He was admitted into St. George's Hospital under Dr. Ogle's care in August in the same condition, but he had then acquired an unhealthy yellowish aspect. The functions of the stomach, bowels, kidneys, and liver appeared to be in all respects natural, but, though for a time he improved, he subsequently got thinner and weaker. A few weeks only before death vomiting came on, which hastened his exit. The diseased mass was of the encephaloïd form, containing numbers of cysts. The lumbar glands were the only parts of the body affected by disease.

Dr. Ogle next exhibited a specimen showing a

LAYER OF FALSE MEMBRANE LINING THE DURA MATER, APPARENTLY FORMED FROM EXTRAVASATED BLOOD (FROM A CASE OF DEMENTIA).

The whole of the upper part of the dura mater covering the left cerebral hemisphere was lined by the membrane, which was tough and for the most part firmly adherent to the dura mater. It was in many parts of a very pink hue, and in places studded by small accumulations of desiccated blood. A portion of the dura mater on the opposite (the right) side contained also specks of effused blood, and from its surface also a thin layer of membrane could be peeled, the arachnoïd membrane covering the brain substance corresponding being thickened and opaque. The patient, a man, aged 78, was admitted into the Wells Asylum under Dr. Boyd in a very excited and demented state, and requiring to be fed by compulsion. Having for a short time become incoherent, he died about seven weeks after admission.

Dr. Broadbent showed a specimen of an

ANEURISM OF THE MIDDLE CEREBRAL ARTERY OF THE RIGHT SIDE.

It had been taken from a woman, aged 59, brought into St. Mary's Hospital on Saturday evening, December 2, in a state of insensibility. The limbs were motionless and relaxed; the left pupil was contracted; pulse 66; respiration regular and without stertor. She died in about three hours; the only previous symptoms were flatulent dyspepsia and occasional giddiness. When the head was examined blood was found beneath the arachnoid in various situations, chiefly in the interpeduncular space, hiding the optic commissure and tracts, the crura cerebri and even the pons, extending along both fissures of Sylvius, especially on the right side, and appearing upon and between the convolutions of the anterior and lateral part of the hemispheres. Blood was also found about the entrance to the fourth ventricle and in the velum interpositum, leading to the supposition that hæmorrhage had taken place into the ventricles bursting out in various directions. The ventricles, however, contained only bloody fluid, and no clot except the descending cornu on the right side. The floor of the third was torn through. Further examination led to the discovery of an aneurism in the right Sylvian fissure embedded in the anterior lobe of the hemisphere, and beyond it there was, in the tract of the middle cerebral artery, extensive softening, chiefly of the middle lobe. The aneurism had not ruptured.

Dr. Hilton Fagge showed a specimen of

FIBRO-CYSTIC TUMOUR OF THE UTERUS.

The specimen was taken after death from Mrs. W., a patient of Mr. Duke's, of Kennington. She died at the age of 64. She had suffered from this growth for at least twenty years. Its nature was not determined during life, but it was not considered to be an ovarian tumour. It did not give her much pain, nor does it appear that it ever caused any menstrual disorder. Indeed, menstruation had probably ceased before the presence of the mass in the abdomen was first observed. She had a miscarriage some years before in India. The growth occupied the right side of the uterus, and was everywhere surrounded by uterine tissue; the cavity of that organ was enlarged, and contained a flattened mucous polypus. The right dilated Fallopian tube, and the right round ligament of the uterus, were stretched over the summit of the tumour, while the fundus of the organ was pushed over to the left side.

The right ovary could not be found; the left ovary and the uterine appendages on that side were healthy. The growth consists of numerous cysts of various sizes. Their walls are made up, according to the observations of Dr. Braxton Hicks and Dr. Fagge, of ordinary fibrous tissue, mixed with some undeveloped uterine fibres. These cysts have not generally any defined limiting membrane; they contained a pink or red fluid. The tumour also contains a large number of masses of earthy matter, which Dr. Stevenson kindly examined, and found to consist of phosphate and carbonate of lime. The case is of interest, as being an example of a rare form of disease, of which, indeed, only three or four instances seem to have been recorded till within the present year.

OBITUARY.

DR. C. G. RITCHIE.

Last week we could do no more than make known the loss of this young Physician, and allude briefly to the melancholy accident which led to the sudden termination of his short but honourable and prosperous career. We are not all Dr. Marigolds. It is no easy matter to do the "cheap Jack" with the head of a sick child resting on your shoulder. Death drives you into seclusion, and you can only say, "Quick. Shut the door! Don't let those laughing people see." But it is almost beyond human endurance to have to step out on the platform, and, as soon as you know it yourself, to announce publicly the death of your own friend—to sit down and, with the half-closed glistening eyes following every scratch of the pen, write such tidings for readers unsympathising from want of knowledge. To say more than the simple truth would be wretched mockery, and yet the plain truth only, though enough to rouse a suspicion of fond flattery, sounds cold and heartless. Still one cannot alter the way of the world or the world's troubles. What has been before is now, and will be again. "Che sara, sara." Before the inevitable we must all learn to bend, not break. So it being true, and no turning away from the fact having power to alter it, we strain ourselves to comment upon the sudden death of Dr. Charles George Ritchie. He was only 23, but already reading and thinking men had begun to see that he promised to be worth something to his friends and the world if he had but time to ripen. The public must now take upon trust an estimate of those merits which a few years more of life would have made known to all.

One glowing July morning last summer twelvemonth, a bright young fellow walked into a working room, modestly introduced himself, and set eyes for the first time on the marvels of the human ovum. He noted carefully every particular pointed out to him, watched patiently the steps of tedious dissection, and the mode of unravelling those minute structures, verified some of his book knowledge, corrected many of his misconceptions by observation, stated his difficulties in the spirit of an earnest learner, displayed some of the scepticism of inexperience as to the possibility of seeing all that it was promised to show him, grew more and more engrossed as the day went on and his knowledge and confidence in his teacher increased, and at last soared into enthusiasm when he witnessed the perfect demonstration of a pathological condition which had only been partially and obscurely seen and doubtfully stated by Rokitansky. Day after day he submitted in the same patient way to teaching and guidance, perseveringly trying his 'prentice hand, curiously telling over and over again his new earnings, and at last gaining steadiness, skill, and success in doing for himself what a week before he had been half inclined to think incredible and impossible. It was a great treat to an old stager, who had looked long enough on these things to become somewhat sluggish and hopeless, and who had tried often enough, and in vain, to rouse others younger and more able than himself to work at them more vigorously than he did, to watch the growing zeal, the pushing inquisitiveness and unbounded delight of this novice. Henceforward his labours in the same direction were incessant.

In that seven days' work there is the clue to the character and life of young Ritchie. Fortunate in a pleasing person and manners, he soon made friends; quick of thought and sight, he was an apt learner; patient and persevering, he made sure progress; careful and reasonably hard of belief, he stepped forward observantly, and was not easily misled; conscious of power and honesty in himself, he was willing to trust to the leading of those who dealt truly and openly with him; thirsty for knowledge, craving for distinction, determined to win early and fairly a first position, he was a good representative "Young England" Doctor. But it is all over. Young-like, he strove too much, and too soon. He was not strong enough for the flight he essayed. Overtasking had weakened his frame. Worn and weary, he sought sleep and rest, and he died from the narcotism of a dose of morphia, which could not have been a very large one.

"Pocula Lethæos ut si ducentia somnos
Arente fauce traxerim."

We can only add that Dr. Ritchie was the son of the well-known Physician and Professor in Glasgow, whose papers on the ovaries were reprinted in the "Contributions to Ovarian Physiology and Pathology," by which the names of father and son will hereafter be best known. The son began the study of Medicine under the father at Glasgow; went to Vienna, Wurtzburg, and Paris for two years; took his degree in Glasgow; and spent a year in Edinburgh under Dr. Simpson, residing in the Children's Hospital. Towards the end of 1863 he came to London, and very soon afterwards began to assist Mr. Spencer Wells in his private practice. The daily routine of this occupation, his literary engagements, and Midwifery practice, which was rapidly increasing, kept him fully occupied. His prospects were unusually good. He had been engaged to attend an English ambassadress in her approaching confinement abroad. But the sad end of it we have all heard.

"Fame is the spur that the clear spirit doth raise
(That last infirmity of noble mind)
To scorn delights, and live laborious days;
But the fair guerdon when we hope to find,
And think to burst out into sudden blaze,
Comes the blind fury with the abhorred shears,
And slits the thin-spun life. But not the praise."

BOOKS RECEIVED.

Ligature of the Left Common Iliac Artery. By W. Hargrave, A.M., M.B. Dublin: T. Deey.

*** "The practice of Surgery appears to be experiencing a remarkable change in the controlling of arterial hæmorrhage by other means than by the ligature. From the position which I have the honour to hold in the School of the Royal College of Surgeons, I cannot, without much more experience than we at present possess, supersede this valuable and well-tested means of commanding hæmorrhage in favour of acupressure, the catgut, lead, metallic, silk, and others; we have now the hemp ligature, which will supersede all others for the firm way in which it remains on the artery, the complete absence of irritation, and no alteration in its strength or soundness."

The Edinburgh Medical Journal, October. Edinburgh: Oliver and Boyd.

*** Dr. Matthews Duncan gives the following as his conclusions on the subject of the mortality of women in child-birth as affected by age:—

"1st. Youthfulness has less influence in producing mortality from parturition than elderliness.

"2nd. From the earliest age of child-bearing there is a climax of diminishing puerperal mortality, succeeded by an anti-climax of puerperal mortality increasing till the end of child-bearing life.

"3rd. The age of least mortality is near 25 years, and on either side of this age mortality gradually increases with the diminution or increase of age.

"4th. Above 25 years, puerperal mortality increases at a much higher rate than it increases at corresponding periods below 25 years.

"5th. Though it is not deducible from anything in this paper, it is too interesting to omit noticing that the age of greatest safety in parturition coincides with the age of greatest fecundity, and that, during the whole of child-bearing life, safety in parturition appears to be directly as fecundity, and *vice versâ*. (See *Transactions* of Royal Society of Edinburgh for 1864, p. 488.)"

MEDICAL NEWS.

APOTHECARIES' HALL.—Names of gentlemen who passed their Examination in the Science and Practice of Medicine, and received Certificates to Practise, on Thursday, December 28, 1865:—

Alfred Bullock Watts, University College; Charles Arthur Patten, St. Bartholomew's Hospital.

The following gentleman, also on the same day, passed his First Examination:—

Robert Harman Smith, Guy's Hospital.

APPOINTMENTS.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

BENNETT, WILLIAM H., M.R.C.S. Eng., has been elected Coroner for the Shaftesbury Division of Dorsetshire.

HINGSTON, C. ALBERT, M.D. Lond., has been appointed Physician to the Plymouth Public Dispensary.

BIRTHS.

BURN, Dr. G. A., 4th Cavalry, Hydrabad Contingent, the wife of, at Hingolee, on November 16, of a daughter.

FINCH, Dr. R., the wife of, at Stainton Lodge, Blackheath, on January 1, of a son.

GIBBON, Dr., the wife of, at 39, Howley-place, W., on December 26, of a daughter.

GORDON, Dr. R. N., the wife of, at the Royal Dockyard, Portsmouth, of a daughter, on December 23.

HEARNDEN, Dr. W. A., the wife of, at Sutton, Surrey, on December 25, of a daughter.

HICKS, ROBERT, M.R.C.S. Eng., the wife of, at Ramsgate, on December 28, of a son.

HOOKER, E. M. C., Dr., the wife of, at Hadlow, Tunbridge, on December 17, of a daughter.

PLUMBE, Dr., the wife of, at Maidenhead, on December 21, of a daughter.

RINGROSE, Dr. E., the wife of, at Potter's Bar, on December 27, of a son.

SALTER, Dr. HYDE, the wife of, at 6, Harley-street, W., on December 30, of a son.

SIMMS, FREDERICK, M.B., the wife of, at 75, Rue de la Pompe a Passy, Paris, on December 25, of a son.

DEATHS.

HILL, WILLIAM P., Surgeon, at Port Elliot, South Australia, on September 30, aged 47.

KELSON, JOSEPH J., M.R.C.S. Eng., at Beaufort House, Park-row, Bristol, on January 2, aged 74.

ROBERTS, JOHN, L.R.C.P. Lond., Resident Medical Officer St. Pancras Infirmary, on December 30, aged 26.

POOR-LAW MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the last census.

RESIGNATIONS.

Bramley Union.—The Bramley District is vacant; area, 2505; population, 8691; salary, £20 per annum. Also the Workhouse; salary, £5 per annum.

Droitwich Union.—Mr. Cramer has resigned the Hanbury District; area, 10,945; population 3118; salary, £65 per annum.

Fylde Union.—Mr. D. Niddrie has resigned the Lytham District; area, 10,220; population, 4076; salary, £25 per annum.

Richmond (Surrey) Union.—The Barnes District is vacant; area, 900; population, 2303; salary, £40 per annum. The Kew District is vacant; area, 341; population, 1100; salary, £10 per annum.

West Bromwich Union.—The East Oldbury District is vacant: area, 1989; population, 8409; salary, £65 per annum. The West Oldbury District is vacant; area, 1809; population, 8849; salary, £65 per annum.

APPOINTMENTS.

Congleton Union.—Charles F. Sutton, M.R.C.S.E., L.S.A., to the Church Hulme District.

Durham Union.—William C. Allen, M.R.C.S.E., L.R.C.P. Edin., to the Western District.

Ely Union.—Henry Pearson, M.R.C.S.E., L.R.C.P., L.S.A., to the Second District.

Pontypridd Union.—Walter Morgan, L.R.C.S.E., L.S.A., to the Workhouse.

Tamworth Union.—William Anderson, M.D., Edin., M.R.C.S. Edin., to the Clifton District.

TESTIMONIAL TO DR. PATERSON.—The sympathisers with this gentleman—who, it will be recollected, achieved great notoriety as a witness in the Pritchard case—have presented him with a piece of plate and £200.

FEVER IN ST. PANCRAS.—The Fever Hospital is full, and a number of cases of typhus have in consequence been taken into the St. Pancras Workhouse Infirmary. In several parts of St. Pancras fever is rife, and we regret to announce that the Senior Surgeon of the Workhouse, Mr. John Roberts, died on Saturday of typhus, caught in the discharge of his duties. He was only 26 years of age.

PHOTOGRAPHS BY MAGNESIUM LIGHT.—The magnesium light is so powerful and so portable, that it has become a great power in photography; for it enables the operator, independently of daylight, to take portraits where and when he chooses, whether of geological specimens in a cellar or of the sick in their chambers. We have seen Mr. T. Skaife, of 118, Pall Mall, operate in this way, and may say that the process is exceedingly rapid, and less wearying to the eyes than that of taking an ordinary photograph. Medical men who may wish photographs taken of patients who cannot leave their rooms may find Mr. Skaife a useful auxiliary.

THE CATTLE PLAGUE.—The case is simply this: The disease spreads much more rapidly, and destroys much faster, than such means of cure as are known can follow; and therefore it is of more profit, or rather it is a smaller loss, to kill, than to try to cure with the certainty of failing in seventy, eighty, or ninety out of a hundred cases. This is the simple and serviceable ground which has been all along held by Professor Gamgee; and to this complexion also the farmers are rapidly coming. Indeed, there is in Scotland at least a broadening conviction that had Professor Gamgee's energetic counsels been taken at first we should not have been in these alarming circumstances. It has been the fate of Mr. Gamgee to see a little too clearly, and to speak a little too soon, for the class in whose interests he labours. Whatever may have been his mistakes and successes before he proclaimed to the country the presence of the rinderpest in the London dairies, since that time as surely as his counsels have been slighted, they have been followed later, a little too late in the day. He declared the disease imported; after much controversy, that is admitted on all hands. He urged the suspension or rigid supervision of the import of foreign cattle; the Commissioners and the farmers have practically recommended the stoppage of the entrance of live cattle from abroad. He strenuously prescribed isolation and slaughter as the sole effectual cure; and for the "killing cure" many of the farmers are now only too willing. He has long, almost if not quite alone, insisted on the necessity and advantage of a National Cattle Insurance Association, as a safeguard against the ravages of this and other epidemics; and the most influential meeting of agriculturists that has been held on the subject of the plague has taken up the idea, and resolved in favour of just such a system of insurance. It is something for any man to have been right, and to have pointed the way, in a time of emergency and tumult of opinion—to have silenced and convinced opponents, and to have led those who have laughed at him. This Professor Gamgee has done, and it is but just that the credit he deserves should be given him.— *The Scotsman.*

A DIFFERENCE OF OPINION.—A recent number of the *Somerset and Wilts Journal* contains a long account of an inquest held in consequence of a difference of Medical opinion. The particulars of the case were as follows:—On Tuesday, November 28, John Franklin Rawlings, aged 8 years, was taken ill at Upton Noble. The next day, his step-mother hearing that Dr. Banks, of Evercreech, was in the village, asked him to see the boy. He complied, and pronounced the case one of scarlatina, recommended that the child should be kept warm, and, in reply to Mrs. Rawlings, said he did not think the parish authorities would consider the case one that legitimately called for free attendance and medicines. On the following day the child died. About this time Dr. Heginbotham, of Bruton, had engaged a sister of the deceased as nurse for his children, and fearing infection, went to the residence of Rawlings, and made a post-mortem examination of the body, and gave it as his decided opinion that the child died of acute inflammation of the windpipe. This intelligence having been noised abroad, some of the village authorities demanded an inquest. The father of the child, to save inquiry, proceeded to Evercreech, and asked Dr. Banks for a certificate of the cause of death. A dispute arose about the charge for the certificate, Dr. Banks demanding 2s. 6d. for it. Rawlings afterwards paid 2s. only. In the ensuing week, the guardians, the relieving officer, the village policeman, and others discussed the merits of the case, and finally it was agreed that there should be an inquest. On Thursday, the 7th inst., the inquest was held at Rawlings' house before Dr. Wybrants, Coroner, and a jury of which the Rev. Henry Taylor, rector of Batcombe, was the foreman, and the above facts were deposed to, Dr. Banks having been kept in ignorance of the proceedings. As Dr. Banks had a majority of partisans on the jury, it was decided that the inquest should be postponed till Tuesday, December 12, in order to give him an opportunity

of explaining the matter connected with the certificate, and to hear the evidence of the post-mortem examination from Dr. Dr. Heginbotham. During the inquest Dr. Banks accused Dr. Heginbotham of a breach of Medical etiquette in visiting his patient, and a dispute, which we suppose was found very edifying by the jury, ensued. The verdict of death from natural causes was finally returned.

The following are the last week's Cattle Plague Returns. By comparison with those of the previous week, it will be seen that there have been 8207 attacked, 5161 deaths, 757 slaughtered, and 1167 recoveries, since December 16 :—

Census Divisions.	1. Attacked. Week ending December 23.	Week ending December 16.	Week ending December 9.	2. Result of reported Cases from the Commencement of the disease. Attacked.	Killed.	Died.	Recovered.	Remaining.
1. Metropolitan Police District	86	43	129	7175	3089	3222	280	584

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

Dr. Wahu's book shall receive due notice.

A Country Practitioner.—There is no such journal in the present day as the *Medical Gazette*. The old *Medical Gazette*, one of our progenitors, was far too respectable to have noticed any such obscene work, neither was there any review under that name.

Gelatine in Ophthalmic Practice.—In our last number, p. 717, appears a letter from Mr. J. Z. Laurence, in which the use of gelatine discs as media for the application of atropine to the eye is ascribed to Mr. Streatfield. Messrs. Savory and Moore claim the priority of application for Mr. Ernest Hart, for whom they made the gelatine discs before they were used by any other ophthalmic Surgeon. The matter was only mentioned incidentally by Mr. Laurence, who publishes an invention which he believes likely to supersede the gelatine discs. Time will show which is best.

Voting by Proxy.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—In computing the comparative interest taken in the election of the Council of the College of Surgeons by "Fellows by election" and "Fellows by examination," you appear to forget that the large majority of the former are gentlemen who have been in practice for some years, and are busily occupied in practice, and therefore unable to leave home and personally tender their votes. By far the larger proportion of the Fellows by examination are comparatively junior in the Profession, and not yet so fully occupied as their seniors, who have been longer in practice. I am authorised to inform you that Mr. Sankey, of Dover, is in favour of voting by proxy. I am, &c.,

C. Holman, M.D.,
Secretary of the South-Eastern Branch of the British Medical Association.

Reigate, January, 1866.

The Title of Physician.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—I shall feel greatly obliged if you will be good enough to answer me the following queries in your next week's number. 1st. I am L.F.P. and S.G., and L.M. ; have I a right to be called "Physician," or, am I only "Physician" by courtesy? 2nd. Should I be doing wrong by taking the title and calling myself "Physician?" 3rd. Does the Faculty allow its Licentiate to take the title, or does it only wink at its being done? If you will kindly answer the above, I shall feel much obliged.

I am, &c.,
Medicus.

We ought to have the words of the licence before giving an opinion.

Poor Law Medical Reform.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—Since the last publication of the list of subscribers to the Association I have received the following sums of money :—Cod, G., Watford, 5s. ; Worth, E. J., St. Germans, 5s. ; Irving, W. B., Newark, 10s. ; Hair, Jas., Sudbury, 5s. ; Hall, E., Ulverstone, 10s. ; Fenn, E., Uckfield, 5s. ; Griffin, R., Weymouth, 21s. As the year 1865 has now passed, I think it due to the subscribers to lay before them a short statement of the accounts :—In January, 1865, there was a debt of £8 7s. 1d. ; and during the year, I have received from twenty-nine of the three thousand and odd Poor Law Medical Officers £14 3s. 1d. ; but as the expenditure during that time has been £10 13s. 1d., for printing 750 pamphlets for the Members of the House of Commons and the subscribers, with postage and sundry small expenses, it follows that there is £4 17s. 3d. still due from the Association.

I am unwilling to say one word by way of reflection on my brethren, but it must be obvious to them, that without adequate funds, meetings cannot be held, or the necessary steps taken to impel the Poor Law Board to improve the system of Poor Law Medical Relief. I am, &c.,

12, Royal-terrace, Weymouth, January 1. Richard Griffin.

The Early Physical Signs of Pneumonia.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—In your journal of last week, under "Notices to Correspondents," is a letter from Dr. Waters, of Liverpool, drawing attention to an error in the remarks I made when his paper "on the Early Physical Signs of Pneumonia" was under discussion at the Medico-Chirurgical Society. My mistake was in supposing that in the cases he described distress on percussion existed coincidently with the loudness and roughness of the respiration, and he writes as if my misapprehension on this point affected the whole gist of my argument. On this account only I trouble you with these few lines. The existence of dulness would have strengthened my arguments ; but its non-existence makes no alteration in my view of the case. I cannot doubt that the loudness and harshness of the respiratory murmur, which Dr. Waters described as preceding fine crepitation in the cases referred to was a species of exaggerated or supplementary breathing, due to consolidation, more or less complete, of adjacent lobules or lobulets. There is no other physical explanation of the fact, and if the consolidation was confined to a few scattered lobules, one could no more expect to discover dulness on percussion, than one can in many cases of so-called lobular pneumonia, or commencing secondary deposits.

I am, &c.,

13, Manchester-square, Henry W. Fuller, M.D.

The Cattle Plague.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—It has been sufficiently established by the most reliable authorities that the cattle disease is solely imported from the Steppes of Russia, and is never propagated otherwise than by contagion. Why it should be indigenous to the Eastern part of Europe is, in our present state of knowledge, difficult to determine ; but this much is certain, that from its strictly contagious nature it may altogether be regarded as a specific animal poison, producing well-defined symptoms, and running, in most instances, a regular course. Like typhus and its modifications, it is essentially a blood disease, and is produced by the virus being imparted to this fluid. In some way or other, according to Spinola, after the poison having remained dormant in the system for some time, it ultimately produces a change in the condition of the blood, which is marked by a derangement in the functions of the various organs. Its effect on the brain causes dulness, irritability, and nervous depression on the lungs, cough and hurried breathing in the stomach and intestines, diseased secretions, dysenteric purges, and we may add, congestion and inflammation of the mucous membrane, and on the skin, harsh and staring coat. As in all diseases of a contagious nature, in this instance also, the preventive measures are decidedly the most important of all, for when the disease has fairly broken out, it is only too often next to impossible to stay its progress, or to abate the violence of its symptoms. Thus disinfectants of all classes should be freely employed together with the utmost cleanliness, the observance of which should be made compulsory upon all those employed in the management of cattle. The chloride of lime is of all disinfectants the one most in use, both from its cheapness and ready application ; but from the experience I have had in my own practice, I give in all such cases the preference to the exhalation of the tars, both wood and coal. I remember an instance of a long-continued typhus in a manufactory being immediately checked by causing the wells of the establishment to be painted all over with coal tar, and I would suggest the same expedient being resorted to in the cattle plague. The sheds, slaughterhouses, and stalls might easily be coated in a similar manner, thereby offering an easy prevention to this terrible calamity. One might also put open vessels, containing equal parts of wood and coal tar, in places where cattle are generally kept, which might be changed once or twice a day as required.

Upon the first appearance of the malady, nitre should be given to counteract the catarrhal and inflammatory symptoms ; these being abated, arsenic may be exhibited in small and repeated doses in warm gruel or any other mucilaginous vehicle, as possessing the double quality of retarding the process of putrefaction, and destroying or neutralising the effects of every exuberant low animal or vegetable poison, whilst it acts to some extent as a tonic if used in moderation, owing to its affinity to iron, with which it is not unfrequently found.

The disease being of a decidedly putrid character, the chlorates, chlorine water, or diluted phosphoric acid, may be given with benefit as the signs of putrefaction become more marked. Stimulants are objectionable, as they contain but little nourishment, and, by the false excitement they create, rather tend, by the subsequent reaction, to hasten the fatal termination of the disease than otherwise. Astringents are alike to be depreciated, as they have no effect in neutralising the poison, and by causing an abnormal contractivity in the system prevent its being eliminated by the natural ways ; the pure tonics are alone admissible, but for obvious reasons, not at the outset of the malady ; they should, however, be administered with caution.

Of all the tonics, iron and its salts are the best, the citrate being the most efficacious, though somewhat an expensive drug in veterinary practice.

The hot air and vapour baths, as well as other methods employed to promote perspiration, are doubtless of the greatest utility in inducing a salutary crisis in the milder cases ; but in the severer forms or in the more advanced stages of the malady, the vital powers are so much reduced as to render the employment of a mere expulsive and decidedly depressing remedy wholly inadmissible, to say nothing of its inability to reach the seat of injury or to neutralise the morbific poison.

The diet should be of a bland, pure, and nutritious character ; the water used for drink should not be medicated, and the animals should be permitted to use it freely. Cleanliness, I repeat, is here of the utmost im-

portance, and the bedding should be changed as often as it becomes offensive. The milk of diseased cattle is positively injurious, and restrictions should be laid upon the sale of it, even for some time after recovery. The meat is at no stage of the disease fit for food. The dead bodies may be rendered innocuous by having them buried in deep pits and the carcases covered with quicklime. Finally in the most virulent cases, the animal should be put to death at once, thereby ending its sufferings and checking the further spread of the infection. Though the notion universally prevails that this disease is incurable, I have no doubt, from the unmistakeable nature of its symptoms and its comparatively slow course, that some plan of treatment might yet be adopted to stay the progress of this terrible infection; and having given the matter my full and unbiassed attention, I offer the foregoing to the Profession, trusting that in the hands of a skilful and liberal-minded veterinary Surgeon the suggestions I have thrown out may lead to the desired result. I am, &c.,

F. E. JENCKEN, M.D.

AN AMERICAN VIEW OF MR. SYME'S CRITICISMS.

It is not a little surprising that the greatest opponent acupressure has yet met with should be a colleague of the ingenious inventor himself. Professor Syme has omitted no opportunity to disparage, and even denounce it, and that not always in the most gentle phrase. These attacks have, as might have been supposed, provoked severe replies from Professor Simpson, as may be seen in the *Medical Times and Gazette* The communications are exceedingly pungent and well written, and marked by the raciness of style so peculiar to the author. It is hardly possible that Professor Syme could fail to smart under them; and yet it is certainly his own fault if he is made to suffer. His conduct affords an apt illustration of the sentiment of Terence—

"Si mihi pergit quæ vult dicere, ea quæ non vult audiet."

Steel is not the only substance that cuts. To assume, as seems to have been the case in the present instance, that nothing good can emanate from the brain of an obstetrician, was rather a bold conclusion, fraught with evil consequences. The Surgical Professor in the University of Edinburgh has never, it would seem, employed acupressure; and yet, according to our author, he has set himself up as its most uncompromising enemy. When, or how, this controversy may end, time alone can determine. It is much to be regretted that there should ever have been any occasion for it. Disputation too often distracts the Profession, and curdles the milk of Professional brotherhood."—*American Journal of Med. Sc.*, July, 1865.

At the Royal Observatory, Greenwich, the mean height of the barometer in the week was 29·912. The mean daily reading was above 30 in. on the first four days.

The general direction of the wind was south-west.

* The average weekly numbers of births and deaths in each of the above towns have been corrected for increase of population from the middle of the ten years 1851-60 to the present time.

† Registration did not commence in Ireland till January 1, 1864; the average weekly number of births and deaths in Dublin are calculated therefore on the assumption that the birth-rate and death-rate in that city were the same as the averages of the rates in the other towns.

‡ The deaths in Manchester and Bristol include those of paupers belonging to these cities who died in Workhouses situated outside the municipal boundaries.

§ The mean temperature at Greenwich during the same week was 42·7°.

‖ The usual returns not having been received from Edinburgh, Glasgow, and Dublin, averages of the returns of the six previous weeks have been substituted for the correct numbers.

APPOINTMENTS FOR THE WEEK.

January 6. *Saturday (this day).*

Operations at St. Bartholomew's, 1½ p.m.; St. Thomas's, 9½ a.m.; King's, 2 p.m.; Charing-cross, 1 p.m.; Royal Free Hospital, 1½ p.m.
ROYAL INSTITUTION, 3 p.m. Prof. Tyndall, "On Sound" (Juvenile Lectures).

8. *Monday.*

Operations at the Metropolitan Free Hospital, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 9 a.m. and 1.30 p.m.
MEDICAL SOCIETY OF LONDON, 8½ p.m. Lettsomian Lectures—"On Certain Painful Affections of the Fifth Nerve," Lecture I., by Dr. F. E. Anstie.

9. *Tuesday.*

Operations at Guy's, 1 p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; St. Peter's Hospital for Stone, 3 p.m.
ETHNOLOGICAL SOCIETY OF LONDON, 8 p.m. J. F. Campbell, Esq., "On the Physical Forms of the Lapps." Col. Fayre, "Notes on the Ethnology of the Indo-Chinese Nations and Tribes." Miss A. P. Irby, "On the Characteristics of the South Selavonic Races."
ROYAL MEDICAL AND CHIRURGICAL SOCIETY, 8½ p.m. Mr. Barwell, "On the Pathology and Treatment of Lateral Curvature of the Spine." Dr. Radcliffe, "On Acute Uncomplicated Myocarditis."

10. *Wednesday.*

Operations at University College Hospital, 2 p.m.; St. Mary's, 1½ p.m.; Middlesex, 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; St. Thomas's, 1½ p.m.
HUNTERIAN SOCIETY (Council, 7 p.m.), 8 p.m. Dr. Bright, "Observations on Diphtheria."
MICROSCOPICAL SOCIETY, 8 p.m. Mr. G. G. Lobb, "On an Opaque Illuminator by Prof. Smith, of Gambia, Ohio, U.S.;" "On the best Method of Illumination with High Powers for Difficult Objects."

11. *Thursday.*

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Surgical Home, 2 p.m.; Royal Orthopædie Hospital, 2 p.m.; West London Hospital, 2 p.m.

12. *Friday.*

Operations, Westminster Ophthalmic, 1½ p.m.

ORIGINAL LECTURES.

ON GENERAL AND LOCAL CHEMICAL DISORDERS ARISING FROM PEROXIDATION,

AND ON THE MECHANICAL DERANGEMENTS THEY PRODUCE.

By H. BENCE JONES, M.D., F.R.S.

PART III.—LECTURE IX.

(Continued from page 2.)

ON BRIGHT'S DISEASE.

Causes of Tubular Nephritis.

It is scarcely possible for disease of the arterial and interstitial structure of the kidney to exist without an affection of the tubes. It is far more possible for the tubes to be affected without the interstitial texture participating in it. The malpighian tuft must be considered as part of the tube, and the slightest increased action, pressure, or thickening in the tube must immediately affect its malpighian tuft.

Of all the names that have been given to this form of disease, that of tubular nephritis appears to me the most simple. In its comparative mildness, in its occasional intensity, in its long duration, and in its rapid and perfect cure, it resembles slight, severe, chronic, and rapidly-curable bronchitis. If it were not for the albumen poured out, and for the urinous matters kept in, there would be, as in bronchitis, a peroxidation set up in the tube outside the blood. This would cause increased flow of blood in the vessels, increased formation and shedding of epithelium, increased pressure and thickening from fibrin. Then obstructions would come on, stoppage of the blood, stoppage of oxidation in the most obstructed part, and production and deposit of fat and alteration of the composition of the nitrogenous texture by the stoppage of nutrition, whilst around the obstruction a widening circle of increased action would exist.

Of all the causes that affect the tubes of the kidney cold is the most striking.

The sudden stoppage of the removal by the skin of water, salts, lactic and hidrotic acids, urea, and probably a multitude of other substances, immediately causes an accumulation of these or their parent substances in the blood. No sooner does this occur than on every mucous membrane and in the lymph that diffuses into every structure these substances are poured out. The greater part of the skin excretion must ultimately pass off by the kidneys or bowels. Hence increased chemical and mechanical action, increased flow of blood, increased oxidation, and, if this becomes excessive, obstruction occurs; then follow altered oxidation and altered nutrition, whilst albumen, epithelium, fibrinous casts, and blood globules are thrown out in the urine. The substances or their parents that the cortical structure should secrete are left behind in the blood, and from it they pass with the lymph into the structures according to their power of diffusion. In the cellular tissue these lymph effusions can most easily accumulate, and the chemical action set up by the urinous substances acting on the cellular substance probably is the cause of so large an amount of fluid being poured out. It is probable also that sometimes, from the excessive hardness of the effusion in the legs, that some fibrinous as well as albuminous and urinous matters are poured into the cellular tissue.

Sometimes the inflammation in the tubes may be as slight as in the slightest catarrh, lasting a few days and showing scarcely any symptoms. At other times the intensity of the action may be so great that it can only be compared to the most intense croup.

Many cases arising from cold, scarlet fever, irritants, or pressure will require no treatment at all. As soon as the causes pass away the complaint ceases. In other cases the increased action, the mechanical obstruction, and the tertiary diseases are so intense that no time for any treatment is allowed. Thus, after scarlet fever the patient may in a few hours sink from the violence of the secondary disease. In the vast majority of cases of tubular nephritis the disease lasts for some weeks, and is far more influenced by treatment than any other form of Bright's disease.

Another frequent cause of tubular nephritis is scarlet fever. It has been said that an internal desquamation in scarlet fever causes tubular nephritis, but in the secondary affections of the eyes, ears, and glands after scarlet fever scaling does not occur. Moreover, the scaling of the skin is only the result of the altered nutrition arising chiefly from the increased circulation which the increased chemical action in the skin produced. If shedding of the epithelium does occur in the tubes of the kidney, alterations in the chemical and mechanical actions in the tubes must have preceded this scaling and these actions, and not the mechanical scaling, are the cause of the tubular nephritis.

Although the scarlet fever poison has never been insulated, or its amount at different times determined, yet judging from small-pox you may be pretty sure that it multiplies, and that the action which we see on the skin goes on more or less strongly in every part of the body, so that at the time when the eruption begins to decline the amount of poison oxidised or unoxidised in the skin and textures must be at its highest point. This must be taken up by the lymphatics, and must be thrown out by every excreting surface, more especially by the kidneys, through which the greater part of all extraneous substances pass and undergo further oxidation. Even for a fortnight after the eruption declines the elimination of oxidised poison must continue, and during all this time in the kidneys, the eyes, the ears, or the glands unmodified peroxidation may be set up.

Many other poisonous substances, as cholera poison, turpentine, cantharadin, copaibæ, etc., when taken by the stomach, the breath, or the skin into the blood for a few minutes even, begin to pass off in a great part by the kidneys and give rise to the same tubular nephritis.

A peroxidation spreading up from the pelvis of the kidney, or increase of pressure on the arterial system consequent on obstruction to the free flow of blood in the renal vein—as, for example, during the last weeks of pregnancy—may also give rise to tubular nephritis.

On the Signs and Symptoms of Tubular Nephritis.

In all lung affections or bowel troubles you would expect to learn many things from the more or less careful observation of the expectoration or the evacuations. In diseases of the cortical structure of the kidney, without the most careful microscopical examination of the urine, you will get nothing more than the fact that albumen is shown by chemistry to be present. The interpretation of the meaning of the albumen depends on the general history and circumstances under which it occurs, but still more on the microscopical appearances which the urine presents; and without the microscope no accuracy of diagnosis is possible. Common-sense, or even good guessing, without a microscope may lead you right, and the microscope may only help to lead you wrong; but if you become skilful in its use, and not over-refined in drawing conclusions from a single cell or a particle of fibrin, and employing it as one means, and not the only help, to a right diagnosis, you will find that in this tubular nephritis more especially it will serve you well.

Masses of epithelium of the form of the renal tubes, fibrinous exudations in casts of the tubes, exudation cells, mucous cells, blood cells, pus cells, these all may occur, in every variety, according to varying states of congestion, inflammation, and suppurative deposit or production of fat in different parts of the tubes of the kidney at the same or at different times. It is in tubular nephritis that these appearances mostly occur; and according to the intensity or stage of the attack the microscopic appearances will be more or less pronounced. Moreover, as tubular inflammation is more curable than either of the other forms of cortical disease, so the appearance of these products of inflammation—altered epithelium cells and casts—indicates that the least dangerous of the three diseases is present, and that if the interstitial and vascular structures remain free perfect recovery may take place. Hence excess of fibrinous casts in the urine, other things being favourable, should lead you to a far more hopeful prognosis than when no casts and no tubular epithelium are found. When cirrhosis or amyloid disease (even in extreme cases) are present, no microscopic appearances may be found, and after careful watching for months for the slightest microscopical evidence of disease, I have found the cortical structure of both kidneys almost entirely disappeared.

Consequences of Tubular Nephritis.

Not only do albumen, fibrin, and blood globules come out, but urea, and its parents and progenitors, are prevented from escaping by the altered conditions produced in the tubes. These urinous substances cannot be kept in the blood, but they diffuse back into every texture, and in the cellular tissue

set up increased chemical action, and water, albumen, and sometimes even fibrin are poured out. In the loose cellular tissue under the eyelids the effects of the irritating fluid are generally most perceptible, even when the lowest part of the denser cellular tissue about the ankles shows as yet no appearance of effusion. The more rapidly this acute dropsy comes on, the harder the swelling is to the touch, in other words, the more fibrin is mixed with the other products of this effusion; and in the most intense cases of tubular nephritis, scarcely any impression can be made by the finger even where pressure can be most strongly applied.

This primary urinous acute dropsy differs altogether from the secondary anæmic dropsy, which, in tubular nephritis, and in other forms of Bright's disease, comes on when the blood globules and albumen in the blood have, by long-continued wrong chemical and mechanical actions, fallen so low as to produce anæmia. Then, as in anæmia from other causes, if little urine is passed, œdema becomes evident in the lowest parts of the limbs or body, and the slightest pressure leaves its mark, and the water can be moved from place to place, because no fibrinous matter has been effused.

The primary dropsy may continue even after the secondary dropsy is set up, for the two causes may be in action at the same time, or the secondary dropsy may more or less quickly come on after the first dropsy has passed away.

When urea and its progenitors exist in the blood, not only does it diffuse into the cellular tissue, but it passes also into the serous and other textures of the different organs. Hence the disposition to pleurisy, pericarditis, peritonitis, pneumonia, bronchitis, and other secondary diseases, which so readily occur in acute tubular nephritis. Even the affection of the brain which occasionally is met with in the most acute tubular nephritis must be attributed to a strong chemical action on the nervous substance rather than to the slower poisonous action of the urinous matters which I have brought before you when speaking of uræmia. Increased oxidation, in the form of a more or less acute inflammation, may be set up by the action of undetermined descending excretory matter on one or all of the substances of which the organs are composed, whilst in uræmic poisoning no increase of oxidation may take place.

The Treatment of Tubular Nephritis.

The first indication is, as far as possible, to remove the causes of the attack. When cold is the cause, warm baths, vapour baths, and warm clothing may help to restore the action of the skin. Tartarised antimony has no strong action on the kidneys, and has a very decided action on the skin; and when it acts on the bowels or on the stomach, causing vomiting, it removes urinous substances from the blood. Hence it is a most important remedy in the acute dropsy from cold. Even when poisonous substances are passing out of the blood, as after scarlet fever, cantharides, turpentine, in extremes cases tartarised antimony may sometimes be used. In slight cases simple dilution with the purest water washes the impurity out of the blood.

The second indication is to stop the thickening of the tube, and to relieve the obstructed vessels. Abstraction of blood by cupping glasses on the loins can hardly be expected to effect the circulation in the tubes of the cortical structure of the kidney; whilst general bleeding, even to a few ounces, has a distinct effect on the pressure of the blood in the malphigian tufts. Hence, if blood at all is taken, it should be by venesection. Digitaline in small doses acts on the nerves that regulate the circulation rather like a stimulant, but in large doses or long continued the pressure on the arteries is diminished; and of all diuretics this is the only one which is admissible in acute tubular nephritis. As the disease becomes more chronic iodide of potassium may be used in diuretic doses. In ten minutes after the first dose it is present in every part of the kidney, and probably may be found there for many days after the last dose has been taken.

The last indication is to relieve the symptoms and complications that occur.

Of these, the dropsy is the most important. In the acute stage you have to contend with the urinous dropsy. Strong vapour baths or hot air-baths, used to the greatest extent that the strength will bear, are most efficacious. Strong action on the bowels by those watery cathartics that have the least action on the kidneys—as, for example, jalap, gamboge, and claterium. If the strength admits of it, emetics, tartarised antimony, and ipecacuan may be given.

When the acute stage is over, the tendency to anæmic dropsy begins. To prevent this, and after the anæmic dropsy is set up, small quantities of iron should be given. Nitre, cream of tartar, broom tea, and other diuretics may be used, sometimes in very large doses. Even tincture of cantharides may, in the more chronic state, be prescribed. In a very short time the whole of the anæmic dropsy may be removed, and then iron in larger quantity should be given to prevent a return of the effusion.

The treatment of the secondary inflammations should be carried on with allowance for the general debility which will appear when the increased arterial action subsides.

Counter-irritation is to be preferred to local bleeding, because it saves the red blood. Mercury is hardly ever to be used, as in this form of disease its poisonous action is most quickly and violently set up.

ORIGINAL COMMUNICATIONS.

CASE OF INJURY OF THE HEAD, FOLLOWED BY CONVULSIONS AND PARALYSIS—RECOVERY.

By CAMPBELL DE MORGAN, F.R.S.,
Surgeon to the Middlesex Hospital.

The following case I take to be one of great practical interest. It may appear to be somewhat unnecessarily detailed, but the symptoms were so variable, and in many respects peculiar, that, let them proceed from what cause they might, they should, I think, be carefully and fully recorded. That such cases do occur from time to time is very probable. Dr. Brown-Séquard, as will be seen, says that he has read similar cases. I have never myself met with any which in the severity and sequence of the symptoms resembled this, unless as the result of some positive injury to the base of the brain.

James H., a bricklayer's labourer, aged 73, was admitted into the Middlesex Hospital on October 9, 1863, at 4 p.m. He was brought to the Hospital in a light cart, having been shortly before knocked down by it. He walked into the Surgery, and there appeared little the matter with him beyond a contusion of the left knee, which was painful and tender, and a small contused wound over the left eye, and a still smaller one behind the ear of the same side. He said that he had not been stunned by the fall, nor had been giddy or sick. He spoke quite rationally, complaining of the pain in his knee, but he walked to the accident ward, and soon after took some food. The sister of the ward says that he talked quite collectedly to her and to the other patients during the evening, that there was nothing peculiar in his manner, and that he never alluded to the head, but complained only of the knee. He had been, it appeared, a very healthy man, had never had fits, but was a hard drinker.

At 9 p m., five hours after his admission, he was seized with convulsive twitchings of the left side of the face and the left arm, and in a few minutes afterwards fell into a state of semi-consciousness. He could with some difficulty be roused to put out his tongue, which was drawn towards the left side. The pulse was 88, small, and not very compressible. The pupils were contracted and insensible. When roused, he gave evidence of understanding any simple direction, but he did not attempt to speak.

At 10 p.m. the convulsions were more marked, and extended to the right arm; but nothing was noticed in the legs. He was still conscious enough to endeavour to put out his tongue. The breathing was slightly stertorous.

12.45.—There was now hemiplegia of the left side, and some loss of sensibility. When the right leg was pinched he gave evidence of uneasiness; but the left side, even the injured knee, might be pinched far harder without his showing any consciousness. There was no reflex action excited on tickling or pricking the sole of the left foot. The pupils were contracted and fixed. There was no appearance of want of sensibility or power in the face. The respiration was stertorous, chiefly diaphragmatic—40 in the minute—but somewhat irregular; the pulse 102, and small. He was still slightly conscious. On putting liquid into his mouth it brought on cough, but was soon swallowed, and he coughed occasionally from mucus collecting in the throat. There was no tendency to vomiting; he sweated profusely. The bowels acted from an enema, but apparently without his consciousness. The head was again carefully examined. There was no trace of

puffiness. Movement and percussion did not seem to give rise to any pain. The contusions were very slight, and there was scarcely any ecchymosis around them. There was no ecchymosis beneath the conjunctiva, and no blood in the ear.

October 10, 1.30 a.m.—Up to this time the symptoms had been regularly increasing; a slight improvement now took place. The breathing became more regular, quieter, and slower; the pulse became larger and slower by six to eight beats. He appeared conscious when the left leg was pinched; but the paralysis was quite as complete. The surface was less perspiring. Observations were now made on the temperature of the surface. In both axillæ the thermometer stood at 97°; on exposing the hands to the air for some time the right showed a temperature of 96°, while the left never fell below that of 96¼°; the left calf, after exposure, fell to 90°, while the right remained at 91°.

10 a.m.—He remained in much the same condition, the breathing becoming somewhat quieter till this time, when spasmodic twitchings recurred on the left side of the face. They were continual, and at times there were severe exacerbations when the spasm extended to the neck, and the head was jerked to the left side. The breathing was more thoracic, thirty in the minute, but still stertorous. He was slightly conscious, and endeavoured to put out the tongue when asked; but it also seemed to be affected with the spasm, and he could not protrude it. Pulse 86, moderately full. The pupils were small, slightly affected by changes of light. The paralysis and anæsthesia remained in the left arm, and he did not evince pain or move at all when the right arm and hand were pinched or tickled, but there was marked sensibility in both legs.

1 p.m.—The left arm is now in a state of contraction from strong spasm, principally of the biceps. The face and tongue are still affected by the spasmodic twitchings. He can move the right arm, though it still seems devoid of sensation. He has some slight voluntary power over both legs, but they are powerfully affected by reflex action.

2 p.m.—The head and eyes are now spasmodically drawn to the left side, and fixed. The skin of the face, especially on the right side, is dusky; the respiration laboured and stertorous, and he seems almost entirely unconscious. The impression on the minds of those who now saw him for the first time, and were not aware of the phases which presented themselves in the course of the case, was that he was dying. This state continued for more than two hours, and then gradually diminished, and he became more conscious than he had been since his first attack. In the course of the evening he spoke several times, and said he was a little better. He lay with both legs drawn up, and appeared to have some voluntary power over all his limbs. The pulse rose to 100, and the skin became hot and dry. Towards night there was continued muttering. As some reaction appeared to be coming on, I ordered ice to the head, and a drachm of strong mercurial ointment to be placed in the axilla.

October 11, 9 a.m.—Had no sleep, and wandered all night; but he is now more conscious than yesterday, and says he is better. The spasm of the left side of the face continues. The knees are drawn up, and he has sensation and voluntary power in both legs. He complains much when they are pinched. Both arms are flexed and somewhat rigid; the left hand is firmly clenched. Pulse, 120; respiration, 36; the skin dry and warm; the tongue dry. He has passed no water since yesterday; but there is no distension of the bladder. He complains of headache, and has a troublesome cough. During the night he took a pint of beef tea.

12 noon.—The twitching of the left side of the face still continues. He can put out his tongue and talk so as to be understood; but he wanders and mutters when left to himself. The knees are still drawn up, and he can move both legs. The left arm is again paralysed and rigid.

1.30.—The general condition remains much the same. The arms and legs were again exposed for some minutes, and their temperature measured. The disposition to the maintenance of heat on the left side, in which there had been most tendency to paralysis, was still more marked than before.

Temperature of right leg,	77°	left leg,	94°
,, right hand	75°	left hand	95°

He passed a large quantity of urine about an hour ago.

Towards evening he became very drowsy, muttering continually; roused with difficulty, and relapsing immediately into the drowsy state. The twitchings of the face were less marked. Pulse 120, weak.

At night the temperature of the limbs was measured under the bed-clothes, without exposure. The same tendency was found as before.

	Calf.	Axilla.	Hand.
Right . .	94°	100°	98°
Left . .	97°	100°	100°

A blister was ordered to the neck, and he was directed to have a few drops of brandy in water every three hours.

12th.—He slept about three hours at intervals during the night; while awake he mutters constantly. There are occasional slight twitchings in the face. The left arm is flexed and rigid, and he has no power of moving it. He moves both legs, but there is evidently much less power over the left than the right. He complains when they are pinched.

On taking the temperature in the middle of the day it was found that while the right hand and foot remained much as before, the left foot was 10° lower than the right, while the right hand remained a few degrees above the right. A careful examination proved that the left leg had entirely lost sensibility, and was nearly paralysed; neither could any reflex action be excited in it. He complained much of any pinching or pricking of the right leg—so much, in fact, that it was a question whether there was not hyperæsthesia; but the left leg might be pinched with forceps or pricked without his evincing the slightest consciousness of it. The left arm, too, seemed to have lost sensibility, and remained flexed, but he had a very slight power over it. The face was slightly paralysed on the left side, the features being drawn to the right. He is still only semi-conscious, and mutters continually; sleeping naturally at intervals.

8 p.m.—There is now some sensibility in the left arm, and he has more power over it. To some extent he has sensation in the left leg, and reflex movements can be excited in it, but he has no voluntary power over it.

13th.—To-day he appears quite conscious, and complains of cold. He puts out his tongue readily. He sleeps much, and there is less muttering. There is still some spasmodic contraction of the left arm; he can move it slightly; but there appears to be little or no sensibility in it. In the left leg, on the contrary, the sensibility is now acute, and he complains much of soreness in it. A slight pinch makes him cry out; but he has no voluntary power over it. The temperature is again 2° in excess of the right. He ate this morning some bread and milk, which he swallowed quite naturally. Pulse 84.

14th.—Slept fairly last night. Pulse 96; good power. He has considerable power of movement in all directions over the left arm; but only to a slight extent in the fingers. The sensibility is still much below the natural standard, and the temperature is still a little above that of the opposite side. The hyperæsthesia of the left leg still continues, and he complains much of pain in it, though he can move it without pain. The face is drawn to the right side. The tongue is dry in the centre, moist at the edges. He complains of feeling cold.

15th.—He sleeps a good deal, but is very noisy and unmanageable when awake. He still complains of pain and sensitiveness in the left leg, but he can move it more freely. The left arm and forearm are returning to their natural condition. The left side of the face is flaccid. His appetite is improving; he is calling out for more to eat.

16th.—The sensibility and power of movement over the left leg are now nearly natural, though the temperature is about 1° above that of the right. The power over the arm appears to be perfect, though it is still weak. The face is assuming a more natural expression. He complains greatly of pain in the forehead, is very restless and noisy at night, but sleeps a good deal in the day.

From this time he rapidly improved. The restlessness subsided under the influence of small doses of morphia. He had for some days a tendency to irregularity in the action of the bowels; sometimes there was diarrhœa, sometimes constipation. The urine was often alkaline and overcharged with phosphates.

On the 24th he got out of bed at night, and walked about the ward. His memory is greatly impaired; he can hardly recollect anything from hour to hour.

He continued to talk somewhat wildly occasionally; but still there was marked improvement from day to day.

On the 30th there was a little numbness in the left extremities; but his memory was returning, and he had regained strength.

He was discharged on November 3 convalescent.

I confess that I am unacquainted with cases which are quite like this, and I found difficulty in explaining the cause of the symptoms which presented themselves. My own impression cer-

tainly was that some slight laceration had taken place at the base of the brain, probably in the neighbourhood of the pons Varolii, or crus cerebri; but I could not account for the symptoms being so long delayed. It evidently was not one of those cases in which the real damage done to the brain is masked by the depression from concussion. I referred it, therefore, to Dr. Brown-Séquard, who has kindly favoured me with the following remarks :—

"The case is one of considerable congestion, amounting to inflammation in several parts of the base of the brain, particularly the crus cerebri of the right side, and also the upper part of the pons Varolii of the same side. Together with that affection there was also congestion, with serous effusion either in the ventricles or on the surface of the cerebral lobes. This state of the encephalon was due to a concussion. I have seen several cases like yours, but due to quite a different cause —either excess of mental work or anxiety, or hard drinking, abuse of smoking, etc. All the patients except one have recovered. One of them has completely recovered after having been, if possible, in a much worse condition than your patient. I have read some cases almost identical with yours, as regards the principal features, but I cannot now find my notes about them, etc."

Being unable myself to offer a better explanation, I should be inclined to accept the solution which Dr. Brown-Séquard's great experience and singular acumen have led him to furnish. Still, there are difficulties in the way, and from his remarks it would appear that there have been few opportunities of verifying by post-mortem inspection the opinions which have been formed on this class of cases. Thus the symptoms of concussion were either altogether absent, or were so transient as to be unnoticed; this we should hardly expect to be the case where congestion and inflammation so speedily arose from it.

The extremely rapid invasion of symptoms is not easy to explain. There is no doubt that within a few minutes of their occurrence the man was talking rationally, and that he made no complaint about his head. It is, however, of little use to speculate on what was really present; the point of chief practical importance is that symptoms of the most alarming kind may follow an injury of the head, and may yet be attended with little real danger. The alternations in the symptoms which I noticed on watching him very carefully for two or three hours after they first appeared, satisfied me that their cause could not be any extensive injury, but that they were rather the evidences of some reflex irritation. Even on the following day, when he appeared to be dying, I had, from what I had previously seen, strong hopes of his recovery. This want of uniformity in the symptoms, and the fact that they came on so long after the injury, and without any intermediate cerebral disturbance, were, I think, the most valuable indications of the real amount of mischief that had taken place.

CASE OF FATAL POISONING ASCRIBED TO CHLOROFORM.

By EDWARD BRADFORD,
Deputy Inspector-General of Hospitals, and Honorary Surgeon to the Queen;
AND
FRANCIS COLLINS, M.D. Edin., and L.R.C.S. Edin.

On November 23, 1865, I was summoned in great haste, about 10.30 a.m., to visit Mr. ——, aged 25, M.R.C.S., Eng., and I reached him in a few minutes after. I found him in bed undressed in a state of complete insensibility, his countenance pale, lips livid, pupils contracted, and his breathing stertorous, the surface of his body was warm; pulse at the wrist scarcely to be felt. The pulsations of the heart could be heard and felt, about 120. The respirations were short and jerking, 20 in a minute, at times they almost ceased. He did not appear to have vomited.

I found on inquiry that he had been apparently well on the previous evening and in good spirits. He had been seen about 8 o'clock a.m. on the stairs partly dressed, by a member of his family. He had returned to bed, and not having appeared at the usual hour, his father at 10.20 went to rouse him and found him in the state described. On a small table at the side of his bed stood an 8 oz. bottle rather more than half full of chloroform, and an empty tumbler. An attempt had been made to give him some brandy, but he was unable to swallow, and this having been spilled over his person and nightdress, I could not ascertain whether his breath had any smell of chloroform. No sponge or handkerchief was near him. I could not find any trace of any other narcotic poison in the room. I did not perceive any smell of chloroform in the room. At some distance from the bed under a wash-stand there stood a vessel containing urine and some frothy matter, which I took to be soap lather and saliva.

I immediately inferred that he had swallowed chloroform, and as circumstances forbade all probability of intentional injury, that it had been taken in mistake for chloric ether, which I was informed he sometimes made use of.

I attempted to excite vomiting by means of a feather, strong ammonia was held to his nostrils, and cold water dashed on his face, but no effect was produced. Air was freely admitted, and every effort made to sustain respiration. It was then attempted to introduce the tube of the stomach pump, but this induced suspension of respiration and of pulse, and it was of necessity abandoned. Strong ammonia was applied to the region of the heart, to the legs and thighs, the nape of the neck and spine, but it produced little apparent effect except slight vesication on the nape of the neck. Large injections of hot water and of turpentine were repeatedly thrown into the rectum, and mostly retained. No urine was passed. The electric apparatus was out of order.

About noon some indications of improvement were observed. His respiration became more regular and full; at times he sighed deeply; his lips were less livid, and his pulse was full and regular at 120; the surface of the body and limbs continued warm, and there was slight perspiration on the forehead and epigastrium. All sensation and all power of voluntary motion were still entirely suspended; he was unable to swallow, his eyes were insensible to light and their pupils contracted. About 4 p.m. his pulse again became weak, and at times it could scarcely be felt at the wrist. His respiration became slower, and gradually sunk so low as twelve in a minute. Loud mucous râle was heard over the chest obscuring the sounds of the heart; he continued warm, and through the whole day he was entirely free from all convulsive action. The movements of the heart and of respiration became constantly more feeble, and they finally ceased soon after 8 p.m.

On the 26th I made a careful attempt to ascertain the quantity of chloroform which might be supposed to have been swallowed by weighing what remained in the bottle and calculating the quantity known to have been otherwise consumed. It will suffice to say that I was satisfied that at least one ounce by weight could not be accounted for. The bottle had on the 10th contained 9 oz. by weight. Its sp. gr. was 1486. E. B.

Examination of the Body Forty-four Hours After Death, by Order of the Coroner.—The body was well nourished, and much fat was deposited under the skin. The dependent surfaces and the neck were becoming very livid. The limbs were rigid. Head: The blood vessels and sinuses were filled with dark, liquid blood. A small quantity of limpid fluid was effused on the surface of the hemispheres of the brain under the arachnoïd membrane. The vessels of the pia mater were loaded with dark blood. The cerebral substance was apparently quite natural. About half an ounce of limpid fluid was contained in the ventricles. This, as well as the substance of the brain, had no unusual odour. Chest: Extensive and firm adhesions of old formation existed on the left side, connecting the lung to the ribs and to the diaphragm. A soft adhesion of about half an inch in diameter, not apparently of recent formation, also existed between the anterior surface of the heart and the pericardium; this had been separated before it was observed. The heart was larger than natural, and its muscular substance less firm in consistence than usual. The left cavities were quite empty; their lining membrane and the valves were healthy. The right auricle and ventricle were, together with the great veins, distended with dark blood, which was fully and firmly coagulated. The lungs were extremely congested with dark blood, but no change of structure was observed. The bronchial membrane was healthy. Abdomen: About four ounces of serous fluid of pale colour was found in the abdominal cavity. There was none in the cavities of the chest. The liver and spleen were apparently healthy. The stomach was contracted and empty. On being opened, about half an ounce only of a turbid, reddish, mucous fluid could be collected; this was quite destitute of odour. The blood vessels of its cardiac extremity were extremely congested with dark blood; this appearance, however, did not extend to the pyloric extremity of the organ.

The intestines contained much air and some fluid matter, but they were of healthy aspect. The kidneys were of healthy appearance. A little urinous secretion could be squeezed from them, but we were not able to detect distinctly any unusual odour. The bladder contained about two ounces of urine, which was of healthy appearance and odour.

The opinion delivered by us at the inquest, based on these facts, was briefly to the effect that although no direct proof existed that chloroform had been swallowed, yet that no other cause could be assigned for the sudden death of the deceased than the agency of that or of some other narcotic substance.

This opinion was strongly controverted, and an attempt was made to show that death had resulted from natural causes, and that the symptoms and post-mortem appearances were inconsistent with the effects of chloroform.

The respected Physician who advanced this view will, no doubt, feel it incumbent on him to make public the grounds on which he was induced to form it. We are constrained to say that his opinion was not based on personal observation.

It is in its scientific aspect alone that we desire to draw attention to the case. The instances(a) in which chloroform taken into the stomach in large quantities is known to have caused death are so few (only four are recorded), and they differ so much from each other (as reported) that they afford no sure standard by which the essential results of this substance when thus taken into the stomach can be established.

In this belief we do not hesitate to repeat the opinion given at the inquest, and are content to vouch for the accuracy of the facts stated.

P.S.—The coroner's jury were unable to come to a decision as to the immediate cause of death.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

GUY'S HOSPITAL.

ULCER OF THE STOMACH—OPENING THE SPLENIC ARTERY—DEATH BY HÆMORRHAGE.

(Under the care of Dr. PAVY.)

The following case is of interest as showing one rather rare cause of hæmatemesis, and the uncertainty of life after hæmatemesis from such a cause. The life history is unfortunately meagre; but the details of the autopsy are carefully given, and have much value:—

A man, 63 years of age, was admitted under Dr. Pavy's care on September 20. He had been ill eight weeks before admission, and had then brought up a considerable quantity of blood, and had pitchy stools at that time. Ever since the loss of blood he had had costiveness. No hardness could be felt, and no place was found to be tender. He complained of indigestion, flatulence, and impatience of food. He died suddenly on October 20, after vomiting a large quantity of blood.

Autopsy by Dr. Moxon.—The body was blanched and spare; the skin, especially of the legs, had a half-micaceous chaffiness; no jaundice tinge and no stains on legs. The brain was excessively anæmic; the vessels to the naked eye looked natural. In the bronchi there was much grumous black-grained fluid, which extended as far as the quaternary divisions. The lungs were blackish in colour. The dependent half of the left was œdematous, with watery serum; the right was bulkier, but dry. The left ventricle of the heart was closely contracted, its cavity being very small.

The stomach was much dilated, and contained about a pound of coagulated blood of black colour. An ulcer, about $3\frac{1}{2}$ inches diameter and circular, was in the cavity walls at the lesser curvature, extending further on the hinder than on the fore wall of the cavity. The stomach coat was eaten through in two separate places—one in front of the upper edge of the size of a fourpenny piece; the other, behind the upper edge, larger than a shilling. The first was filled in by the liver, which formed its floor; the second, by the pancreas. The liver substance was not eroded, at least not so as to be evident to the naked eye; but a section showed that the portal canals within one and a-half inch radius of the ulcer-floor had the fibre-tissue very much increased. The substance of the pancreas was very firm and hard, not more so, however, when it formed the floor of the greater perforation. The lobular substance came into the boundary of the cavity, and had no granulations or other covering. At the upper part of the pancreatic part of the ulcer there was a dark-coloured, slightly elevated spot, which proved to be the splenic artery. Its anterior wall was torn transversely by a rent an inch and a-half in height. On tracing the gastric artery, the cardiac brach was found to pass to the left of the ulcer just at a safe distance. The pyloric branch on the floor of the ulcer was plugged by very firm old tissue. The pyloric branch of the gastric artery was doubtless the source of the hæmorrhage, which is related as having occurred ten weeks before death. The edges of the ulcer were thickened to double the thickness of the rest of the stomach wall. The ulcer had an even edge, and section showed the muscular tissue thickened in due proportion along with the other layers in the wall. *Liver* patchy, with fibrous degeneration of its edge and about some of its superficial veins. *Spleen.*—Its capsule was opaque, not very thick; the organ soft, and much shrivelled and flaccid. *Kidneys* very white. No appearance of amyloid by T.

UNIVERSITY COLLEGE HOSPITAL.

CIRRHOSIS (?) OF LIVER IN A CHILD THREE YEARS OLD—JAUNDICE—ASCITES.

(Under the care of Dr. REYNOLDS.)

For the notes of this case we are indebted to Dr. Andrew Stuart.

E. E., aged 3 years, was admitted into Hospital October 11, 1865. His parents were both questioned as to their habits, and these, as far as their statements can be believed, were sober. Mother during pregnancy with this child took scarcely anything spirituous, and only occasionally a glass of beer. Never indulged in spices of any kind.

The child now and then, after dinner, used to drink an ounce or two of beer, but was never given gin, or spirit of any kind, or spices. The child has always been strong. The mother states that she thought the child's belly larger than it ought to be, but attributed its size to the child's great appetite. A month before admission became poorly, feverish, complained of pain in head, and after three days its skin was noticed to be yellow, face and conjunctivæ more so than elsewhere. Urine was scanty, and very yellow, and the stools were almost white, and of the consistence of clay. A week after this, the abdomen was noticed to increase in size, and it has continued to get larger up to present time. Has suffered from measles and ascarides.

Present State.—Child is strong-looking, well-nourished; jaundiced tint of skin over whole body; conjunctivæ very yellow; no œdema of legs; bowels rather confined; stools like clay; respiration calm; pulse 116, regular, weak. Abdomen very much distended; veins of upper part distended, and too visible. Percussion note is dull as high as umbilicus, and also in both flanks; the dulness changes with the change of position of child. Fluctuation perfect over dull area. Circular measurement $30\frac{3}{4}$ inches. Upper line of liver dulness on level with right nipple; lower line a finger's breadth below margin of false ribs; edge indistinctly felt. Splenic dulness not increased; heart and lungs natural; urine dark orange-coloured, non-albuminous, sp. gr. 1028; contains bile pigment.

Was ordered generous diet and a little wine, ten grains of calomel and jalap when necessary, a hot air bath every other night, and this prescription:—Potass. nit., gr.v.; sp. ether. nit., ℥xv.; liq. ammon. acet., ℥x.; aquæ menth., ℥ss., three times a-day. A flannel corset fitting the whole length of the abdomen and lacing behind was applied so as to keep up firm pressure over the abdomen continually, and was tightened as it became loose.

Under this treatment the abdomen got gradually less, and on the 28th the liver could be very distinctly felt two and a-half inches below the margin of the thorax, its surface being hard and granular, its edge well defined and very hard. The yellow tint of skin had considerably diminished, and that of face replaced by a healthy rosy hue.

On November 4 it was noted that the superficial veins of abdomen were no longer visible. Fluctuation could not be detected. Circular measurement of abdomen twenty-one and a-half inches on level with umbilicus. Urine natural coloured; no bile pigment.

The following was the last note taken just before discharge:

—Looks in excellent health. Cheeks ruddy. Very slight yellow tint of ocular conjunctiva. Abdomen looks about as large as that of any healthy child of the same age; measures round twenty and a-half inches; no fluctuation. Liver dulness, upper border, two fingers' breadth below right nipple. Edge can be very distinctly felt nearly three fingers' breadth below margin of thorax; feels hard and rounded. Surface of liver feels hard and finely granular. Child is fat and strong, and its appetite is excellent.

ST. GEORGE'S HOSPITAL.

CASES OF CHOREA TREATED BY CALABAR BEAN.—CLINICAL REMARKS.

(Cases under the care of Dr. OGLE.)

Case 1.—Harriett L., aged about 20, was admitted with severe chorea June 14, 1865. She was at once purged with calomel, scammony, and castor oil, and took one grain of sulphate of zinc and two of sulphate of iron, in the infusion of valerian, every six hours. The zinc was increased, so that on the 27th she was taking nine grains of the zinc. From time to time, also, she took a morphia draught at night and a dose of castor oil, and had wine daily.

On July 4 the former treatment was discontinued, and the potassio-tartrate of antimony was given in one-grain doses every six hours; subsequently every four hours, with one-sixth of a grain of extract of belladonna. Later on the extract of belladonna was increased and the antimony discontinued, being replaced by the sulphate of zinc. These were augmented, so that on July 22 she was taking five grains of the sulphate of zinc and three grains of the extract of belladonna every four hours. A shower bath was then ordered every morning, and on August 1 the liquor potassæ arsenitis was given every six hours. This was subsequently prescribed every four hours, until August 23. During this period occasional aperients were resorted to.

On the 23rd she came under Dr. Ogle's care; he continued the above treatment until the 31st, when he determined, as she did not appear to gain ground, to try the Calabar bean. Accordingly, he directed her to begin with half a-drachm of the tincture (supplied by Bell to the Hospital, and having the strength of one drachm of the bean to one ounce of rectified spirit of wine) administered three times a day in water, and increased it by ten drops at a dose, *making no alteration in diet*. She very quickly improved in muscular steadiness, and on September 10 the nurse reported "she has cut her own food to-day for the first time." The dose of the bean was raised to ʒj. three times a-day; and on the 19th the wine was omitted. She so quickly and so satisfactorily recovered that she was discharged from the Hospital as almost quite well. On inquiry of the nurse of the ward (Roseberry), Dr. Ogle learned that the patient made her appearance about the middle of November, and that she had become so stout and looked so well that she was hardly recognised by the nurse. She had quite lost all choreic symptoms.(a)

Case 2.—Hannah W., aged 13, pale in face, but otherwise healthy, became an out-patient September 15 last. She was affected by chorea, which was mainly but not entirely confined to the "right" side (both arm and leg). The speech was much affected; the tongue feeling, as she described it, "too large for the mouth." The pupils were equal, and natural in character. Symptoms of the disease had shown themselves for six weeks. She had never had rheumatic or scarlet fever or other severe disease, and had not suffered from worms, etc. No other member of the family had been similarly affected.

Dr. Ogle ordered her twenty minims of the tincture of Calabar bean in water three times a-day, making no alteration in diet, and giving no other remedy.

On the 22nd, when she came, the mother said the "shaking was on the other side" now. The pupils were rather enlarged. The dose was increased to thirty drops three times a-day.

On the 29th the statement was that she was "stronger," but she still "rolled the tongue," and the speech was still affected. The tincture was then increased to forty drops three times a-day.

On October 6 it was stated that she eat better, but that there was still a difficulty in opening a book with the hands. The pupils were natural; sight good.

She went on with the same dose of the Calabar bean until November 3, when it was stated that there was no shaking whatever. Food was taken with a natural appetite. The pupils appeared to be natural. She was discharged as being quite well.

Dr. Ogle stated that he had one or two other patients with chorea under his care who were at present taking the Calabar bean, and that alone, apparently with marked benefit. At the same time, he had had some cases under his care in which no good appeared to attend its use. He considered that choreic patients who were out-patients were better adapted for a trial of the services of the bean than those who were in-patients, as in the latter the use of the remedy becomes complicated by the changes of food, rest, and care incident to residence within the Hospital. Dr. Ogle proposes to try the eserine, or active principle of the Calabar bean, the alkaloid thereof, in chorea as well as in other forms of disease.

(a) With reference to the case of so-called paralysis agitans, which Dr. Ogle referred to in our number for September 2 last as having been treated by the Calabar bean, the dose was increased up to 1½ drachm three times a day of the tincture. The pupils were not at all affected by its use, nor the powers of vision. The patient, aged 52, suffered much from pain in the head, and was treated by sulphate of zinc and extract of belladonna. He had previously been galvanised for eight weeks without good results.

KING'S COLLEGE HOSPITAL.

A CASE OF EPITHELIOMA OF THE HAND.—CLINICAL REMARKS.

(Under the care of Mr. SPENCER WATSON.)

The principal point of interest in this case is the peculiar aspect of the tumour when the patient first presented herself. It then resembled, at first sight, a sebaceous cyst on the point of suppurating; and the absence of any ulceration on the surface made it very unlike the greater number of epithelial growths. The great hardness at once showed that it could scarcely be regarded in the light of a sebaceous cyst, and the result of the incision made it evident that it was not so. In the absence of any history of irritation in this part, the position of the tumour is somewhat noteworthy and difficult to be accounted for.

Mrs. B., aged about 60 years, applied at King's College Hospital on September 17, 1865, with a tumour of the size of a horsebean occupying the dorsal aspect of the metacarpo-phalangeal joint of the thumb of the left hand.

The woman has no marked cachexia, but is somewhat worn and haggard, and appears to be in suffering. The tumour is of a hemispherical form, of a purple tint, smooth on the surface—excepting over the centre, which is paler than the rest of the skin covering it, and has a roughened appearance, not, however, amounting to anything like ulceration; it is hard to the touch, and the integument adherent, but it seems distinctly circumscribed, and not involving any of the deeper tissues. At the inner side of the elbow there are two slightly enlarged lymphatic glands, which are somewhat tender when touched.

Mr. Watson, thinking that he might possibly be able to enucleate the mass, made an incision across it, and with a scoop extracted a portion of the contents, which broke away easily; but the peripheral portion of the growth was too adherent to the skin and subtegumentary structures to allow of enucleation. The pieces that were removed were submitted to microscopic examination by Mr. Watson, and subsequently and independently by Dr. John Harley, and they both came to the conclusion that the disease was epithelioma. The loculi of the arcolar tissue were filled by collections of epithelial cells in globular masses, such as are very characteristic of this disease.

September 24.—There is now a sluggish ulcer in the place of the raised tubercle; the patient herself extracted a piece of the contents of the tumour.

26th.—Mr. Watson having determined to remove the whole of the disease, made two curvilinear incisions, one on each side of it, and dissected off the included tissues. After its removal a microscopic examination of the growth gave the same appearances as the previous one had done.

October 4.—The wound commenced suppurating.

10th.—The wound cicatrizing.

23rd.—The site of the incision covered over by healthy cicatrix tissue.

November 7.—The line of the cicatrix continues healthy; the hands swells frequently, and she complains of great pain in the arm. The enlarged glands at the elbow have become

very much smaller. Her health is very indifferent, as she suffers from winter cough.

HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST, BROMPTON.

CASE OF PHTHISIS—FATAL HÆMOPTYSIS FROM THE RUPTURE OF A SMALL ANEURISM OF A BRANCH OF THE PULMONARY ARTERY.

(Under the care of Dr. COTTON.)

E. C., aged 28, male. Admitted November 4, 1865, with symptoms of ordinary phthisis in the third stage. Pulse 100, respiration difficult, cough severe with abundant purulent expectoration, night perspirations, emaciation, great exhaustion. Hæmoptysis first occurred about five months back, but was moderate in degree and easily controlled. Since that period the expectoration has frequently been streaked, but the hæmorrhage had never been great until a few days after admission, when it came on suddenly, and amounted to more than half a pint. On November 24, about three weeks after the previous attack, the bleeding recurred to quite an equal extent, producing great exhaustion, under which in the course of a few days the patient sank.

Post-mortem Examination (from notes taken by R. D. Powell, M.B., Resident Clinical Assistant).—Body emaciated; great anæmia. Right lung pale and emphysematous. In the upper lobe there existed a cavity of the size of a walnut, surrounded by a considerable amount of scattered tubercle. Left lung small, dense, heavy; bronchial tubes considerably dilated; mucous membrane much injected. Substance of lung itself was toughened throughout, and studded with yellow tubercle, and several small cavities made their appearance as the lung was divided, owing to the escape of softened tuberculous matter. A large excavation occupied a great portion of the upper lobe, containing much tubercular *debris*, but no blood. Another large cavity was found in the lower lobe. In the lower and anterior part of the latter cavity, a small, irregular-looking clot was discovered, partly decolourised, and on turning this aside a small bulging was seen, which on further examination proved to be a small aneurism on the cavity side of a moderate-sized artery, running in a direction transverse to the lower end of the cavity. This artery was exposed to an extent of about three-quarters of an inch, but was supported on one side by lung tissue. The aneurism occupied the whole of the exposed part of the artery, but owing to a constriction in the middle appeared to form two aneurisms; the larger dilatation was about the size of a pea, contained no coagulum, and was not ruptured; the smaller dilatation was rounded and filled with an adherent and partially decolourised clot, and was evidently the source of the fatal hæmorrhage, an opening having been found in its upper part where its walls were most attenuated. The artery itself, when laid open, measured transversely two-eighths of an inch. The heart was healthy; and no tubercle was found in the other organs.

Note.—In this very rare case, a small branch of the pulmonary artery, running along the walls of a cavity, instead of being, as usually happens, obliterated, had remained pervious; and, wanting the support of lung substance upon the cavity side, had dilated into a small aneurism, the walls of which, no doubt, easily gave way, not only from want of support, but from the softening or degeneration of tissue which was only too likely to accrue in such a case.

THE SKULL OF BEN JONSON.—A statement appeared in the *Times* of November 11, 1865, from a lecture delivered at Hull by Dr. Kilburne King, to the effect that Ben Jonson's skull had been extracted from Westminster Abbey on the occasion of the interment of John Hunter's remains, and was now in the possession of some private individual. The whole story has been just set at rest by a lucid description of the circumstances out of which the story grew in an interesting work just published by Mr. Frank Buckland, son of the late Dean of Westminster—"Gleanings of Natural History," third series, vol. vi., pp. 141—189. It there appears, with much curious detail, that the skull of Ben Jonson rests, beyond question, some twelve or eighteen inches beneath the triangular stone which bears his name in the north aisle of the nave of the Abbey, in the place in which the remains were found in an upright position (according to tradition) at an accidental opening of the grave in 1849.

TERMS OF SUBSCRIPTION.

Twelve Months (Prepaid) stamped for post £1 10 0
Six Months (do.) 0 15 0
Regularly transmitted by Post throughout Great Britain, and to the most distant of the British Colonies.
The Journal can be obtained of all Booksellers and Newsmen, Unstamped, for £1 6*s. per Annum.*
Post-office Orders and Drafts on Army or Navy Agents, should be made in favour of Mr. JAMES LUCAS, 11, *New Burlington-street, W.*

Medical Times and Gazette.

SATURDAY, JANUARY 13.

CHLORODYNE *versus* THE PHARMACOPŒIA.

ANY ONE who is engaged actively in the Practice of Physic must be aware of the great popularity of a compound called "chlorodyne." Not only is it found in very many houses as a domestic medicine, but singularly enough it is prescribed by scores of Medical men, as if it were an established and orthodox "officinal" remedy. It is said to be the invention of a retired Indian Medical Officer, who had been in the habit of taking narcotics, and who made many experiments on his own person to find out a compound narcotic and stimulant, which should give the greatest amount of comfort with the least ill effect afterwards. That compound was introduced to the world as chlorodyne; a word which is certainly a singular experiment in Greek. It soon appears to have become popular, and of course was analysed and imitated. Narcotics in considerable variety, as morphia, chloroform, prussic acid, and Indian hemp; stimulants, as peppermint and capsicum;—and some sweet basis, such as treacle or liquorice, to give it consistency and render it easily miscible with water—these are said (*plus* a little perchloric acid) to be the ingredients; at all events, it is out of these that imitations are made which are said to be indistinguishable from the original.

As for its virtues, we have less to say than most of our brethren, for we never prescribed it ourselves, and never shall. We met, some years ago, with a case of gouty disturbance of the heart in a plethoric person in which a dose of it brought the patient into great danger. We think, too, that such of our Professional friends as use it as a medicine, or sanction its use in families, should give a friendly caution that there may be some risk of abuse. When we hear of ladies, young and old, taking a few drops at night for a "bad cold," or for "fatigue," or "restlessness," or "indigestion," or "colic," or "diarrhœa," we cannot help fearing that it may be but the thin end of a wedge, and that it may be the forerunner of stronger and worse stimulants. Clearly Paterfamilias ought to have a hint of this.

However, the abuse of a thing is no argument against the use, so we will not dwell on that; and our present purpose is to point out the naked fact that a certain compound of narcotics and stimulants, called by the funny name chlorodyne (which we suppose means *Greenache*, if it means anything), has an immense sale amongst the physic-taking public, and that it is prescribed by many orthodox Practitioners. Of course, it would not be thus singularly popular did it not supply a want and fill a place.

This want is very easily defined.

In the first place, human beings want something warm, comforting, and solacing against fatigue, irritability, and malaise. The most innocent remedy for this purpose that we wot of, is pure wine, in good quantity;—perhaps a little

spirits for old people. But many persons are parsimonious in the item of wine; they stint themselves from economy, or abstain "on principle," as they think; but then they must take something by way of compensation. Certes, the teetotallers do not object to chlorodyne; and we would call attention, by the way, to advertisements which appear from time to time of suspicious stimulants and cordials for the use of this irritable fraternity. For our own parts, we think a "bumper of Burgundy" more honest, more pleasant, and quite as cheap in the long run as chlorodyne. We can't think a woman virtuous or delicate merely because she will not, in public, drink or eat enough to compensate for her fatigue or exhaustion of mind or body. If she shirks a glass of wine at dinner, and takes a dose of chlorodyne at night, we are inclined to think her a hypocrite.

Secondly, the Medical Practitioner, like all other rational beings, hates waste of time; and it is a waste of time to write out the details of common formulæ for every-day cases. He wants *compounds* ready to his hand. Suppose a *mère de famille*. Up comes the cook after breakfast. "Please, mim, what pudding will you please to horder for the young ladies' lunching?" and suppose that madame, instead of saying rice pudding, were obliged to say, so much rice, so many eggs, so much milk, &c. What a monstrous waste of time! But this is just the case of the Medical Practitioner! He wants compounds ready to his hand, of known name and composition; for a purgative draught; for a common astringent, an anodyne, or diaphoretic, and so on; and he finds chlorodyne in one word save the trouble of an elaborate formula.

Thirdly, let us call to the minds of our readers that the principle of chlorodyne is not a new one. It is after the pattern of remedies which have always been in vogue. Old Pharmacopœias abound with similar compounds. There is the mithridate, the theriaca andromachi, and their descendant the confection of opium; the liquid laudanum of Sydenham; the paregoric; the compound chalk and opium powder, and the storax pill—all compounds of opium and spice. And it is instructive to note this fact: no sooner are these *improved* off the face of the Pharmacopœia than a new one starts up! This is a palpable indication of a public want. The appointed guardians of public health ought to fill it, but do not; and whilst they are doubting or disputing, the secret remedy creeps into use! We do not blame the persons who invented, nor those who sell, it; they found a want, and filled it; whilst the authors of the Pharmacopœia did not.

Moreover, *compound* narcotics are wanted, in which some ingredients shall be complementary to or antidotal to some others. This is quite an old field, but it has never been worked at thoroughly, and we can only hint at it now.

And now for a word about this long-expected and much-fought-over publication, the Pharmacopœia. Let us go into any society, Medical or chemical, scientific or commercial, connected with Physic, and the opinion is unanimous. The Pharmacopœia authorities wasted time, temper, and money in attempting what they were quite unable to do or to control; whilst they did very imperfectly what they were quite competent to do. All their attempts at controlling or directing processes of manufacture have been received with a chorus of derision by manufacturing chemists of every degree; whilst if they had been so far able to agree amongst themselves as to give an additional number of working formulæ for the Practitioner, their labours would have been received with as much thankfulness and satisfaction as the international jealousies of the three kingdoms would have permitted.

We say that it is absurd for a Pharmacopœia Committee to meddle with anything like manufactures in the present day. It is keeping up the ghostly forms of two centuries back, and is as unreal a thing as it was for George the Second to call himself King of France.

The division of labour is nowhere seen more palpably than in Medicine; for as Medicine was formerly a part of the *rerum naturæ cognitio*, or general philosophy, so chemistry was formerly a branch of Medical knowledge. In the days of Hoffmann, Mead, and Mayow, Physicians were the chemists, and could dictate the processes of manufacture. Even in 1767 we find Dr. Cadogan claiming to be author of the best method of preparing carbonate of magnesia. Times are quite changed now. The manufacture of chemical substances is carried on on the large scale by men each of whom has his own process, and aims, not at following the directions of Physicians, but at finding how he can make a definite compound best and most cheaply. What is the use of filling a Pharmacopœia with processes which are gathered from manufacturers? Physicians do not guide manufacturers, but follow them. What is the use of experiments to determine, for example, the best method of making salts or solutions of iron, when practical workers say that the resulting formulæ are uncertain, and each uses his own? Would the Pharmacopœial Committee like to undertake the charge of a chemical manufactory? If so, they would never live to be bankrupts—the place would blow up in a week.

Whether it be chemical compounds or vegetable extracts, the manufacturer will have his own way. He finds out how to get the best result at the least cost, and it is useless to dictate to him. One glance at Mr. Squire's "Companion to the Pharmacopœia" will show how fruitless are the elaborate directions which the Committee took such pains to write.

On the other hand, there is the other function which the Pharmacopœia Committee could discharge admirably. They could give us convenient formulæ for every-day use; useful purgatives, anodynes, preparations of opium fit for every condition, diaphoretics, salines, antacids, carminatives, and the like. Within this scope the authority of the Committee is unimpeachable. The President of the College of Physicians would be completely at sea in a manufactory; but his own daily work might furnish the Profession with some of the most useful formulæ. Our Scottish and Irish brethren, too, with the shrewd practical habits of the one, and the quick imaginative intuition of the other, and both admirable Practitioners, might outvie each other in friendly rivalry. There is so much more to be said on this matter that we shall return to it next week.

THE NATURE OF RINDERPEST.

While specifics are being on all sides vaunted as curative of the cattle plague, and modes of prevention recommended, all of which, with the exception of the use of the poleaxe, advised by Mr. Gamgee, have only to be tried to prove their futility, there are patiently working, among the Medical Profession, men who, having learned by their experience in treating human diseases how great is the help afforded for this purpose by a knowledge of the relations and nature of any disease, now seek by careful investigation to discover the nature of this one. They naturally endeavour to discover whether this disease is identical or not with any which affect the human species, and if not identical, to what disease or class of diseases it is most nearly allied. The importance in guiding the efforts at treatment, of the identity, or even only of the close analogy of Rinderpest to any known human distempers, would be exceedingly great. This is strikingly manifest in the recent statements which have been published concerning its nature by Mr. Ceely, Dr. Murchison, Dr. Quain, and others, to the effect that the Rinderpest is variola in cattle; for if they are right we are almost certain of two things—one being that the disease will run its course in spite of any treatment, and the other that by vaccinating cattle they will become proof against the contagion of this pest.

The position of the cattle plague among the exanthemata

seems to be universally admitted. Some have thought it to be identical with typhoid fever; others, that it is scarlatina; and others, that it is variola. The constitutional, and more especially the nervous, symptoms, together with the condition of the intestines, have appeared to be the points of resemblance between the Rinderpest and typhoid. In confutation of this statement, it has been pointed out, in regard to the intestinal lesion, that there is no true ulceration observable in the cattle disease (Dr. Smart), and no exudation of inflammatory products, and that the glands of the intestines are not specially affected or the seats of the congestion (Dr. Murchison, Dr. Smart). The evidence of its affinity to, if not identity with, scarlatina is more powerful. Dr. Smart, in the report to the Edinburgh magistrates, indicates the following points of resemblance of it to scarlatina :—The general congestive, but non-inflammatory vascularity of the mucous membranes, especially of the alimentary tract—the tendency to epithelial desquamation from the general mucous surfaces —the congested condition of the kidneys in all cases—and the invariable presence of albumen and blood cells in the urine, besides the general symptoms.

That Rinderpest is small-pox is asserted by Mr. Ceely, on the following grounds :—There is cutaneous eruption, rarely detectable before the fifth or sixth day, consisting of roseola, papules, vesicles, and pustules. They may be met with on various parts of the skin, "but more particularly about the alæ nasi, the cutaneous surface of the lower lip, the cheeks, and under the jaw." He mentions also the sides of the neck, over the shoulders, and along each side of the spine, inside the thighs and the udder of the milch cow, as being often thickly covered with it ; and about the buttocks, near the vulva, and the scrotum and prepuce as other seats of it. Small, red, acuminate papulæ are preceded and accompanied by patches of roseola. Their summits soon yield a limpid fluid, which as quickly becomes turbid and puriform, and pass into crusts or scabs. These vesicles are often coalescent or confluent. In protracted cases the scars of previous pustules may be seen, especially when the hide has gone through the first stage of tanning.

Dr. Murchison is strongly impressed, also, with the belief that Rinderpest is small-pox. He has seen large, well-developed *vesicles* in a few cases. He describes the minute pimples (which are to be found most abundantly on the back of the neck and shoulders, in the neighbourhood of the mouth, on the udder and scrotum, and on the skin surrounding the anus and the entrance to the vagina), as softening at their summits into *pustules*. These pustules, he adds, speedily dry up, and form a scab, on detaching which the subjacent cutis appears raw or superficially *ulcerated*. He also holds the anatomical lesions (as of the mucous membranes) to be identical in the two diseases.

Lastly, Mr. Rayner, of Uxbridge, has been consulted by Mr. Hancock, a Veterinary Inspector, on account of the effects of a slight wound he received on the back of the hand whilst dissecting an ox which had died of the cattle plague. This wound, which was attended with marked constitutional effects, assumed the appearance, according to the opinion of Mr. Rayner, of the vesicles of vaccinia; Professor Spooner, Dr. Quain, Dr. Murchison, Mr. Ceely, and others who have seen Mr. Hancock's hand, hold the same opinion. Dr. Quain describes the appearance at the time it was presented to him as exactly that of a declining vaccine vesicle.

These arguments and statements, though very weighty, are far from conclusive. Dr. Smart states that there are no *true ulcerations* of the mucous membranes of the intestines, stomachs, or mouth, and that the high colour of the tissue of the fourth stomach, as microscopically determined, is due, not, as has been stated, to sub-mucous or intra-mucous *extravasation*, but to vascular congestion in its most extreme form. He admits that there are *ulcer-like* depressions in the fourth stomach, but asserts that they are abrasions not penetrating beyond the epithelium. So, also, he asserts that the ulcer-like appearances in the mouth are not due to a true ulceration of the tissue subjacent to the epithelial layer. A similar statement is made by Dr. Sanderson, who seems to be carrying out with the greatest care the important part allotted to him of the duties of the Commission. He has, he says, carefully observed the appearances presented by the cutaneous eruption in all its forms, and watched them with all attention, and he states that *vesicles never occur* at any period of the disease; the so-called flattened vesicles described by Dr. Murchison on the udder being solid elevations, the structural elements of which are epidermal. He says, also, that it is through the softening and breaking up of these elevations and their becoming gradually semi-fluid, that they acquire an unreal resemblance to pustules. He also points out that the so-called scabs are not produced by the desiccation of pustules, but by the incrustation of the abundant secretion from the sebaceous follicles.

It seems somewhat doubtful whether Dr. Murchison is quite correct in considering the state of the intestines in Rinderpest as identical with the state of these organs which is described as sometimes observed in small-pox. In the former there is always marked *congestion* with, at least, only doubtful ulceration or extravasation; while in the latter cases there are sometimes inflamed, ulcerated, and enlarged follicles, with petechial patches. And even if in cattle plague it is true that true ulceration of the intestines and ecchymosis are observable, as well as congested kidneys, etc., which are universally admitted to be present, still, as Drs. Gregory and Copland remark, these are only such as are observable in low and malignant fevers.

With these difficulties around us, it seems vain to attempt to come at present to any definite conclusion. The small-pox theory as to the nature of this terrible disease is now being tested, so that we expect soon to be able to announce to our readers that it certainly is or is not identical with variola. If it is identical, then vaccination or inoculation with the matter of variola ought to render cattle insusceptible to the influence of cattle plague, and those animals which have recovered from an attack of the latter disease ought not to be affected by inoculation with variola matter.

Since the above was in type, we have received a letter from Dr. J. Fairmann, which we publish in another column, containing the important statement that a cow which had only recently recovered from severe cow-pox, has since died of Rinderpest. If this case be confirmed by other observations, it will certainly go far to disprove the variola theory of the cattle plague.

THE MEETING OF THE MEDICAL PROFESSION AT LIMERICK JUNCTION.

The late meeting of the Irish Medical Association, under the presidency of Dr. Mackesy, was the occasion for our friends upon the other side of St. George's Channel expressing their opinions upon several legislative enactments and other matters concerning the Medical Profession. A full report of the meeting is contained in the *Irish Times* for December 30 last.

Among many resolutions which were passed, there was one expressing sympathy with the Medical Officers of the Army and Navy, and a strong hope that the Commission at the Admiralty would not disappoint the just expectations which have been raised.

The fact is, that the Government authorities will be well contented to allow Medical Associations to pass as many resolutions as they please, *so long as the public services can be recruited*. The whole thing turns on the question of demand and supply. The Commission lately sitting at the Admiralty, whose report went in last Wednesday, is said to have behaved liberally on the whole to the Army

Medical Officers. Still, Commissions have no sympathy with our Profession, and a Committee sitting at the Admiralty, nominated by the powers that be, constituted in great part of men holding official appointments, cannot be expected to yield much out of a mere desire to advance the interests of our Profession. They care little or nothing about obtaining a superior class of men when it involves any additional outlay of money. The question with them has doubtless been, what it will ever continue to be—Can a sufficient number of men be obtained on the present terms or not? If they can, that ends the matter! We should not be the least surprised to hear that the results arrived at by the Commission will be withheld until after the next examinations for the public services; and if candidates be forthcoming, the appointment of a Committee will have answered its purpose, of course.

To return, however, to the report of the meeting of the Irish Medical Association as given in the *Irish Times*. Dr. Chaplin, in moving a resolution bearing upon the public services, appears to have spoken on a subject which few out of Ireland would have dared to approach, much less employ the terms he has done. He is reported to have spoken in strong terms of condemnation of the alleged lowering of the standard of Medical education, and of competition of Medical colleges for fees.

"As regards the pay of young Medical officers," he said, "10s. a-day was not sufficient for them. There were at present 600 Assistant-Surgeons in the army, and it would be probably several years before some of them became regimental Surgeons. That was all very well so long as young men remained unmarried, but if they should get married, was that sufficient to maintain their families in the manner in which they would be expected to live? He believed not, and therefore he submitted that their pay ought to be increased. (Hear, hear.)

We think ten shillings a-day sufficient at first, but there is no adequately progressive rate of increase in the pay, and there is no chance whatever for promotion within reasonable limits. To whom belongs the blame if this state of things be allowed to continue?

THE WEEK.

SIR J. Y. SIMPSON, M.D., BART.

The announcement that Her Majesty has been pleased to confer a baronetcy on Professor Simpson, of Edinburgh, will be received by the whole Profession with unmixed satisfaction. No worthier representative of practical beneficent Medicine could have been selected for State honours, for no Physician since Jenner has conferred so great a boon on mankind as has the discoverer of chloroform. It is, of course, true that the highest gifts in the power of the State to bestow are totally inadequate to reward the man whose discovery could annihilate the agonies of difficult parturition, disarm the Surgeon's knife of its terrors, and save hundreds of lives by the avoidance of shock and suffering in long and difficult operations—such as ovariotomy; operations that without chloroform would never have become legitimate Surgical proceedings. The benefactors of mankind are not always or even often recognised, but it would be ungracious did not the Profession hail with pleasure the due honour which has been rendered to Medical science in the person of Professor Simpson.

SUICIDE AND INSANITY.

Were it part of the plot of a sensation novel that a man, occupying a position in decent English society, is permitted to go at large after having let a number of people into the secret of his fixed intention to destroy himself, and after giving other evidence of unsound mind, and yet that none of his friends consider it their business to interfere and rescue the madman from the responsibility of self-control, the reviewers would certainly damn the book as improbable and untrue in the highest degree. Nevertheless, readers of the daily papers will often find instances which prove that such a picture might be painted from the life. A man, perhaps, loses a small sum of money; this, in penny-a-liners' phrase, preys on his mind, and he tells his friends that he is ruined, that he shall not live long, that they will soon hear of his death; but no one sends for a Doctor and has him put under restraint or surveillance. A day or two after he is found hanging from his bed-post, or with his throat cut. A jury is summoned; they hear all the evidence, and immediately return a verdict of "suicide while in an unsound state of mind," and in a week or two the thing is forgotten. The *Times* of Friday, January 5, contains a case of the kind. Mr. J. N., holding a high position in a public office, was found dead in his watercloset with his throat cut on Tuesday, January 2. He had lent some money which he could not get repaid, but he was in perfectly solvent circumstances. The day before his death he had been to the City, and told persons in his office that they would not see him alive much longer, and the report adds, "the result was anticipated!" If a Doctor sign a certificate of lunacy on insufficient evidence, or even place an outrageous patient under temporary restraint, he is liable to an action at law, with all its pains and penalties. But we should like to know what is the proportion of lives yearly sacrificed to the apathy and folly of friends and relatives, compared with the number of persons who in the same time are unnecessarily confined in lunatic asylums.

FROM ABROAD.—MUSCULAR POWER OF INSECTS—M. BOULEY ON THE CATTLE PLAGUE.

M. Plateau, in a communication to the Academie des Sciences, observes that, believing the muscular power of the invertebrata has not sufficiently attracted the notice of physiologists, he has instituted a series of experiments upon insects, from which he has drawn these conclusions:—1. Independently of their power of flight, insects possess, in relation to their weight, enormous power, as compared with the vertebrata. Thus, while a powerful horse can only exert during some instants an amount of traction effort equivalent to about two-thirds of its own weight, the common cockchafer will exert a traction equal to fourteen times its weight. This amount of power is also considerably less than that possessed by other of the coleoptera, the most vigorous of these upon which the experiments have been yet tried being the *donacia nymphœæ*, which exerts traction power equivalent to forty-two times its weight. 2. When we compare two species of insects of the same group which differ notably in weight, it is the smallest and lightest which exhibits the greatest proportionate power. 3. These results are not due to the muscles being relatively more voluminous in the smaller animals, but to their being endowed with a greater energy and muscular activity.

M. Bouley, on the occasion of M. Leblanc's communication to the Academy of Medicine on the outbreak of cattle plague in the *Jordin d'Acclimatation*, made a highly interesting speech, of which we give the chief passages. On his return from his visit of inspection in England, towards the end of August, he observes, he was enabled easily to predict that the ravages then taking place were but the prelude of those which were to follow, and that England would have to pay millions for the fault she was then committing in not opposing to the scourge the barriers which had arrested it in Germany during more than half a century. The 60,000 deaths which are admitted by the Commissioners are far below the actual amount, and yet the disease goes on frightfully increasing.

"The causes of this immense disaster are complex: the powerlessness or inertia of the central authority, which did not believe itself sufficiently armed by law to enable it to act, and through constitutional scruples feared to assume the responsibility of energetic action called for by the circum-

stances; the absolute liberty allowed in the sales of cattle just as in normal times; the concentration of affected animals in the weekly markets, and especially those of London; the transformation of these markets into immense focuses of infection, whence the disease radiated in every direction; the operation of private interests seeking only to save themselves at the expense of that of the public, every owner of cattle seeking to diminish losses when menaced by sending his contaminated animals to market, transporting with them necessarily the germs of the malady. These are the principal circumstances which have favoured the spread of the disease in England.

"But over all these there is one which predominates, and that is the ignorance of the English Government and public as to the nature of the disease,—an ignorance systematically kept up by the daily press, which, unpossessed of any technical knowledge, has derived its inspirations solely from the commercial interests it desired to protect. This ignorance has the more deeply taken root and exerted its influence because the English public has not had much faith in veterinary science, which does not enjoy on the other side of the Channel a high repute. I must even take courage to add, because the truth should be known, that its want of credit is not quite undeserved. Not that there are not, I hasten to add, a number of eminent men in England who do honour to their Profession, and who, had their voice been listened to, would have saved their country from the scourge it is now enduring. Such men there certainly are, but the mass of English veterinarians exert no influence on public opinion, whence a want of faith and the ease with which the voice of the organs of the Profession has been smothered by the daily press. This powerless condition of the Veterinary Profession in England seems to me to be due to the insufficiency of its instruction. There are no schools organised and maintained by Government. The teaching takes place in colleges maintained by private subscriptions, and the course of instruction only lasts for two sessions of six months each, while in France, Belgium, and Germany the course of study occupies four years. I believe that this is a certain condition of inferiority, and that diplomas of veterinary capacity accorded after such a short, and therefore insufficient, course of study, are not, for a great number of those who obtain them, veracious diplomas. Hence the want of credit of those who possess them, and the impossibility in which the Profession has found itself, in spite of the remarkable men who may be found in its ranks, of rendering service to the country by enlightening it respecting the dangers which it was incurring and the means of obviating these."

In Holland the disease, imported from England, not being promptly dealt with, has produced a loss of not less than 20,000 head of cattle, and is not yet arrested; while in Belgium, where the central government applied sanitary measures with rigour, the loss has been quite insignificant. In France, the speedy slaughter of forty-three beasts attacked in the Department du Nord and Pas de Calais at once arrested the progress of the disease which had there appeared, and the future importation from countries already affected was strictly prohibited. Still, "perfide Albion" contrived to inoculate her wary neighbour by means of two gazelles, which, purchased in London, had been transported to the coast in a railway van ordinarily employed for bringing meat to London. M. Bouley feels convinced that it was in this van the animals became affected. At all events, there can be no doubt but it was they who conveyed the disease to the Paris garden, they being the first animals affected with it there. The prompt and costly slaughtering of every animal there affected, or threatening to become so, at once stopped the ravages of the disease. But these had already taught their lesson as effectually as if direct experiments had been tried; and it was completely proved that not only may the disease attack the smaller ruminants, but also animals of a widely different nature, as the peccary, or wild boar of South America. M. Bouley confesses that had he known this fact he would not have handled the diseased parts with such equanimity as he did at Glasgow, having at the same time a fresh excoriation of the thumb highly favourable for inoculation. The French Government also learned its lesson, and extended its prohibition of import to all quadrupeds whatever except the horse, ass, mule, and dog. Thanks to the effective measures taken, four months have since passed and no reappearance of the disease has taken place in France; and even should it be by chance re-imported—and M. Bouley emphatically denies that it can be in any other way produced—similar prompt measures will again extinguish its germs. Prompt slaughtering is, in fact, the great safeguard, the deaths of a few saving hundreds of thousands.

"But this measure ceases to be applicable and becomes irrational when the epizootic has attacked an immense number of animals, for slaughtering in such case only increases the mischief. There are always from 10 to 15 per cent. of the animals who may either escape or recover from the disease, while the poleaxe is a certain destroyer, every one struck perishing. General slaughtering, then, should be proscribed, whilst partial, and especially initial, destruction at the instant the disease manifests itself in a new locality is the condition of common safety. The experience of the Departments du Nord and Pas de Calais prove this."

THE RINDERPEST PARASITICAL?

(From a Provincial Physician.)

The discussion as to the identity or otherwise of Rinderpest and small-pox goes on, but as no amount of theorising or of assertion will settle this disputed yet most important question, we must be content to wait for its absolute determination until a sufficient number of satisfactory experiments have been carried out. These, we are glad to say, are in progress in several different quarters, and we shall look with great interest for the results which may be arrived at. In the meantime, the discussion of the question of the intimate nature of cattle plague has received a new and unexpected impulse, and speculation upon it is being directed into a fresh and hitherto unexplored channel.

Our readers are probably aware that a letter from Dr. Fenwick appeared in the *Times* of last week, announcing the discovery by him of the existence in the flesh of animals which had died of cattle plague of parasitical entozoa in very considerable numbers. These entozoa he describes as existing in greatest quantity in the muscles of the heart, but also in large numbers in other parts of the muscular system. He says:—"In the heart they are either round, oval, or elongated at one end, with the projection terminating in a small bulb. In the other muscles they often resemble a common earthworm, are divided into segments and filled with granules." They are "usually about $\frac{1}{120}$th of an inch in length, but occasionally three or four times as large." He adds: "I have examined microscopically the various organs of a considerable number of animals destroyed by this disease, and I have been surprised to find how invariably the muscles have been literally infested with entozoa—in fact, I have not met with a single exception; while, on the contrary, in the healthy animals I have dissected the muscular structure has been either entirely free from entozoa, or only a few isolated specimens have been observed.

Dr. Fenwick very modestly disclaims attaching any exaggerated importance to his discovery; but to us it seems that the announcement of this fact is one of very great and singular importance as well as interest, whatever its exact bearing upon Rinderpest may be. It may, of course, be that the existence of these animals in the diseased flesh is a coincidence only—that is, that they may be able to seize upon and develope in the muscle merely because it has become a suitable soil or nidus for them, because being diseased it is in a weakened state, and therefore unable to resist their entrance, just as lumbrici and ascarides develope in the feeble intestine, or the achorion on the morbid scalp; but it is also possible that the presence of these parasites may have a deeper meaning, and that they may have a more intimate connection—direct or indirect—with the etiology and essence of the disease.

Of the facts as stated by Dr. Fenwick we have ourselves proved the truth, having within the past few days examined the flesh of several diseased beasts with the result of finding the parasites described in all of them. (a)

We already know that the human body is liable to one disease (trichinosis), which consists in the development within its muscular portion of myriads of parasitical animals, the growth and multiplication of which produces a low form of fever, with diarrhœa, prostration, etc., and in many cases destruction of the life of the inhabited individual. It is also highly probable that other diseases, with whose intimate nature we are yet unacquainted, may be hereafter found to be due to the growth and multiplication within the body of vegetable or animal organisms. In fact, the tendency of modern research has been to show the possibility that diseases having a specific origin, and course, and duration are due to some matter, material, or cause, which is either endued with life or something akin to it; with something, at all events, which has the power of reproduction, and which, like the seed of a vegetable or the egg of an animal, when again planted or deposited under suitable circumstances and conditions, is able to develope over again the same series of phenomena as its parent did. If this be not a vital development, the analogy which it presents to life, as we see it manifested in undoubted organisms, is so close as to make us always look anxiously to any fresh facts corroborative of this view. Recent researches with very high powers of the microscope have shown how likely it is that a world of life and vital development may exist in a much lower stratum of organised animal matter than we have been accustomed to consider proved, and that even granular matter may have within itself the power of development, and if so of reproduction.

With respect to the parasites described by Dr. Fenwick: if, as he says, and as there is no reason to doubt is true, they are always found in Rinderpest muscle, and only occasionally, and then in very small numbers, in muscle reputed to be healthy, they have in all probability something more than an accidental connexion with it, and if so, if they are really part and parcel of the disease, they are doubtless introduced into the body of the living animal by means of ova, exhaled with the breath of the diseased, or conveyed in the morbid discharges. We would suggest to those who are conversant with the higher powers of the microscope whether a new field for inquiry and observation is not opened by a consideration of these facts, and whether a rich harvest of knowledge may not be likely to be acquired by a careful examination of the nasal and other discharges (by which the cattle plague disease is so readily and certainly communicated from one animal to another), or by the secretion, which is an equally potent virus, of the vaginal canal.

Further, we think this subject widens out and acquires a still increased importance by considering that a discovery of what may possibly prove to be the intimate nature of cattle plague *may be* a most important step towards the elucidation of the real nature of some of our human exanthemata. If cattle plague can be shown to be in any way, as trichinosis is, intimately connected with its parasitical phenomena, surely its analogies with scarlatina, small-pox, and other allied diseases will go a long way towards increasing the probability of these disorders being also due to the growth in the human body of some definite organism, and not to mere chemical catalysis or fermentative action; and if so, by showing us the exact nature of their cause, will help us one step further, and that a long one, towards the end of all such labours and inquiries, the saving of life by the prevention of disease.

(a) Not only have we found the round or oval bodies described by Dr. Fenwick in great numbers, but in one case we have also seen long strings or trains of smaller round bodies, very like to the smaller globular particles seen in the interior of the entozoa, and which were doubtless the ova of these animals escaped from the parent bodies. In this case, also, we found a great abundance of fungous matter growing both as infiltrated threads and bunches of fungus, in or upon sections of muscle cut from its interior at the moment of examination. The entozoa were here also in unusual abundance; in places positively in masses. The transverse striæ of the muscular fibre were in many parts obliterated, and the flesh itself presented to the naked eye a pale, rough, almost granular, appearance, something analogous to that of finely cirrhosed liver.

REVIEWS.

The Principles and Practice of Medical Jurisprudence. By Alfred Swaine Taylor, M.D., F.R.S. London: John Churchill and Sons. 1865.

Taylor's "Manual of Medical Jurisprudence" has, since it first appeared, grown to rather unwieldy proportions, so its author has now wisely determined to restrain its growth in the future editions through which it is destined to pass. To do this alone, however, would be to rob us of what the manual was evidently tending to become - a comprehensive and exhaustive treatise on Forensic Medicine. We are therefore glad to find that the author has also prepared for the use of the Medical and legal professions the work before us, which justly professes to treat of the "Principles and Practice of Medical Jurisprudence."

The present volume is the result of a revision of the plan of the Manual, with the addition of other subjects besides those contained in it. Among these are "The Signs and Phenomena of Death, with an account of the Changes which take place in the Dead Body; Putrefaction in Air and Water, and its Conditions; the Identity of Bones, Skeletons, and Mutilated Remains; Sudden Death; the Presumption of Survivorship; Spontaneous Combustion; Life Insurance and Medical Evidence."

In the introductory section on Medical evidence we find some interesting remarks on the defects of coroners' inquests. Our author writes:—

"The 4th Edward I., stat. 2, on which coroners profess to act, directs that, 'upon information,' they shall 'go to the place where any be slain or suddenly dead,' and make due inquiry as to the cause, etc., before a jury selected from persons living in the neighbourhood. The information upon which a coroner generally acts is—1. Notice from a beadle or other officer of the parish (whose zeal is sometimes stimulated by a fee or salary) of any death from sudden or supposed unusual causes. 2. Notice from a Medical man who may have attended the deceased, and who communicates his suspicion that the cause of death is not natural. 3. Notice from a registrar of deaths that no cause has been assigned in a particular case, or that there has been a rapid death after a short illness.

"The conclusion to which experience leads in reference to these inquiries is, that the system affords no certainty for the detection of crime; that it affords no protection to those who are wrongly charged with crime; and lastly, that in some cases it screens a criminal by a verdict based upon an imperfect inquiry, in which the important Medical facts are either not understood or are misinterpreted by the jury.

"Admitting that some crimes (which might have remained concealed) have been brought to light by this system, it is my opinion that, as the inquiry is now conducted, it fails to exercise any deterring influence on criminals.

"In a large proportion of cases, no inspection of the dead body is made. This is probably in order to avoid the expense of a post-mortem examination. It would be easy to point to cases in which death by poison has been thus concealed, and the fact has only come to light by accident some years afterwards. With rare exceptions, indeed, is it justifiable on the part of a coroner to hold an inquiry on a dead body without a strict external and internal examination of the body? Either the inquiry is neeessary or it is not. If not necessary, the coroner is to blame in holding it; if necessary, an inspection of the body is the very essence of the inquiry, where it refers to one who has been slain or is suddenly dead."

Having adduced cases to establish his position, he continues:

"There is a popular notion, in accordance with the ancient statute, that sudden deaths only require an investigation by the coroner; but this is an error. A large proportion of sudden deaths take place from well-known natural causes, easily elicited by a proper Medical inquiry, and they strictly demand no judicial proceedings. On the other hand, in all cases of chronic poisoning, the form which secret murder has of late years assumed, the person has lingered on with intermitting symptoms, and death has taken place only after an illness of some weeks' duration. There is no provision for the detection of such cases. There discovery appears to be a matter of accident." As a rule, it may be said that all inquests in which there has been no Medical inspection of the body are a vain mockery, and the sooner the public mind is imbued with this proposition the better for society."

The present system of electing coroners without applying any preliminary test of ability or capacity is strongly condemned; as is also the system of selecting the nearest Medical Practitioner, whether he has had any experience or not, to report at the inquest upon the cause of death. For the removal of these defects of coroners' inquests, Dr. Taylor then offers the following valuable suggestions:—

"Let a well-trained gentleman be appointed as a stipendiary judge in every county or borough; let him, upon the same sources of information as are now open to the coroner, hold inquiries or not, according to his judgment. There are many coroners who are quite competent to fill such an office. In each county, borough, or district, there should be appointed, as in some States on the Continent, a skilled Surgeon – skilled in the inspection of the dead body, and in a knowledge of the causes of death; and a skilled chemist, skilled in the processes for the detection of poisons. To these three officers, and, if necessary, to assistants appointed by and under them, all inquiries into crimes connected with the death of persons should be exclusively remitted. Proper salaries for skilled Surgeons and analysts would secure competent men, and probably turn out in the end to be less costly than the present system. The duties of sanitary officers (which are not heavy) might be shared by the Medical and chemical gentlemen appointed to these offices.

"Some such regulations as these must sooner or later be made if the public desire to have the duties of an important office properly fulfilled. The value of life is greater in England than in any other country; but this remark applies only to cases of crime which are actually detected, and to the prosecution and punishment of criminals. I believe that we are greatly inferior to other nations in our means for the scientific detection of crime and murder by secret poisoning. In the case of William Palmer (1856), there was evidence to show that his wife, his wife's mother, two of his children, his brother, and one of his personal friends, had all died from poison under his roof, within two or three years before the death of Cook—for the murder of whom Palmer was tried and convicted. His wife had been poisoned by tartar emetic, and his brother by prussic acid. The deaths of at least two others in his house were probably violent. Where was the coroner's inquest for the protection of life?"

Another subject of interest treated in the section on Medical Evidence is that of Medical Experts. After indicating the necessity for calling in Medical or scientific experts, the author resumes:—"There is, however, a strong public feeling against the admission of the testimony of experts. One able writer remarks: 'It is impossible to shut out such evidence altogether, but there is nothing which brings more discredit upon the administration of justice. There is one consequence of its admission which is common to all cases in which it occurs – it is, that no difficulty has ever been found in obtaining any amount of evidence of this description, on either side of any point in issue. There is a contest as to whether a vitriol or a gas manufactory is a nuisance. Twenty chemists of fair character and scientific acquirements come forward to swear that the effluvia evolved by these processes are producing the most deadly fevers, and twenty others equally eminent will give just as positive testimony that the gases are absolutely wholesome, and rather fattening than otherwise. These things are of every-day experience.' . . . It cannot be denied that experts have frequently introduced into their evidence speculative fancies and idle theories, not warranted by a proper induction from the facts; but it is quite clear that in all trials requiring special knowledge, if justice is to be administered, the Court must be assisted by those who possess the knowledge. . . . The cause of the evil is that the solicitors on each side are allowed to search the whole Profession until they can find one or more persons ready to adopt their respective views; and when once in court, provided a man can call himself a 'Doctor,' his qualifications and experience sometimes escape a rigid scrutiny. Persons have thrust themselves or been thrust into cases as experts without any pretensions to such a title, either by their Professional standing or experience. A man who may be engaged only in the ordinary routine of Medical practice, and who may have had no special experience on the subject on which an opinion is required, will be described by his counsel 'as a most eminent member of the Profession, on whose opinion the jury are as much entitled to rely as on that of the very respectable gentleman called on the other side,' etc. The nomination of experts as witnesses by the judge who tries a case, or by the Lord Chancellor in his department, would do away with most of the objections which now tell with so much force against the evidence of experts. As long as they can be retained by either party—and the Profession is large enough to furnish a great variety of experts—so long will the objections to the present system continue, and the good be confounded with the bad."

After illustrations and comments, Dr. Taylor resumes:—"But the question regarding this employment of experts as assessors, and the avoidance of the imputation of their appearing as hired retainers in a case, is practically answered in the Admiralty Courts. Four Masters of the Trinity House, experienced in all the rules of navigation, give their opinions on questions submitted to them, as experts, by the Court; and without creating any charge of injustice in the decisions of the Court, they constantly guide these decisions by answering certain difficult nautical questions. In a case in which two ships come into collision, both parties contend they are right, or the case would not be litigated. The question turns upon the respective positions of the ship, the setting of certain sails, the direction of winds, tides, and currents, and whether the helm should have been ported or starboarded before the collision. These nautical experts, as their opinions are now received, acquit themselves with satisfaction; but if such a trial took place before a jury, and each captain were allowed to select his own experts as witnesses, there would be the same dissatisfaction as that which now exists in reference to trials involving other branches of scientific evidence."

"There can be no doubt that the present system discourages some eminent and upright men, who could by their special knowledge solve many important questions, from appearing as witnesses." . . . "As counsel on both sides look on the experts opposed to them in the light of hired advocates, it is obvious that so long as this system lasts, it must have a deterring effect on the higher and better class of witnesses, who, whenever they have the option, will avoid placing themselves in such a position as to have imputations of venality and untruthfulness thrown out against them in a public court." . . . "It is a fact worthy of note that even in criminal trials where life is concerned no provision is made by the English law for the calling by a judge of independent Medical witnesses or experts interested only in the manifestation of the truth."

A number of excellent engravings form a valuable feature in the volume. Some serve to show the form of poisonous leaves, fruits, etc., and the appearances of their active principles under the microscope, as well as those of mineral poisons. Others render intelligible the shape and arrangement of apparatus used in searching for poisons. The microscopic appearance of ordinary and of menstrual blood; of the human and of several kinds of animal hair; and of the different kinds of fibres found in textile fabrics are also among the number.

Everything enlarged upon in the volume is set forth in a clear and remarkably simple manner. Indeed, few writers have better apprehended what matters require explanation, and what may be assumed to be known to their readers, than the author of this work. The matter of it covers twelve hundred pages, independently of the tables of reference, etc.; yet nowhere have we noticed in the volume anything not to the point, or that could be removed without detracting from the interest or usefulness of it. Assuredly none who have call to peruse the pages of this treatise will find occasion to pronounce Medical Jurisprudence to be a "dry, dull" study.

Australia for the Consumptive Invalid: the Voyage, Climates, and Prospects. By Isaac B. Brown, junior, late Surgeon-Superintendent H.M. Emigration Service. 8vo. Pp. 137. Map. Hardwicke. 1865.

The Surgeons of Her Majesty's emigration service, although a small body of men, are nevertheless a very important one; few persons have any notion of the responsible nature of their office, or of the power that is placed in their hands. Mr. Brown, although but comparatively a short time in the service, has availed himself of his opportunities for observation, and has published his experience of Australasian climates in a volume that will reflect credit on the service to which he belonged. Mr. Brown has wisely appended an excellent map of Australia; for doubtless a knowledge of Australian geography is anything but universal; only a small percentage of ladies or gentlemen in ordinary society would, we suspect, be able to give at all a satisfactory reply to the questions, What is the distance from

Sydney to Adelaide? and which is the southernmost of the two cities? It would be well, perhaps, if a greater familiarity with the splendid Southern Empire belonging to Englishmen were cultivated.

In the first place, it is encouraging to learn that the voyage to Australia is not a dangerous one; the best proof of which, Mr. Brown says, p. 18, is "the commercial test, ships in the Australian trade being insured at almost the lowest rates. Of all the ships despatched by Her Majesty's Emigration Commissioners, only one has met with an accident." It appears from a table furnished by the Commissioners that four and a quarter millions of human beings—that is to say, a number greater than what would now represent a half of the entire population of Ireland—have sailed for Australia with the loss only of 5094.

The remarks Mr. Brown makes in reference to what is to be expected by change of climate are such as would be endorsed by any Practitioner of experience. It is too often that exaggerated accounts lead to false hopes of benefit. He says there is a form of consumption "in which the hereditary taint is so strong, and the constitution is so thoroughly affected by the presence of tubercle, that from the first one sees that nothing will prevent or retard the course of the disease. In fact, in these cases interference seems only to aggravate matters; and it is here that to recommend change of climate is indeed positive cruelty. To turn to the account of those cases reported by Drs. Heineken and Renton, as having gone to Madeira to die within a few weeks or months of their arrival, how many would have been far happier at home, and have been spared many sorrowful partings and the separation from spiritual communion with those nearest and dearest, which in this fatal type of the disease is the only consolation left."—P. 27.

Mr. Brown's predilection is evidently in favour of the climate of Tasmania; he describes it as "the most lovely and healthy of all parts of Australasia. The first assertion I will leave those to contradict who can; it is a matter of taste; but the second I make fearlessly, for there is a larger proportion of old people to be found in Tasmania than in any other part of the globe. I know nowhere where a pink complexion and a white beard are so often seen in unison; where with age the senses, instead of failing, ripen into mellowness; where memory and all other faculties remain perfect to the last." Mr. Brown gives an example of Tasmanian longevity:—"There is now, or was a few months since, living in Launceston an old man, named John Dell. He was born on Guy Fawkes' day, 1763, served for many years as corporal of the guard of George III., and emigrated to Tasmania as a soldier. He has eighty-six descendants living in Tasmania, and is hale and hearty. He will go to the theatre with his great grandchildren, and hear and appreciate the acting. He can write and read without glasses, and can not only remember what happened fifty years ago, but can relate consecutively the events in his life from that period down to the present time.

"The weather of the Tasmanian summer and autumn is truly delightful. Atmosphere almost uniformly transparent; the sky clear from clouds and vapours. One may bask in the sun, and think oneself on the beach at Hastings, or climb the hills and imagine one is breathing the air of the Highlands of Scotland. It is in these months that ladies from New South Wales and Victoria come to gain fresh roses and fresh vigour for the next year."

Mr. Brown, nevertheless, says,—"I look on New South Wales as the best place for invalids who require a warm climate; but they must not live in Sydney itself. The Illawarra district, or Bathurst, will be found quite warm enough in winter for any one who any one who has come from England."

Chapter xi. is especially interesting, and we should say invaluable, to the intending traveller. It contains advice on the choice of ship and cabin, furniture and outfit, exercise, diet, and amusement during the passage. The practical character of the author is shown by the minuteness with which he has gone into details which might at first sight be insignificant, but which, in reality, in a most important degree affect the comfort of the passenger. Imagine the misery of a ninety days' voyage with blankets just one single inch too short, contrasted with the comfort of blankets of ample proportions under the same circumstances! "Outfitters," says Mr. Brown, "seldom allow for 'tucking in.'"

Mr. Brown has contrived to make a pleasant readable book on what might be supposed to be a not very enticing subject.

PROVINCIAL CORRESPONDENCE.

SCOTLAND.

Edinburgh, January 2, 1866.

We had occasion to refer, in our last letter, to various important sanitary improvements which were being organised by our Lord Provost Chambers. The numerous proposals which have been suggested are being considered, and in a short time a matured plan will be brought forward by the principal authorities for the improvement of those parts of our city where vice finds a too prolific breeding-ground, and where

> "Hopeless anguish pours his groan,
> And lonely want retires to die."

This reform movement, now spreading over many large and crowded cities as a doubtfully contagious epidemic of blessings, has extended to the managers and supporters of our Royal Infirmary, who laid a report before the contributors to this charity at their last meeting; the general objects of which will be favourably regarded by the numerous readers of your journal, who are acquainted with the condition of this Hospital.

The Infirmary consists of two main departments, the Medical and Surgical, which occupy two separate buildings. The present Medical house was built in 1738, as a general Hospital for the treatment of both Medical and Surgical cases, admission being granted, since its foundation, "to the curable distressed, from whatever corner of the world they came, without restriction." This almost peculiar catholic character of the Hospital, among other causes, increased the number of applications to such an extent as to necessitate an increase in the accommodation, and about forty years ago the present excellent Surgical house was built, the old building being removed for Medical cases. At present, the Surgical department can accommodate 252 patients, and the Medical about 258, and there is a separate Fever-house, which has beds for sixty cases. However suitable the old building may have been at the time of its foundation for the treatment of diseases, its low roofs, defective ventilation, and sparing supply of ordinary conveniences, have now rendered it totally unfit for modern principles of treatment and for modern ideas of Hospital accommodation. Last year the managers reported that extensive repairs were required, and at the same time recommended that a committee should be appointed to consider the question of building a new and more suitable Medical Hospital; and the report of this committee has just been published. They consider a new building necessary, and propose two plans: the first, to rear the new house on the site of the present Hospital, at an estimated expense of £15,000; and the second, to increase the present site, by the acquisition of a street directly opposite the University, by which an improved access would be gained for the Infirmary from South Bridge-street, and the total cost of which would be about £100,000. We are glad to find that the managers strongly urge the adoption of the second proposal; it would give additional space and necessarily increase the ventilation of the whole Infirmary, and an important city improvement would be effected by the much-to-be-desired opening up of one of its finest buildings, the University, which would result from the removal of the opposite and obstructing street. This report is to be discussed on the 15th inst. There can be little doubt that the second proposal will be adopted, and that a Medical Hospital will be reared in every way worthy of the world-renowned reputation of the Edinburgh Medical School.

A fourth report on the cattle plague has been recently presented to the magistrates; and now Dr. Smart gives the Profession a further cause to thank and congratulate him by the publication of a most elaborate table, the results of about one hundred dissections which he has made in his persevering researches on this the most important Professional question of the day. Such a publication will certainly increase the credit which Dr. Smart unquestionably deserves for his important observations on Rinderpest, and these investigations—which we believe are unequalled in extent, and which have placed at his disposal the largest mass of data which we have met with—will add greatly to the value of any opinion to which he has committed himself. In this report attention is directed to the dermal eruption, which is at present occupying so much of the attention of those who are interested in the investigation of Rinderpest, and which has suggested some differences in the nosological position of the disease. Dr. Smart, we believe,

does not consider himself entitled to give any final opinion on the matter. He is inclined to favour the view of a similarity between Rinderpest and Scarlatina, but until more special attention has been directed to the natural history of the eruption, the question must remain an open one. We understand that an opportunity will be soon given him of continuing the special investigation of this important practical question. Meanwhile, Edinburgh has suffered to a deplorable extent. Previous to the outbreak, there were about 1600 cows in the city, and of those three-fourths have perished, the greatest proportion from the disease, but some to avoid it. Dealing with a pestilence of so virulent a character, we can never be satisfied with any treatment which does not comprehend a specific cure or a certain method of prevention. Should Dr. Murchison's view of the analogy between Rinderpest and small-pox be the correct one, the whole Profession will have reason to congratulate itself that the despairing and querulous cry for Medical aid which has been raised by the *Times* will be immediately and satisfactorily answered. Still, with a difficulty so gigantic, and, for all scientific purposes, so novel, the first duty of the Profession, and the most natural prelude to successful treatment, is a searching inquiry into the pathology and symptomatology of the disease. We must congratulate ourselves, basing our laudation on results alone, that this task has been assigned to such able, persevering, and careful observers as Drs. Smart and Murchison, and their fellow-labourers in the Veterinary Profession, Messrs. Gamgee and Simonds.

At the last meeting of the Medico-Chirurgical Society, Dr. Gillespie read an interesting paper on a case of death while under the influence of chloroform. The case is one which presents the most frequent characters of chloroform accidents. The unfortunate patient was a young lady of 17, of a very nervous disposition, and the chloroform was administered for the trifling operation of tooth extraction. Death was caused by the employment of only fifty minims of the anæsthetic, and only a few seconds after its administration. It may not be altogether superflous to remark that the chloroform had been administered contrary to Dr. Gillespie's advice, and at the earnest entreaty of the patient and her friends.

At the same meeting the retiring President, Professor Maclagan, delivered an able valedictory address, in which he gave a *resumé* of the proceedings of the society during his presidentship. The important results of Dr. Thomas Keith's cases of ovariotomy were, *inter alia*, referred to in the following words:—"Dr. Keith's cases up to the present time are thirty-seven in number (besides one operated on the day before yesterday); of these nine have died, and twenty-eight recovered. The last eight cases in succession have done well; of the last twenty-one, three only have died, and all the recovered cases are now in perfect health. Such results are full of promise and encouragement, and are not the less interesting to this society that through it most of the cases have been communicated to the Profession." Dr. Moir, F.R.C.P., was elected President for the ensuing year; and Drs. J. Warburton, Begbie, Haldane, and Gillespie, Vice-Presidents.

Shortly before the Christmas vacation a mutiny was threatened by the Medical students of the University because of the published intention of the Senatus to continue the lectures of the Medical Professors during the week which has for a long period been devoted to Christmas relaxation and festivity. Indignation meetings were held, and an extensively signed petition presented to the Senatus, requesting a repeal of the obnoxious resolutions. This was first denied by the Senatus; but, on a favourable response having been given to a similar petition presented to the University Court, the request of the great body of the students of Medicine was granted, on the understanding that an attempt would be made by the Senatus to change the commencement of the session from November to the beginning of October.

(From another Correspondent.)

January 10.

The first baronetcy ever bestowed upon a Scotch Professor, or a Physician practising in Scotland, has been conferred by Her Majesty on our distinguished townsman, Professor Simpson. We can think of no one more worthy of the high honour. By his great discovery of 1847 suffering humanity throughout the world has become his debtor.

To Obstetrical science his genius has contributed many of the most important discoveries of late years. Meantime he is storming the established principles of Surgery with the invention of acupressure, which promises as far to surpass the old ligature as it, in its day, excelled the torturing cautery. Nor have his talents been bounded by the vast demands of Medical science and practice pursued in so enthusiastic a spirit. He has over and above all this found time to enrich literature with many valuable treatises on antiquarian and other subjects. Long may Sir James Young Simpson be spared to enjoy those honours of which, as the just reward of individual talent and energy, he has a right to feel proud!

GENERAL CORRESPONDENCE.

ON THE SMALL-POX OF CATTLE IN BENGAL.

LETTER FROM DR. MACPHERSON.

[To the Editor of the Medical Times and Gazette.

SIR,—With reference to a view now very currently entertained of the identity of the Rinderpest and of small-pox, it may be interesting to call attention to the fact that in Bengal the natives have long looked on one of their most common murrains as small-pox. They apply the same names to the disease in man and in cattle, the commonest being "Mátá" and "Gotíe."

The following extracts from *Transact.* Med. and Phy. Soc. of Calcutta, and from the Official Report on Small-pox, Calcutta, 1844, give a general account of this form of murrain, and are submitted for the judgment and information of those who are engaged in the investigation of the disease now so prevalent. I do not presume,—not having had an opportunity of studying cases of the Rinderpest—to offer any decided opinion of my own, though there are, undoubtedly, some very strong points of resemblance between the two diseases.

Mr. G. G. Macpherson, of Moorshedabad, writes in December, 1832:—

"I learned that the cows in Bengal are subject to a disease which usually makes its appearance about the end of August or early in September, to which the same names are given as to variola in the human subject,—namely, Basant, Mátá, or Gotíe.

"The animals which were at first affected, amounting in one shed to eighteen or twenty, had been for a day or two previously dull and stupid; they were afterwards seized with distressing cough, and much phlegm collected in the mouth and fauces. The animals had apparently, at this time, no inclination for food, or, at all events, they were unable to satisfy their hunger. Their sufferings seemed to be greatest on the fifth and sixth days, when there was considerable fever and pustules made their appearance all over the body, especially on the abdomen, which terminated in ulceration, the hair falling off wherever a pustule had run its course. The mouth and fauces appeared to be the principal seat of the disease, being, in some instances, one mass of ulceration, which in all probability extended to the stomach and alimentary canal. In those cases where the mouth was very much affected, the animals died apparently from inanition, whereas, in those cases in which the power of mastication, or even of swallowing, was retained, recovery was much more rapid than might have been expected from the previous severe sufferings and reduced state of the animals. The mortality may be calculated at from 15 to 20 per cent.

"From the above description of the disease, it will be plain that the Gotíe assumes a much more serious complexion than the Jennerian disease of cows. It must be inferred from Dr. Jenner's writings that the animal not only continued to secrete milk, but that the milk was used; while in this country, what little is secreted is never made use of, and, perhaps, owing to this circumstance, the milkers in India are not affected with cow-pox. It is an extraordinary fact, and worthy of remark, that while the cows were thus affected, no case of variola amongst the natives in the village presented itself; and although the people were averse from handling or going much among the cattle at the time of disease, still they all scouted the idea of infection, stating that they never heard of any one contracting disease from the cow. The disease assumed the character of an epidemic, all the cattle in the neighbourhood being affected."

Mr. Lamb, of Dacca, in 1836, reported as follows:—

"The disease among cattle known under the appellations of Basant, Mátá, Sítlá, or Gotíe chiefly prevails during the months

of December, January, and February, though not quite unknown at other seasons of the year. When a cow or bullock is first attacked, there is a discharge of saliva from the mouth; then follows universal tremor, with great heat of the head, chest, and body, as far back as the loins, while the hind quarters are cold. The whole body then becomes hot, and the animal suffers from intense thirst, the flow of saliva ceases, and the mouth becomes dry and hot. After the fever has subsided a day or two, the hair becomes so loosely attached that the slightest rubbing brings it off in handfuls. On the fifth day the eruption appears about the udder, sometimes only a few pustules, at other times they are numerous and confluent; but the result of the attack does not seem much dependent on the eruption. Whether the pustules are numerous or rare, the disease is almost equally fatal, and unless measures are taken to separate the diseased from the healthy, it speedily runs through the whole herd, sparing few. In those who do escape after taking the infection, the favourable symptom is a spontaneous diarrhœa, in which the dejections are large, watery, and offensive. When the hair is rubbed off after the pustules have appeared at the udders, the skin is found covered with sores. Many die before the eruption makes its appearance, but the fever is known by the discharge of the saliva, by the falling off of the hair, and loosening of the teeth. In favourable cases, three or four days after the eruption has come out, the teeth acquire firmness in the gums, and the animal is able to pick up a little grass. Cattle are said not to be subject to a second attack of mata. Sometimes the disease is exceedingly fatal; at other times it is comparatively slight, without sure reference to known or apparent cause; it is, however, at all times greatly dreaded, as it is too often the cause of utter ruin to villages. I have been unable to hear of its frequent co-existence with small-pox among the natives, and the disease is little known in the city of Dacca. Last year, when nearly a thousand deaths from small-pox occurred in Dacca, the disease only appeared in one quarter for a short period, and I was not aware of its presence till it had ceased, after carrying off fifteen or twenty cows."

Early in the winter of 1843, Dr. Duncan Stewart, of Calcutta, "was told that the cattle were dying in great numbers of small-pox. He visited all the cowsheds, and inspected many sick cows, but not one had any pustular eruption he could discover on its body. He saw several very fat and healthy-looking cows die after about three days' fever, with convulsive tremors, blood-shot eyes, and parched mouths. These the natives insisted in calling cases of inward Mátá. He observed in others, and generally for a few days, signs of fever, such as panting, lowing, thirst, loss of appetite; then followed violent purging, profuse salivation, and pituitary discharge from the nostrils; but on the fourth day ulceration of the tongue and palate, with bloody purging followed, and death usually occurred on the fourth or fifth day. In a good many cases certain rough elevations were pointed out to me on the skin having the hair turned back or ruffled over a small phlegmonous base. A number of these undoubtedly were caused by the burrowing of vermin or by the bites of insects, but many may also have been pustules, without supposing they possessed a specific character. Except in three cases out of many hundreds he inspected, he never found anything like papulæ, or vesicles, or pustules on the teats or udders of cows. The mortality among the cattle commenced much about the same time with that caused by small-pox among the inhabitants. The mortality in January had risen to 934 within the month, so as to affect materially the supply of milk and butter. It was asserted that the native butchers were in the habit of slaughtering the cattle the moment they were suspected, and the panic among beef eaters became almost universal. It was not generally known that the mortality was very great at the same time among fowls and pigeons; he saw dead fowls taken out of poultry yards in dozens in the morning, said to have died in the night of the universal small-pox, but could see nothing the matter with the birds, unless a certain degree of swelling and redness about the eyes." During the same epidemic, a cattle-keeper (Mr. Greenfield) whose notion of the disease may be referred to, reported that "he had lost sixty cows with a disease that had been all over his neighbourhood, like strangles or glanders; no eruption on skin, or udder, or teats; only the eyes, tongue, and throat were affected. They were all suddenly taken ill, and seldom lived more than three days. No purging nor discharge of water appeared."

I have myself observed the disease in Calcutta, three or four times in the course of eight years, usually towards the end of the rainy season, but I regret that I have no detailed notes of the symptoms. They were in a general way those described by Dr. Stewart, but I never saw a very fatal epidemic of the disease, nor one nearly coinciding in date with small-pox such as he described. Although all the accounts of this disease, as published, leave a great deal to be desired, yet they say enough to establish a few points of importance:—

1. All observers agree that one of the main features was the attack of the mouth and fauces.

2. All the Professional observers speak more or less of a pustule or eruption.

3. The three Medical observers all found or suspected affections of the bowels.

4. They describe a disease of varying mortality; but none of them talk of a plague at all equal in intensity to that now so general in England, or that prevailed lately in Egypt, and seems now to ravage Burmah and some parts of Southern India.

5. Respecting the communicability of the disease, the natives know well how catching it is among cattle, but they never dreamed of infection to man or to other animals.

6. In the way of treatment little was done. The natives gave various vegetable purgatives, but more usually had recourse to charms and incantations, which were doubtless quite as efficacious as arsenicon.

7. Some feeble attempts were made at the separation of cattle, but generally the murrains were left to exhaust themselves.

Respecting the communicability of the disease something more remains to be said. It has already been stated that the disease varies extremely in intensity, and many observers have conceived the idea that the milder cases of Mátá might be analogous to the vaccinia of Jenner, and have endeavoured to communicate the disease of mild Mátá to the human subject, in hopes of finding it to be the true cow-pox of ordinary vaccination. Accordingly, various attempts at transference of Mátá to children were made, of which three may be considered to have been successful, although I am quite aware of the many deceits which native assistants are willing to practise to bring about a result desired by their superior.

Mr. Macpherson inoculated children with crusts got from one of the cattle suffering from the epidemic of which his description has been given above. The result was the production of the genuine vaccine disease; at all events, of what he and many others considered to be such. Lymph supplied from this source was sent over the country and to Calcutta, and it speedily became mixed up with the lymph previously in use. No disastrous accidents happened, as with the lymph procured in 1837 by Messrs. Brown and Furnell in Assam.

Encouraged by Mr. Macpherson's success, they made use of some scales or scabs taken from the back or abdomen of a cow affected with Mátá, reduced them to a pulp with water, and inoculated four children. "In all four vesicles, in every respect resembling in their progress and when mature genuine vaccinia, were produced, and went through the same regular course, the constitutional disturbance on the eighth day only being more severe than I have usually seen it in the latter." From these many native children were inoculated, and no doubts of the genuineness of the lymph were excited until two English children were punctured from one of them, and it was found that fatal small-pox supervened.

This case might probably have prevented my making any further experiments on the subject had not other cases occurred, in which lymph sent from Calcutta, believed to be pure English lymph, had not, also on more than one occasion, appeared to produce small-pox; in which cases, when the disease was epidemic, I believe that such a result could only have been produced by the child having, previously to vaccination, got the poison of small-pox into its system, or by the trick of a vaccinator wishing to please his superior by making sure of the lymph producing some result, and using some small-pox virus.

Thinking, therefore, that the disastrous result in Mr. Furnell's case might have been so produced, I selected a mild case of Mátá, one in which there was a small irregular vesicle with no areola on the udder; altogether not a very promising case, nor what I should consider a true example of the Jennerian disease in cows; still the best case I could find. I was assisted by a particularly trustworthy native sub-Assistant-Surgeon, Hurronath Mitter. Three children were inoculated with thickish fluid from the teat, and the result was that in two of the children a very tolerable vaccine disease was produced. It was in August, 1856, at the season of the year (the rainy

one) when vaccination does not run a regular course in Calcutta. The disease strongly resembled true vaccinia, and was passed through 80 or 100 children. The chief differences from true cow-pox were the earlier development of the vesicles, their being more acuminated, their soon being filled with pus, and not forming scabs—in short, they ran their course three or four days faster than the regular vaccine. There was also considerably more fever than is usual after vaccination. There were by the middle of September some symptoms of the vaccinia becoming more regular; but as, on the whole, I was not satisfied that I was propagating the real vaccinia, I gradually dropped the use of it. No untoward accident from its use was brought to my notice.

There are many points in these experiments which are not satisfactory to my mind, and which cannot now be solved; but with reference to any experiments now to be made with the so-called Rinderpest, they seem, such as they are, to be worthy of being alluded to. As far as I am aware, no attempts to communicate human small-pox to cattle in India have been successful. I am, &c.

Dr. John Macpherson,
late Superintendent-General of Vaccination.

35, Curzon-street, Mayfair, January 10, 1866.

THE SMALL-POX HYPOTHESIS OF THE CATTLE PLAGUE TESTED.

Letter from Dr. John Fairmann.

[To the Editor of the Medical Times and Gazette.]

Sir,—Next to knowing what a disease is, stands in importanee our knowing what it is not, and I believe the following facts will help us to arrive at this latter conclusion. I returned yesterday from a short journey into certain of the plague-stricken districts; and going there with a strong hope that the hypothesis of there being some sort of absolute relation, at least, between the cattle plague and small-pox would be confirmed by my own observation, I confess to a most unpleasant disappointment, because if such relationship were proven, some prospect of prevention and cure would arise. I inspected carefully cows in all the stages of the disease, but in not one of them did I observe anything approaching to the much-disputed eruption, either on the skin, or on the udder, or around the vulva, or at the entrance of the vagina, or on the tongue or gums. A congested state of the vaginal mucous membrane, either in patches, or streaks, or more diffused, was considered to be the one indubitable sign of the animal being stricken. But the most important fact that came to my knowledge—most important as having a positive value—was this:—In a large herd, on one of the farms I visited, the cow pox had prevailed extensively during the autumn and onwards of the past year; there have been six cases of the cattle plague among them (three being sick at the time of my visit), and three of these six have died; one at least of these three, and two of those three still alive, had the cow pox, and, curiously enough, one of those dead had the cow pox and the cattle disease more severely than the others in either case. There can be no reasonable doubt of the two essential elements of this fact—that the cow pox had been present, and that one at least of the three dead had it severely, because (in addition to other evidence) the two servants that had been and are still in charge declared such to have been the case; and I myself observed the marks of the cow pox on the udder of one of the cows now under the disease, and saw the marks of infection on the fingers of one of these servants, having been, too, previously informed by the family Medical attendant that this man had shown him the regular vaccine vesicle and pustule on the hands.

As already said, I returned much disappointed, though aware that the varioloid nature of the disease was as strongly denied, and by as competent observers, as it was affirmed; but the foregoing facts could not but have their legitimate influence upon me. Notwithstanding all this, however, I strongly urged the propriety of vaccinating healthy stocks; this can do no possible harm, and if there be the smallest spot to support the least etiological relation between the two diseases, the experiment would well merit a fair and extensive trial. The fear is that the conditions essential to valid experiments will not be strictly attended to. But after all has been done, and if vaccination be found nugatory, would it not be well to try extensively the inoculation by small-pox matter from the human subject, as has been suggested and tried in some isolated instanees? The experiments of Professor Boeek in the case of constitutional syphilis lend some support, I think, to this trial of inoculation. I am, &c.

John Fairmann, L.R.C.Phys. Edin., ete., etc.

THE ACUPRESSURE CONTROVERSY.

Letter from Dr. Brown.

[To the Editor of the Medical Times and Gazette.]

Sir,—Dr. Simpson has most unwarrantably introduced my name into a letter which you have published, as I never expressed publicly any opinion on the subject in question.

It is true that I was present when Mr. Syme tore the pamphlet "with his fingers," and that I regretted his taking a step which was liable to misrepresentation; but being now compelled to give my evidence as a witness, I beg to say that what Mr. Syme did was done with the most perfect coolness as the deliberate reply to an imputation on his fidelity as a teacher, and not as an expression of dissent from the proposed substitution of needles for ligatures.

I am, &c., John Brown.

23, Rutland-street, Edinburgh, January 8.

*** Mr. Syme called the act a "public execution." Let Dr. Brown explain this on any "charitable hypothesis," and we shall be delighted to insert the explanation.

THE LATE DR. RITCHIE AND THE JENNER MEMORIAL WINDOW AT BERKELEY.

Letter from Dr. John C. Thorowgood.

[To the Editor of the Medical Times and Gazette.]

Sir,—The sad occasion of the death of that excellent and talented young Physician, Dr. Charles George Ritchie, may be a fit one for drawing attention to a work in which he was earnestly engaged at the time of his decease. The work I allude to was the collection of subscriptions for the proposed memorial window to Dr. Edward Jenner in the parish church of Berkeley, in Gloucestershire.

The interest that I felt in this proposal to erect some memorial of Jenner in his own native village was the means of making me acquainted personally with Dr. Ritchie, and during my brief visit to him he was lamenting to me the slow progress in the growth of the subscription list for the erection of this window.

I can hardly imagine that any very great sum would be required to prepare and put in the window; but surely men in the Profession, and out of it, too, should rather regard it as a privilege to contribute something to a fund having for its object a substantial memorial to Jenner, and the names of the Committee are enough to satisfy the most particular of men that any surplus of funds would be disposed of in a proper and satisfactory way. I am, &c.,

John C. Thorowgood, M.D.

Queen Anne-street, January 10.

EXAMINATION AT THE UNIVERSITY OF LONDON.

[To the Editor of the Medical Times and Gazette.]

Sir,—I cordially assent to the proposition in your editorial remarks that the London University expects too much from those applying for its degrees.

If a student must study practical chemistry he must resort to some large town where it is taught; and if he wants to study botany he must resort to some small town not surrounded for miles by stone walls and not void of green fields To fill a vasculum with plants, a student in Manchester, Birmingham, Liverpool, and other large towns, has to tramp all day—a day wholly lost to other studies. If he want to study zoology practically, he must make friends with some gamekeeper far remote from any town. As no student can be ubiquitous, he must select one of these studies in preference to another; and yet the University expects that he shall know all.

I must also call your attention to the fact that there may be much mental discipline and trained observation without the power, suddenly, to make that known. Any man can see the difference between an apple and a pear, a lettuce and a cauliflower; but few can put into writing a description of each in botanical

language. In every science there is a vast amount of words with technical meanings; and a memory of wondrous tenacity is required to remember these and their definite use. I think I know a great deal about steam engines, but I was completely *nonplussed* when a friend began to speak of "bushes and bearings" as important parts of them.

Do you think that any examiner in the University could stand a test like this? The chemical Professor shall be taken into a conservatory every day for a week, and shall on each occasion be told the name of every plant, the colour of its petals and sepals, the time of its showing flower, the time of its flowering, the duration of its blooming, the nature of its fruit, the size of its seeds, and the period they require for germination. The conservatory shall be a very large one, like the botanical kingdom is. At the end of the period three plants shall be presented to him, and if he can name all the points noted to him he may receive a medal of the order of memory. But to test him fairly, as compared with a student, he shall at the same time be required to go with another guide through a museum of zoology, and he shall have pointed out to him the moths, butterflies, insects, fishes, birds, molluscs, shells, etc., with which such collections abound; he shall be taught names, anatomy, habitat, habits, food, homes, etc., of each; and at the end of this probation he shall be called upon to name a moth, the appearance of its eggs, its larva, and its chrysalis; to give a succinct account of nudibranchiate molluscs; and to describe technically the difference between a crab and a lobster, and any two crabs and any two lobsters. Do you think he would pass? I might similarly frame a style of examination which would test the anatomist, the botanist, or the physicist; but refrain from want of space.

I would suggest that the examiners really form a board, at which all questions to students shall be read aloud, and each member of the board shall be asked whether he, as an accomplished gentleman, is able to answer it; if not, a vote should be taken "whether that question be put to the student." As it is, each examiner expects the student to excel in his branch, and if very defective in that he damns him altogether.

I was a diligent student in my time, burned no end of midnight oil, and day by day did my duty in the lecture-room, in dissecting-room, and dressing, etc., in Hospital; I took sundry prizes and gold medals in my "school," and earned distinction at the London University; but yet I escaped, almost miraculously, being plucked at the Hall; and at my first examination for M.B., for my want of knowledge of botany, I sat up all night cramming Henslow's book, just before I went in, and remembered enough of it to pull through; while another, who has since made his name deservedly famous, was rejected because he could not describe some flowers, etc., laid before him.

As regards the after career of students successful at the Schools and Universities, I am afraid little can be said favourable. If they want Medical renown, they may obtain it at the expense of worldly success. If they want "pudding," they must forget their learning and study human nature as it is. Experience tells us all that humbug and ignorance pays better than science; and in Medical knowledge we may say certainly much learning increaseth sorrow.

I am, &c. M.D. London.

Cottage Hospitals.—From the Fifth Annual Report of the Fowey Cottage Hospital it appears that during the past year there have been fifteen severe cases received in this modest institution, two of them necessitating amputation. All have done well, and this at an outlay under £20. We congratulate Dr. Davis, the founder and Medical officer, on the great success which has attended his efforts, at so small a cost, to ameliorate the condition of the sick poor in this primitive and out-of-the-way little nook on the wild Cornish coast.

Harveian Society of London.—The following is a list of the names of gentlemen elected as officers of the Society for the year 1866:—*President:* W. Tyler Smith, M.D. *Vice-Presidents:* B. G. Babington, M.D., F.R.S.; T. Ballard, M.D.; J. B. Walker, Esq.; C. S. Webber, Esq. *Treasurer:* Henry William Fuller, M.D. *Hon. Secretaries:* J. Brendon Curgenven, Esq.; Charles R. Drysdale, M.D. *Council:* J. D. Allen, M.D.; Victor De Meric, Esq.; J. Eardley, Esq.; John Evans, Esq.; J. Gayleard, Esq.; J. Stewart Lamb, M.D.; James R. Lane, Esq.; J. Z. Laurence, Esq.; Edwin Lowe, Esq.; J. M. Moullin, Esq.; Chas. Royston, M.D.; J. C. Whaley, Esq.

REPORTS OF SOCIETIES.

THE PATHOLOGICAL SOCIETY.

Tuesday, January 2.

Dr. Peacock, President.

The following report would have appeared last week but for an accidental delay in the forwarding of the MS. by the Post-office. It is an amplification of the report we gave at page 15 in the number for the previous week. As in that report we were able to give a complete account of Mr. Gamgee's remarks, we need not here reproduce them. It will be remembered that, in the main, Mr. Gamgee agreed with Dr. Sanderson and differed from Dr. Quain and Dr. Murchison.

A report of the meeting for December 19 will appear next week.

Dr. Quain read the following

CASE OF INOCULATION BY CATTLE-PLAGUE POISON, PRODUCING APPARENTLY A VACCINE VESICLE.

The subject of this phenomenon is Mr. Hancock, a Veterinary Inspector of the Uxbridge district, who, whilst superintending the post-mortem examination of a bullock dead of the cattle plague, received a slight wound on the back of the left hand; the operator was engaged at the moment removing the skin from the neighbourhood of the scrotum. The subject of the inquiry (aged about 30), and showing a mark of old successful vaccination, was at the moment in perfect health, and took no notice of the accident, which occurred on December 3. On the fifth day—*i.e.*, December 8—a papula, hard and slightly raised, was felt and seen in the site of the puncture. This gradually increased in size till December 12, when a distinct vesicle appeared at the site of the papula, and then he began to feel ill; on the following day he felt worse; he had pains in the back and limbs, and felt feverish. He then consulted Mr. Rayner, a Surgeon at Uxbridge, of great experience, who recognised the appearance on the hand as being due to vaccination. The vesicle on this the tenth day resembled that of vaccination; on the ninth day it was full of lymph; the edges were elevated, of a brownish colour; the centre depressed, of a brownish colour also; the whole being surrounded by a large red areola. The hand was swollen beyond the knuckles, and the swelling extended up the arm; the lymphatic vessels were inflamed, and pain and uneasiness were felt in the arm-pit. There was much febrile disturbance. On December 15 and 16 the symptoms were more severe; there was evidence of increased fever, and severe pains were felt in the back and head. He then resolved to come to town for my advice, and he came on December 18, having first called on Professors Spooner and Symonds at the Royal Veterinary College, and showed them his hand. These gentlemen were so good as to approve of his desire to see me, and I saw him on that day. The feverish symptoms had partially subsided, so likewise had the local inflammatory action. There was still the vesicle now filled with rather turbid brownish fluid, the outer edges resting on an inflamed basis being somewhat irregular, the centre brownish and depressed. The appearances were exactly those of a declining vaccine vesicle. They are figured in the drawing presented to the Society. I asked Dr. Murchison, who was engaged in seeking the analogies which cattle plague bears to the diseases of man, to see this case. I sent for Dr. Sanderson also, but failed to find him, he being also engaged for the Commission. Dr. Murchison was struck with the appearance which he saw, and has since zealously and very ably pursued the inquiry. I communicated the fact to Mr. Ceely also, who saw Mr. Hancock on December 20, the fourteenth day of papulation, the nineteenth of puncturation. Mr. Ceely was quite satisfied of the vaccine character of the appearance which he saw. Mr. Hancock has called on me once since then, and again yesterday. The appearance presented by the hand yesterday seemed so striking that I requested him to attend our meeting. These appearances are also shown in a drawing. There is the dry, black, central, depressed crust; the red, semi-transparent, glistening, elevated margin; and the surrounding halo,—an appearance almost identical with the declining vaccine vesicle figured on the temporal region in plate 1 in Mr. Ceely's "Further Observations on the Variola Vaccine."(a)

(a) Deighton, Worcester. 1842.

Mr. Hancock then showed his hand to the members of the Society, after which Dr. Quain, at the request of the President, made the following observations :—

Dr. Quain said that this was not the first time that the cattle plague had been said to resemble small-pox. In the last century an epidemic among cattle had been described as small-pox by Layard; yet although the subject had often been discussed he was not aware that, until the present time, any positive fact had been arrived at. There had been many statements in the newspapers to the effect that Rinderpest and small-pox were allied, but they were mere surmises, unsupported by proof. Mr. Ceely (Dr. Quain continued) had for the last six weeks been investigating the subject, and had pointed out there was an eruption in Rinderpest. In some cases the eruption had escaped notice. It was not a little strange that the first notice of the existence of the eruption, or rather of its effects, was recognised by tanners. They refused to receive the skins of cattle which had died of Rinderpest, as it was found that the hides were spotted. Mr. Ceely had found that the eruption was on the back of the neck and on the shoulder, as well as on the udder, vulva, etc. Having found an eruption, the next thing was to learn what its nature really was, and the question of its being small-pox was raised. At this point in the inquiry Mr. Hancock's case occurred, and gave a fresh impulse to inquiry. Dr. Quain then remarked on the extreme importance of the question—If the Rinderpest really was small-pox, vaccination would doubtless prevent it. It was, he said, remarkable how some cattle exposed to the contagion failed to take the disease, and in some of these instances it had been asserted that the cattle had had the vaccine disease in early life. In such instances the vaccine disease saved the animals, and it was but reasonable, Dr. Quain argued, to confer immunity on oxen by producing the disease artificially by vaccination or by inoculating them with small-pox matter. It seems, however, Dr. Quain added, that it is no easy matter to induce small-pox in cattle, and that there yet remains much to do before its result can be established positively. Dr. Quain concluded by saying that Dr. Sanderson, Mr. Spooner, and Dr. Murchison were present, and would no doubt be able to make some remarks on the question and on the bearing of Mr. Hancock's case on it.

Dr. Sanderson had no intention of expressing any opinion as to the precise significance of the appearances exhibited in Mr. Hancock's arm or on the question whether or not small-pox is identical with Rinderpest. Early in December his attention had been called by Mr. Ceely to the remarkable analogy between the two diseases, and he had read a communication to the Harveian Society for the purpose of illustrating this analogy, and, at the same time, maintaining that, however like, the two diseases could not be regarded as identical. He saw no reason to modify the views then expressed, for it appeared to him that neither the symptoms during life nor the post-mortem appearances justified an opposite conclusion. At the same time, it was to be remembered that questions of this kind could only be solved by experiment. As regards the eruption on the skin, he had had opportunities of observing it from its earliest appearances both in mild and in fatal cases, and that there appeared to him to be no analogy whatever between it and the eruption of small-pox. Whereas the vesicles of small-pox originate in a definite manner, have a definite duration, and contain a transparent fluid which is gradually transformed into pus by a process which is invariable in each vesicle, the so-called flattened vesicles have no relation to the severity of the malady or the stage of its progress, contain no serous liquid, being, in fact, not vesicles at all, but solid elevations beneath the cuticle, which occasionally soften, if the animal lives long enough, into a semi-fluid material having a remote resemblance to pus.

[Mr. Gamgee then made some remarks, a full report of which is contained in an article on page 14 of the last number of this journal.]

Dr. Murchison said he believed with Dr. Sanderson that the eruption in the Rinderpest did not always pass through the regular stages seen in the eruption of small-pox in the human subject, but he could not help thinking that these differences were to be accounted for by the structural difference of the human skin and the skin of oxen. Again, it was not in the eruption solely, but in the general history of the disease, that its analogy to variola in the human subject was to be traced. He had not maintained that they were identical, but he really felt convinced that the more Rinderpest was studied the more did it seem to resemble variola. The visceral lesions of human small-pox—which, by the way, Dr. Murchison said had not been recently studied—were strikingly like those seen in the animals which had died of the cattle plague. Even the remarkable ecchymoses and eschars found in the third and fourth stomachs of cattle had also been found in the stomachs of persons who had died of unmodified variola. Dr. Murchison then said that it was acknowledged that in some countries, as in India, cattle did suffer from small-pox, and there it was very fatal to them. Now, it would be very remarkable if small-pox in cattle was limited to the East, and another disease, which certainly closely resembled it, should exist here. There was no doubt in India that certain epidemics among cattle were epidemics of small-pox, for experiments showed that inoculation with the matter from the animals produced sometimes variola, and sometimes the ordinary appearance of simple vaccinitis. Dr. Murchison then read the reports of Indian Medical officers to prove this. Dr. Murchison concluded his remarks by saying that, there were, at all events, reasonable grounds for making experiments. A few experiments would easily settle the question; and if they showed the disease to be small-pox we should have in vaccination a means of putting a stop to it.

Dr. Sanderson remarked that in order to guard against the impression that the difference in the eruption of small-pox in the human subject and in the diseased cattle was due to differences in the skins, he had pointed out the difference between the eruption of Rinderpest and the eruption of undoubted small-pox in sheep.

Dr. Sanderson exhibited a specimen showing

THE CHANGES IN THE MUCOUS MEMBRANES OF THE GUMS, LIPS, AND CHEEKS IN CASES OF RINDERPEST.

He stated that in seven cases of Rinderpest in which the mucous membranes had been inspected day after day, from the moment that the increase of the temperature of the animal indicated that it was infected, the alteration in question always occurred earlier than any constitutional symptom of the malady, and at a period when the animal exhibited to an ordinary observer no sign whatever of disturbance of health. The earliest change seen (or rather felt) consists in the formation on the gums of minute red elevations, or nodules, often not larger than a poppy seed, which are so little redder than the surrounding surface that they can only be discovered by touch. Twelve hours later they have become opaque, larger, and more visible. A day later they are found to have not only extended into patches, but to have softened in the centre. As they increase in size they become confluent, assume a greyish-yellow colour, and become softer. Having arrived at this stage, they either peel off, leaving a red, easily-blending surface, or remain, assuming the appearance of moist diphtheritic concretions. In his preparation both of these results are met with in different parts. From first to last these structures are epithelial. The process of their formation appears to consist, first, of exuberant development of young epithelium at the surface of the membrana propria; secondly, of the breaking down of these structures, so as to form a granular mass, in which numerous nuclei are still visible. On the surface of the papillæ a similar change takes place; but there is no visible thickening of the epithelium; the obvious change being that the true structure is detached in patches, sometimes leaving the tip of the papilla bare and red, sometimes the base. This alteration is very striking, in consequence of the brightness of the colour which these patches of denudation exhibit. Dr. Sanderson remarked that the alterations described were of great importance in relation to the diagnosis of cattle plague. From the constancy with which they had been observed in all cases, the mildest as well as the most malignant, and from the uniformity of the characters they exhibited, he thought that the experience of this country was in accordance with the opinion of those who had enjoyed the largest opportunity of seeing the disease in Russia, that they are almost pathognomic. Anatomically, the eruption on the mucous membrane of the mouth is strictly analogous to that which occurs on the skin. At the edges of the lips they are seen to be continuous with each other. Neither has any resemblance to the affections of the same parts observed in small-pox.

Medical Society of London, 32A, George-street, Hanover-square.—The second lecture of the course of Lettsomian lectures, on "Certain Painful Affections of the Fifth Nerve," will be delivered by Francis Edward Anstie, M.D., F.R.C.P. (Senior Assistant-Physician Westminster Hospital), at half-past eight p.m. on Monday, January 22, 1866.

OBSTETRICAL SOCIETY OF LONDON.

WEDNESDAY, NOVEMBER 1, 1865.

Dr. BARNES, President.

THE PRESIDENT announced that the Council had resolved to hold a *conversazione* in March next, for the purpose of exhibiting a full collection of instruments used in obstetric practice.

Dr. BARNES exhibited a monstrous Fœtus brought to him by Mr. Thane, of Canonbury. Also, a voluminous Fibroid Tumour, weighing 1 lb. 13 oz., which, with the assistance of Dr. Hicks, he had successfully removed from the uterus of a lady a month ago.

Dr. RUSSELL, of St. Albans, laid before the Society the particulars of a case of Hydatiform Degeneration of the Ovum.

Dr. AVELING read a

CASE OF OVARIOTOMY IN WHICH THE PEDICLE WAS TIED AND RETURNED, AND THE LIGATURE REMOVED IN FORTY-EIGHT HOURS.

The operation was performed as follows:—As soon as the cyst was reached it was tapped, and the fluid (twenty-one pints) withdrawn. No adhesions existed, and the sac was withdrawn easily. The pedicle, which was short, and about four fingers in breadth, was transfixed by a needle carrying a double thread. The two ends of each ligature were then brought up on either side, and drawn through two wire coils five inches and a half long. Each coil had fitted upon its end a cross-bar; and around these cross-bars the ligatures were secured after they had been drawn sufficiently tight to compress the vessels. The pedicle, after it had been placed in the hook of Dr. Aveling's polyptrite and crushed through, was then returned *in situ*, and the wound closed with iron-wire sutures. The coil-clamps were removed in forty-eight hours; and the patient made a favourable recovery.

Mr. SPENCER WELLS said that no one method of dealing with the pedicle could be applicable in all cases of ovariotomy. A long pedicle was dealt with so successfully by the clamp that he desired no better method; but it was still doubtful what was the best mode of proceeding when the pedicle is short. The plan of leaving the ends of silk or twine ligatures hanging out through the wound was so unsuccessful, that the apparatus of Dr. Aveling would probably prove of great advantage in cases of short pedicle in weak patients.

Dr. MARION SIMS said that the clamp was a great improvement on the ligature. He thought Mr. Baker Brown's plan of severing the pedicle by the actual cautery promised great results. He viewed Dr. Aveling's method with favour. He always used a silver wire, and left it to be sacculated. He said the distal end of the severed pedicle did not slough where the wire was applied. The wire became imbedded and hidden in its tissue.

Mr GEORGE ROPER read the particulars of a

DIFFICULT CASE OF LABOUR, IN WHICH THE CERVIX UTERI WAS HYPERTROPHIED AND UNEVOLUTED.

A. E., aged thirty-seven, in labour with her eighth child, was found to have the cervix uteri elongated and enlarged, so as to fill the vagina. The os externum was sufficiently dilated to admit the hand, but the os internum was undilated. The occiput presented. Version having been tried and failed, and the funis being pulseless, the head was perforated, and after some difficulty the child was extracted. During extraction the cervix uteri protruded from the vulva, and the effects of pressure and distension on it could be well observed. The difficulty consisted, not in having a rigid os uteri to deal with, but the entire cervix had to be expanded, dilatation of the os internum constituting the chief difficulty. The author discussed the question whether craniotomy alone, or dismemberment and exvisceration of the fœtus, is the best for such a case.

Dr. J. MARION SIMS read a paper on

PROCIDENTIA UTERI.

He said that a procidentia was complete when the vagina was inverted and formed its outer covering—incomplete when the cervix only passed through the vulva; that a broad pubic arch, divergent rami, a relaxed perineum, and a retroversion, were essential to its production; that in some cases the infra-vaginal cervix was elongated, and came down first, but that in the majority of chronic cases a vagino-cystocele formed the first stage of procidentia. For the first he advocated amputation of the cervix, and said this was generally alone sufficient; but for the second he preferred to narrow the vagina. This idea, he said, originated with Marshall Hall; but he did not think the operation had ever succeeded till the introduction of metallic sutures. He then gave an account of the operation from the time he first performed it in 1857 till now, showing its gradual advancement to its present state of perfection. He illustrated the subject fully by diagrams. In 1857 he narrowed the anterior wall of the vagina by exsecting a large ellipsis of it, and then bringing the lateral borders together with silver sutures. Afterwards he simply denuded the surface of its epithelial membrane; then he simplified the operation by making a V-shaped scarification; and subsequently he made it trowel-shaped or triangular, the point being at the neck of the bladder, and the broad portion in juxtaposition with the cervix uteri. In all these methods, the object was to remove the cystocele, and afford a support to the parts just at the anterior cul-de-sac. By diagrams he illustrated the method of operating, and claimed for it, when properly done, the greatest success. He did not pretend to institute a comparison between this and the perineal operation for the same trouble; but he had been driven to work out this plan in consequence of having often failed with the other. He only wished to add another resource to our means of curing such a disgusting infirmity, for we now had three methods: 1st, amputation; 2nd, the perineal operation; 3rd, the narrowing of the vagina, as advocated by him.

Mr. NUNN stated that he had on several occasions operated for prolapsus uteri after the plan recommended by Mr. Baker Brown. In most of the cases a partial rupture of the perineum had existed. In them the result of the operation was satisfactory on the whole. Where no rupture of the perineum existed, as in young women who had never borne children, Mr. Brown's operation failed. He also stated that he had himself adopted, and had also seen Mr. Brown on many occasions practise, a proceeding *somewhat* resembling that described by Dr. Sims—namely, the removal of a V-shaped portion of the mucous membrane of the vagina reaching from the fourchette to within an inch or so of the cervix, the difference being that this removal was made from the posterior instead of the anterior or vesical wall of the vagina.

Mr. SPENCER WELLS said that the operation suggested by Dr. Marshall Hall had been performed many years ago in London. He (Mr. Wells) had seen two ladies upon whom it had been performed by the late Dr. Hemming, of Kentish-town.

Mr. CHAMBERS regarded Dr. Sims' proposal as a valuable contribution to female Surgery; but, in common with Mr. Baker Brown, he (Mr. Chambers) had for years past combined the two operations in cases requiring such a procedure, and he felt bound to say that the anterior operation, as performed by Mr. Brown, was a very simple one when compared with Dr. Sims'.

Dr. WYNN WILLIAMS remarked that, as regards the success of the operation performed by Mr. Baker Brown, he had met with several cases, and he must say that the patients appeared to him to have been but little benefited by the operation. He recommended a pessary, which acts by making tense the mucous membrane reflected from the vagina to the uterus, the uterus being suspended between the blades of the pessary.

Dr. WILKINS, of William's Town, Australia, stated that he had operated on two cases of procidentia uteri, following closely the method of Mr. Baker Brown as described in his book. Permanent success had followed the operation, even though one of the cases had been of twelve years' standing. Dr. Tracey, of Melbourne, has also operated on several cases, and he believed with similar results.

The PRESIDENT said he had himself performed Mr. Brown's operation several times. He had found prolapsus return in spite of the provision of a good perineum. Further, he had repeatedly seen the uterus remain *in situ* notwithstanding large perineal luxation. It seemed to him that Mr. Brown's operation was performed in the wrong place. It had no effect in providing support where it was wanted—namely, anteriorly, at the connexion of the cervix uteri with the base of the bladder. This object seemed to be perfectly accomplished by the admirably reasoned-out and ingenious operation of Dr. Sims.

Dr. SIMS, in reply, said that no one method of operating could be applicable under all circumstances to all cases. If there was a lacerated perineum it was proper to restore it. If there was elongation of the infra-vaginal portion of the cervix, then the proper operation was amputation of the cervix, and this was probably all that was necessary in such cases. In the majority of cases of procidentia—in all those where a vagino-cystocele formed the first stage of descent—he was

satisfied that the operation he had described—viz., that of narrowing the vagina by forming a longitudinal fold of its tissue on the anterior surface, reaching from the neck of the bladder to the neck of the womb—would be one of the safest, simplest, and best.

MEDICAL NEWS.

KING AND QUEEN'S COLLEGE OF PHYSICIANS IN IRELAND.—Licentiates in Medicine admitted in October, November, and December, 1865 :—

James Thomas McMahon, Thorney, Cambridgeshire, October 5; Thomas Bernard Ryan, Nelson-street, Tipperary, October 10; William Westropp Brereton, 65, Fitzwilliam-square, October 10; Arthur Croker, General Hospital, Phœnix-park, October 28; John William Jones, Bangor, North Wales, October 31; Mark Anthony Kilroy, 10, Upper Gloucester-street, October 31; John Randal Croker, 37, Lower Dominick-street, November 25; Francis Sparrow Risk, 7, Richmond-place, Brighton, December 6; Stopford William Halpin, Arklow, December 7; Thomas William Patterson, Letterkenny, December 7; Edward Alfred Birch, 5, Castlewood-terrace, Rathmines, December 19; John Mallet Purser, 32, Hardwicke-street, December 19; William Hay Maturin, Gartan Glebe, Letterkenny, December 21; William Rhys Williams, Bethlehem Hospital, London, December 28; Lennox Robertson, Newport, Monmouthshire, December 28.

Licentiates in Midwifery admitted during the months of October, November, and December, 1865 :—

James Thomas McMahon, Thorney, Cambridgeshire, October 5; Thomas Bernard Ryan, Nelson-street, Tipperary, October 10; William Westropp Brereton, 65, Fitzwilliam-square, October 10; Arthur Croker, General Hospital, Phœnix-park, October 28; William Duncan, Savannah, Georgia, U.S., October 28; Richard Malcolm Graham, Clonmel, November 8; Daniel Ambrose, Loughill, Co. Limerick, November 8; Francis Sparrow Risk, 7, Richmond-place, Brighton, December 6; William Thomas Greene, 2, Carlton-terrace, Rathmines, December 9; Stopford William Halpin, Arklow, December 7; Thomas William Patterson, Letterkenny, December 7; John Mallett Purser, 32, Hardwicke-street, December 19; Andrew Richard Cowell, Miltown, Co. Dublin, December 21; Lennox Robertson, Newport, Monmouthshire, December 28.

ROYAL COLLEGE OF SURGEONS.—The following gentlemen have just passed their Preliminary Examination in General Knowledge, conducted by the College of Preceptors under the superintendence of the authorities of the above institution, viz. :—

Robert Argles, A. J. Atkinson, Cornelius Biddle, H. B. Blackburn, C. P. Bellamy, H. G. Biggs, W. W. Cooke, C. C. Connon, T. L. Close, W. J. Daniel, G. R. Dawson, Walter Date, T. J. Dixon, F. H. Drake, D. W. Duke, H. G. Dyer, N. E. Davey, W. W. Dove, Alfred Edwards, Ralph Floyer, A. G Greenway, William Greaves, J. A. Horsford, William Hugman, W. S. Hughes, W. S. Holroyd, William Hodson, Charles Jervis, H. T. Jones, C. R. B. Kutley, J. D. Lloyd, Arthur Lattey, T. J. Lidbetter, Jonathan Lamplugh, H. C. Martin, Charles McCann, G. A. Menzies, S. S. Noakes, T. J. Ollerhead, F. J. Parson, R. F. Palmer, G. S. Payne, H. G. Peacock, M. H. Payne, T. J. Preston, L. L. Powell, W. G. Ranger, Edward Roe, Frederick Robertson, J. B. Slater, G. A. Slack, A. F. Simkins, F. H. Spencer, Richard Snagg, W. M. Turner, Philip Thornton, F. E. Thurland, Edwin Tipple, W. P. Thornton, E. G. Whittle, and W. P. Yates.

There were thirteen gentlemen referred back to their studies. The ages of the seventy-five candidates varied from 16 to 28 years.

NEW FELLOWS.—The following Members of the Royal College of Surgeons, having been elected Fellows at previous meetings of the Council, were admitted as such on the 11th inst. :—

William Allard, Tewkesbury, Diploma of Membership dated April 12, 1839; Henry Sharp Taylor, Guildford, Diploma of Membership dated June 12, 1840.

APOTHECARIES' HALL.—Name of the gentleman who passed his Examination in the Science and Practice of Medicine, and received Certificates to Practise, on Thursday, January 4, 1866 :—

Horsley Thomas Mapleson, 34, Devonshire-street.

APPOINTMENTS.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

BISHOP, Mr. W., has been elected Dispenser to the Western Dispensary, Broadway, Westminster.

GREEN, EDWIN S., L.R.C.P. Edin., has been elected Resident Medical Officer to the York Dispensary.

GROSVENOR, A. O., M.D., has been appointed House-Surgeon to the London Surgical Home for Diseases of Women, Stanley-terrace, Notting-hill.

JONES, EDWARD S., L.R.C.P.L. has been elected House-Surgeon to the Weston-super-Mare Hospital and Dispensary.

MCWHINNIE, ANDREW M., F.R.C.S. Eng., has been appointed one of the Surgeons to the Hospital for Diseases of the Skin, Blackfriars.

PEARCE, FRANCIS D., M.R.C.S. Eng., has been appointed Honorary Assistant Surgeon to the 26th (Kingsbridge) Devon Rifle Volunteer Corps.

PROPERT, Mr. J. LUMSDEN, has been appointed Surgeon to the A Division of the Metropolitan Fire Brigade.

ROBERTS, JOHN C., L.R.C.P. Edin., has been appointed one of the Surgeons to the Dispensary, Peckham-rye.

SMITH, C. H., M.R.C.S. Eng. has been appointed Assistant-House-Surgeon to the General Dispensary, Sheffield.

SNOOK, JAMES W. M.R.C.S. Eng., has been elected Resident House-Surgeon to the Bradford Infirmary and Dispensary.

THOMAS, Mr. W., has been elected Resident House-Surgeon to the Bradford Infirmary and Dispensary.

VEITCH, A., M.D., has been appointed Resident-Surgeon to the Birmingham and Midland Counties Lying-in Hospital and Dispensary for Diseases of Women and Children.

WEBSTER, GEORGE, M.R.C.S. Eng., has been appointed one of the Surgeons to the Dispensary, Peckham-rye.

WRIGHT, EDWARD S., M.R.C.S. Eng., has been appointed Surgeon to the Great Eastern Railway Provident Society.

BIRTHS.

ANDERSON, Dr. MCCALL, the wife of, at 1, Woodside-crescent, Glasgow, on January 5, of a daughter.

BOURBOUCHAKI, Dr. J. N., the wife of, at Boulogne-sur-Mer, on January 4, of a son.

BROWN, Dr. FREDERICK J., the wife of, at Rochester, on December 31, of a daughter.

COCKELL, F. E., M.R.C.S. Eng., the wife of, at Dalston, on January 1, of a daughter.

DAVIE, M.D., Assistant-Surgeon G. S., the wife of, at Perth, on December 30, of a daughter.

EDWARDS, H. I., M.R.C.S. Eng., the wife of, at Bampton, Devon, on December 29, of a son.

HODGES, H. B., M.R.C.S. Eng., the wife of, at Hertford, on December 28, of a daughter.

JONES, M.D., JOHN E., the wife of, at Brynffynon, Dolgelley, N. Wales, on December 29, of a daughter.

MACILWAIN, GEORGE, F.R.C.S., of Albany Courtyard, the wife of, at Matching-green, Essex, on January 6, of a son.

PALFREY, Dr., the wife of, at 25, Finsbury-place, E.C., on January 7, of a daughter.

SANDERS, HENRY S., Surgeon 49th Regiment, the wife of, at Notting-hill, on January 3, of a daughter.

SPURGIN, F. W., M.R.C.S. Eng., the wife of, at Sidmouth-villa, Hammersmith, on December 30, of a son.

SWAIN, ISAAC H., M D., the wife of, at Shaftesbury, Dorset, on January 6, of a daughter.

MARRIAGE.

LONEY—LUKE.—January 9, at St. George's, Hanover-square, Dr. Wm. Loney, R.N., Staff Surgeon H.M.'s Hospital, Haulbowline, to Margaret Rose, eldest daughter of the late Henry Luke, Esq., of Exeter.

DEATHS.

GUEST, EDWARD, F.R.C.S. Eng., at 20, Halsey-street, Chelsea, on January 4, aged 49.

HENRY, RICHARD, late Staff Assistant-Surgeon Royal Artillery, at Seacombe, Birkenhead, on December 21.

MCKEE, WILLIAM, L.R.C.S. Edin., at Wesley-street, Liverpool, on Decem- 22, aged 72.

SISSON, ANDREW, M R.C.S. Eng., at Reigate, Surrey, on January 4, aged 57.

POOR-LAW MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the last census.

RESIGNATIONS.

Bridgewater Union.—Mr. W. J. Bonnor has resigned the Chilton Polden District; area, 9230; population, 2447; salary, £43 per annum.

Derby Union.—Mr. John Lindley has resigned the First District; area, 937; population, 20,012; salary, £50 per annum.

Fulham Union.—Dr. C. M. Meller has resigned the Walham-green District; salary, £50 per annum.

Glandford Brigg Union.—Mr. Moxon has resigned the Kirton District; area, 11,672; population, 2593; salary, £30 per annum.

Plympton St. Mary Union.—Mr. Langworthy has resigned the Fourth District; area, 9720; population, 2748; salary, £25 6s. per annum.

Stroud Union.—Dr. Turner has resigned the Fourth District; area, 4894; population, 4147; salary, £61 per annum.

Tonbridge Union.—Mr. W. J. Procter has resigned the Sixth District; area, 7774; population, 2878; salary, £65 per annum. Also the Seventh District; area, 4500; population, 1385; salary, £35 per annum.

APPOINTMENTS.

Freebridge Lynn Union.—Joseph W. Barrett, M.R.C.S.E., L.S.A., to the First North-Western District.

Highworth and Swindon Union.—Alfred L. Griffith, M.D., M.R.C.S.E., L.S.A., L.M., to the Fourth District.

THE PARIS IMPERIAL SOCIETY OF SURGERY.—Out of forty-eight candidates, the Society has chosen the following ten foreign correspondents :—Donders, of Utrecht; Longmore, of Netley Hospital; Bilroth, of Zurich; Brown-Séquard, of Boston; Holmes, of London; Humphry, of Cambridge; Gurlt, of Berlin; Neudorfer, of Prague; Smith, of New York; and Emmert, of Bern.

THE BARONETCY OF PROFESSOR SIMPSON.—From the *Caledonian Mercury*, January 8 :—"We have very great pleasure in announcing that Her Majesty, recognising the valuable services of our fellow-citizen, Professor Simpson, in the advancement of Medical science, has offered that gentleman a baronetcy. In stating Her Majesty's intention, Earl Russell intimates that the distinction is a recognition of the Professor's many services to the science of Medicine, especially in the discovery and the application of chloroform, by which pain in Surgical operations has been alleviated and human life in consequence rendered more secure against disease. The honour thus sought to be conferred must be all the more gratifying to Dr. Simpson, as it was entirely unexpected, and, moreover, has never before been conferred on any member of the Profession practising in Scotland."—(From the *Daily Review*, January 9.)—"The announcement in yesterday's paper, which was received with so much gratification by the public, gave intense delight to the Professor's students. When Sir James made his appearance in his class-room yesterday, the students, taking leave to dispense with academical propriety on the auspicious occasion, rose from their seats *en masse*, and cheered vociferously. When the applause had subsided, Sir James briefly acknowledged the demonstration. He said that he could not affect to misunderstand what their congratulations meant. Of all congratulations in a case of this kind, those of his class were perhaps the most pleasant of any. The honour conferred had come upon him as a complete surprise. He felt almost ashamed that he should have been the individual selected by her Majesty to receive an honour intended for the whole Medical Profession ; and perhaps that honour ought to be regarded by him as all the greater, seeing that it was the first time a baronetcy had ever been given to a Scotch Professor or a practiser of the healing art in Scotland. As it had been given, among other things, for the advancement of Surgery, he would now proceed at once to the Surgical subject which was to form the topic of to-day. Sir James then proceeded with his prelection."

PRESENTATION TO DR. EDMUNDS.—On New Year's Day the Committee of the Victoria Benefit, Sick, and Provident Assurance Society presented Dr. Edmunds with a very handsome silver salver, accompanied by a tea and coffee set, and other articles of silver plate. The salver bore the following inscription :—"This salver, and other articles of silver plate, amounting in value to 100 guineas, was presented by the Victoria Benefit Society to James Edmunds, Esq., M.D., in recognition of his distinguished services and Professional skill as Physician to the Society.—London, Jan. 1, 1866."

MEDICAL CHARITIES.—The friends of the following institutions will be glad to learn that the late Captain John Sykes, of the Royal Navy, formerly of Bolsover-street, Portland-place, has bequeathed £100, free of legacy duty, to each of the following institutions, viz.:—The *Dreadnought* Hospital Ship, London University Hospital, the Royal Free Hospital, Gray's-inn-road ; St. Mary's, Paddington ; the Brompton Consumption Hospital, and £50, also free of legacy duty, to the Convalescent Hospital, Walton-on-Thames. The deceased also made liberal bequests to other institutions not strictly Medical.

LIBERAL BEQUESTS.—It always affords us great pleasure to chronicle the acts of charity conferred on our numerous Medical charities by benevolent individuals, one of whom, the late William Borradaile, Esq., of Worthing, has made the seasonable bequest of £2400 to the following provincial Hospitals, exclusive of large sums to other institutions not strictly Medical,—viz., £500 to the Sussex County Hospital, Brighton, and £100 each to the Infirmary and Dispensary at Wells, Somerset, and the same amount to the Infirmary and Dispensary at Worthing. The same gentleman has left £500 to each of the following metropolitan Hospitals,—viz., the Charing-cross, the Brompton Consumption, and the Seamen's Hospital *Dreadnought*, off Deptford.

CONVEYANCE OF CATTLE PLAGUE BY THE WIND.—Mr. J. A. Clarke, writing to the *Times* on the spread of the cattle plague says,—"Though conveyance of the pest by dogs, by birds, and vermin, and by other subtle agencies might probably be checked, or seldom found to work mischief, there remains carriage of the virus by the wind, against which a thickly-settled country like this, having a farmstead at about every half mile, must be utterly helpless. It is a well-observed fact that in this neighbourhood the pestilence has travelled with the gale, a homestead, in several cases, having been smitten immediately upon a near and infected homestead becoming situated to windward, while (as in my own case) the closest neighbourhood has not brought the pest as long as the wind blows contrary. Field grazing in the summer will, of course, present every facility for disseminating the disease ; brooks and ditches will form no sanitary barrier between healthy and infected animals ; and every hedge, bush, and tree-trunk may retain a store of the poison past all power of applied disinfectants to remove."

EXTIRPATION OF THE SPLEEN.—M. Philipeaux, in the present paper, refers to a communication he had made to the Academy of Sciences in 1861, in which he stated that the splcens extirpated from three Albino rats were found, on examination being made seventeen months afterwards, to be reproduced, the structure of the new organ being quite normal. M. Peyrani, however, having repeated these experiments came to the opposite conclusion that the spleen, whether totally or in part extirpated, is never reproduced. This led to M. Philipeaux experimenting again on very young field mice and rabbits, and then to his surprise he found that when the spleen was totally extirpated no reproduction took place. When, however, a portion of the organ was left behind (three millimetres out of sixteen in the field mice, and five out of forty in the rabbits) reproduction to a greater or less extent was always found to take place. He therefore concludes that in his former series of experiments he must have inadvertently left a portion of the organ behind, and that the spleen once completely extirpated will not be reproduced, although, perhaps, in some instances a supernumerary spleen may undergo development. He is, however, still at issue with M. Peyrani, and believes this author to be in error when he declared that a partially removed spleen is not reproduced.—*Comptes Rendus*, December 11.

THE following are the last week's Cattle Plague Returns. By comparison with those of the previous week, it will be seen that there have been 9956 attacked, 6630 deaths, 794 slaughtered, and 1242 recoveries, since December 23 :—

Census Divisions.	1. Attacked. Week ending December 30.	Week ending December 23.	Week ending December 16.	2. Result of reported Cases from the Commencement of the disease. Attacked.	Killed.	Died.	Recovered.	Remaining.
1. Metropolitan Police District	31	86	43	7238	3103	3263	284	588

ROYAL GEOGRAPHICAL SOCIETY.—M. Du Chaillu has returned to England, and made his appearance at the Royal Geographical Society on Monday last. He was exceedingly well received, and gave a very amusing account of his expedition. He stated that for the last two years he had no opportunity of speaking either English or French, and had, therefore, to claim the indulgence of the audience for any deficiency they might observe in his pronunciation, proceeded to read his papers. He left London on the 6th of August, 1863, and on the 9th of October in the same year he reached a point called Ferman Bay, on the African coast, immediately to the south of the Equator. He advanced eastwards to the Ashira country, where he had been on a former journey, and where he was well remembered and kindly received. He had many offers of marriage pressed upon him, but these he had respectfully declined. (A laugh.) In reading the works of Grant, Speke, and Burton he observed many words which were identical with and which closely resembled words used in the district he had traversed, and he had no doubt that the tribes of western and eastern Africa had formed originally one common stock. He had seen during his travels numbers of gorillas, and he saw nothing after his renewed experience to retract in the account he had already given of those animals.

(Cheers.) After he and his party had been about three weeks in Ashira a visitation of smallpox ravaged the country. Misery and destruction were spread on every side, and he was himself reduced to a most dejected and prostrate condition. He could not procure sufficient nourishment, and he and his eleven companions had upon one occasion nothing to eat for four days but two monkeys, and very agreeable food they thought them. (A laugh) He was ultimately enabled to continue his journey eastward, and in the course of those travels he met with a singularly diminutive race, their average height being only from 4ft. 4in. to 4ft. 5in. After he had advanced 200 miles further than any European had yet penetrated his undertaking was brought to an unexpected termination by an accident. He reached a village in which one of his men fired off a gun, and, contrary to his intention, two of the natives—a man and a woman—were thus unfortunately killed. The villagers became at once excited, and attacked himself and his party with their bows and arrows. He could not blame them for the suspicion and irritation under which they acted, and he, therefore, forbade his men to fire on them. He then ordered his followers to retire, which they did, at first in good order, while he himself remained in their rear, as he believed he was in a less degree than they an object of resentment to the excited natives. A panic, however, soon seized his party; he found it impossible to check them; they threw away all the articles which they carried; he himself felt compelled to join them in their flight and to part with many of the most valuable things which he had in his possession. The result was that, although his men energetically rallied, he lost all his instruments as well as his ammunition, and all that could have enabled him to continue his journey with advantage. He at once, therefore, retraced his steps westwards, and immediately afterwards made his way back to England. M. Du Chaillu concluded his address by expressing his gratitude to Sir R. Murchison and to Professor Owen for the support he had received from them throughout his labours, and amid all the opposition with which he had to contend.

THE WEATHER AND THE DEATH RATE.—The following is an extract of a letter on the weather of 1865, by Mr. Plant, of Birmingham:—"A prevalence of temperature under 40 degrees increases our average death-rate to a most serious extent. In the thirteen weeks ending April 1 cold weather alone increased our death rate 25 per cent. Immediately, however, the mean temperature recovered, then the mortality recovered its average. This is illustrated by the following table, and it also explains that the public health does not materially suffer by excess of heat:—

Mortality in the Six Large Towns in England.—Rate of Deaths per Annum of every Thousand Persons Living:—

	Per Week per Thousand of Population. Highest.	Per Week per Thousand of Population. Lowest.
13 weeks ending April 1. Mean temperature 36°.	40·9 Liverpool & Manchester	25·5 Salford, Birmingham, Bristol, and London.
6 weeks ending May 27. Mean temperature 55½°.	30·7 Liverpool.	19·2 Birmingham & Bristol.
13 weeks ending July 1. Mean temperature 55½°.	33·2 Liverpool.	18·4 Birmingham & Bristol.
2 weeks ending Sept. 16. Mean temperature 66½°.	33·5 Liverpool and Salford.	19·7 Bristol.
6 weeks ending Oct. 7. Mean temperature 60°.	33 9 Liverpool, Manchester, and Salford.	19·3 London and Bristol.

"Leeds was not found in either the highest or lowest mortality. The difference of mortality between the three months ending April 1 and the quarter terminating July 1, is represented by the returns from Liverpool and Manchester, 40·9 and 33·2; and the other town named 25·5 and 18·4; the mean temperature for the respective quarters being 36 deg. and 55½ deg. The hottest period in the last six years was the fortnight ending September 16—mean, 66½ degrees; but it made no important change in the public health; indeed, the range in the healthiest towns for the six months, from April to October, was altogether immaterial. On the average (per annum), in every thousand persons living, twelve to fifteen more persons die every week in Liverpool than in Birmingham or Bristol. There is an average weekly rate of mortality in Liverpool of thirty to thirty-five per cent. beyond Bristol. Unless the high rate of mortality in Liverpool is from overcrowding, I am at a loss to divine the cause. In the six weeks ending July 1, for every eighteen persons who died in each week in every thousand of the living population (per annum) in Birmingham, there died thirty-two persons, on the average, in Liverpool, and the like number in Manchester. In the four weeks ending May 6, for every twenty-one persons who died in each week in Bristol, in each thousand of persons living, (per annum), thirty-two died in Liverpool; and in the six weeks ending November 18, the disproportion was represented by twenty and thirty-nine. It matters not what is the relative disproportion of population; the rate, of course, is all that is required. Bristol stands at present the healthiest of the six large towns. Birmingham is the next, and London ranks the third in pre-eminence. Satisfactory as the public health of Birmingham is, if the municipal authorities would arm their Medical officer, Dr. Hill, with power to receive each week the death returns of the borough in detail, so that he might at once carry into effect every sanitary improvement which such important information would present to him—if he were thus provided, like Dr. Letheby, the Medical officer for the city of London, where the most dense population in the world is still a healthy community under his sanitary supervision, there is no reason whatever why Birmingham, situated so favourably on an elevated sand bed, and the borough standing on more ground than Manchester, which has a population one-third larger, should not be the healthiest of all our large towns. The mortality of Manchester is very great, and I understand there is no special Medical officer for that city. I am, Sir, your obedient servant, THOMAS L. PLANT, M.B.M.S. Birmingham, December 31, 1865."

THE MURDERER ROBINSON. — Charles Christopher Robinson was executed on Tuesday, at Stafford. There was far more evidence of his insanity adduced at his trial than has been brought forward in the cases of many who have been respited. The convict, however, is said to have admitted the justice of his sentence before his execution.

THE FIFESHIRE CAVES.—At the meeting of the Royal Society of Edinburgh on Tuesday evening, Lord Neaves presiding, Professor Simpson gave an account of the visits paid by him last summer, along with other eminent Scottish antiquaries, to the caves on the coast of Fifeshire, at East Wemyss. There were, he said, eight or nine of these caves, and on the walls of most of them they had found sculptured symbols almost identical with those found upon the sculptured stones of Scotland. These sculptured stones were found along the east coast, running northwards from Fife, only two having been discovered south of the Forth. They were for the most part monoliths, and the symbols had hitherto been supposed to possess a sepulchral character, an idea which was not, he thought, consistent with the circumstances that the very same emblems were now found inside these caves, which were the abode of man in his archaic condition. In these caves they found representations of the elephant, the horse, the dog, with collar round his neck, exactly like those found in the sculptured stones. They had also the bear, the deer, the swan, the peacock, the fish, the serpent; also the comb and mirror, the spectacle ornament, the horseshoe, etc. Mr. Stewart discovered something like a human figure in one of the caves, provided, as Lord Monboddo would have our ancestors, with tails, and perhaps constituting the missing link for which the Darwinians were searching. They had in some cases the symbols of Christianity. As to the age of these stones, he believed Mr. Stuart would throw great light on that point in his forthcoming volume; but it was a remarkable circumstance that these symbols, first found on the sculptured stones, and now on these caves, had not hitherto been discovered in the sculptured stones of any other country, so far as they had learnt. Some of them were evidently pre-Roman, while the series continued down to the time of Christianity. The cave sculptures, he had no doubt, were coeval with the monoliths. They found crosses on them in considerable numbers, sometimes the cross standing on a tripod, and in one case they had the cross and tripod inverted. For himself, he had come to no conclusion as to what was the purpose of these carvings, for he thought their supposed sepulchral character was taken away by the position in which they were found. As Dr. Mitchell had found, there were even yet families in Scotland who lived in caves, on the Galloway coast, and they had recently had the description of the district of Charteris, in France, where about 150,000 people still lived in caves. No doubt caves formed a very good shelter for man in his rude state—much better, perhaps, than anything he could construct for himself. In some of these caves had been found the stone weapons in use before man had metallic tools to work with, and at the time

when animals which now had no existence were walking over France and England in great abundance. It was a curious circumstance that in Gray's-inn-fields, now the very centre of London, there had lately been discovered the skeleton of an elephant, and near it a flint hatchet of the same form that was found on the courses of the French rivers, the Sâone and Loire, showing that over the site on which London now stands the early Briton had hunted the elephant, and at a time when the British lion was a reality and not a myth. When they looked into this subject it seemed that they were only at the beginning of it. They must yet examine the whole surface of many caves in this and other countries to see if man had left any such traces as those they had discovered in the caves of Fifeshire. Lord Neaves expressed the thanks of the Society to Professor Simpson. He said he felt it of great importance that there should be accurate observation of the facts regarding these remarkable symbols, of which the secret yet remained to be discovered. How far any of the symbols they had met with were to be considered as Phœnician was a question of some difficulty. The Phœnicians had certainly visited the southern parts of England; but the subject was involved in great obscurity, and they ought gladly to receive all who contributed to the ascertained facts. In the present instance they felt under the greatest obligations to Professor Simpson and the ardent antiquaries with whom he had been associated in his inquiries,

The late Mr. Anderson, of the Royal Institution.—Visitors to the lecture theatre of the Royal Institution will miss one familiar face this season—Charles Anderson. Mr. Anderson, who always stood behind Faraday, and handed him the various apparatus, and assisted in the experiments with such precision and coolness, is now numbered with the departed. The deceased was a good instance of a steady course of sobriety, punctuality, and attention to duty. He was born in Edinburgh in 1790, was very early left an orphan, and enlisted in the Royal Artillery, in which he gradually rose to the rank of Sergeant, and retired in 1827 with the best testimonials, after twenty-two years' service at Gibraltar and other parts of the world. He then became Chemical Assistant at the Royal Institution. How greatly his services were appreciated may appear from the following extracts, which the old man caused to be printed for circulation amongst his friends :—

"Royal Institution, 21, Albemarle-street, 1828.

"*First Report* of a sub-Committee, consisting of Messrs. Dolland, Faraday, and Herschall, appointed to conduct the experiments on glass for optical uses at the Royal Institution.—To the General Committee of the Royal Society and Board of Longitude.

"For the maintenance and superintendence of the fire, and for the execution of other manual operations, your sub-Committee has engaged Charles Anderson, formerly Sergeant in the Royal Regiment of Artillery, at the moderate pay of one guinea per week, and find in him in all respects what they could desire, and likely to prove useful, not merely as a labourer, but for a variety of purposes of a higher class—an expense which they doubt not will meet the sanction of the Committee.

"*Second Report.*

"The assistant, Sergeant Anderson, engaged by the sub-Committee, has fully justified their choice, and has proved a useful and valuable servant, not only in mere mechanical processes, but in taking specific gravities, keeping notes of the processes which pass under his immediate inspection, in addition to those made by Mr. Faraday as journalist of the sub-Committee—writing up entries in the minute-book, and, in fact, performing the duties of a clerk.

"1830. Philosophical *Transactions*, page 3, Mr. Faraday says, in his paper on Optical Glass :—

"'A room and furnaces were built at the Royal Institution in September, 1827, and an assistant was engaged (Serjeant Anderson, of the Royal Artillery), whose steady and intelligent care has been of the greatest service to me in the experiments that have been proceeding constantly from that time to the present.'

"1846. Philosophical *Transactions*, in a Note, page 3, Mr. Faraday says :—

"'I cannot resist the occasion which is thus offered to me of mentioning the name of Mr. Anderson, who came to me as an assistant in the glass experiments, and has remained ever since in the laboratory of the Royal Institution. He has assisted me in all the researches into which I have entered since that time, and to his care, steadiness, exactitude, and faithfulness in the performance of all that has been committed to his charge, I am much indebted.'—M. F."

These were followed by numerous testimonials "In recognition of the integrity, zeal, punctuality, diligence, and devotedness to the service of the Institution uniformly manifested by Mr. Anderson during a period of twenty-one years." Like many other active men, Anderson died in harness. He attended Professor Tyndall's first juvenile lecture in the week after Christmas, but that was his last appearance. The history of Mr. Anderson, who rose from a humble position to one of great trust and importance and responsibility, and fulfilled its duties so as to gain the respect of the most scientific men of the day, may be an encouragement to many an industrious young man.

Action of Absinthe on the Economy.—A discussion on the innocence or danger of absinthe *per se* having taken place between MM. Deschamps and Decaisne at the Académie des Sciences, M. Pécholier communicates the result of the investigations which he has been carrying on for the last two years at some of the absinthe manufactories. These have convinced him that the absinthe contains no hurtful substance whatever beyond the alcohol which is its vehicle. The various juices and essences are added by the manufacturers in such proportions only as to be completely inoffensive in the results they produce; and yet absinthe drinkers seem to be justified in the assertion that, taken in the same quantity and in the same degree of alcoholic concentration as brandy, it exerts much more marked and rapid effects on the economy. This is explained by M. Pécholier by the fact that absinthe is generally taken fasting, when the stomach is empty, and consequently it undergoes much more rapid absorption. Of course, a quantity of alcohol which passes rapidly and almost all at once into the circulation produces much more effect than the same amount which is so gradually absorbed that a portion has become already destroyed and eliminated. The intoxication produced by absinthe takes place very rapidly, and ceases as promptly if additional quantities are not taken. The conclusion of the author is, then, that the more energetic effects of absinthe as compared with alcohol are not due to its composition, but to its mode of consumption.—*Journal de Pharmacie*, November.

Prison Dietaries.—The following extract from the "Report of the Directors of Convict Prisons for the Year 1864" (p. 11) must be very gratifying to those who have been in any way instrumental in bringing about so considerable a reform:—"The actual saving during the year in the estimated expenditure for rations for the convicts was £22,581 13s. 6d., the reduction of the dietary having taken place in July. There has been a saving on the estimates for the present year as compared with last year of £25,834 on the item of victualling convicts." This saving, it should be observed, is effected on the dietaries of about 7000 convicts. The authorities of the county and borough gaols, by adopting the new dietaries, which are understood to have been very successful wherever they have been introduced, might add to this sum of £25,000, saved in the convict service, a still larger aggregate sum for the whole of England and Wales. If the new dietaries were in use throughout England and Wales, a saving of not less than from £65,000 to £75,000 a-year might be effected in the food of all classes of prisoners. Taken at the very moderate estimated saving of £50,000 a-year, the old dietaries, which have been in force nearly a quarter of a century, must have cost the nation upwards of a million of money. The printed reports from one of our county gaols bear testimony to the perfect success of the new dietaries. They effect a considerable saving, they keep the prisoners in good health, and they are so unpopular with these folk that they declare their intention of not troubling the authorities of said prison any more. We commend these facts to the serious attention of the visiting justices of all our county and borough gaols.

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

J. W., M.D.—The subject of Professor Hancock's lectures will, we are told, be advertised in this journal next week; it is stated they will be on the Anatomy and Surgery of the Foot, but Professor Huxley will commence the Course of College Lectures.

Dr. Handfield Jones's concluding lecture on "Nervous Diseases" shall appear next week.

Dr. E. Watson's letter has been received, and shall appear shortly.

Aliquis.—Dr. Jeffery Marston, Royal Artillery, Portsmouth.

A Constant Reader.—Medical Register Office, 32, Soho-square, London.

J. H. G.—Messrs. Lawrence and Cæsar Hawkins are the Serjeant-Surgeons to the Queen.

P.—A committee of inquiry *must* be appointed on the Hong-kong affair. It will then be seen whether the Doctors were to blame.

The *Rowing Almanack* for 1866 is a most useful compendium of information on aquatic subjects, but we are sorry to see it disfigured by an advertisement which smacks of the "Manly Vigour" school.

M. H. and a Student.—The list is published in another column. You can both enter on your Hospital studies at once, and thus save half a session, taking care to register in March next.

Associate, King's College, Clapham-road.—Make your applications to Mr. Francis Mason, F.R.C.S., of Conduit-street; he is the honorary secretary to the testimonial to Sir Wm. Fergusson.

G. P. R., M.D., and W. D. S., M.D.—The testimonial will be confined to the past and present pupils of the distinguished Surgeon. The first correspondent is answered above. The second can organise an independent testimonial.

A Hospital Surgeon.—It is a rare operation. Œsophagotomy has only been performed twice in this country; the first by the late Dr. Scott, of Southsea, and the second by Mr. Cock, of Guy's. A case is recorded in an early volume of the Memoirs de l'Academie Royale de Chirurgie de Paris.

A Candidate.—It is stated that great alterations are about to be made in the examination for the Fellowship of the College of Surgeons; not, it is hoped, by lowering the standard.

Erratum.—In Dr. Jencken's letter on Cattle Plague, page 28, line 29, *for* "wells," *read* "walls."

Voting by Proxy.—In continuation of the tables which have already appeared in the *Medical Times and Gazette* on the above subject, it is believed that the following analysis will add to the interest taken in the subject by a large number of the Fellows of the Royal College of Surgeons, and more especially by those members of the British Medical Association who discussed the subject at the last meeting of that institution. It appears that, at the thirty-third annual meeting of the Association, held in Leamington in August last, there were present 229 members, of which number 53 were Fellows of the College, viz., 13 by examination and 40 by election. Of the above number who attended the annual election of Fellows into the Council of the College of Surgeons on July 6 of the same year, the numbers of the examined and elected Fellows were nearly balanced, though still in favour of the former, viz., 7 by examination and 19 by election, making a total of 26. There are 2394 members of the British Medical Association, of which number 375 are Fellows of the College, viz., 95 by examination and 279 honorary and elective. Of the former who voted at the last July election, there were 58, of the latter 77. Consequently there were 241 who did not attend, viz., only 39 of those by examination, and as many as 202 of those by elections.

Diphtheria.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—Can any of your readers inform me the safest and best practice in diphtheria, which almost takes off every child it attacks in this country?

California. I am, &c. Inquirer.

The Griffin Testimonial Fund.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—The following subscription has been further received on behalf of the above fund:—Dr. Hutchinson, Bishop Auckland, 10s.; amount previously announced, £132 4s. 3d.; received at *Lancet* office, £9 9s.

I am, &c.

Robert Fowler, M.D., Treasurer and Hon. Sec.

145, Bishopsgate Without, January 10, 1866.

Recurrent Swelling of the Tongue.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—Allow me to ask your numerous and learned readers for some enlightenment in the following case:—A gentleman, 63 years old, a scholar, with sedentary habits, very moderate smoker, fond of snuffing, with rather atonic colon and rectum, but healthy stomach, found himself several times waked up from his sleep by a swelling of the tongue, which is so considerable that the mouth gets nearly filled by it, and articulation impossible. After a few hours the swelling is over, and only some redness remaining; no pain. I am, &c.

London, January 10, 1866. Inquirer.

The Effects of Alcohol on the Blood and Tissues.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—May I ask you to be so kind as to allow me, through the medium of your columns, to inquire how Dr. H. Bence Jones arrives at the conclusion that the result of the introduction of alcohol into the blood is increased oxidation of the tissues of the body, and especially of the connective tissue of the liver and kidneys? Dr. Bence Jones says that, "weak or strong it combines with oxygen;" which there is no reason to doubt, since it is precisely what occurs in the combustion of alcohol in the presence of free oxygen, carbonic acid and water being the resulting products. It would therefore appear that the effect of this chemical process on the blood, and through the blood on the tissues and secretions, would be to deprive them of a portion of the oxygen which they would otherwise receive, but which is expended in oxidising the alcohol. If this be true, suboxidation, not peroxidation, of the tissues would be the result; and the conditions which Dr. Jones ascribes to increased oxidation—namely, "increased circulation, increased secretion, and increased effusion of lymph"—must be accounted for by some other cause than that assigned to them in Dr. Jones's lecture. Altered nutrition would, doubtless, be produced, and would probably be sufficient to induce all the other morbid changes which occur.

The importance of attaining an accurate knowledge of the causes which localise diseases, which experience proves to be so frequently produced by a substance so widely employed as alcohol, is, I trust, sufficient apology for my trespassing on your valuable space. I am, &c.

London, January 10, 1866. Physiologist.

The Treatment of Constipation.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—The report of "Three Cases of Constipation" in your last number, induces me to send you the particulars of one resembling them in its obstinacy, though in many points different, and relieved by other means. The patient was a very spare woman, aged 55 years, with a complexion remarkably sallow, though her health was usually good. She reminded me, however, that I attended her three years and a half before for inflammation of the bowels. Whilst gathering peas in the field, on July 15, 1864, she was seized with severe pain in the lower part of abdomen and back; afterwards vomiting occurred at intervals; but the following day it became incessant. The bowels acted. The message coming in the night, and her home being three miles away, I prescribed for the vomiting alone, that being the symptom most dwelt upon by her husband. On the 17th—the day following—I found but little pain in the body, and no pyrexia. The vomiting, however, was constant, and the matter ejected bilious. There was no hernia. I gave her an emetic and calomel with opium, one dose.

On the 18th, the unrelieved vomiting had caused some prostration; bowels not opened.

20th.—Vomiting constant and stercoraceous; hiccough persistent; a little tenderness on pressure exists in left lumbar region near its inner margin; the bowels roll incessantly, causing a griping pain; the whole abdomen is tympanitic except in left iliac region, in which part is decided dulness, and a lump as large as one's fist. I could trace no history of organic mischief, and learnt that the bowels were generally healthy in their action.

To-day the symptoms of exhaustion were pressing, the pulse being thready and weak. Brandy was given, and a grain of opium every four hours. I exposed the body to cool air, and sprinkled upon it cold water, without benefit. About noon she had an enema of castor oil and turpentine, and after a time, one of soap and water; but no stool followed.

21st.—Vomiting less stercoraceous. The enema has brought away much flatus. Continue the pills.

22nd.—No relief to bowels; the flatus still passes; the rolling distresses her much, but the other symptoms are less severe; the tendency to sink is decidedly less. Continue the pills.

23rd.—Stercoraceous vomit; flatus passes, but no fæces. Besides three or four warm water enemata, I ordered one containing half a drop of croton oil in mucilage; it was, however, useless.

24th.—Her state being the same, at 11 a.m. I passed an O'Beirne's tube into sigmoid flexure of colon, and threw up the same dose of croton oil. As the enema was slow to return, I advised the tube to be kept in the bowel twelve hours.

At 4 p.m. some fæces came away, and still more did so after soap and water had been injected. A fair motion, though not a copious one, was thus secured. All her symptoms quickly left her, and on the following day, I found the lump wanting, and the whole abdomen free from tympanitic sound.

On the 26th, the bowels acted freely, after which time she slowly recovered strength. I would, moreover, take this opportunity of mentioning the good result afforded by the internal use of tannic acid in a case of hæmoptysis from cancer of the lungs. All other styptics had failed; but gallic acid and tannin in equal parts (gr. ijss.) every hour, gave speedy relief; and the raspberry sputum, which under the microscope showed more cancer cells than blood globules, has for the past fortnight ceased.

I am, &c.,

Collingham, Newark, Dec. 30. E. G. Wake, M.D.

Promotion by Selection.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—Whether the Medical Department of the Army is to form a general staff or not, promotion through all its grades should be strictly regulated by seniority, as in Artillery and Engineers. Whatever may be Sir James Gibson's opinion now, a reference to the Blue Book will show that his evidence before the former Commission was to this effect, and on that occasion he gave expression to the general desire and feeling of the department.

In order to qualify a Director-General to promote by selection, he ought to be intimately acquainted with the relative merits and endowments of six hundred Surgeons scattered over the world, many of whom he has never seen. How would Artillery and Engineers relish the practice of pitchforking a junior second Captain into the rank of Lieutenant-Colonel, for some alleged superiority or accidental distinction? Yet promotion to the grade of Deputy Inspector-General is made from the entire number of Surgeons and Surgeons-Major by selection for so-called merit and ability. That is, a Surgeon happens to be at a station where there is a negro rebellion, a rising of the aborigines, or a visitation of yellow fever. He writes a long report, gets recommended by the General commanding, and attains administrative rank and position *per saltum*. Now if this system of promotion for merit has worked beneficially for the public and the department, its blessings ought to be extended to the scientific corps of Artillery and Engineers. Even with the best intentions, an able and upright Director-General cannot do otherwise than inflict great injustice on individual officers, and confer a very questionable benefit on the State, by exercising this practically irresponsible power of selection, and if he is pliant and compressible, a wide aperture is afforded for the agency of influence and solicitation. Shut this door, and one main cause of wide-spread discontent among Surgeons will be extinguished, viz., the uncertainty of promotion. Senior Surgeons who have served long and faithfully in every climate look for promotion in their turn to the rank of Deputy-Inspector as their just and natural right—and bitter is the feeling of dissatisfaction when that for which they have long looked and laboured is conferred on a lucky junior who owes his premature advancement to accident or influence, rather than merit or ability. Medical officers would acquiesce in selection, if thereby the worthiest were promoted; but as this has not been the case, and cannot

possibly be—owing to the inherent difficulties attending the appreciation of relative merit in a body of officers so numerous and widely scattered—the operation of selection must necessarily be as injurious to the public as detrimental and disheartening to the department. Surgeons will, as heretofore, take the earliest opportunity of retiring from a service where promotion is a lottery, and where the long and faithful performance of duty does not with certainty lead to promotion. Every man ought, *quamdiu se bene gesserit*, to attain promotion in his turn, as in Artillery and Engineers, and the advantages to the public service and to the department attending promotion by seniority far outweigh the specious and imaginary benefits ascribed to selection for so-called merit and ability, which is a sham and a delusion. But, it may be asked, is merit not to be encouraged? Are Medical officers who have distinguished themselves not to be rewarded? By all means. If an Assistant-Surgeon or Surgeon, has deserved well of his country, let him not be pitchforked over the heads of his seniors, and thus rewarded at their expense. If he has signally served the State, let him be rewarded by the State, which can readily be done without injustice to others, by conferring brevet rank; the pay and privileges of the superior grade with honorary distinction or decoration. The Director-General can also appoint a meritorious officer to staff or regiment, to Artillery or Engineers, and possibly to this or that station at home or abroad, and thus in various ways advance the views and interests of the deserving, without promoting them over an indefinite number of seniors, a proceeding which never fails to arouse deep and wide-spread discontent. I am, &c.,

A Regimental Surgeon.

COMPOSITION AND QUALITY OF THE METROPOLITAN WATERS IN DECEMBER, 1865.

The following are the Returns of the Metropolitan Association of Medical Officers of Health:—

	Total Solid Matter per Imperial Gallon.	Loss by Ignition.(a)	Oxydisable Organic Matter.(b)	Hardness.	
				Before Boiling.	After Boiling.
Thames Water Companies.	Grains.	Grains.	Grains.	Degs.	Degs.
Grand Junction	21·35	1·28	0·96	12·08	6·10
West Middlesex	21·14	1·02	0·69	13·00	4·99
Southwark and Vauxhall.	22·20	1·38	1·10	13·48	5·08
Chelsea	20·19	1·01	1·08	12·00	5·00
Lambeth	20·74	0·98	0·84	12·00	5·89
Other Companies.					
Kent	26·21	0·48	0 19	18·90	6·81
New River	20·60	0·51	0·48	15·00	5·00
East London	24·21	0·92	0·86	15·94	5·86

(a) The loss by ignition represents a variety of volatile matters as well as organic matter, as ammoniacal salts, moisture, and the volatile constituents of nitrates and nitrites.

(b) The oxydisable organic matter is determined by a standard solution of permanganate of potash, the available oxygen of which is to the organic matter as 1 is to 8; and the results are controlled by the examination of the colour of the water when seen through a glass tube two feet in length and two inches in diameter.

METEOROLOGY.

From Observations at the Greenwich Observatory.

Mean height of barometer	29·685 in.
Mean temperature	43·2
Highest point of thermometer	51 S
Lowest point of thermometer	32·2
Mean dew-point temperature	38·7
General direction of wind	S.W.
Whole amount of rain in the week	0·52 in.

BIRTHS and DEATHS Registered and METEOROLOGY during the Week ending Saturday, January 6, 1866, in the following large Towns:—

At the Royal Observatory, Greenwich, the mean height of the barometer in the week was 29·685. The barometrical reading increased from 29·31 in. on Wednesday to 29·95 in. on Saturday.

The general direction of the wind was south-west.

* The average weekly numbers of births and deaths in each of the above towns have been corrected for increase of population from the middle of the ten years 1851-60 to the present time.

† Registration did not commence in Ireland till January 1, 1864; the average weekly number of births and deaths in Duhlin are calculated therefore on the assumption that the birth-rato and death-rate in that city were the same as the averages of the rates in the other towns.

‡ The deaths in Manchester and Bristol include those of paupers belonging to these cities who died in Workhouses situated outside the municipal boundaries.

§ The mean temperature at Greenwich during the same week was 41·2°.

APPOINTMENTS FOR THE WEEK.

January 13. *Saturday* (*this day*).

Operations at St. Bartholomew's, 1½ p.m.; St. Thomas's, 9½ a.m.; King's, 2 p.m.; Charing-cross, 1 p.m.; Royal Free Hospital, 1½ p.m.

15. *Monday.*

Operations at the Metropolitan Free Hospital, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 9 a.m. and 1.30 p.m.

Medical Society of London, 8 p.m. Dr. Tilbury Fox, "On Leprosy, with Notes taken during recent Travel in the East."

16. *Tuesday.*

Operations at Guy's, 1 p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; St. Peter's Hospital for Stone, 3 p.m.

Anthropolooical Society of London, 8 p.m. Meeting.

Pathological Society, 8 p.m. Meeting.

17. *Wednesday.*

Operations at University College Hospital, 2 p.m.; St. Mary's, 1½ p.m.; Middlesex, 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; St. Thomas's, 1½ p.m.

18. *Thursday.*

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Surgical Home, 2 p.m.; Royal Orthopædie Hospital, 2 p.m.; West London Hospital, 2 p.m.

Harveian Society of London, 8 p.m. Dr. Drysdale, "On the Medical Aspects of Prostitution."

19. *Friday.*

Operations, Westminster Ophthalmic, 1½ p.m.

Royal Institution, 8 p.m. Prof. Tyndall, "On Radiation and Absorption with Reference to the Colour of Bodies, and their State of Aggregation."

ORIGINAL COMMUNICATIONS.

ON

ENTOZOA (?) IN THE MUSCLES OF ANIMALS DESTROYED BY CATTLE PLAGUE.

By LIONEL S. BEALE.

For some time past I have been engaged in researches upon the bodies in question, and as public attention has been already called to the subject by Dr. Fenwick in a letter to the *Times* of January 3, 1866, and in a communication from one of your correspondents, I propose at once to describe briefly what I have observed. The results of my observations will be given in detail in my report to the Royal Commission, but it seems desirable that a few of the facts ascertained in connexion with this most interesting matter should at once be published.

The bodies in question are without doubt very definite, very common, and very easily detected. They are for the most part spindle-shaped bodies, each embedded in the sarcous tissue of an elementary fibre. I have also, but in a few instances only, seen these bodies lying free amongst the elementary muscular fibres. They have been found in considerable number in the muscles of every animal dead of cattle plague in which I have sought for them, with one exception,(a) and in all the different muscles examined from a single carcase. They are commonly met with in large numbers in the muscular fibres of the heart.

These bodies are exceedingly distinct; they vary much in size, but invariably exhibit the same general characters. There is little difficulty in finding them if only very small pieces of muscular tissue be subjected to examination; but being very transparent, they are easily hidden from view if surrounded by normal elementary muscular fibres, and thus they may escape detection. They vary in number, and I should think that in some cases I have seen them as numerous as one to, at the most, twenty muscular fibres (Fig. 2), while in others perhaps they may not be found in greater number than in the proportion of one to a hundred muscular fibres. The smallest are oval, but as they grow they become spindle-shaped, and usually one end is pointed, while the opposite extremity is more or less rounded (Figs. 2 and 3). In some there are slight projections from different parts of the surface, as if there were

Fig. 1.

Fig. 2.

Figs. 1 and 2.—Entozoon-like bodies of different sizes; elementary muscular fibres magnified with a low power (25 diameters). The longest is $\frac{1}{10}$th, the next $\frac{1}{18}$th, and the smallest about $\frac{1}{5}$th of an inch in length.

(a) The exception was an undoubted case of cattle plague, the post-mortem examination of which was witnessed by Prof. Browne, of the Veterinary Department of the Privy Council.

Fig. 3.

Fig. 3.—Rounded extremity of one of the entozoon-like bodies, showing how it is surrounded with the sarcous tissue of the muscle. Magnified 215 diameters.

tendency to the formation of segments or lateral pores. But in the larger ones the outline appears perfectly uniform. In all there is a distinct investing membrane of a peculiar structure, varying in thickness in bodies of different sizes, the outer surface of which is in contact with the sarcous tissue, or with the sarcolemma, save in the few instances in which the bodies are free. Even when the peculiar bodies lie embedded in the sarcous tissue, being surrounded on all sides by a thin layer of it, the transverse markings of the contractile material are perfectly distinct (Fig. 3). The masses of germinal matter in the affected tissue are not larger than those of adjacent muscular fibres. There is no evidence of granular, fatty, amyloid, or other form of degeneration. And whatever these peculiar bodies may eventually be proved to be, it is certain that they grow within the contractile material, and by their growth excite no irritation. The muscular tissue in contact with

Fig. 4.

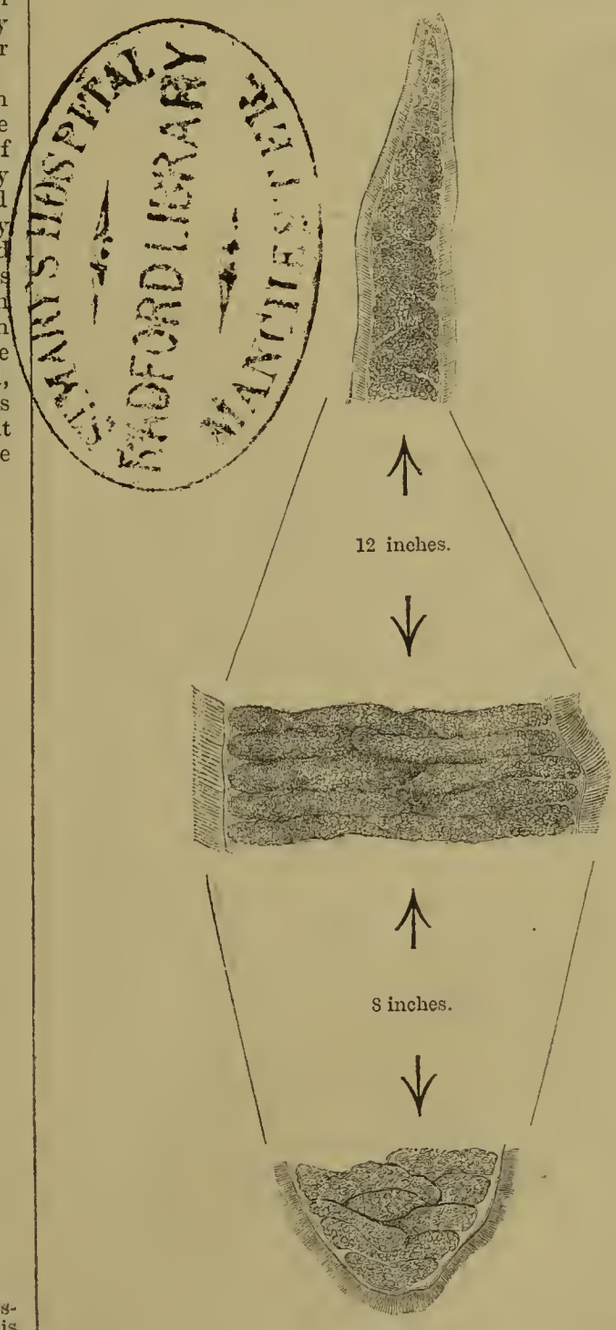

Fig. 4.—The upper extremity, central part of the body, and the lowest portion, of the same entozoon-like body magnified 215 diameters. The whole of this was surrounded by a thin layer of muscular tissue and sarcolemma. The division of the mass into small collections of granules like segmentation was very distinct.

them seems, as it were, slowly to make way for their increased growth, without the occurrence of inflammation or any other morbid change.

A notion of the general form, size, and appearance of the worm-like body when examined under a quarter of an inch object-glass, magnifying 215 diameters, may be formed by reference to Fig. 4.

Structure of the Investing Membrane.—Not the least interesting point in connection with these curious bodies is the investing membrane, and it is very desirable to draw the attention of Helminthologists to its anatomical characters (Fig. 4).

The tissue is very transparent, and varies in thickness in different parts. It appears to exhibit delicate transverse markings, but upon careful examination it is found that these are caused by the linear arrangement of minute hair-like fibres. These processes of the investing membrane were described by Mr. Rainey in his paper in the *Phil. Trans.* for 1857.(b) He says they increase in size and distinctness as the animal grows larger.—"They have not the sharp and well-defined outline of true cilia, nor are they pointed like setæ, or curled like cirri." In a specimen in my possession, however, the bodies in question seem to be pointed, and the whole appearance under a power of 1000 diameters is such as would result if the investment consisted of very delicate transparent conical hairs, terminating outwards in pointed

Fig. 5.

Fig. 5.—Cilia-like bodies covering the whole surface of the external investment or envelope. Magnified 1000 diameters.

processes. In other instances the extremities appear blunt and a little rounded (Fig. 5). When pressed firmly, fluid seems to be forced into the processes, and they exhibit the remarkable appearance delineated in Fig. 6. After lying in water for some time, the projecting filaments exhibited the usual characters of cilia, and would no doubt be termed *cilia* by any anatomist. These hair-like processes appear to be connected with one another when the specimen is perfectly fresh, and in young specimens there is no indication of such a structure. It would seem that they are developed as the body grows, and although formed together in a mass, readily become separated so as to give rise to the structure described. The structure of this membrane is so beautiful and delicate that it might be employed as a test object for estimating the defining power of object-glasses.

The peculiar structure of the external investment, covering, or sheath, will be understood by reference to Figs. 4, 5, and 6, and I shall not here enter into a more minute description of it. I regard it as a peculiar formation, and feel quite certain that the appearances do not result from any modification occurring in the layer of sarcous matter, which was immediately in contact with the body under consideration during its increase in size.

Of the Contents of the Entozoon-like Body.—The contents of these spindle-shaped bags, cysts, or investments, without doubt, form the most important part of the mass, and are well worthy of the most attentive consideration. When examined by a low power, the matter occupying the cavity appears granular, and there are distinct indications of the mass being sub-divided into smaller portions, the divisions being most distinct transversely. I do not think these are distinct septa, but the appearance is such as would result if each of a number of masses of germinal matter in the interior of a cavity, with extensible walls, were to divide and sub-divide into numerous masses, which were capable of growth and multiplication. The appearance is given in Fig. 4. The entire contents of every one of these bodies I have seen exhibit the same characters. There is no indication of alimentary canal, ovary, or any secreting gland or other *organ*. It is, therefore, only necessary to call attention to the small individual particles of an aggregation of which each of the peculiar bodies in question entirely and invariably consists.

These bodies are for the most part of an oval form or spindle-shaped. When perfectly mature the body is curved, one extremity being rounded, while the other is almost sharp as represented in Fig. 6. They are flattened, and apparently consist of a transparent material, which exhibits here

Fig. 6.

Fig. 6.—*a*. Portion of membrane with hair-like processes distended with fluid and subjebted to strong pressure.
b. Two of the small bodies in their fully developed form from the interior of a very long, worm-like cyst. They all exhibited the characters of the two represented. Magnified by the $\frac{1}{26}$th = 1800 diameters.

and there spots differing in refraction from the rest of the mass. These are irregularly disseminated through the mass, and give to it a granular appearance when it is examined by low powers, but under the influence of high magnifying powers the appearance is such as to render it doubtful if, at least in all cases, there are actual granules distinct from the general mass. The body is rendered more transparent and the granules more distinct by liquor potassæ.

The bodies approximate to one another very closely in dimensions, but it is difficult to find two of *precisely* the same figure; and it seems to me most probable that they change in form when they escape into the surrounding fluid by the rupture of the sac. In their general appearance, these bodies so closely resemble the nuclei of tissues, that under low powers one might be easily mistaken for the other. But upon careful examination by the highest powers ($\frac{1}{26}$ and $\frac{1}{50}$), it will be found that the outline is sharper, that the general mass is more uniform, while the alterations in form are greater than are observed in muscle-nuclei. Moreover, these bodies are often seen in such great number (fifty or a hundred or more being in the field at one time) that they cannot be mistaken for nuclei. They are also smaller than the nuclei of muscle, and very much smaller than the greatly enlarged muscular nuclei seen in the muscles of animals destroyed by cattle plague.

Upon the whole, it seems to me almost certain that, at least up to a certain period of its existence, each of these little bodies is capable of giving rise to others like itself, by division and sub-division, and these to more in the same way. To what extent this process is capable of being carried, I can form no idea. The spindle-shaped elongated cysts, in which these particles grow and multiply, sometimes reach a very great length. In a specimen of muscle sent to me by Dr. Eade, of Norwich, I found two as much as the *quarter of an inch in length*, and one is so narrow that the muscular fibre in which it lies still exhibits its normal diameter. Although I have never seen a distinct pore or aperture in any part of the

Fig. 7.

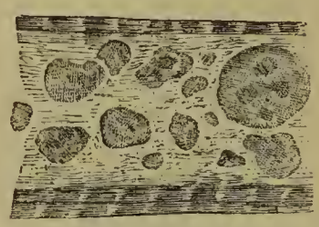

Fig. 7.—Tubular space in the central part of an elementary muscular fibre, extending from one extremity of a very young entozoon-like body. Showing minute masses of germinal matter, probably an early stage of development of the bodies found within the envelope of a fully developed organism. Magnified by the $\frac{1}{50}$th = 2800 diameters.

cysts, it seems not improbable that an orifice might be formed at one or other extremity, or at a point of the body where the external wall is thinner than in other parts. In this way, the escape of these bodies from their parent cyst, a few at a time, would be effected, while the process of multiplication, still going on within, would not be interfered with. But whether the individual masses are able to migrate from one part of the body to another, or, after having been produced in enormous number within the cyst, they are destined to remain dormant until, by the death of the animal, opportunity for a far more distant migration is provided, or whether, as is, perhaps, upon the whole, least probable, from the collection already described, a true entozoon is evolved, must be determined by future research.

Tenacity of Life.—The little bodies in question are very tenacious of life, and they are not permeated by the carmine fluid till long after every mass of germinal matter (nucleus) of the muscles, vessels, and nerves, have been deeply coloured,—a fact which shows that at any rate these bodies are quite distinct from the muscle-nuclei, and have not descended from them. After remaining for many hours in the carmine fluid

(b) "On the Structure and Development of the Cysticercus Cellulosæ, as found in the Muscles of the Pig."—*Phil. Trans.*, Vol. 147.

they take the colour like every other kind of living matter, and several specimens exhibited one spot darker than other parts.

I have tried some experiments with the hope of causing these bodies to multiply, but my attempts have hitherto failed. In water the bodies may remain for several days without undergoing much change.

Conclusion of Previous Observers.—Professor Siebold states that these peculiar bodies were discovered by Miescher in the muscles of a mouse in 1843. Hessling(c) found them in the muscular fibres of the heart of the sheep and ox. They have been also found in the deer. By Siebold and Bischoff they have been seen in the muscles of the mouse and rat. The latter observer found them in all the muscles of a rat in 1845. In 1855, Rainey(d) found and figured similar bodies in the muscles of a pig, and inferred that they represented the early period of development of the "*cysticercus cellulosæ*" of that animal; but later writers, and especially Leuckart and Cobbold, do not consider the evidence upon which this inference rests at all conclusive.

The form of the body, the peculiar structure of the external investing membrane, would incline one to regard the bodies as some species of entozoon in an imperfect stage of development, and from the character of the contents I doubt if any zoologist would consider them allied to the gregarinida or psorospermiæ. There is, I think, no doubt that these bodies are of an animal nature. There is no character that renders it at all probable that they belong to the vegetable kingdom. I am not aware of any gregariniform body exhibiting either the form, very considerable size, peculiar contents, or general characters of the bodies in question, although some species do attain considerable dimensions.(e)

The nature of these very peculiar and striking bodies has not yet been made out, and, although it is possible that they may have nothing whatever to do with the cattle plague, the constancy of their occurrence in very large number in the muscles of animals that have died of this disease is remarkable. Moreover, as there can be no doubt that bodies capable of rapid multiplication, far less than those forming the contents of the spindle-shaped cysts would be competent to give rise to all the symptoms observed in cattle plague, if they passed into the vascular system, it seems of the utmost importance that the natural history of these bodies should be traced out.

Conclusions.

The facts concerning these entozoa (?) may be summed up as follows:—

1. That in almost all, if not in all, animals dying of cattle plague, entozoa or entozoon-like bodies exist in considerable number in the voluntary muscles of the system and in the heart.

2. These or closely allied species have been known for more than twenty years, but their nature has not yet been determined. They have been found in the ox, sheep, deer, pig, rat, mouse, and perhaps other animals.

3. They are occasionally found, but in very small numbers, in animals apparently in perfect health when killed.

4. In the muscles of a calf killed by cattle plague, under *six months* of age, these bodies were found in immense numbers.

5. They vary in length from less than the $\frac{1}{300}$th of an inch to at least a quarter of an inch in length. They are, for the most part, embedded in the contractile material of the elementary muscular fibre, but they are occasionally found free.

6. They are for the most part spindle-shaped, and the external investment or envelope exhibits a very delicate and peculiar structure, being completely covered with delicate hair-like processes.

7. The mass within appears granular to low powers, and exhibits a division into numerous segments, but it is found to consist entirely of minute bodies resembling one another, possessing very definite characters, less than the $\frac{1}{2000}$th of an inch in their longest diameter, and of peculiar form, being oval, flattened, the body slightly curved laterally, with one extremity blunt and the other almost pointed.

8. The entire mass increases in size as these small bodies increase in number, probably by division and subdivision, within the cyst.

I trust that my object in thus calling attention to these facts will not be misunderstood. It is almost impossible in recounting facts to avoid speculating a little upon their import, but I trust that I have avoided committing myself to any theory upon the nature of the cattle plague. No one feels more strongly than I do the importance of thoroughly investigating every fact that can be discovered in connexion with this terribly fatal malady. Does it not seem more likely that we might find out how to prevent the attack than that we should discover a remedy to cure the disease when established, and is it probable that we shall discover the means of preventing its occurrence until we have a thorough knowledge of its nature? While, therefore, it appears very desirable that the facts should be generally known, it would be premature to adopt any theory, and it is advisable that steady investigation should be prosecuted with as little theorising as possible.

Now, quite apart from the question of cattle plague, ought we not to have learned long before this the exact nature of these very definite bodies, so common in the muscles of many animals? Here is an entozoon-like body, inhabiting muscles, which appears to have been well-known for more than twenty years, and yet little seems yet to have been discovered concerning its natural history. Entozoa are not common in the voluntary muscles, and the number of species hitherto discovered is very small; while, on the other hand, are not the facts recently made out in connexion with certain muscle-inhabiting entozoa sufficiently significant to render it desirable that any others that may be discovered should be investigated carefully and immediately?

We cannot regard these things as unworthy of attention in face of the fact that, like trichinæ, they inhabit the striped muscles only, and, like them, are found in the muscles of animals of many different classes and orders, extending over a wide geographical area. Are the species of muscle-inhabiting entozoa, or entozooid bodies, so common and so numerous that we may look upon the presence of those in question as a matter of no importance, to be dismissed without further notice? while, on the other hand, are we so well acquainted with the natural history and migration of the now common, but terrible, trichina that we can afford to omit to study any fact which seems to offer even a very slight probability of leading to the discovery of more concerning it? There are surely few subjects in which minute, earnest, scientific research has yielded such important results as have been discovered in recent investigations upon entozoa. It has been shown clearly and unmistakably enough that the lives of many persons might have been saved, and the serious and dangerous illness of *hundreds entirely prevented*, if certain meat sold for food had been subjected to careful microscopical investigation by any intelligent observer. One minute's observation would have at once condemned every particle of the meat to the flames, and have prevented a most serious loss of life.

As regards the cattle plague, let it be borne in mind that living particles of extremely minute size are quite competent to give rise to all the symptoms observed. Such minute living particles might be germs of entozoa or some other form of germinal or living matter. It may be remarked that the intestinal derangement which is so remarkable in cattle plague is such as might be caused by the passage of minute germinal particles to or from the blood of the animal, and if such germs were obstructed in the capillaries, the circumscribed patches of vascular congestion which are invariably met with in the disease would be explained. On the other hand, it might be asked if there are any facts yet known in connexion with cattle plague and some other fatal diseases which resist all modes of treatment yet adopted, which render such a theory untenable?

It would, I think, be at least as easy in the present state of our knowledge to bring an array of facts and arguments in favour of the doctrine of cattle plague being due to entozoa, as it has been to adduce facts and arguments in favour of the small-pox doctrine, while although many facts may be urged against both views, I doubt if there are any yet known which render either of these, or the typhus, or typhoid, or scarlatina notions altogether inadmissible. Nor would it be difficult to propound new theories altogether; but as time wears on it seems to become more and more certain that no such short roads to knowledge will be hit upon even by the most sagacious, the most fortunate, or the most ingenious. Thorough, prolonged, and thoughtful scientific investigation seems now the only course open to us, and that ought to be prosecuted by many, and in earnest.

CONDITIONS UNDER WHICH CHOLERA APPEARS IN ITS HOME.

By Dr. JOHN MACPHERSON.

(Continued from page 7.)

A Remarkable Outbreak.—The case before alluded to may be here conveniently introduced. A first-class ship arrived in the Hooghly in the early days of January. There was no cholera in the vessel coming up the river, or during the month. There was very little in the city of Calcutta. A party, consisting of a gentleman and his wife, European nurse, a young lady, and two children, landed in perfect health, on a Sunday. They went to a house in which there had been no cholera for several years, not, however, in a particularly good situation, and small for the party that was received in it. After their arrival, there was a total of eight adults and ten children living in the house. Of these, two adults and three children were residents, two adults and three children from up country, and the rest the new arrivals. Five of the new arrivals occupied a small room on the upper flat—that is, the three females and the two children. They had one bathing-room off it. The rest of the occupants of the house were partly up-stairs and partly down. The nurse and children appear to have had slight diarrhœa during the week, and the children and the young lady ate on Saturday some rather indigestible native fruit. The children having slight diarrhœa, got a dose of Gregory's powder from their mother on Sunday morning. I was sent for at 8 o'clock p.m., and found one child far gone: she died at half-past 12 at night. The other child was in the earlier stage of the disease. About midnight the father had an attack of the disease, which was checked, and towards morning the nurse (who during the evening had felt ill, and had got a dose of rhubarb from her mistress) was seized. She was sent off to the General Hospital, close at hand, before 7 a.m., where she died at 7 p.m. All who could possibly leave the house—*i.e.*, all but its resident occupants—were ordered out of it. The young lady, who had been in devoted attendance on both the children, went at 11 a.m. to Wilson's Hotel. She was seized with cholera late on Monday night, and died at 4 p.m. on Tuesday. The second child, after a long struggle, rallied from her first attack, but in less than twenty-four hours had a relapse; however, she eventually recovered. One of the occupants of a room down-stairs was suffering from chronic diarrhœa. No more cases occurred in the house, or in the servants' out-houses.

A few reflections on these cases naturally occur. The sufferers had just arrived from sea. They were crowded into a space quite unwarrantably small, and hence, probably, an attack of cholera at an unusual season of the year. All the four undoubted cases had suffered previously from diarrhœa, attributed to the eating of indigestible food. They unfortunately had aperient medicine given them, and no purgative is safe at such a time. None but those who lived in the room, and the father, who was constantly in it, were attacked. The cases, as in such sudden outbreaks, were peculiarly severe. Out of the four cases in which cholera was undoubtedly developed there were three deaths. None of the other occupants of the house and none of the servants were attacked, not even the invalid with chronic diarrhœa. The immediate breaking up of the party appears to have exercised a most salutary effect. When such an outbreak and even worse ones are possible in European houses, it seems wonderful that the whole native population is not swept off, considering the infinitely more unfavourable conditions under which they live.

Cholera Attaches itself to Places.—But if cholera attacks certain classes of people more readily than others, it also appears to be able to attach itself for a time at least to particular spots, as to certain houses, streets, or barracks, or even boats or ships, camping grounds or banks of rivers. It generally selects inhabited spots, and that, like most other diseases, it finds its nest where there is most population and most filth, is beyond all doubt. Undrained Calcutta remains a lasting proof of this: though much money has been spent—little short of a million sterling—the new system of drainage for the European quarter alone has not yet come into operation; yet there appears to be something beyond any mere filthiness of locality. A good many years ago the large airy houses in Middleton-row were almost deserted, as being a hotbed of cholera. This was attributed to a tank in the neighbourhood which had been filled up some years previously. There has since then been no change in the drainage. The habits of the class of people that live there now are much the same as before, only the class is less wealthy, yet Middleton-row has not more cholera now than any other part of the city. I know another neighbourhood in Calcutta where cholera used not to be common in former years, but in which there have been many cases of late years, the only change in its neighbourhood being the excavation of an excellent tank of water. What has been said of neighbourhoods applies equally to particular houses, which, in common parlance, "have got a bad name name for cholera." But cholera will sometimes localise itself not merely in a particular house or ship, but affect only one side of it. Sometimes defective sanitary arrangements may be discovered that seem to account for this, but much more usually none. In a fleet of thatched country boats sailing up the Ganges cholera has been found to cling for a fortnight to particular boats, yet on the most minute examination it could not be discovered that these boats differed in hygienic conditions from the boats that were not attacked, or that the hygienic conditions of the attacked boats were the least different during, from what they were before, or after the attack. It was long supposed that there were certain localities which cholera would never reach, owing to peculiarity of geological formation or height above the sea. Gwalior was considered one of the exempted spots, yet it has had at least two severe visitations, and it is known that the mountain sanatoriums cannot always count on exemption. Undoubtedly no spot in Lower Bengal is safe from its ravages.

Attaches itself to the River.—But the apparent fondness of cholera in Bengal for one particular kind of spot, if one may say so—that is the banks of the rivers Hooghly and Ganges—is specially remarkable. For a ship to come up the Hooghly during the cholera season and not have a few cases of it is very unusual; in the old days for a regiment, European or native, proceeding by water, to escape it was equally unusual. Even when the transit was shortened by the aid of steam, a detachment of Europeans seldom got off scot free; and I have read but recently of the frightful sufferings of coolies (tightly packed, no doubt) in steamers proceeding to the tea plantations in Cachar, scarcely inferior to those of the unfortunate men lately abandoned in the *Eagle*. As illustrative of the way in which cholera occurs on the Ganges, my own experience is subjoined. We left Calcutta with a detachment of 400 rather sickly young Europeans on August 4, 1842, or in the height of the rains. The boats were thatched, and many of them leaky, the roof of the Hospital boat not high enough to allow one to stand erect. Still, the boats were average ones, as was also the commissariat. During the first month there was a good deal of fever, dysentery, and diarrhœa,—sourish bread and bad water got the credit of provoking the two last,—yet we had no cholera. The season was remarkable for a succession of violent gales. On September 8, when we had been drawn up an hour or two on a bank which was known to be one where we were likely to get cholera, but which we had to seek owing to the violence of the storm, and before any of the men had been many yards from the boats, the first case of cholera appeared—of course, a fatal one. Next day we moved off, but the cholera accompanied us, attacking both Europeans and natives, and attaching itself to three or four boats in particular, and getting worse when we lay for two days on a bank close to a native bazaar. In a fortnight as we proceeded upwards we thought we had got rid of the disease, but a last case showed itself singly as late as October 16. It will be observed that the cholera did not attack us at first during the confusion of our start, or when we were in Lower Bengal, where there is most cholera, and where we were drinking the Hooghly, which is far more impure than the Ganges water. We got cholera whenever we reached a bank which was supposed to be a likely one for it, and before we had been there two hours. We were losing the disease, when it appeared to be aggravated by our lying to again for a couple of days. None of the officers, some sixteen in number, who lived in a superior class of boats, got the disease. It would be hard to offer a positive opinion as to how the disease reached us, or how it left us, though easy enough to offer conjectures.

Ships going into the Hooghly constantly get cholera on board. So sensible are naval men of this, that captains of her Majesty's vessels often keep their ships at the mouth of the river, or at Diamond Harbour, in hopes of escaping the disease, and in this they are often, though not always, successful. Captains, as a general rule, attribute cholera to something caught by the men on shore. It has been attempted to make out that the ships lying much in shore, and near the mouths of the sewers, suffer most, but there is little of certainty in this. Moving a ship from the shore to mid-

stream will often serve to stop cholera; at other times be of no avail; generally any change of place does good. The only sure way of stopping cholera without sending the crew on shore is to go to sea. A vessel is pretty sure to have a case or two while dropping down the river; but as surely as she goes to sea, so surely does she lose her cholera. This applies to coolie ships, as well as to ships with European passengers. Such a thing has happened as cholera breaking out at sea among coolies a fortnight after leaving Calcutta, but it is the rarest thing possible. Seamen thus get cholera by visiting Calcutta, and lose it by going to sea. As bearing on what has already been said of the period of the year at which cholera prevails most, it may be added that the risk of getting cholera on the Hooghly, either after arrival or on the way down (on the way up it is comparatively rare), is infinitely greater in the hot than in the cold months, and this is a matter of much importance with reference to the sailing of troop or coolie ships.

The water of the Hooghly, although the stream is large, it is well known, is full of impurities of all sorts, and is cleaned very imperfectly before it is put on board ship. Yet captains of vessels are quite satisfied with it, and never on the voyage home attribute any bad results to its use. Invalids with chronic diarrhœa never attribute any injurious effects to it. The ordinary drinking water in Lower Bengal is never free from impurities, especially organic ones.

Extent and Influence of Epidemics. — With reference to epidemics of cholera in Lower Bengal, we have ascertained at what seasons they are most likely to occur. It would be very desirable to know, also, their extent. Unfortunately we have no statistics to show this, though we know in a general way that its devastations are often frightful. Besides the extent of an epidemic, the inquiry how far the presence of cholera reacts on other diseases, on the ordinary diseases of the place, and on diarrhœa in particular, is an interesting one. An examination of the returns of Calcutta mortality, already referred to, enables me to answer part of the question satisfactorily. It is quite certain that a cholera epidemic does not affect one of small-pox. This was observed on its first outbreak, and has remained true of it. In Calcutta the hot weather months are the small-pox ones. In the seasons of the greatest epidemics of small-pox cholera ran its usual course. When, however, we come to consider the coincidence of other diseases with it, cholera would appear to exercise a quite perceptible control. If we take the Calcutta returns for the native population for twenty years—from 1849 to 1860—and distinguish the months of the greatest prevalence of cholera from those of its least, the following results appear:—

During the six months of the maximum prevalence of cholera there were 61,984 deaths by it, 68,181 by other diseases. During the six months of the minimum prevalence of cholera there were 24,286 deaths by it, 82,548 by other diseases; or, to put it in another way, in a series of twenty years the maximum of deaths by cholera was in two Aprils. These two months yielded 16,193 deaths by cholera, to 9607 deaths by all other diseases. The minimum of deaths by cholera was in one July and one August. These two months yielded 2432 deaths by cholera, to 12,232 by other causes.

Figures on such a large scale speak distinctly for themselves. It seems impossible to doubt that the prevalence of cholera has a very marked effect on the diseases of the country, which are from one-fourth to one-fifth less prevalent when it is epidemic. The commonest of these diseases are fever, diarrhœa, and dysentery.

The European population of Calcutta is too small and not sufficiently fixed to enable us to examine whether the same holds true with them; but during an epidemic, among the men of H.M. 96th, I was surprised at the small number of admissions from fever and bowel complaints.

As to the prevalence of diarrhœa during cholera epidemics, the Calcutta returns say nothing, and it is difficult to give a positive opinion on the subject, seeing that Calcutta is never free from a great deal of diarrhœa and bowel complaints. My impression is that among Europeans there is usually more diarrhœa—at all events, they observe it more, as they are more anxious about themselves at such periods. Premonitory diarrhœa is often present, but often absent, and relations, and often Doctors, too, make it a point of honour to ascertain that diarrhœa has been going on for some time, and neglected. Be that how it may, many a patient attributes his attack to having taken an aperient, and during cholera seasons tens of thousands of opium, and assafœtida, and similar pills are distributed to the people—judging by the steady demand for them—with much success. Among European soldiers during the severe epidemic in 1842, on board boats, I gave every man who complained of diarrhœa a glass of brandy or wine with thirty or forty drops of laudanum, and he seldom appeared again as a cholera patient. It may be said confidently that during cholera seasons patients in private life who are early treated for diarrhœa very rarely get cholera.

Communicability of the Disease.—On one other point of my experience I would remark, as all other Indian officers have done before me—that it is very unusual for the attendants who are commonly employed to rub the extremities of cholera patients in their cramps, to get attacked. I have often seen the the most beautiful devotion of native servants to their masters and mistresses, and they do not lose heart, as European soldiers going to attend on their comrades during an epidemic do. I have very rarely indeed seen a Medical officer or an Apothecary attacked. I never had to imagine that the performance of post-mortems was dangerous to myself or to my assistants. Like my neighbours, I have had occasion to spend hours, I may say days, in a cholera atmosphere, and never took any special precautions; but I never had the disease, and no European in any of the different houses I have occupied ever had it.(a)

Many other interesting subjects of inquiry suggest themselves. Is the character of the disease altered at all in the course of years? Are its ravages as extensive as formerly? Is the mortality among those attacked as great as ever? But to investigate these and kindred subjects would be beyond the limits of these notes, and accurate observations on many points are wanting.

The object of this paper will be served if it recalls attention to the facts, that cholera in its own home is never wholly absent, has very decided seasons of maximum and minimum prevalence; that it appears to influence the prevalence of most diseases, although it does not affect that of small-pox; that it attacks more specially those who are moving about, who are overcrowded, and who dwell in ill-aired localities; and that it also attaches itself to particular spots and neighbourhoods, where it is very difficult to discover any defect or specialty of hygienic arrangements.

To endeavour to determine how far cholera in other parts of India or of the world follows rules in any degree analogous to those that prevail in Lower Bengal, would be to enter on a very wide field of investigation.

SUCCESSFUL CASE OF OVARIOTOMY.

By J. C. GOODING, M.D. Edin.

J. C., aged 49, married, sterile, states that she first noticed enlargement of the abdomen in September, 1862, which enlargement always appeared central. Menstruation, previously regular, had ceased just before. She has never suffered pain or other inconvenience than that recently caused by the size and weight of the abdomen.

In October, 1863, I first saw her—she was then the size of a woman at the seventh month of pregnancy—and diagnosed ovarian disease. From this date up to January 2, 1865, she gradually increased in size. Various forms of dyspepsia, at first slight, but augmenting in severity with the increasing enlargement, caused much suffering, till at last almost all she took was rejected. There was no pain. She measured at this time 45 inches round. I tapped and removed 36 pints of thick, dark-brown fluid; a mass, about the size of a cocoanut, evidently composed of an aggregation of smaller cysts, occupied the left iliac region. An elastic belt was worn, with the view of at least retarding the refilling of the cyst. She recovered rapidly, soon becoming ruddy and fat.

For some weeks she enjoyed comfort, the abdomen, however gradually enlarging, the dyspeptic symptoms began to recur. I recommended ovariotomy, which, at first accepted, was eventually declined, from her objection to leave home for London, as I advised. It became necessary to tap again on May 27 (five months after the first), when she measured 43 inches round; 32 pints of similar fluid to that first removed

(a) The people who remove the excretions and those who wash the clothes are not more liable to be attacked than other classes of the population. According to the domestic usages of Calcutta in all well-regulated European houses (there are no privies, and water-closets are unusual), the excreta of each individual are received in a separate vessel and soon carried away by the sweeper. The arrangements in native houses are very bad, and the public privies are generally offensive. There is an *odor stercoreus* around every native village.

was obtained. The mass of smaller cysts had doubled their former size. There was some febrile disturbance and an intermittent pulse for a few days, but on the whole she rallied well. On September 25 (four months after)—ovariotomy in the meantime being again declined—she measured 45 inches, and was suffering so much from the mechanical effects of the growth, it was necessary to tap a third time; 27 pints of a blacker fluid was withdrawn. The mass of smaller cysts had increased considerably, but was moveable. The pulse was regular. She was a considerable time in regaining moderate strength, and before she had done so the size of the abdomen was again so great as to prevent her taking walking exercise. The tumour pressed downwards and forwards so much that she often stood before a table and rested her belly thereon to obtain relief. There was no swelling at the ankles, although before the first and second tappings the legs had been twice their natural size from œdema. I concluded from these two facts, and the mobility of the mass after tapping, that there were no adhesions posteriorly. I again strongly recommended ovariotomy; for her strength was giving way under this rapid accumulation and evacuation of bloody fluid. Everything seemed in her favour; heart, lungs, kidneys, digestive system when not incommoded by pressure, all healthy. Uterus normally placed and mobile; no portion of tumour to be felt on vaginal examination; few adhesions believed to be present. She at last resolved to undergo ovariotomy, but would not consent to leave home. Under these circumstances, I did not hesitate to operate, although I had wished her to benefit by the great experience of Mr. Spencer Wells.

On December 6, with the kind assistance of Drs. Eves, Wright, Hooper, and Mr. Rooke, who gave chloroform, I performed ovariotomy. She measured 45 inches round; 20 inches from ensiform cartilage to the pubis. The bladder was empty. A five-inch incision was made midway between the umbilicus and pubis. There were a great many adhesions above and to the right and left of the incision. Most of them yielded readily, but in breaking down those where the punctures in tapping were made the cyst gave way. I extended the incision two inches, to afford a ready exit for the fluid, as the sac could not be drawn out on account of some very firm adhesions near the epigastrium. These were, with considerable difficulty, torn through and the large cyst withdrawn; the remainder followed, as there were no adhesions posteriorly. A long, narrow pedicle was secured with a clamp. There was no bleeding, but some of the fluid had escaped into the pelvis. This was wiped out with flannel; but rather than prolong the exposure, care was not taken to clean it absolutely. The right ovary seemed healthy. The wound was closed by seven silk sutures, which included the peritoneum. A knuckle of small intestine lay just under the wound. Fresh air was admitted by the window into the room, which had been previously heated to 68° F. Two hours after the operation, the pulse, which had been for the first half-hour intermittent, was regular and of good strength, 111. Skin warm; aspect good. Six hours after she was perspiring freely. Pulse 100, good. Three and a-half ounces of urine were drawn off. Hitherto had only ice.

December 7, 2 a.m.—Pulse 105, good; perspiring freely. urine three ounces, slightly ammoniacal; has had no sleep. A few teaspoonfuls of beef juice have been taken at intervals. Nepenthe, ɱx. At 4 p.m. she felt refreshed by sleep. Pulse 102, good. The use of the catheter agitates her so much, I allowed her to pass water in towels placed for its reception; several were saturated with very ammoniacal urine. Great thirst. An ounce of champagne was soon rejected. Ice continued.

On the second day the pulse ranged from 96 to 100, good strength. Skin moist. Urine freely passed; less ammoniacal. Flatus passes freely. Has been sick twice.

Third day,—Sleeps fairly. Has taken beef-juice freely. Pulse 104 to 108. A slimy, bilious motion passed about midday. Eight ounces of urine were passed in bed-pan. Complexion "as yellow as a guinea," as nurse says.

Fourth day.—Slept well after nepenthe. Took beef-juice and sago, gruel, and gin and water. A copious, offensive, bilious motion passed. Urine free, loaded with lithates, not so ammoniacal. Perspires freely. Pulse 90, good. Complexion much clearer.

Fifth day.—Removed sutures; no pus followed. Deep part of wound healed; only an inch or two superficially, near the clamp. Pulse 104, soft. Ordered brandy and water.

14th.—Eighth day.—The pulse since last report has ranged from 96 to 104. The bowels have acted almost daily. The urine is free and healthy. Removed clamp; stump firmly united to the lower angle of the wound.

January 1, 1866.—The patient continued to progress favourably. Occasional flatulence was always relieved by an enema. The appetite has improved under the use of tonics. The dead portion of the pedicle has been cast off and the wound almost healed. She has been walking about the room for several days past, and to-day took an airing in a Bath-chair.

6th.—The wound is completely cicatrised; the site of the pedicle resembling an umbilicus. Her strength is fast returning.

The solid part of the tumour consists of a large cyst, whose walls were the thickness of two lines, except at the lower part, where a large mass of closely aggregated, thin walled cysts grew. The interior of the large cyst was studded with numerous small cysts. At the site of the firm adhesions these had attained the size of an egg. These smaller ones were filled, with the exception of two or three that contained disintegrated blood, with fluid having the physical characters of glycerine. The whole weighed 6 lbs. 12oz., and there was about 35 pints of thick, black fluid evacuated during the operation.

This, I am told, is the first case of ovariotomy that has been performed in Cheltenham.

6, Sussex-place, Cheltenham.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

SAMARITAN HOSPITAL.

CASES OF OVARIOTOMY.

(Under the care of Mr. SPENCER WELLS.)

Our volumes last year contained a series of cases of ovariotomy performed by Mr. Spencer Wells in the order in which the operations were performed. We propose to continue this series in the same order. From his first case in 1858 till his first in Hospital in 1866, Mr. Wells has completed ovariotomy in 75 Hospital patients. Of these 54 have recovered, and 21 have died, a mortality exactly of 28 per cent. Of the last 10 Hospital cases only 1 has proved fatal. Five of these cases we have now to report.

Case 71.—*Multilocular Cyst—Never Tapped—Cyst Inflammation—Ovariotomy—Recovery.*

An unmarried schoolmistress, 34 years of age, came from Oxfordshire, at the end of September, 1865, to consult Mr. Spencer Wells, by the advice of Mr. Jones, of Leamington. Mr. Wells saw her on October 3, when she was suffering from abdominal pain, feeble rapid pulse, vomiting, furred tongue, and hot dry skin—symptoms which, in the absence of friction sound, he referred rather to cyst inflammation than to peritonitis. A multilocular ovarian cyst, hard to the right side and fluctuating to the left, extended half-way between the umbilicus and the sternum. It had been of very rapid growth, as she had not noticed any enlargement of the abdomen until after Easter, 1865. The increase had been slow till July, but rapid since. The inflammatory attack had come on on September 29, after the journey to town. Rest, linseed poultices with laudanum, and morphia in small doses led to a cessation of the urgent symptoms, and she was admitted to Hospital on October 9. The catamenia appeared on October 8, scantily, three weeks after the preceding period. The intervals generally varied from three to five weeks. Sometimes there was excess amounting to menorrhagia, and "large lumps" often passed. There had never been amenorrhœa or dysmenorrhœa. She was kept under observation in Hospital, as she was still feverish and the pulse seldom below 120. There was also cough, and pain under the right clavicle, but nothing abnormal could be detected in the lung. These symptoms would have led to further delay; but as the tumour was growing rapidly and the suffering from distension was increasing, ovariotomy was performed on October 25. Dr. Ritchie gave chloroform; Dr. Marion Sims, Mr. Smyly, of Dublin, and Dr. Walker, of Peterborough, were present. The incision was commenced one inch below the umbilicus, and carried downwards to the extent of six inches. A patch of vascular adhesion directly beneath the incision was sepa-

rated, and one large cyst tapped and emptied. On tapping a second cyst it gave way, and the contents escaped. Mr. Wells then broke up the tumour and drew it out. One portion of it was firmly pressed into the pelvis, behind the uterus, but was not adherent there. A pedicle as thick as two fingers was secured in a small clamp about three inches from the right side of the uterus, and the tumour was cut away. The left ovary was healthy. Two small vessels which bled on the surface where the adhesions were broken down, were stopped by torsion. The wound was closed by six deep sutures. The tumour was composed of ten pints of fluid and four pounds of small cysts with mucoid and puriform contents.

The patient went on remarkably well for the first forty-eight hours. She said the night after the operation was the best she had had for six weeks. On the second day uterine epistaxis came on. On the third afternoon a sharp attack of peritonitis came on suddenly. The pulse rose to 130; there was vomiting of grass-green fluid, and pain. Opium was given and hot poultices applied. She improved on the fourth day. The pulse fell to 112. There was some vomiting, and the urine was highly concentrated; but uterine epistaxis and perspiration went on freely. On the fifth day improvement continued, and all the stitches were removed. On the eighth day the clamp came off. On the tenth and eleventh days the bowels acted after a teaspoonful of castor oil. Cicatrisation was complete on the twenty-first day. The patient left the Hospital on the twenty-second day after operation, soon afterwards returned to the country, and has been heard of since as quite well.

Case 72.—*Ovarian Tumour—Pleural Effusion—Four Tappings—Ovariotomy—Recovery.*

On March 2, 1865, a single woman, 42 years of age, a teacher of music, was admitted into the Samaritan Hospital under the care of Mr. Spencer Wells, to whom Dr. Brabant, of Havant, had sent her. She was a healthy-looking woman, but rather thin. She complained of constant coldness of feet, her mammæ were enlarged, and the areolæ deeply injected, but no follicles were to be seen. Her bowels were regular; her appetite indifferent; she occasionally suffered from piles. Her spirits were good; her sleep was disturbed by coughing. The right side of the chest was bulging, and was dull on percussion as high as the third or fourth rib; the respiratory murmur was almost inaudible in the dull part. On the left side percussion was clear, the murmur distinct. There were no cardiac murmurs. The urine was normal in quantity and quality. In the abdomen was found a fluctuating tumour, which occupied the hypogastric, umbilical, left iliac, and left lumbar regions. It reached about two inches above the umbilicus. The abdominal parietes were of normal thickness, and unmarked with lineæ albicantes or dilated veins. The girth at the umbilical level was 37½ inches, the distance from the umbilicus to the ensiform cartilage 7 inches, to the symphisis pubis 8½ inches, to the right ilium 9 inches, and to the left ilium 9½ inches. According to the patient's statement, she had menstruated during the previous week, and also during the week immediately before that; she had lost but very scantily each time. She had commenced to menstruate at the age of 15, and had continued regular till she was 38. She then saw nothing for four months, but afterwards the catamenia returned regularly till within five or six weeks of her admission to the Hospital, when the periods came more frequently, but less copiously than before. The uterus felt heavy and not very moveable. The cervix was soft, the os uteri closed.

The patient said that she had always enjoyed good health until she was 40 years of age, when her strength began to fail. She soon found that her dresses were too tight, and fourteen months before admission she discovered a small tumour in the abdomen, whose size remained almost stationary until within the last few weeks, when it began to increase somewhat rapidly.

On auscultation, a double murmur was heard over one portion of the tumour, very closely simulating the fœtal heart. Although the character of the patient was quite unblemished, this murmur, and the state of the os and cervix uteri, as well as the condition of the right side of the chest, made some delay advisable. The patient went home, but returned to the Hospital on May 23. The tumour now filled the entire abdomen, reaching up to the sternum. The respiration was much oppressed. Dr. Savage having introduced the uterine sound, and shown that the uterine cavity was only three inches in length, Mr. Wells tapped and emptied a cyst of twelve pints of clear, viscid, ovarian fluid. On examining the right side of the chest, it was evident that the pleura was full of fluid.

On June 12, Dr. Jenner saw the patient, and recommended a blister, with the internal administration of iodide of potassium and bark. On June 17, the respiration being very much oppressed, Mr. Wells tapped at the same spot as before, and removed eighteen pints of amber-coloured, viscid fluid. There was no great relief, and the Medical treatment was pursued. On July 25, Mr. Wells tapped again, removing fourteen pints, and then sent the patient home for the benefit of country air.

She was re-admitted into the Hospital on October 31, having been tapped early in the month by Dr. Brabant, who reported that the state of the chest had greatly improved. Dr. Jenner examined her again on November 3, and said that there was nothing in the state of the chest to forbid ovariotomy. The patient was suffering much from pressure on the rectum, producing piles. The uterus was jammed up against the pubes. There had been no catamenia since the first tapping; the urine was very scanty; the pulse rapid and feeble. Notwithstanding these very unfavourable symptoms, Mr. Wells performed ovariotomy on November 8, 1865, Dr. Brabant, Dr. Boeck, of Christiana, and Dr. Makeyeff, of Moscow, were present. Dr. Ritchie gave chloroform.

An incision was made five inches in length midway between the umbilicus and the symphisis pubis. Six pints of fluid had previously been evacuated through a small trocar, so as to lessen the shock of withdrawing suddenly the pressure from the diaphragm. Some extensive adhesions to the anterior abdominal wall were easily broken down; a large cyst was tapped, but as its contents were too viscid to escape, the whole of the interior of the tumour was broken up by the hand, and the mass in this way removed. The pedicle was as thick as three fingers, and sprang from the left side of the uterus. It was secured in a clamp and kept outside, but with some traction. The right ovary felt rather hard, but as it was not enlarged it was left alone. The wound was closed in the usual way by six deep sutures.

The patient rallied well, but the pulse went up to 150. Pain was relieved by opiates. The urine was somewhat scanty, but high-coloured. Next day she was better. The pulse remained at 120, but there was no sickness; urine was abundant, and the skin was moist. On the second day the pulse was 116. Some bile was vomited with relief. On the third day Mr. Wells removed two stitches; the rest he took away on the fifth day. On the sixth and seventh days there was some vomiting of bile and mucus. The urine, too, contained a good deal of mucus. Nitromuriatic acid was prescribed. The bowels were acted upon on the eleventh day after a teaspoonful of castor oil. On the thirteenth day the clamp was removed. The patient was put on quinine. She gradually regained strength, left the Hospital on the twenty-first day after the operation, and arrived safely in Havant, where she soon acquired strength.

The tumour removed at the operation was examined by Dr. Ritchie, who reported that it was a semi-solid mass, weighing from six to seven pounds, and in structure identical with the tumour described and figured by him at page 291 of Mr. Wells' first volume on "Diseases of the Ovaries."

Case 73.—*Ovarian Cyst Tapped Twice—Pregnancy—Tapping—Birth of Living Child—Ovariotomy four months after—Recovery.*

On the 9th of May, 1865, a married woman, 40 years of age, was admitted. She was sent to Mr. Wells by Mr. Ward, of Newark, who had tapped her twice, removing nearly four gallons of fluid each time. The first tapping was in April, 1864; the second in February, 1865. She had been married three years, and had not had children. The catamenia became scanty about the time of her marriage, and got less and less till they "quite left her in November," 1864. The abdomen was very large, and nothing could be detected except a very large ovarian cyst; but on examining *per vaginam* the cervix uteri was found soft, short, and velvety, and very distinct *ballottement* was felt. The mammary areolæ were injected, the corpuscles well developed, and a little colostrum was squeezed from the nipples. Taking these signs into consideration, with the cessation of the catamenia in November, although the patient would not believe that she was pregnant, Mr. Wells made the diagnosis of an "ovarian cyst in front of the uterus, which contains a six to seven months' fœtus." Symptoms due to distension being urgent, he tapped and removed eighteen pints of clear fluid. The enlarged uterus was then felt nearly up to the umbilicus, the collapsed cyst to its left, and the fœtal heart was heard below

and to the left of the umbilicus. Great relief was obtained, and she went home in a few days. A healthy child was born at the full term of pregnancy, but the patient was too weak to nurse it. The cyst refilled; she suffered from pain and loss of rest from distension, and she was readmitted on the 25th of November, 1865. She was much emaciated, but was otherwise in a fair state for ovariotomy, and Mr. Wells performed the operation on the 29th of November. Dr. McDonnell, of Dublin, Mr. Wright, of Nottingham, and Mr. Jones, of Leamington, were among the visitors. Dr. Ritchie gave chloroform. An incision, 4 inches in length, was made upwards from 2 inches above the symphisis pubis, and a closely-adhering cyst was opened and emptied of fluid and large lumps of fatty fibrine before any adhesions were separated. Then some very firm and extensive adhesions to the abdominal wall were broken down, and the cyst was drawn out after separating a long strip of the left broad ligament, which was expanded over it and adhered to it. This strip was tied and cut off, after securing a long pedicle in a small clamp. The ligature on the broad ligament was tied to the clamp. The right ovary was healthy. There was scarcely any bleeding, but a few clots due to the separated adhesions were sponged from the pelvis. The wound was closed as usual. The patient made an excellent recovery. A troublesome cough, with expectoration of very viscid mucus, went on for several days after the operation, but it did not interfere with the healing of the wound, which was well united on the fifth day, when Mr. Wells removed all the sutures, and the clamp also, as there was some prolapse of the pedicle. The bowels acted daily after the ninth day, and the patient returned to Nottinghamshire on December 23. She bore the journey well.

ABERDEEN ROYAL INFIRMARY.

LOCOMOTIVE ATAXY—TREATMENT BY IODIDE OF POTASSIUM—PARTIAL IMPROVEMENT.

(Under the care of Dr. ARCHIBALD REITH.)

THE following cases, for the report of which we are indebted to Mr. Fowler, are the first cases of locomotor ataxy which we have published in our Hospital Reports. They will be read with interest, as the disease is now exciting considerable attention in this country. Trousseau has given a most interesting account of progressive locomotor ataxy, and it may now, we are glad to say, be read in English. Dr. Bazire has just published the first part of his translation of the Professor's lectures. Dr. Bazire has added to the lecture on locomotor ataxy a most valuable record of cases observed by himself at the Hospital for Epilepsy and Paralysis, with important observations thereon.

James M., aged 39, plasterer, was admitted into John Forbes' Ward March 23, 1865.

Previous History.—His health generally has been very good, and he has been very temperate in his habits. He has never had any disease with the exception of measles and hooping cough in childhood. About three years ago he passed water very frequently for a week; but he did not feel ill at the time, nor did he observe anything peculiar in the urine. His father died of cancer of the penis, aged 72, and his mother of natural decay, at the same age. Other near relatives healthy. He declares that he was never addicted to venereal excess of any kind.

History of Present Illness.—In the month of November, 1863, without any known cause or premonitory symptom, he began to lose the power of his right leg. The weakness seemed to commence at the ankle, and gradually crept up to the knee, and was accompanied by partial loss of feeling and a sensation of deadness. About two months subsequently the left leg became almost suddenly in the course of one day similarly affected, though not to the same degree. There has been no change in condition for the last fourteen months. He has used a few simple remedies, but without benefit; and he did not persevere in their employment, because he thought he would recover spontaneously.

Present Condition.—Body well nourished, firm, and wiry. Skin natural. Feet habitually cold.

Nervous System.—He has no pain in the head nor giddiness. Consciousness and memory perfect. The mouth is drawn slightly to the right, best seen when he smiles. He is sometimes troubled with jerking of his legs. When he attempts to walk, he feels as if he had got a blow on the thighs, and his legs suddenly start up. If he attempt to put one leg before the other, it is sometimes jerked outwards or forwards, and planted rather forcibly on the ground without his control. His gait is that of a drunken man; but although he staggers forward in a rather precipitate manner, yet with the assistance of a stick he manages to get along without falling. When his eyes are shut, however, or when he has no support, he can scarcely move a step without falling; and if his two feet be placed parallel close together, with his eyes shut at the same time, he falls over as if he had no idea of the perpendicular, and has to be supported. He does not think his legs have wasted since the commencement of his attack. Speech quite unaffected. No abnormity in the spine.

Organs of Sense.—The left pupil is a little larger than the right. Taste unimpaired. There is partial anæsthesia in the right leg. He has sometimes stinging pains in his thighs apparently depending on the feelings above mentioned. Respiratory, circulatory, and digestive systems healthy. Urine natural.

The treatment consisted in the administration of iodide of potassium in doses of 5j. daily. The facial paralysis disappeared; but when he left the Hospital on April 17 he did not appear to walk better, although he himself thought he could.

LOCOMOTIVE ATAXY—TREATMENT BY IODIDE OF POTASSIUM—PARTIAL IMPROVEMENT.

[Reported by Mr. GALLOWAY.]

Jane S., aged 19, domestic servant, unmarried, was admitted into Ruth's Ward May 11, 1865, complaining of inability to walk.

Previous History.—She has not had robust health since her childhood, when she suffered from scarlatina, typhus, and "remittent" fevers. She had inflammation of the eyes shortly after birth, and they continued weak for four years afterwards. Her mother died four years ago of cancer of the womb; her father is still alive, and in good health; but he has had three or four attacks of transitory paralysis of one side of the body. Menstruation is regular.

History of Present Illness.—About eight months ago her right knee swelled and became painful. She was treated with tinct. iodin., applied externally; but after some improvement the knee again got worse, and she was admitted into the Surgical wards of this Hospital about a fortnight ago. The swelling of the knee gradually subsided, and she was then transferred to the Medical wards. She now complained of inability to walk, the loss of power being so gradual that she does not remember when she first felt it. She thought that the state of her right knee was the cause of it until it began to appear in the left leg. Before she became unable to walk she had a feeling of weakness across her back, latterly amounting to a dull aching pain. She has suffered for the last two months from a constant headache, like a feeling of weight on the top of the head, with a darting pain, sometimes over the right side near the brow. She feels her sight getting dim, and her eyes growing tremulous.

Present Condition. — Stout and well-made, though not robust. Hair and iris dark. There is slight swelling of, and a feeling of stiffness in the right knee and also in the ankle.

Nervous System.—She complains of severe headache, almost constant, like a weight on the top of her head, and of pain of a sharp darting character over the right eyebrow, and over the right side of the head. There is pain behind her eyes, mostly in the right. She complains, also, of a dull aching pain across the loins. When she walks she staggers as if she were drunk, and would often fall if not supported. She cannot walk at all with her eyes shut, and would instantly tumble down if she had nothing to lean upon. When her feet are put together and her eyes closed at the same time, she immediately falls over. In bed, however, she moves her legs quite well, and has so much power in them that several persons holding them cannot prevent her from moving them. Sensation is unimpaired in both limbs. *Organs of Sense.*—There is a tremulous motion of the eyeballs from side to side; no difference between the pupils, which contract equally to the stimulus of light. Her sight has lately become dim and misty, but she sees moderately sized type perfectly. Respiratory, circulatory, and digestive systems healthy. Urine healthy. Catamenia regular.

Large doses of iodide of potassium were given till July 4, when she left the Hospital relieved of her headache, but with little perceptible improvement in the walking.

Clinical Remarks.—Locomotive ataxy is commonly mistaken for paraplegia. The features of each are so distinct

that it is surprising Physicians did not sooner recognise the difference. Duchenne's vague definition of locomotive ataxy is, "Progressive abolition of the co-ordination of movement, and apparent paralysis, contrasting with integrity of muscular power; these are the fundamental characters of the disease." Trousseau's is more definite, but commits science to what is yet but theory—"A spasmodic neurosis characterised by a want of co-ordination of the voluntary movements, often complicated with disorders of sensibility and partial paralysis." The chief feature of the disease, when fully formed, is, more or less, inability to perform the reflex functions of standing or walking. On attempting to walk the patient finds his legs refusing to obey the ordinary co-ordinating power; they are thrust outwards or forwards spasmodically, and planted on the ground in an irregular way beyond the control of the individual, who is in constant danger of losing his equilibrium. If he succeeds in getting a start he moves forward in a precipitate manner, staggering and stumbling, and is obliged to use a staff to prevent himself from falling. A paraplegic patient, on the other hand, if able to assume the erect posture, drags his legs slowly, but uniformly along, his difficulty being not to control the movements of his legs, but to get them to move at all. The most characteristic differences between locomotive ataxy and paraplegia are the following:—First, *in bed*, the patient with the former affection has complete power over the voluntary movements of the legs, as was well seen in the two cases above recorded, both of whom tossed about their legs with the utmost facility, and defying all attempts to hold them, while in paraplegia the power of voluntary motion is in a greater or less degree lost; secondly, in locomotive ataxy, if the eyes be shut, the patient can no more walk, or even stand, with his feet together than a person can stand or walk on stilts who has never been accustomed to them, while nothing similar is observed in paraplegia, or indeed any other kind of paralysis. In fact, a patient with ataxy closely resembles a tyro endeavouring to walk upon stilts. These diagnostic marks are, therefore, very important, and ought not to be overlooked. They were well seen in the above cases. A woman affected with paraplegia was brought beside the girl S——, and the differences between them were most striking.

Locomotive ataxy seldom comes on without premonitory symptoms. The chief of these are rheumatic pains, partial and temporary attacks of paralysis, and disorders of urinary and generative organs. The pains are irregular, coming and going, and are generally mistaken for rheumatism. They were so in the girl S——; but that they were not rheumatic was at once evident from the fact that they were confined to one knee and ankle—a point of some importance, for rheumatic pains of this kind are mostly due to lesion of the nervous system. There does not appear to have been any other premonitory symptom in this girl, except amaurosis, which was, however, but slight, and the excessive pain on one side of the head. Amaurosis is a very common symptom, as also paralysis of the third and sixth nerves, and indeed of any nerve. The paralysis of the ocular nerves is, in general, more persistent than that of others. Transitory attacks even of hemiplegia may occur, and it is singular that the father of the girl S—— was thus affected, although there is no history of ataxy in him. The premonitory symptoms in the man M—— were partial paralysis of the left facial nerve, and at one time what looks very much like incontinence of urine. He also had cutaneous anæsthesia, which is a frequent attendant on the disease.

The usual post-mortem appearances found after death in these cases are grey degeneration of the posterior columns of the spinal cord, and atrophy of the posterior roots of the spinal nerves. So long as the posterior columns were believed to be the channel for the transmission of sensitive impressions to the brain, this state of parts existing with little or no loss of sensation, but with loss of the reflex power of standing and walking, was rather perplexing, especially as the anterior columns were free from disease; but since the experiments of Brown-Séquard have shown that the posterior columns have not the office formerly assigned to them, and moreover that section of them causes hyperæsthesia, instead of anæsthesia, together with locomotive ataxy, the pathology is more intelligible. But how does it happen that with atrophy of the posterior roots there is often little or no loss of sensation? The explanation given is, that the hyperæsthesia which would be produced by disease of the posterior columns alone is counteracted by the atrophy of the posterior roots, in which some nerve tubes remain intact, sufficient to account for the persistence of sensation. This may be true, but it is not quite satisfactory. It is to be regretted that the state of the sympathetic nerve has not received the attention it deserves. There seems evidence to show that that nerve has more to do with reflex motion than has generally been supposed. Last year M. Voisin presented to the Société de Médecine of Paris a case of locomotive ataxy of the upper extremities where the cervical sympathetics were found diseased.

An attempt has been made to distinguish locomotive ataxy caused by disease of the posterior columns from that caused by cerebellar disease. I am afraid this will be found impossible in practice, at least in many cases. It may be possible to diagnose the locality of the lesion, whether in the cerebellum or in the spinal cord; but that both varieties belong to the same category I have no doubt. For, in ataxy from spinal disease, we also find sometimes structural change in the optic nerve, the optic tract, the corpora quadrigemina, and the motor oculi, without disease in the cerebellum; and yet in some cases of so-called ataxy, the only lesion found has been cerebellar. The ataxy likewise is not confined to the legs, but may proceed to the upper extremities, or even affect them solely, as in Voisin's case just mentioned. The cerebellar and spinal diseases are, therefore, probably varieties of the same evil, the ataxy being the symptom. And here I may be permitted to quote some observations of Dr. Hughlings Jackson. Speaking of cases of paralysis of one or more cranial nerves, with paralysis of both legs, and no paralysis of the arms, except now and then a little paralysis of the hands or fingers, he says:—"One of three inferences may be drawn from these facts. 1. The symptoms may by some be considered to occur together by a coincidence. 2. That the paralysis of the cranial nerve is the result of reflex action, set up by the disease of the cord which produces the paraplegia. This is the explanation given by Dr. Brown-Séquard. 3. That there is a tract in the higher part of the nervous system which contains nerve-fibres from the legs and not from the arms, or, at least, only from the fingers or hands. Some of these cases resemble, and perhaps are, locomotive ataxie. There is in some a loss of power in walking properly, whilst the legs seem to retain considerable power. This, of course, applies only to those whose sight is merely impaired. When the guiding power in the legs is lost, we use the eyes to direct our movements. Even in health 'we lean,' says a distinguished physiologist, 'on our eyesight as on crutches.' Patients who have ataxie, therefore, cannot walk in the dark, or when their eyes are shut. Blindness, following loss of guiding power in the legs, seems then to be not so much a complication as the loss of a similar faculty. But, when the patient has lost both these helps to guide himself, it is just possible that he may struggle his way from object to object by touch. But a third factor in the general power to guide movements is frequently affected also, there is numbness of the fingers; so that the power to combine movements in the legs, or to do so in a supplementary way by help of the eyes, or of touch, is lost altogether. This, I think, renders it plausible that there may be in the higher parts of the nervous system a tract of nerve-fibres passing from the legs, fingers (tips) to the corpora quadrigemina for the general purpose of guiding movements in progression."(a)

The prognosis of locomotive ataxy is bad. Patients, if they do mend for a little time, mostly go from bad to worse till they can no longer maintain themselves in the erect posture, and die cachectic. Various remedies have been tried. Electricity and nitrate of silver are favourite remedies with some, but not much confidence can be placed in them. There is this comfort, that the disease may remain stationary for many years.

Note.—The second patient has just recovered from an attack of typhus. The symptoms of ataxy are more developed, but there is now some loss of voluntary power in the legs, probably from extension of the disease to the grey matter.

A Severe, but Just Punishment.—A court-martial has been held on private Bernard Daly, of the 40th Regiment, for a savage and unprovoked attack on Surgeon-Major Webb, M.B., during the time he was undergoing a Medical inspection at the Chatham General Hospital. Daly, having been found guilty, has been sentenced to be dismissed Her Majesty's service with ignominy, to be branded with the letters "B. C.," and to be kept in penal servitude for five years.

TERMS OF SUBSCRIPTION.

Twelve Months (Prepaid) stamped for post £1 10 0
Six Months (do.) 0 15 0

Regularly transmitted by Post throughout Great Britain, and to the most distant of the British Colonies.

The Journal can be obtained of all Booksellers and Newsmen, Unstamped, for £1 6*s. per Annum.*

Post-office Orders and Drafts on Army or Navy Agents, should be made in favour of Mr. James Lucas, 11, *New Burlington-street, W.*

Medical Times and Gazette.

SATURDAY, JANUARY 20.

ENTOZOA AND RINDERPEST.

In connexion with the still vexed question of the nature of cattle plague, we would direct our readers' attention to the elaborate and interesting paper and drawings of Dr. Beale which we publish in the *Medical Times and Gazette* of this day, on the nature of the entozoa found in the voluntary muscles and in the muscular tissue of the heart of animals that have died of the cattle plague. Attention was drawn to this matter by Dr. Fenwick in the *Times* of January 3, but it is evident that the bodies in question had not escaped Dr. Beale's notice, and he must have been for some time actively engaged in minutely investigating the question. We would add, if it were not unnecessary, one word of just eulogy on the thoroughness of his investigation.

It is clear, in the first place, that these bodies are found universally in all the muscles of beasts which have died of the cattle plague. Dr. Beale certainly brings forward one case in which they were not found; but, with this exception, the testimony of all observers as to their universality is unanimous. That they are found in *very small* number in some few beasts apparently healthy is a fact also to which due weight must be given.

The second question is, What are they? Dr. Beale's account of the investing membrane and of the contents renders it impossible, we think, for any one to doubt that they are entozoa.

We have heard it said that they are more closely allied to the Gregarinidæ or Sporospermiæ; but what member of either of these classes is known to attain a length of *a quarter of an inch*, or to possess such a structure as these bodies exhibit?

Again, the form and structure of the minute bodies occupying these cysts put us in mind of many of the larval forms of entozoa at a very early period of development.

Indeed, looking at all the facts, it seems difficult to escape the conclusion that these bodies are true *entozoa* in some imperfect stage of development, during which most rapid multiplication proceeds, and that, like many members of their class, they have to undergo another migration before they reach their fully developed state.

Their connexion with cattle plague is altogether another matter, and nothing can be more cautious than Dr. Beale's remarks upon this point. Yet we suspect that they will throw a light upon the subject which will be new to some of our readers.

We are all familiar enough with the word *zymotic*. We know how it is applied to a class of febrile diseases which are produced by the implantation of a poison, and in the course of which that poison is multiplied a millionfold, just as yeast is in fermenting beer. We are not equally familiar with the class of "*febrile helminthic* disorder," yet we have one marvellous example of it in the case of the trichina disease. Certain worms are swallowed; they hatch myriads of young ones, which immediately begin to bore the intestinal canal, and wander all over the body to lodge themselves in the muscles. During this process the unlucky "host" (as the unwitting victim of worms is courteously called by the helminthologist) suffers from general febrile disorder, diarrhœa, acute pains in the abdomen, and weariness and aching of the limbs. In most fatal cases the patient is said to have died "with all the symptoms of severe typhus." Now, is this not a tempting field for speculation? May not the Rinderpest be an *acute helminthic?* We must still maintain the reserve which this journal has hitherto kept, and wait a bit before deciding. If not the cause, at any rate these bodies seem to accompany the cause so closely that they may furnish a clue to it some day.

Meanwhile, the observations made upon the minute structure of these bodies may be the end of a thread which, cleverly and intelligently followed up, might, perhaps, lead to the determination of the nature of some obscure and fatal diseases which it is of the utmost importance should be discovered, and of which we are now utterly ignorant; for this may lead not only to the prevention of disease, but to its extirpation.

If we were well acquainted with the natural history and migration of the trichina, can it for a moment be doubted that every civilised Government in the world would at once take measures for annihilating the noxious race? Nor does this seem a very difficult matter. Microscopical investigation of the muscles of every slaughtered pig would infallibly discover the trichinæ, and the thorough combustion of every particle of the animal might be enforced by law. Civilised man would then be spared the pain of hearing of such dreadful and preventible catastrophes as those of Heltstädt and Hedersleben.

THE POLYMORPHISM OF DISEASE.

In these times, when science is apparently budding so freely and division of labour an economical necessity, it is highly important for the prevention of narrow views that attention be closely directed to the teachings of analogy and to the generalisations of trustworthy observers in departments of Medicine other than those which we severally may have selected for our own special study. In this age of neck-to-neck race for eminence, enlarged views are perhaps comparatively far too rare. It is manifest that living beings, animals, plants, and even chemical bodies, wander considerably from their ideal pristine type; the degree of variation, as the rule, being in direct ratio to the simplicity of organisation. At the same time, as a salutary check to ultra interpretations, there is a law of limitation, in virtue of which species preserve each their *essential*, though they may vary as regards *accidental*, features.

The best exemplication of this truth is afforded by components of the vegetable kingdom, the whole of which, as Dr. Hooker truly observed, is pervaded by the element of mutability; and no better illustrations are afforded than by the history of the potato, of wheat, and of garden flowers in general. Analogous instances in the animal kingdom in the lowest forms of life are referred to by Quatrefages in his "Metamorphoses of Animals," and illustrated by the facts of "the alternation of generations." When this theory was first promulged, the word Di-morphism was coined, used timidly, then more frequently and freely, and now has given place to the more correct designation—polymorphism. Very admirable examples are given by De Bary, who has shown that *uredo*, *uromyces*, *puccinia*, and *æcidium* are but stages of the same coniomycetous fungus. It would appear also that there are from four to six aspects of pyrenomyeetes, and the third

volume of Tulasne's "Carpologia" contains similar evidence in his magnificent plates of polymorphism in the entomogenous *sphericæ*, and other allied groups; and as fructification has been regarded as the only real differential test of species in fungi, it is easy to understand that the natural variations of one have been looked upon as separate and distinct kinds of plant. In the mineral kingdom, the same condition is confirmed by the behaviour of certain crystalline salts. In the animal kingdom, the principle of natural selection interferes somewhat. Many of the various species of acari are thought mere modifications, to be accounted for by the influence of differences of habitat and the like.

No less is polymorphism exhibited in the case of diseased conditions. The instances of intestinal and other entozoa will at once occur to the mind. There is scarcely a disease which has not a considerable range in aspect according to the different degrees of intensity in quality or quantity of the virus, and the state of the living being upon whom it plays; hence the varying character of epidemics — malignant, sthenic, asthenic, fatal, or mild. As the local expressions of disease depend, of course, upon the degree of development of the general condition, variations are met with accordingly, and this is an important consideration at the present time in reference to Rinderpest. It is asserted that the chief objection to the reception of belief in its identity with small-pox exists in the contrast presented by the eruption in the two cases. Is the affirmative consistent by analogy with what we know of diseases in general? Variola, vaccinia, and cow-pox are now admitted to be identical in nature. Bastard vaccinia must be included also; and the French have adduced evidence in support of the view that grease and apthous stomatitis of horses are modifications of variola; whilst in India the latter, as to its eruption, assumes unusual garbs in man and animals. Puerperal fever may be erysipelatous, gastro-enteric, or malignant. Measles may be mild (as in the East)—malignant, abortive, as in Rubeola sine catarrho, or anomalous, as Rubeola notha, and the pseudo-measles of Dr. Salisbury. Scarlatina is peculiarly mild in the puerperic woman in Ireland; and its least expressed form is not unlikely Rosalia. In northern climates leprosy assumes the tubercular, and in India the anæsthetic form by preference; whilst in mid-climes one occasionally observes its least expression, Morphœa, as the total disease. In Scotland Sibbens is its remnant. Syphilis is mild in the East, bad in India; and Radesyge is supposed by Dr. Böeck to be a peculiar phase in Norway. The distinctions of gout, rheumatic gout, and rheumatism are not well defined. Gonorrhœal rheumatism is a puzzle as to its exact relations. Turning, however, to examples that are more immediately appreciable by the eye, and, therefore, not so likely to mislead —viz., eruptions on the surface, we observe the same polymorphism in acute specific diseases; for some early stages may represent the total malady. This opens out the wide question of "abortive forms" to which Dr. Stokes especially directed attention. In typhoid fever we frequently notice certain special characters peculiarly marked, as in the "latent" cases. Erratic and metastatic occurrences are further illustrative. Amongst the more chronic maladies, there is no dearth of examples. Eczema is rarely observed to be vesicular; fissuring, squamation, papulation, or even erythema, may predominate, or a translation of morbid action to the mucous membranes may take place, and alternate with the changes usually noted on the surface. Strophulus in its several forms and lichen, the whole parasitic group of diseases, and the phases of scabies only confirm what has been said. Age, sex, constitution, texture (*e.g.*, the hairy covering of animals), the transmission through different species, hereditary peculiarities are some of the chief agencies in effecting modification; and in reference to hereditary peculiarities, it is worth noting that in eruptions the local changes are peculiarly well marked and obstinate.

The duty of the scientific man is clearly indicated by the often repeated words of Mr. Bentham in reference to plants—"That neither size nor outline affords any basis for distinction into species until it has been ascertained, from extensive comparison of forms brought from different localities in the widest area over which the species can be traced, what are the average characters of the type and what is their range of variation." The doctrine of polymorphism is an important one to be aware of, since the various influences that play upon the individual differ much at and in different times and places; and whilst close similarities are often produced, it is all the more needful that diseases should be studied in their entire history, and that no one special feature be exalted into undue significance, if we would travel the safest road in the discovery of truth.

SCURVY.

The fact that a disease called sea-scurvy still exists in Medical nomenclature is humiliating in itself, and cannot be too strongly reprobated as a disgrace to the mercantile marine of this country. More than half a century has now passed away since it claimed its scores of victims from the Royal Navy; but that service now knows the disease only in name. The remedy has been applied, is simple and efficacious; but the merchants of Great Britain, and the underwriters connected with her shipping, still, with unaccountable blindness to their own interests, persist in ignoring the fact that risk of an outbreak of scurvy indicates great and grave risks to ship, passengers, and cargo. For, when the tables of this disease kept on the *Dreadnought* show that from 20 to 90 per cent. of a ship's crew are often prostrate from scurvy, it boots not to speculate how many of our East Indian and Australian vessels are lost from this cause alone. A short-handed ship, in a north-west gale off the Cape, or in a smart squall near the Line, has to struggle for existence against fearful odds, known only to those who have seen the use, and felt the want, of helping hands at such a time. The art of navigation, with its scientific aids and appointments, has steadily increased, year by year, as our commerce has extended over the globe; and the prospects of comparative immunity from danger at sea should increase likewise. But the number of vessels that sail from port, "and have not since been heard of," has by no means diminished in a justly proportionate degree, nor will it diminish as long as bad and insufficient lime-juice is carried in our ocean-going ships, and scurvy is thereby allowed to reduce indefinitely the available force of the crew on the homeward passage. The *Dreadnought* Hospital ship, always a great depôt for scurvy, has entered from 80 to 90 cases per annum during the last 10 years. In 1865, however, an increase of no less than 20 per cent. has obtained, and of 103 cases brought in during the past year, 1 only was admitted from a foreign vessel. This fact raises the average of British-made scurvy during the last year in a still greater degree; for in former years from 12 to 14 cases have been sent from ships not carrying the British flag. A correspondence has lately been going on between the Board of Trade and the Seamen's Hospital Society, which formed the subject of a leading article in the *Times* of December 16, and of a letter to the same journal two days after, from the resident Medical officer of the *Dreadnought*. The Board of Trade not being furnished with powers to appoint Medical inspectors of lime-juice, have proposed to the local Marine Boards of the chief ports in the kingdom to institute such inspectorships. Two only out of seven to whom communications were addressed have enclosed favourable replies, and the project is likely to be abandoned, unless the Board of Trade apply for powers to appoint inspectors under their own jurisdiction. It is urged by the local Marine Boards, and in some degree supported by the *Times*, that such inspection would involve an incalculable

amount of trouble and inconvenience, and that a partial inspection is worse than useless. To this latter opinion we heartily subscribe. But it has been clearly proved to the Board of Trade by facts, into the particulars of which we need not enter here, that an inspection of lime-juice in ships proceeding to ports east of the Cape (and this latter restriction lessens the number of examinations considerably), would be effectual in removing three-fourths of the scurvy now annually brought home by our mercantile marine. We cannot agree with the *Times* in entertaining the idea that forcible interference is not necessary. The Board of Trade, at the instance of the Seamen's Hospital Society, have given warnings and instructions over and over again, all of which have been habitually disregarded. Lime and lemon juice are adulterated to an enormous extent for the purpose of shipment, and lose their identity in all but the name. The Merchant Shipping Act, as at present constituted, affords no remedy whatever for this evil; and so our sailors go to sea, are supplied with these filthy mixtures, and on their return are hoisted into the *Dreadnought*, or are laid up in lodging-houses, helpless for the present and ruined in stamina for the future. An appeal from the underwriters (who are chiefly interested in this matter) to the Board of Trade would act powerfully in the right direction. In counting the cost of inspectorships, let the cost also be counted of those annual and apparently mysterious losses of men and money in open sea, the amount of which the members of Lloyds' know, perhaps, a little too well. We shall aid commercial economy as well as humanity by removing this national disgrace, and so materially improving the sanitary condition of the men in our merchant navy.

THE WEEK.

THE SCIENTIFIC STUDY OF THE RINDERPEST.

We have reason to believe that we overstated the opinions of one of the speakers in the recent discussion at the Pathological Society in our notice January 6, page 14. That notice was written under difficulties which we have already explained, and last week we gave a full and accurate report of what took place.

It is one thing to state arguments forcibly and yet precisely, and another to come to a conclusion; the former is difficult, the latter easy. And in reference to the Rinderpest there have been, we think, more conclusions than arguments, and more explanations than facts. To state arguments broadly and yet clearly, forcibly and yet fairly, requires judicial calmness and considerable mental vigour; whilst, on the other hand, making theories and drawing conclusions is often but the sign of a prurient ingenuity—a sort of thing for which a schoolboy ought to be whipped. We have now to say, then, that although Dr. Quain urged that the amount of evidence as to the relationship of Rinderpest and Variola was too considerable to be overlooked, he did not by any means conclude that they were identical diseases. In the discussion we have alluded to, Dr. Quain particularly drew attention to the many absurdly ingenious surmises in the newspapers—Rinderpest being compared to all sorts of things, among others to Small-pox. It may be right to cut the Gordian knot sometimes, and "guesses at truth" by first-rate men on perplexing subjects are sometimes useful; but that every schoolboy who carries a pocket-knife should be allowed to have a cut at it is simply a vexatious annoyance. There have been so many of these theories that it is not impossible that some one of the theorisers may be right by accident. In an important question like the present, however, "conclusions" and "explanations" do little more than choke up the way of investigation. An ingenious first-year's student would make theories and plans of treatment good enough for the newspapers by the yard. The absurdity of the suggestion that we should treat Rinderpest by hanging onions round the affected animal's neck does not altogether destroy the effect of its repetition sixty or seventy thousand times by the printing machine of the *Times*. The logical power of machinery is of the sort reprobated by Dr. Johnson. It is rather a raising of the voice than the enforcing of an argument. The newspapers and the public are not alone to blame. A readiness to put forward conclusions is, we, think, one great bane of our department of science. Medical science is manifestly uncertain, and those who have not vigour enough to keep their minds balanced amidst conflicting arguments—who cannot trace resemblances without ignoring differences—are always groping about for some theory to rest on. They will come to an anchorage, although it often turns out that their anchor ground sinks from under them, as in the case of Sindbad, who came to rest on a whale's back. Hence, in every important investigation there are heaps of generalities to be got rid of before we can arrive at scientific generalisation. To be always ready to found a doctrine on facts, whether many or few, is a sign of restlessness from weakness, rather than of activity from vigour. In great contrast to this is the temperate way in which such men as Quain, Murchison, Sanderson, Ceely, Gamgee, and others have investigated the Rinderpest. In the discussion it was very noticeable how carefully some of the speakers guarded themselves from allowing it to be believed that they wished to force the question to an issue on the then evidence. Dr. Quain, to whom we have to apologise, justly considers that we must wait the result of experiments before we can with anything like precision conclude that the resemblances of the two—we may still call them two—diseases are essential and characterise small-pox, whether human or bovine, and that the apparent differences are such as might be expected necessarily to occur when small-pox appears under such varied circumstances as it must do when it affects both men and cattle.

THE COMMITTEE AT THE ADMIRALTY.

There is, very naturally, a great desire on the part of the Medical officers of both services, as well as the Profession generally, to know something of what the Committee has recommended. Until the Report has been published nothing positive can be known; but so many rumours are afloat, that there can be no harm in stating what we have heard, and believe to be probable. The inquiry has terminated, then; but, as far as we can gather, the recommendations of the Committee, in the case of the Naval Medical officers, have not been finally settled yet. With regard to the Army, it is understood that an optional earlier retirement at a small rate of pay will be recommended, and that some concessions will be advised as to matters affecting relative rank and position. The pay of Surgeons will remain the same, or nearly so; but a slight addition to that of the Surgeons-Major, and some little increase to the Senior Assistant-Surgeons' pay, are said to have been recommended. The Committee are likewise said to have recommended the addition of a few Deputy-Inspectors to the present number. We have endeavoured to ascertain whether anything has been suggested in the way of promotion for the junior grades; but we believe nothing has. If this be so, there will remain the hopeful prospect for a man now entering of retirement at twenty years as an Assistant-Surgeon on a small retiring allowance. It is simply ridiculous to suppose that Assistant-Surgeons of twelve years' service will quietly and contentedly submit to proceed to India, where they will have to serve in a subordinate rank to those Medical officers of the Indian Army who have attained the rank of Surgeon by virtue of their twelve years' service, in accordance with the terms of the Indian Medical Warrant. It struck us with surprise that no Army Assistant-Surgeons were examined before the Committee. The men who entered upon the faith of the Royal Warrant of 1858 were unquestionably a better class of men than the Department commonly attracts, and we know that the Crimean War drew some able young men into

the Army. For what length of time does the Government expect these to continue in their subordinate capacity? It is tolerably well known that the most irksome duties—the petty details, the monotonous, half-Professional, half-military duties—fall to the lot of the Assistant-Surgeon. Of this there is no reason to complain, perhaps; but a long continuance in a subordinate office is a sure means of promoting that habit of relying on others which tends to unfit a man for a position of weight and responsibility when he does attain it. Hope and independence are driven out of him. The Government authorities, perhaps, neither wish for nor require any independence or decision of character in their Medical officers; but a man in a high position abroad must possess them, or bring discredit on the Department to which he belongs. Every epidemic at a colony, every disaster in the field, teaches us this lesson. The Naval Medical Department has come to a standstill for want of men, and that service must be something very different from what it now is before the deficiency will be supplied. We hope our Profession has learnt this lesson. The recommendations of a Committee are one thing; their approval by the authorities, quite another. Our belief remains the same: if men be forthcoming, improvements will not.

DEAF MUTISM.

A MEETING was held on Monday evening in the Hanover-square Rooms for an object of no less physiological than philanthropical interest. It was convened primarily to raise a sufficient sum of money to provide a chapel with class and lecture-rooms for the deaf and dumb of London; and secondly, to give a number of these unfortunates an evening of amusement—tea, dissolving views, and addresses in sign language. How perfectly possible it is to address a large assembly by sign language is proved by the feat performed by the Rev. S. Smith, the Secretary and Chaplain to the Association in Aid of the Deaf and Dumb, who, standing in front of the Chairman, Capt. the Hon. R. Grosvenor, managed to reproduce on his fingers the whole of the Chairman's tolerably long address, sentence by sentence, almost as rapidly as it was uttered. The whole history of deaf mutism involves a problem of great Medical interest. What is the defect in nervous structure which entails it? How often does it depend simply on absence or defect of the auditory nerve, or in what proportion does such a defect coexist with a radical deficiency in the whole nervous centre? A certain proportion of deaf mutes are imbecile, but a larger proportion, as the results of training show, are capable of an extraordinary progress in mental culture. Still, on watching the deaf mutes who crowded the Hanover-square Rooms on Monday, we were struck with the remarkable cranial conformation—often defective in size and development—the small forehead, and scanty lower jaw, which a large proportion of them exhibited. Probably low cranial development may be, in part, the result of the absence of one great channel by which ideas and materials for thought are obtained. But it is also, we have little doubt, a mark of general congenital cerebral deficiency, of which the deafness and dumbness are only the most striking proofs. Still, there are not wanting instances of great intelligence and aptitude for acquirement amongst deaf mutes. Some of them have been admirable painters; others have learned to perform well the duties of ordinary business—they have been good accountants and handicraftsmen. The subject of the alleged location of the powers of speech and expression by words in a particular portion of the brain has lately attracted considerable notice in France. We believe that the location of speech in the anterior lobes of the cerebrum is an assumption which does not stand the test of pathological facts; but it is certainly true that the cranial development of a large proportion of deaf mutes is below the average—a circumstance closely connected both as cause and effect with the absence of speech and hearing.

FEVER AND SMALL-POX HOSPITALS.

THE St. Pancras guardians, roused by the death of their Senior Surgeon, Mr. Roberts, from fever, are urging upon the Government the necessity of providing more Hospital accommodation for fever and small-pox in London. A deputation from the parish had an interview with Mr. Villiers at the Poor-law Board on Monday last, the result of which was that the President acknowledged that the parochial authorities had made out a very strong case, and promised that the whole matter should receive the earnest consideration of the Board. We suppose that whatever is done will be paid for by the ratepayers of the metropolis; and we do not see why the guardians of parishes should not be bound to provide suitable Hospital accommodation, at a proper distance from the crowded populations of town, for their fever and small-pox cases. The fever-stricken poor should not be at the mercy of a charitable institution to receive or reject them according to its means of relief. The sum of 1s. a-day paid to the London Fever Hospital by the parochial authorities for every case admitted is totally inadequate to provide nursing, medicines, and nourishment; and the fact is that at present the resources of the Fever Hospital are bearing a large part of a burden which should fall on the parochial funds. Fever now is rife in St. Pancras as well as in other parts of London, and it is likely to increase whilst high prices, inclement weather, and destruction of the dwellings of the poor by railway companies continue. We are very sorry to see that a promising young Surgeon, Mr. Stuart, of University College Hospital, has fallen a victim to fever during the past week.

FROM ABROAD.—THE OUTBREAK OF TRICHINOSIS AT HEDERSLEBEN.

THE outbreak of trichinosis at Hedersleben, of which we gave some account in our number for January 6, is of so remarkable a character that we recur to it again on the occasion of two communications just published by Drs. Rupprecht and Kratz in the Berlin *Medicinische Wochenschrift*. To Dr. Rupprecht the subject is not a new one; for he was the historian of a similar, though somewhat less formidable outbreak which occurred at Heltstadt, of which place he is a *Sanitätsrath*, or Sanitary adviser. The account he then gave was supposed by some to have been exaggerated, but the ravages of the disease, as observed at Hedersleben, surpass those observed at Heltstadt; for Dr. Rupprecht repairing there during the fourth week of the epidemic, found matters to be worse even than they had been represented. Ample investigation is likely to take place, as not only is Dr. Kratz, an enlightened Physician of the locality, preparing an elaborate report on the subject, but Virchow has sent some of his assistants to work out the details. It seems that on the second day after eating the pork about twenty of the factory hands were seized with "trichinous cholera," which, notwithstanding suspicions of its true nature expressed by Dr. Kratz, was pronounced to be true cholera. However, the discovery of trichinæ in great numbers set the matter in its proper light; but a week had been lost in treating the patients for cholera, while, owing to the cholera panic that prevailed, many of the workpeople already infected with trichinæ fled the town and perished amidst great misery, some of whom would have had a better chance of recovery had they remained in the excellent Hospital attacked to the factory. It is evident that in all similar cases early diagnosis of this diarrhœa, which sometimes only accompanies the disease, is of great importance, and Dr. Kratz reports that it may always be distinguished by its being accompanied by a peculiar muscular pain, a sense of painful distension, like muscular weariness, especially affecting the flexors of the extremities. This pain is increased on every movement, or by the slightest pressure, Appearing at so early a stage, it can only be due to reflex irritation, derivable from the innumerable trichinæ in the

intestines. In the Heltstadt outbreak diarrhœa was not one of the early symptoms of the disease, and any of the muscular pains which were observed at a later period were explicable by the presence of the trichinæ. In Heltstadt, too, the first deaths did not take place until the third week, and were all due to paralysis of the respiratory organs, brought on by the migration of the trichinæ to the diaphragm and other respiratory muscles. But at Hedersleben three deaths occurred within six days after the infection, and were the consequence of widely-extended gastro-enteritis. The disease in both towns followed the eating the flesh, however prepared, the symptoms being most virulent from the chopped raw flesh. But cooking, unless very complete, affords no security, the trichinæ of the surface alone being destroyed. In Heltstadt, with about 4000 inhabitants, there occurred 158 cases with 27 deaths; while in Hedersleben, with only 2000 inhabitants, there were 309 cases with, up to the time of Dr. Rupprecht's visit, 60 deaths, and 20 more certain to follow. In one ward of the factory Hospital he found 25 patients, 18 of whom were dying. Dr. Kratz gave benzine a very complete trial, but it is very doubtful whether it proved of any utility, for it seemed to exert no effect upon the migration of the trichinæ, while these animals could be kept alive in it for several hours. Continued in large doses for some days, Dr. Rupprecht believes that it may favour the occurrence of the muscular exhaustion which is to be dreaded in the disease.

Notwithstanding the great attention which has been paid to swine since the prevalence of *trichinosis*, it has never yet been observed to spontaneously appear in these animals, although in young animals artificial infection may be produced and very severe enteritis or peritonitis result. At all events, an animal, in no wise apparently diseased itself, may convey a most fatal disease to man. Whether season or locality has anything to do with it is doubtful, for the especial prevalence of the affection hitherto observed in Saxony may be due to the great proportionate consumption of swine's flesh in that country. As to the important question of preventing the disease in future, Dr. Rupprecht sees great difficulties arising from popular ignorance and incredulity and the sinister influences of trade interests. He believes that the only security will be the official prevention of the sale of swine's flesh until this has been microscopically examined by authorised experts, and he thinks much may be done by spreading abroad popular information on the subject and generalising the use of the microscope.

Dr. Kratz, in a preliminary report upon the outbreak, states that commencing at the end of October it still remained formidable at the time of his writing, Dec. 10. It differed in several respects from other epidemics that have been recorded. Its most constant symptom at first has been the occurrence of vomiting and choleriform diarrhœa, accompanied by peculiar pains of the flexors of the extremities. Excessive sweating, sleeplessness, small and quick pulse, and great abdominal pain were other symptoms. The diarrhœa sometimes ceased spontaneously, and between the third and fifth week great oppression of the respiration set in, marked by paroxysms of intense dyspnœa, occurring chiefly at night; and when autopsies have been made in these cases abundant migration of the trichinæ into the respiratory muscles, and especially the diaphragm, was discovered. Frequently in the course of the affection there was so considerable a subsidence of the symptoms that a very favourable prognosis seemed admissible; but in many of these cases a sudden aggravation of symptoms occurred, which soon led to a fatal termination. The period of the outbreak of the disease, after eating the infected flesh, was very varied, so that the period of incubation might be said to range from two days to four weeks; individual susceptibility seeming, however, to have little to do with this, the amount of the meat eaten chiefly determining the rapidity of the supervention of the symptoms. The favourable condition of childhood is remarkable, for of more than 100 children affected none have died. This may be due to the more active condition of the alimentary canal at that age; an observation corroborated by the unfavourable results which occurred in the early cases treated by opium. Of about 350 cases from 80 to 90 had died at the date of the report, about 200 of these persons having eaten the flesh completely raw. As to the effects of benzine, Dr. Kratz reserves his final opinion, stating in the meantime that even in the large dose of one and a half ounce per diem it does no harm.

AFFINITIES OF THE RINDERPEST.

(From a Provincial Physician.)

We return to the subject of cattle plague,—a subject, indeed, which increases both in interest and importance; in interest, because of the direct proof, on the one hand, of the identity or otherwise of cattle plague and small-pox, which is now being sought throughout the country by the testing of the preservative influence of vaccination; and, on the other, because of the uncertainty which still exists as to the significance of the parasitic bodies described by Dr. Fenwick;—in importance, because the plague continues its ravages, or rather appears to be steadily on the increase.

Pending the solution of these questions, Dr. Murchison has addressed a long letter to a contemporary, in which he replies to arguments which have been advanced in this journal and elsewhere, and also points out some analogies which unquestionably exist between the two diseases. But whilst admitting that such analogies do really exist, we yet cannot but feel that the points of divergence between them are greater still, and that they are such that if they do prove to be identical we must perforce admit a far greater modifying power in differing constitution than we have hitherto been justified, by our knowledge of disease, in attributing to it. But even in the respect in which perhaps the two affections most strongly resemble one another, viz., the congestions and ecchymoses found in the mucous membranes, the condition of these parts in cases of cattle plague is by no means identical with those described by the various authors enumerated in Dr. Murchison's letter, as found in fatal cases of small-pox. For in our experience not only is the condition of the mucous membranes one rather of passive, poisoned blood congestion, than of one which can rightly be called inflammation, but there has been uniformly an absence of those products which are the ordinary indications of the existence of this morbid process.

We have seen the most copious red spottings and congestions of the trachea and bronchial tubes without any apparent (or the very slightest) hypersecretion of mucus, far less with anything like the ordinary products of inflammation of this mucous surface; and we have again and again seen the vessels of the stomach and bowels gorged with blood, even to the rupture of the capillaries and the formation of direct ecchymoses, and yet the mucous membrane has shown upon its surface nothing nearer to an inflammatory product than a somewhat copious layer of soft gelatiniform mucus. In no one case have we seen anything approaching to the distinct layers of lymph, or to the copious puriform secretion described as found upon the different mucous membranes in certain cases of small-pox.

But how, we again ask, is it possible theoretically to comprehend the identity of the two diseases, when we know that the sheep itself is liable to a disease which, from its close resemblance in many of its characters to human small-pox, veterinarians have most confidently classed with it; and yet these same sheep most readily take the cattle plague, and develope, not small-pox, but a disease with exactly the same phenomena as the beasts from which they are inoculated. Can sheep, therefore, have two forms of small-pox?

But in reference to the argument which has been urged that the skin of oxen may be of such a nature as to be unable to take on the morbid process which results in other animals in development of the ordinary small-pox eruption, we have quite recently seen a portion of the hide of a beast whose loins had been freely rubbed for some days before death with tartar emetic ointment, with the result of the development of as much diffused inflammatory redness, and of as complete, and large, and perfect pustules as could have been produced on the human skin by the application of the same substance. Inability to take on pustulating or suppurating action is therefore clearly not the reason why the eruption on the bovine skin partakes so little of the variolous character.

But, whatever may be our opinions, the sure and only test of experiment will now very soon settle this disputed but most important question. Vaccination of cows and beasts is being most extensively practised; but even on this point we would suggest that as after successful vaccination from one to three weeks must elapse from the time of exposure to the infection before the plague *could* be developed, whilst a much longer time must elapse before we could be sure of immunity, a more speedy, if not a more decisive, proof could be obtained by vaccinating a number of animals which have recovered from the disease. If only one of these developed the true vaccine disease, the point would be settled even more conclusively than by the supposed protection of many hitherto healthy animals.

With regard to the foreign bodies found overrunning the muscular system, and which have been described by Dr. Fenwick as entozoa, Dr. Cobbold has publicly called in question their animal or entozoal nature, and has written to the daily papers some letters in which he expresses his belief that they are "sacs of psorospermiæ, and, therefore, also entophyta rather than entozoa," and that "their granular contents when highly magnified resemble the non-ciliated zoospores of certain confervoid algæ."

The scientific question as to their proper classification and nomenclature is of course very interesting, and a very desirable one to determine; but when this is done, the further question still remains for solution, what is their precise signification, and what is the meaning of their presence in the flesh of the diseased oxen? We know that they are living germs, that they pervade the muscular tissue of the diseased animals, and in our present ignorance, not only of their exact meaning, but also of whence they are derived, and of what are their effects upon the living solids and fluids, it appears to us that they are likely to be just as pernicious to life, and just as likely to be the disease itself, in the case of their being of a vegetable as of an animal nature. As far as we know at present, these bodies are present in every case of cattle plague, and are absent from the flesh of healthy oxen, or if present at all are in such sparse quantity that a long search has to be made to find one. This alone is a very strong fact, and when a similar connection was found between the presence and absence of trichinæ in human muscle and somewhat similar symptoms, no difficulty was found in at once arriving at the conclusion that the presence of the trichinæ and the morbid train of symptoms called trichinosis were really cause and effect.

If these parasitic bodies should prove to be vegetable rather than animal germs, we think the fact should not be forgotten that our late long and dry summer and autumn were most prolific in all the lower forms of vegetable life, and that on the first outbreak of the cattle plague the question was seriously mooted whether it might not in some way be due to the *uredo rubigo* or red rust which infected some sorts of grass to a remarkable extent. In one of the earliest occurrences on a large scale in England of this pestilence, both amongst oxen and sheep, the grass upon which they had fed was observed to be most remarkably affected with this blight, and at that very time we directed our attention to the possibility of a connection between it and the disease, and particularly with reference to the inhalation of the spores into the lungs; but although these bodies could be readily enough traced in the mucus of the air passages of the dead animals, nothing further confirmatory of such an idea could be elicited.

Whilst waiting for the attainment of more definite knowledge, such speculations as these cannot be out of place, but rather must be of use as a means of calling attention to all the circumstances connected with the history of this formidable disease; but we would go further and say, that if by good fortune cattle plague should prove to be modified variola, the presence of these living germs must still be of the most intense significance, and it will then behove us to examine carefully into the condition of the muscular system of human subjects dead of small-pox, and if such or any analogous bodies are found to be present in them, we shall have added one further triumph to those which the microscope has already achieved, and shall have paved the way to a knowledge of specific diseases far in advance of anything we have lately dreamed as likely to be accomplished in our day. Not only so, we think it is the bounden duty of microscopic observers, as opportunities occur, to investigate the condition of the muscles in all the specific fevers, whether of such as are most closely allied in character to cattle plague, as scarlatina, or of others less nearly resembling it, but still specific, such as measles, typhoid and typhus fevers, and (dare we add?) syphilis.

In the meantime it appears to us that the following questions await a solution:—How early in cattle plague do these bodies appear in the muscles? Is their number proportioned to the intensity of the disease? Do they produce symptoms in other animals? Are they ever found in other animals which during life have been kept in fair hygienic conditions, and have appeared to be in good health? Is it possible that they can produce such effects upon the blood as to cause the escape of its colouring matter, or of this fluid itself from the containing vessels? Can they by their growth or decay produce the other phenomena of cattle plague? If the Rinderpest be a modified small-pox, have they still any direct or constant relation to it? Are they in any way related to the uredo?

REVIEWS.

On the Cattle Plague, or Contagious Typhus in Horned Cattle. By H. Bourguignon, M.D. Paris, &c. London: Churchill and Sons. Pp. 379.

This book, although written in excellent English, is yet in style and composition essentially French. It has many of the excellences, a few of the eccentricities, and some of the faults which we are accustomed to look for in the literature of our lively neighbours. It appeared before the Government Commission had given the public the first fruits of their labours, and before the variola theory of the cattle plague had become the prominent scientific topic of the day. The author, however, has evidently read a great deal and has seen something of the disease on which he writes; and his work is not the less interesting that it was promulgated from a lower stage of observation than that we have now attained.

One of the faults of the book is a dogmatic assertion of unproved theories and hypotheses, as if they were established articles of orthodox scientific belief. For instance, we are told in the first page of the introduction, in reference to the antiquity of the cattle plague—an antiquity which is now admitted by all parties—"Nature did not wait until the second half of the nineteenth century to generate a new distemper. No! Nothing new has appeared for a long time in the world of space. The cosmic phenomena pursue their perpetual course, and the organic phenomena, *à fortiori*, do the same." Now we have no hesitation in saying that with regard to disease all this is utterly groundless. Was not the English

sweating sickness of the Tudor age a new disease? Has it ever appeared since, or is it likely ever to appear again? Did Cortes and his companions meet with *vómito* in Mexico, or was there any tradition of it amongst the native populations? Was constitutional syphilis known before the siege of Naples and the return of Columbus? Has the black death ever appeared in an epidemic form since the fourteenth century, and is not cholera, *par excellence*, the pestilence of the nineteenth century, as plague was the pestilence of the seventeenth? We have every reason to believe that from time to time new diseases do originate, and the theory that would trace back all morbific germs or agencies to one and the same epoch of creation is neither supported by observation nor by common sense.

The author's theory of the origination of Rinderpest in Hungary and Russia is, that the disease arises amongst the cattle after bad seasons and scarcity of forage have reduced their power of resistance to infectious and contagious miasmata, which he believes emanate from the swampy soil of the Steppes. He adduces, however, no facts in proof of his assumption. We do not think that in the case of this particular disease well-fed animals resist the morbific influence better than badly fed. The cows of the London dairies were probably better fed than any store cattle in the country, and yet they fell *en masse* before the first breath of the epizootic.

These are instances of the loose assertion of which we complain. There are other faults in the book, of which in our opinion a grave one is the offence against good taste which illustrates a theory of the eternity of the laws governing organic matter, and of the passive submission of matter to the laws of transformation by the Eucharistic belief of the Catholic Church.—P. 19.

We have hitherto spoken of the faults; we now turn to the more pleasant part of our duty. M. Bourguignon has given his readers an excellent summary of the history of the cattle plague, of which the most interesting passages, perhaps, are those having reference to inoculation. Inoculation was first recommended by Malcolm Flemming, in 1755, and afterwards by Layard, in 1757. The possibility of transmitting the disease by inoculation had been established in Holland in 1754, where seventeen animals were inoculated with the morbid secretions discharged from the eyes and nostrils of diseased beasts. That inoculation could be a means of controlling the disease seems, however, to have first suggested itself to the mind of Flemming, who, however, did not himself submit his notion to the test of experiment. Layard gives minute directions for the performance of the operation, and the management of the animals before and afterwards. He recommends that the incisions should not be made near vital parts, but on the shoulders or buttocks. "In the incision is to be put a dossil or pledget of tow, dipped in the matter of a boil full ripe, opened in the back of a young calf recovering from the distemper." The tow was to remain in the wound for forty-eight hours. "On the third day after inoculation, the discolouring of the wound, whose lips appear grey and swollen, will be a sign that the inoculation has succeeded; but the beasts, as Professor Swenke" (the Dutch Physician) "informs us, did not fall ill till the sixth day, which," he adds—evidently recognising an analogy between cattle plague and small pox, "*answers exactly to the observations daily made in the inoculating of children.*" Layard's recommendations, however, were made at the end of the epizootic, and it does not appear that they led to any good result; and the practice of inoculation seems to have been forgotten until it was adopted by the Russian Government in 1853. Of their experiments we quote M. Bourguignon's account:—

"The first experiments in the inoculation of *Tchouma*, or cattle typhus, were made in the year 1853, by order of the Government, in the neighbourhood of Odessa, at the Heridin Farm, by Professor Jessen.

"The first inoculative attempts were very fatal; they caused the death of all the inoculated animals. But it was soon perceived that these grievous results, far from prejudicing the theory, really confirmed it; and that the virus, attenuated in its toxical properties, would prove as effectual as was expected. And truly, in 1854 and 1855, at the Dorpat establishment, the inoculations made with a better selected virus afforded results less disastrous. At Kozau they were still more satisfactory. In fine, passing from experiment to experiment, they arrived at the conclusion that it was necessary to inoculate several heads of cattle, the one after the other, without having recourse to any other virus than the first inoculated, so that they might thereby obtain virus of the second, third, fourth, fifth, and up to the tenth generation. The virus thus attenuated in its morbid effects answered at length every experiment, and oxen thus inoculated could mingle with impunity with diseased cattle.

"At the veterinary establishment of Chalkoff, they inoculated, during eight meetings, 1059 animals with virus of the third generation, and the results were as satisfactory as could be wished for, only sixty animals having sunk under the effects of this preventive operation."

If Rinderpest, small pox, and vaccinia be one and the same disease, it is marvellous that the fact was not discovered during these repeated experiments. It is almost inconceivable that after successive generations of the poison had been propagated, its virulence diminishing with each inoculation, no case has been recorded which assumed the well-known benign characters of cow-pox. Nor on the other hand, that any accident should have led to the suspicion that the operators were working with a virus which was capable of producing in man one of the best known of human diseases. It is, however, useless to argue on an open question which must ere long be completely cleared up by experiment. On any showing it is clear that there is a close affinity between the diseases in question, but as far as evidence at present goes, we think it in favour of there also being some specific difference. Here we must stop—not, however, before saying that, besides the excellent historical account from which we have quoted, M. Bourguignon's work contains much of interest on the production of epizootic and epidemic diseases; some account of an admirable series of experiments conducted by the author, which establish the influence of deprivation of nourishment as a cause of parasitic diseases in the lower animals, and much besides of pathological and social interest. We entirely concur with the author that a study of the diseases of animals and plants should be made a part of general Medical training, although we are not sanguine enough to expect that his project of a College of Natural and Medical Science, to be founded at an outlay of £100,000 or £200,000, as a means of teaching comparative pathology will be realised in the present generation.

The Malformations, Diseases, and Injuries of the Fingers and Toes, and their Surgical Treatment. By Thomas Annandale, F.R.C.S. Edin., Lecturer on Surgery, Assistant-Surgeon to the Edinburgh Royal Infirmary. Edinburgh: Edmonston and Douglas. Pp. 285. Plates.

This volume is the embodiment of the essay submitted to the College of Surgeons of London in December, 1864, in competition for the Jacksonian Prize, which was awarded to it this year. Many additional facts and cases have since been added, and it has attained to a work of considerable size. The author in his preface states that he has been encouraged to present it to the public owing to the want of any book treating specially on these diseases. The work is divided into seven chapters, commencing with 1, Congenital Affections of the Digits; 2, Inflammatory Diseases of the Digits; 3, Tumours of the Digits; 4, Injuries of the Digits; 5, Non-Congenital Contractions and Distortions; 6, Excisions of the Joints and Bones of the Digits; and, lastly, Amputation of the Fingers and Toes.

In the first chapter, on congenital affections, speaking of hypertrophied digits, Mr. Annandale recommends amputation of the distorted organs, provided without injury to the remaining members, as pressure does not always produce satisfactory results. The same method of treatment being applicable to deficiencies or abortive development, supernumerary digits should be removed, unless possessing metacarpal or metatarsal bones of their own, as these have usually independent and useful motions. Webbed fingers are treated on the plan mentioned by Liston, of perforating the root of the web, introducing a foreign body, such as a piece of indiarubber, retaining it till the wound has healed, and then dividing up the remaining portion of it.

The remaining sections relate to contractions and tumours. An immense number of cases and sketches of most curious malformations have been brought together; and the various ingenious methods of treatment adopted will be of great service, as hints in similar cases, which, however, are comparatively rare in general Surgery.

Some slight sketch of development might have been added with advantage to the first chapter. The author gives a case of "intra-uterine amputation with abortive digits springing from the stump." The existence of this state of things we think

hardly sufficiently established to warrant its being beyond a doubt.

In our estimation, by far the most important part of the volume is the second chapter, "On the Inflammatory Diseases of the Digits," as these are of daily occurrence, and very frequently, through negligence on the part of the patient, or carelessness on the part of the Surgeon, fingers or toes become useless or have to be removed, where they might have been saved by proper management—in such cases, for instance, as whitlow, or onychia.

Mr. Annandale mentions an interesting fact with regard to whitlow which has not been generally noticed by other writers on the subject—viz., "that whitlow attacking the first and second phalanges usually recovers under proper treatment, without the slightest extension of the inflammation to the deeper textures; while the same form of inflammation, treated in the same manner, and at as early a stage, when it affects the extremity of a finger, is not unfrequently followed by the destruction of the tendon or bone. . . . A proof that the fibrous sheath resists the extension of the inflammation from the more superficial tissues." The application of nitrate of silver is recommended in the early stage of this disease, and to make a free incision, even before suppuration can be detected.

In the two following chapters, on (1) Tumours and (2) Injuries of the Digits, nothing of any importance, beyond a few interesting cases, can be gathered. Some hints on the present absurd fashion of tight boots, in the following chapter on "Non-congenital Distortions of the Digits," would do well to be more acted on, in saving the hideous distortions of the feet so commonly seen.

The treatment by excision of the joints of the digits either for injuries or disease, we think should be more frequently adopted than it is, as it often happens that what might turn out a useful finger is condemned and lost. The metacarpal or metatarsal bones of the thumb, index finger, or great toe seem most suitable for this treatment. The last chapter contains some useful hints on the method of performing the various amputations which may be required.

The work, which was originally merely a prize essay, has swollen into a considerable volume, and of course a great deal has been said about a comparatively minor subject.

But as a treatise it shows a considerable amount of research and hard work, in bringing facts to bear upon the subject. The plates, which are twelve in number, are good. But the same remark applies here as in many instances, that they should be interpolated amongst the letterpress, as a great deal of unnecessary trouble in alluding to them would be avoided.

As a book of reference we can recommend it to those who desire further information on this subject than is to be found in the ordinary text-books on Surgery.

The Ophthalmic Review. A Quarterly Journal of Ophthalmic Surgery and Science. Edited by J. Zachariah Laurence, of London, and Thomas Windsor, of Manchester. No. 7. 1865.

This is one of the ablest reviews of the day. The article, "Hints on Cataract Glasses," by Dr. Mackenzie, of Glasgow, contains the results of many years' scientific research, and abounds in valuable practical instruction. For ordinary cases Dr. Mackenzie prefers plano-convex to bi-convex lenses; he considers that they are generally made unnecessarily large and heavy, and that they ought not to exceed three-quarters of an inch in diameter; he mentions the singular case of the late Professor of Music in Edinburgh, who, after the extraction of a cataractous lens, retained an amount of accommodative power which is not readily explicable by the generally received theories on this subject. We have next the commencement of a series of clinical lectures by Professor Von Gräfe, on "Amblyopia and Amaurosis." This eminent Surgeon does not express his views in very lucid language. These lectures demand very close attention; but we need scarcely say that they will amply repay any amount of labour that may be bestowed on them. Professor Von Hasner contributes a paper on "Cancer of the Eye and of its Appendages." It is chiefly statistical, and gives an analysis of 155 cases which have come under his observation during the last eight years. In addition to these papers there is much other valuable matter in the form of Hospital reports, reviews, &c.; but we would especially call attention to the "Retrospect of British and Foreign Medical Journals," by Mr. Windsor, as containing notices of everything of importance that has been written on Opthalmic subjects during the last quarter. This will be of great convenience, and will save much time and labour to students of this branch of Surgery.

We heartily wish success to the *Ophthalmic Review*. It cannot fail to attain it so long as it is conducted as it has hitherto been.

On Long, Short, and Weak Sight, and their Treatment by the Scientific Use of Spectacles. By J. Soelberg Wells, Ophthalmic Surgeon to, and Lecturer on Ophthalmic Surgery at, the Middlesex Hospital. Second edition.

The subject of which this book treats is one of great importance, and one on which every Practitioner is liable to be consulted; and yet we believe it to be only too true that the safe and scientific treatment of defective vision by means of spectacles is very little understood, and that their selection and adaptation are in the great majority of instances left to the optician. To those who are desirous of having a sound, practical knowledge of the subject, we would confidently recommend Mr. Wells's book. It is a careful and accurate exposition of the views of the most recent investigators, among whom may be especially mentioned Professors von Graefe and Donders, and it is written with a clearness and simplicity which renders it easily comprehensible even by those who are not deeply versed in optical science; and it contains a fund of useful and practical information, which cannot fail to prove of the greatest value.

Elements of Physics or Natural Philosophy; written for General Use in Non-technical Language. By Neil Arnott, M.D., F.R.S., etc. Sixth and completed edition. Part II. London: Longmans. 1865.

This second part of Arnott's "Elements of Physics" includes the sections on Heat, Light, Electricity, and Astronomy, with an appendix on the art of measuring or geometry, and a popular view of arithmetic and mathematics. There is a charm in this work, depending on the simplicity with which the principles are laid before the reader, and the enthusiasm which pervades the author's exposition of the wonders of nature, which render it extremely popular with all persons who have not received a rigorously scientific education. In this edition some account is given of the most modern doctrines of heat and its equivalents in other forms of force.

PROVINCIAL CORRESPONDENCE.

SCOTLAND.

(*From an Edinburgh Correspondent.*)

Edinburgh, January 13, 1866.

We are very much amused here by a curious trap into which your contemporary, the *Lancet*, has fallen, and about which, I am sure, a considerable amount of soreness will be felt when the truth is known.

In a recent number the *Lancet* admitted to its columns a correspondent who signed himself "H.," about a new remedy for rheumatism, neuralgia, lumbago, sciatica, toothache, and kindred affections, which goes by the name of "Erskine's Brahee Sugar." This letter, or abstracts from it, has been copied into nearly all the dailies, and has created an immense sensation. The demand for the Brahee sugar is immense; and to-day, being in Duncan and Flockhart's, I had the curiosity to ask to see it, and was rather surprised on being presented with a small packet, round which was a stamp of some kind, and for which the modest sum of two shillings and ninepence was asked. The thing looked suspicious, and I would have nothing to do with it. I had not left the shop many minutes when I met a friend with whom I commenced a conversation about this packet, and to my horror he gave me the following information:—The *Lancet's* correspondent, "H.," is said to be brother to a well-known homœopathic practitioner, and this gentleman is said to be supplying the trade with packets of the Brahee sugar. My friend had seen a packet opened, and told me that it contained some small powders made up of what he believed to be sugar of milk—in fact, that the whole thing is probably a piece of homœopathy. I have now before me the bill which accompanies the packet, and it certainly has a

very quackish appearance; while it states that this substance is prepared under *Medical authority*. Query, whose? "Of this remedy," continues the red bill, "a *writer* in the *Lancet*, the leading Medical journal, says—" etc.; "and the following were among the cases reported in the *Lancet*:—" and there is an abundance of the ordinary "*extraordinary cures!!*" Is this *writer* not also the author of the red bill, and can he give an account of his Brahee sugar (of milk) that will satisfy the Medical Profession that it is not a homœopathic humbug? In the meantime, let me caution the Medical Profession and the public not to invest two and ninepence in this suspicious article till they know more about it.

I notice in your columns of to-day a letter from Dr. John Brown; but surely "Randolph" had better have withheld his pen from paper when he began to write such an epistle. Either Dr. Brown must have forgotten Mr. Syme's appearance on the day of public execution, or he must have seen with jaundiced eyes; for other spectators beheld Mr. Syme with a very red face, and evidently in a huge passion, and presenting the very reverse of a cool demeanour; while the story of the quack and the flea powder is fresh in the minds of some, though the author of "Rab" may have forgotten it. Mr. Syme's two or three abortive attempts to rend the pamphlet in twain are trifles, and his final consignment of his opponent's broken arguments to the blood-box, are scarcely to be mentioned after his gloating letter over the hideous scene of a *public execution*.

The recently conferred baronetcy of which we are so proud here has been deprived of all the pleasure which its noble recipient might have expected, by the rude and sudden hand of Death; his eldest son has just died, cut off

> "In the very May-morn of his youth,
> Ripe for exploits and mighty enterprises."

He had graduated but little more than two years, and had already distinguished himself both in the practice and in the literature of his Profession. He had endeared himself to a large circle of friends, and to many of his old college companions he was far more than a mere friend. He had that rare power of winning the regard, almost the affections, of every one who knew him; while his gentlemanly, kind, and sympathising manner towards his patients rendered him an invaluable assistant to his father. As a public speaker his abilities were of a high order, and in the debates of our junior Medical societies he always took a distinguished part. Through his entire character ran a vein of deep humour, which he derived from his father, and which, when occasion required, became the most pungent satire. Even had he not been the son of Sir James Young Simpson, Davie had the talents, the genius, the enterprise, and industry which would have placed him high in his Profession.

> "To live in hearts we leave behind
> Is not to die."

and assuredly he will have a corner in the memories of many more than the writer of this.

"Mortalitate relicta, vivit immortalitate indutus."

GENERAL CORRESPONDENCE.

THE ERUPTION OF THE RINDERPEST.

Letter from Dr. Tilbury Fox.

[To the Editor of the Medical Times and Gazette.]

Sir,—The chief reason for refusing to allow the identity of small-pox and cattle plague is based not upon any apparent contradiction in the general outline and aspect of the two diseases, but upon the differences of eruption in the two cases. Perhaps it may help towards the solution of doubt to direct attention to the very wide range which is often exhibited by the manifestations of variolous eruption in man. As in all other instances, the typical features become strangely modified at times. In ordinary variola we notice a series of transitional stages before the full bloom of the pustular stage—erythema, papulation, vesiculation, etc. Now it would seem, from clinical observation, that any one of these stages may be the sole representative occasionally of the small-pox eruption, and this result is brought about by abortive development or modifying influences, such as vaccination. In 1864, in the *British Medical Journal*, I called attention to an epidemic which I witnessed amongst the patients of the Farringdon Dispensary, and which generally, as the average condition, assumed the form of large flattened bullæ, containing just such a pellet of lymph as is seen in variola. In addition, there were greater and lesser degrees of expression; in some instances appearances exactly resembling variola, in others "bastard vaccinia," in others modified impetigo were observed. I showed that the disease was inoculable, depending upon some specific poison, and argued out the connexion between variola and this disease, which I termed impetigo contagiosa, called attention to the implication of the mucous surfaces, its analogical relations (as exhibited by the experiments of French observers with the grease and aphthous stomatitis of horses), its diagnosis from other diseases (especially furunculoid, referred to by Mr. Gamgee), its rarity at certain periods, and frequent disappearance for years together.

It appears to me that the doctrine of polymorphism, best illustrated by the recent remarkable researches of Tulasne on the coniomycetous fungi, is exemplified by the case of small-pox in an eminent degree; that the results at which I was compelled to arrive (long before any idea of Rinderpest visited us) in regard to the epidemic of contagious impetigo—and I saw a very large number of cases and made many experiments with my colleagues—show how impossible it is to find any objection to the identity of Rinderpest and variola from the differences in the mere aspect of the eruptions; and conversely it appears that my position taken in reference to the nature of I. contagiosa is peculiarly supported by some of the facts which have recently been brought to light in the matter of variola and Rinderpest.

I am, &c. Tilbury Fox.

43, Sackville-street, Piccadilly, W., January 14.

RINDERPEST AND VARIOLA.

Letter from Mr. F. Crook.

[To the Editor of the Medical Times and Gazette.]

Sir,—I have delayed answering your note until I had further satisfied myself by some experiments with the lymph. I have been for some time past considering the nature of the cattle disease, and must confess my opinion lay between malignant typhus fever or small-pox; but the result of later investigations have proved to me that it is small-pox only. For further proof of this assertion I am willing to supply the animal which I shall vaccinate at a market price, that she might be sent into the district where the plague is most prevalent, and I am certain she will come out safe.

I have been asked how it is that the Profession have not found out the nature of the complaint. In reply I say that it is new to us; animals have not been subject to its ravages, consequently science has not been called into requisition upon it.

Again, it is asked, if it is small-pox, how is it other animals have not been attacked? To this I reply that animals of a different species are rarely if ever subject to the effects of a disease, be it ever so contagious, provided they are not inoculated, which the other species may be suffering from. As a preventive to a further spread of the Rinderpest, I recommend instant vaccination of every head of cattle, including sheep, and most particularly deer, which are the nearest allied to our cattle species.

I am, &c.

Vine Cottage, Forest-hill, January 9. F. Crook.

THE SMALL-POX HYPOTHESIS OF THE CATTLE PLAGUE.

Letter from Dr. John Fairmann.

[To the Editor of the Medical Times and Gazette.]

Sir,—It is a rather difficult matter to get hold of reliable and relevant facts generally, and the present instance is no exception. I am now endeavouring to obtain all the information I can in continuation of the principle involved in my last communication to you; and meantime it may be interesting to know that there have been fifteen cases in all attacked by the plague in that herd I referred to in my last communication as having had the cow-pox extensively among them; five of these are dead, one has recovered, and nine remain under such treatment as seems the most promising. I am informed by a letter yesterday that "more than one-half that are now ill and dead had cow-pox last summer."

It would help most materially to arrive at some certainty as to the nature of the disease if information could be got on

this point—whether, where cow-pox has prevailed, vaccinated animals have hitherto escaped the plague; while others, not having had the cow-pox, but in close neighbourhood to the former, have been fatally or otherwise attacked. Any information on this point sent to my address would be esteemed. This is purely a scientific question, primarily, and to be determined by unprejudiced observation and truthful experiment.

I am, &c.

JOHN FAIRMANN, L.R.C.P. Edin., etc.

Staffordshire, Hanley, January 17.

CHLORODYNE AND THE PHARMACOPŒIA.

LETTER FROM MR. W. B. KESTEVEN.

[To the Editor of the Medical Times and Gazette.]

SIR,—May I be permitted to offer a few remarks upon your leader of the current week, entitled "Chlorodyne and the Pharmacopœia?" I am not ashamed to own that I am one of those "many orthodox Practitioners" by whom chlorodyne is prescribed (without reference, be it observed, to its "funny" name). I prescribe it because, as you observe yourself, it "supplies a want;" because it is a compound which practically is in many cases of great service where simple opium, or morphia, have been found to be the reverse of serviceable.

I protest against the imputation that in using this compound, or its imitations, we are allowing a "secret remedy to creep into use." Your own words convey a refutation of the charge, when you tell us that the ingredients are well known, and yourself enumerate these.

That you "have never prescribed it, and never shall," is perhaps to be regretted, as you would otherwise have learnt "its virtues," and would have afforded to suffering a relief not so surely to be obtained from other means. For example, I have to-day prescribed it with complete satisfaction and success in a case wherein a "bumper of Burgundy" would have been strangely out of place, and likely to have done more harm than good.

That chlorodyne and its imitations are compounds affords no argument against their value; for, to adopt your own allusion to domestic or culinary matters, "the proof of the *pudding* is in the eating;" and so, in like manner, the value of a medicine is estimated by its effects.

I respectfully submit, Sir that for myself, as I believe also I may say for others, that with as cordial a hatred of quackery as animates yourself, I have prescribed chlorodyne and its imitations, and hope to continue to do so without the least scruple of conscience arising out of the supposition of its being a secret remedy, seeing that, although not mentioned in the Pharmacopœia, I know its principal ingredients.

I am, &c.,

W. B. KESTEVEN, F.R.C.S.

Upper Holloway, January 17.

REPORTS OF SOCIETIES.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

TUESDAY, JANUARY 9.

Dr. ALDERSON, F.R.S., President.

A PAPER, by RICHARD BARWELL, F.R.C.S., was read on

CERTAIN PRACTICAL POINTS IN THE PATHOLOGY AND TREATMENT OF LATERAL CURVATURE OF THE SPINE.

Certain cases under the care of, and certain investigations undertaken by, the author, led him to perceive that the lateral flexibility and rotatory power of the spine during movement of the limbs had not received sufficient attention either in a physiological or curative point of view. The results of his experiments may be thus briefly stated:—The act of walking produces serpentine undulations of the spine. When the weight is on the left leg, and the right behind about to be lifted from the ground, the lumbar spine curves to the right, and the dorsal to the left. In bringing the right leg forward, the column straightens; and, when that foot is put down, the curve reverses, again becomes straight as the left foot is brought forward and so on. Some peculiarities of these inflexions induced the author to extend the number of his observations on living persons. The lateral movements of the spine, as above described, were found constant in character, various in amount, and with each lateral bend a commensurate amount of rotation takes place. The spinous processes always incline towards, the front of the vertebræ from, the chord of curvature. In fact, Mr. Barwell declares the spine incapable of assuming a lateral bend without at the same time undergoing rotation, which although, perhaps, in part due to the reasons given by Shaw, the sideways distribution of the weight, is also caused by the lateral and posterior position of the forces which bend the spine, and more especially by the action of the semispinalis dorsi and rotatores spinæ muscles. To ascertain the amount of rotation of which the spine is normally capable, the average of ten experiments was taken. The normal rotation average was 43° 17′; the largest amount just over 49°. Movement and weight-bearing with the arms also produce a certain amount of lateral flexion, whose object is twofold—fixation of the spine as a sure basis of action for the shoulder, and balance and economy of power. This flexion is not produced by direct action of the muscles passing between spine and scapula, but by the spinal muscles proper on the opposite side. Thus the column is constantly bending laterally and rotating. These positions are, therefore, not in themselves abnormal, but may become morbid either by fixity or amount. A posture much beyond what the spine can normally assume may, nevertheless, be simply due to muscular action on the one side, inaction on the other; but such cases will (unless treated) overstep the limits of any posture muscular force can produce, and are then due also to some external agency—weight, relaxation of ligament, alteration of bone-surface, etc. But these organic changes are always secondary. Want of balance between muscular forces, either by redundancy or deficiency, is the primary and efficient cause of lateral curvature; and our treatment must be directed to restoration of balance. The mere transference of a weight always carried on one arm to the other side, will not merely be inefficient, but often injurious; so also are many of the exercises prescribed for the left arm. The author, taking advantage of the necessity of balance, and the consequent normal tendency to form double curves, throws the spinal column out of its abnormal balance and rest on the ligaments by causing the pelvis to slope downwards from left to right, thereby necessitating a lumbar curve to the right, a position which, if carefully watched, cannot be long maintained without producing a contrary curve in the dorsal region. Thus in both parts of the spine a posture the reverse of the abnormal is enforced, not by machinery, but by muscular action. Several exercises are used by the author. A few are described as most potent: 1st. The sloping seat, with a fall commencing at an inch and a half in the foot, used for a quarter of an hour thrice a day. 2nd. Lateral gyration of the body, in strict measure, with the back against the wall, the pelvis sloped by a block under the left foot. 3rd. The patient, standing with the feet together, knees straight, a block under the left foot, lifts the left hand over the head, and in it is placed a spring attached above and to the right side. This is extremely potent, and requires careful watching. Certain other contrivances—viz., a thicker sole to the left boot, weighting the right leg and left arm, are used only late in treatment. Against rotation, the following exercise is used:—The patient, standing with the right shoulder about three inches from the wall, lifts the left hand over the head, and leans over till it comes against the wall, and supports some of the weight. She then, with the feet together, passes the head and right shoulder under the left forearm, and tries to see as much as possible behind the left shoulder. All these exercises must be used with caution and in order generally as above given, though variations may occur for particular cases. After each, horizontal repose is to be enforced. In all but very slight cases, these exercises will not suffice without some form of support. The machine commonly called a spinal support is false in principle, aiming at superseding muscular action, thereby weakening the muscles: moreover, it is clumsy, heavy, and barbarous. If it fulfilled its office of keeping pelvis, spine, and shoulder stiff and immovable, it would be unbearable; not fulfilling its office, it is merely irksome and inefficient. A patient with moderate curvature can be straightened by placing one hand on the point of greatest dorsal excurvation, the other in the opposite axilla, and pressing in contrary directions. The bandage invented by Mr. Barwell is so contrived as to prolong this action in the same directions. It consists of webbing straps secured to the pelvis, to the right side below the point of greatest curve, and to the left shoulder. In certain parts of the webbing, strong

india-rubber springs are placed in such wise that the forces act from the pelvis, exactly in the directions of greatest mechanical advantage, such as in practice are found most efficacious in straightening crooked spines. By placing the pad at the right side, a little posteriorly, much power may be exercised on the rotation. The construction of the bandage is such that there is no tendency to flatten the ribs against the spine. The whole apparatus weighs but a few ounces, is worn with ease and relief, and is very efficacious. By means of the exercises above described and the bandage, the action of them being rigidly under surveillance, the author has been very successful in the treatment of even advanced curvatures, as is shown by the appended cases.

The PRESIDENT said that many present would be able to give opinions as to the author's able and interesting paper. He remarked that if such papers were not well received by Medical societies, they would be read at societies for general sciences. For his part, he had an aversion to mechanical restraints. If girls were brought up as boys are, there would be fewer curved spines. The President then spoke on the bearing of mathematics on the subject, and said it was one dangerous to touch without a knowledge of the higher branches of mathematics. He spoke also of the risk of damaging the pelvis in trying to remove the curvature of the spine.

Mr. WM. ADAMS was glad that the subject of lateral curvature of the spine had been brought before this Society, as there were so many members present who could contribute to its elucidation. He had listened with attention to the paper in the expectation of hearing some new pathological facts, or some new theory of the production of lateral curvature, or some new system of treatment; but in all these respects he had been disappointed. Mr. Barwell had relied upon physiological experiments and observations upon the production of curvature in certain attitudes; but all that he had said upon these subjects had been long since brought before the Profession in the very excellent treatise by Mr. Bishop, who had thoroughly investigated the subject from a mechanical and physiological point of view. Mr. Adams was glad to hear Mr. Barwell assert that the spine is incapable of undergoing any amount of lateral curvature without rotation of the bodies of the vertebræ, as this led him to the point he had long endeavoured to insist upon—viz., that rotation of the bodies of the vertebræ always accompanies and, he believes, precedes lateral deviation of the spine. For the diagnosis of this condition, Mr. Adams relied upon the posterior projection of the angles of the ribs in the dorsal region, and the posterior projection of the transverse processes in the lumbar region, rather than upon any lateral deviation of the spinous processes. Mr. Adams believed that no lateral curvature, as judged of by these conditions, however slight, could exist without structural changes affecting the intervertebral cartilages and the oblique articular processes—in fact, that these conditions formed the diagnosis between functional and structural deviations, and practically constituted the broad line, on either side of which our treatment would differ. Previous to these structural changes, we might rely upon gymnastics and partial recumbency, and after these changes in the transverse relations of the angles of the ribs in the dorsal region, or the transverse processes in the lumbar region, we must rely upon firm mechanical support with partial recumbency. The result of Mr. Adams' experience had been to convince him that where lateral curvature of the spine existed in any marked degree, and before it amounted to an external deformity, it was essentially an incurable affection by any and every method of treatment. Mr. Adams did not believe that the structural changes which existed in confirmed lateral curvature admitted of removal, or repair, so as to allow of the affection being cured, unless the case were treated in the earliest stage, and with youth and growth in its favour. It was only in the slightest cases that we could hope to produce a cure. In severe cases of spinal deformity all the Profession were agreed in recommending mechanical supports as the only system affording relief and comfort to the patient. Sir Astley Cooper and Sir Benjamin Brodie always sent such cases to the instrument makers; but in the treatment of the slighter forms of curvature the greatest difference of opinion had always and still existed. Mr. Adams thought that attention to the diagnostic indications between structural and functional affections upon which he had insisted, would lead to the treatment being determined either in favour of gymnastics or mechanical support; but the curability of any particular case must rest upon the evidence of the existence of structural changes. Mr. Adams believed that further experience would convince Mr. Barwell that the employment of elastic force, such as he now recommended, by means of straps, would be quite useless where actual curvature existed; and that either to arrest the increase of curvature or to produce such improvement as the cases admitted of, it was indispensably necessary to use firm mechanical supports.

Mr. BRODHURST remarked that Mr. Barwell had given no idea of the amount of curvature in the cases he had treated. He wished to ask Mr. Barwell if the curvature were slight or severe, commencing or confirmed. He (Mr. Brodhurst) had made many experiments, and had found that when rotation had taken place appliances were useless. He was surprised, too, that Mr. Barwell should have obtained such results from such a bandage. It had been given up in France. He (Mr. Brodhurst) had brought it over from that country in 1851, and had found it fail wherever there was anything like a fixed curve. Mr. Barwell had not told the Society of the nature of his cases, either by description or by photographs, and, as he appeared to have made his experiments on healthy and vigorous persons, he might have arrived at the results he had announced. If he were to try his plan on severe cases of curvature, the trials would not justify his conclusions. Sir Benjamin Brodie had tried a similar method in early life, but had given it up, and had acknowledged that recourse must be had to mechanism when rotation had been established.

Mr. NAYLER stated that he should wish to ask Mr. Barwell how he proposed treating certain forms of lateral curvature, whether by the method just described or not; for example, the lateral curvature which is sometimes seen in young children, in whom it has existed from birth. Again, in older patients the septem of two curves is occasionally so abrupt as to constitute an angle rather than a curve, or there may be three curves, and the superior one situated in the neck; and lastly, he wished to ask how he would treat lateral combined with posterior curvature. There is this objection to the employment of muscular exercises as set forth by Mr. Barwell, that we cannot so accurately or nicely regulate them as to prevent their action on the convex as well as the concave part of the curve; and when this takes place the only possible consequence is an increase of the deformity. One essential condition in the treatment of lateral curvature had been completely overlooked by Mr. Barwell—viz., the removal of the superincumbent weight of the head and shoulders by means of the pelvic instrument, provided with a double crutch. Another point is, to have the pressure properly applied to, and constant in its action on, the weaker part of the curve. Mr. Nayler was greatly surprised to hear Mr. Adams say that lateral curvatures are, as a class, incurable. It was only when attended by certain complications, as when the ribs projected posteriorly, that our means were limited to prevent the deformity from becoming more aggravated. In other instances, and especially in early life, a favourable opinion as to recovery might be given.

Mr. BARWELL thanked the President for his kind remarks. It appeared to him strange that Mr. Adams should be disappointed with the amount of novelty in this paper, for the experiments concerning lateral and rotatory movement of the spine during walking, those fixing the amount of normal rotation permitted by the column, the whole plan of treatment by throwing the spine out of its morbid balance on the ligaments, and other points, were new. He was sorry to hear from Mr. Adams that his experience caused him to look upon lateral curvature as utterly incurable; yet the enunciation of that opinion only confirmed Mr. Barwell in his conviction that the mode of treatment at present in vogue was quite inefficacious—a conviction which had led him to make the above experiments and to devise a better method. The results did not lead him to the same sad conclusion as that to which Mr. Adams had come. The author was surprised to hear from Mr. Brodhurst that a belt similar to his own had been made in Paris, because no mention of such could be found in any one of the many French, German, or Italian writers on spinal curvature, and its construction was the result of entirely independent thought; but Mr. Barwell could well believe it must be ineffective if tried alone, for it is not intended to be so used. The oblique bandage is an adjuvant—a very valuable, indeed a necessary, adjuvant to his method of exercising the spinal muscles when thrown by the position he enforces out of their abnormal posture of repose. Finally, Mr. Barwell showed some photographs from severe cases of curvature, dorsal and lumbar, some of which were cured, others in the course of improvement.

THE PATHOLOGICAL SOCIETY.

TUESDAY, DECEMBER 19.

DR. PEACOCK, President.

Mr. HEATH and Mr. Thomas Smith were appointed a committee to examine further Mr. Gay's case of glandular disease exhibited on the previous meeting.

Dr. Duffin and Dr. Dudfield were nominated auditors.

Dr. MORELL MACKENZIE exhibited a specimen of

COMPLETE ATROPHY OF THE LEFT CRICO-ARYTÆNOIDEUS POSTICUS MUSCLE,

which he had diagnosed, by the aid of the laryngoscope, eighteen months before death. The patient had applied to Dr. Mackenzie in May, 1864, on account of hoarseness and shortness of breath. With the laryngoscope it was seen that, on inspiration, the left vocal cord was not drawn back, but remained in a nearly central position. It was therefore presumed that there was pressure on the left recurrent nerve from a tumour near the arch of the aorta. No evidence of an aneurism could be discovered, but at a later period a hard, nodulated tumour was felt, and seen projecting just above the sternal notch. Dr. Herbert Davies was kind enough to admit the patient into the London Hospital, and afterwards he was taken in by Dr. Parker. At the post-mortem a cancerous growth was found incorporating and completely destroying the left recurrent nerve. The growth appeared to have originated in the thyroid gland, to have penetrated the trachea, and to have grown right across that tube into the œsophagus. In the specimen exhibited the right crico-arytenoïdeus posticus was seen to be large and well nourished, whilst there were only a few fibres of the left muscle.

FRAGMENTS OF A GROWTH REMOVED FROM THE LARYNX.

Dr. MORELL MACKENZIE also exhibited some Fragments of a Growth which he had removed from the larynx of a boy, aged 12, who had suffered from loss of voice for more than seven years. The growth was attached beneath the anterior insertion of the cords and along the anterior half of the right cord. Mr. Mason had examined the case at the commencement and at the termination of the series of operations, which resulted in the entire removal of the growth. Dr. Andrew Clark, who had made an examination of the particles, considered that the growth was likely to return.

Mr. BRYANT exhibited

AN HYDATID CYST DEVELOPED BETWEEN THE RECTUM AND THE BLADDER,

and causing retention of urine and constipation, on which he had operated.

The particulars of the case have been already published.

Mr. BARWELL inquired whether in such a case, the symptoms not being urgent, it would not be better to abstain from operation.

Mr. BRYANT explained that interference was urgently needed, and that all other methods had been tried in vain.

Mr. HEATH asked whether the general treatment of hydatid tumours—that of making a small puncture and suffering the fluid to drain away—might not have been better in this case than by a free incision to set up so large a suppurating cavity.

Mr. BRYANT said he was compelled to enlarge the puncture made by the trocar, because it became continually blocked up by the masses of small hydatids, though these were again and again removed. Not more than a table spoonful of fluid was obtained by the trocar. The opening he made did not exceed an inch and a half in length.

Mr. HUTCHINSON mentioned a somewhat parallel case occurring under the care of a colleague at the London Hospital as illustrating the importance of not deferring operative interference too long. A young man was admitted *in extremis* from retention of urine, very many ineffectual attempts to pass the catheter having been made. An hydatid cyst was found, which had been developed between the bladder and rectum, and pushed the former (as in Mr. Bryant's case) quite out of the pelvis. It was punctured, but the patient sank in three hours.

Dr. C. HILTON FAGGE exhibited hearts showing

DEPOSITS ON THE VALVES IN PYÆMIA.

The hearts had been taken from patients after death from pyæmia, in which there were deposits of granules on the auricular edge of the mitral valve. These deposits resembled very closely those constantly found in cases of chorea. The preparations were taken from surgical patients at Guy's, in both of whom primary amputations had been performed—in the one case the forearm, in the other the leg, having been removed. The first symptoms of pyæmia came on in one patient on the fourteenth, in the other on the seventeenth day after the amputation; and death followed on the ninth and on the eighth day after the commencement of that disease. The post-mortem appearances were well marked, abscesses in the liver being found in each case, as well as commencing disease of the spleen and other organs. With the exception of the deposits on the mitral valve, the heart was in each patient healthy, and the pericardium was also free from disease. The granules of lymph on the mitral valve were quite soft; and although it was not known that these persons had not suffered from rheumatism, still there was no reason to doubt that the deposits on the valve were due to the pyæmia, as the appearances did not resemble those of old rheumatic disease.

Dr. FAGGE added that it was well known that endocarditis may accompany muscular disease of the heart in pyæmia; and he showed a third preparation, taken from a patient of Dr. Barlow, in whom this had been the case. The patient was admitted into Guy's Hospital for rheumatism, but the case was at once recognised to be one of pyæmia; and after death recent pericarditis was found, and the muscular tissue of the heart was in a state of suppuration, forming a cavity through which a probe could be passed into the left auricle, where a mass of soft lymph had formed, occluding the aperture. But, as far as he knew, no cases had hitherto been recorded in which affections of the valves had been met with, apart from disease of the walls of the heart, in this disease. The point was of interest, as suggesting a fresh difficulty in the diagnosis of pyæmia from acute rheumatism. He also thought it cast a doubt on some of the cases recorded by Dr. Kirkes and others, in which rheumatic valvular disease was supposed to be the starting-point of an infection of the blood. He instanced particularly Dr. Kirkes' fourth case, in the Med.-Chir. *Trans.* for 1852. This Dr. Kirkes believed to be an example of rheumatic endocarditis, in which the detachment of matters deposited on the valves of the heart gave rise to symptoms resembling those of pyæmia. If, however, we admit that pyæmia can itself cause endocarditis, it would be much more consistent with the history of the case to suppose that the case was originally one of pyæmia. The disease in this patient of Dr. Kirkes was much more extensive than in those shown by Dr. Fagge; but this was hardly a sufficient reason for rejecting this view. Virchow had expressed his satisfaction at conquering some of the territory which belonged to pyæmia; but perhaps it might hereafter be found that the boundary line now required to be rectified in the opposite direction.

Mr. HUTCHINSON had seen cases in which lymph had been deposited on the valves of the heart during pyæmia. In one of these cases the heart had been previously carefully examined and found free from disease; the lymph was deposited on the tricuspid valve. In another case during pyæmia an endocardial bruit was developed which had not existed before, but no post-mortem examination was allowed.

Mr. BROOKE exhibited some

TUMOURS REMOVED FROM THE SKIN OVER THE SCAPULA

of a young man who desired to get rid of them only because they prevented him from enlisting. They were six in number, and covered a space about equal to the palm of the hand. The history showed them to be nævi, which had undergone alteration.

Mr. CANTON exhibited the

SUPERIOR MAXILLARY BONE

removed from a woman resident in Malta. It had commenced about three years ago after a blow. When seen, the teeth were loosened, the palate softened, and a fungoid mass projected against the nostril. Two partial operations had been previously performed, and a more radical one was undertaken only at the patient's urgent desire. After the bone had been removed, there appeared at the back of the chasm a mass of gelatinous material, like the ordinary nasal polypus. This, however, was entirely scooped out by the fingers, and gave exactly a mould of the sinus of the sphenoid bone. The patient has made, so far, a good recovery, and has returned to Malta.

Mr. Adams and Mr. Bryant were appointed to examine the tumour.

Dr. Murchison exhibited a series of drawings to illustrate the

MORBID ANATOMY OF THE CATTLE PLAGUE,

and especially the question of the relation of that disease to typhoid fever in man. He had before expressed his opinion that they were not related, and these drawings strongly confirmed that view. The first exhibited the condition of Peyer's patches in an ox on the tenth day of the disease; they were quite smooth and flat, and of healthy appearance, contrasting strongly with a drawing of the same glands in man on the sixteenth day of typhoid. Other drawings showed ulceration of Peyer's patches in typhoid—a condition which never occurred in the cattle plague, so far as his observation extended (twenty-nine examinations). The solitary glands, however, were often found enlarged in the latter disease; and these might be mistaken for a condition analogous to typhoid; but, in fact, they were no part of the disease at all, occurring often in healthy oxen. In healthy oxen, also, Peyer's patches were sometimes elevated and prominent, which renders their almost atrophied condition on the tenth day of the disease even more striking. Another drawing was taken from a case of unusually intense disease, and showed an exudation, not of the ordinary viscid mucus, but of solid lymph adhering to the membrane of the intestine.

Dr. Murchison also showed a drawing of a supplementary nipple in the male.

In answer to Mr. Nunn, Dr. Murchison stated that in his opinion the cattle plague is an exanthematous disease. An eruption that is apparent on the skin after removing the hair has lately attracted attention, and he had at an early period noticed vesicles upon the udder like those of cow-pox. A man inoculated from the hide of a diseased animal had a vesicle exactly like that of cow-pox—so much so, indeed, that he was sent up to London on that account by Mr. Rayner, of Uxbridge. Still, inoculation from the diseased animals generally produced merely the same unhealthy inflammations as other putrid matter.

(To be continued.)

OBSTETRICAL SOCIETY OF LONDON.

Wednesday, December 6, 1865.

Dr. Barnes, President.

The following gentlemen were elected Fellows:—Drs. Brunton, Moxey, M. M. Orsey, A. E. Sansom, and Messrs. H. M. Townsend and S. Spencer Ferris.

Dr. Ritchie exhibited a Dermoid Cyst developed in the Fallopian Tube, about the size of a plum, composed of four loculi which contained dendritic growths, similar to the dermoid cysts of the ovaries, and which he thought bore analogy to uterine mole pregnancy. He considered that, arguing from this case, it was not impossible that dermoid cysts might some day be found in the uterine cavity, the result of conception.

Dr. J. Braxton Hicks exhibited a Polypus weighing 2¼ lb., removed by Dr. Oldham with the wire-rope écraseur. Before removal it reached from the vulva to just beneath the umbilicus. The patient was doing well.

Dr. Greenhalgh exhibited a Polypus removed by the wire-rope écraseur; and also a Growth removed from the Cervix of a Pregnant Woman without hæmorrhage, but the patient aborted a few days afterwards.

A paper, by Dr. R. Uvedale West, was read on

AN ANOMALY OF THE PLACENTA.

In this paper, which was illustrated by drawings, the author related several cases of "battledore placenta," in which the funis was inserted in the membranes, and divided into its vessels, at a considerable distance from the edge of that organ; and described how great doubt and awkward embarassment may arise to the accoucheur when, as happened to the author, this anomaly occurs with one of the funes of a twin placenta, through its accidental tearing away from its very laccrable attachment.

A paper, by Professor Berry, Birmingham, was read on

TWO CASES OF OBSTRUCTED LABOUR; WITH REMARKS.

After alluding to the obstructions which occurred to the birth of the child, he instanced a case of obstruction by an ovarian tumour, in which the child had been, with considerable force, delivered by the forceps. The next day, after coughing, the patient felt something descend. Dr. Berry was then called in, and, on examination, found it to be an ovarian tumour, the pedicle of which was traced through a rent in the upper part of the vagina. Opiates were given; and, two days afterwards, a ligature was put round the pedicle, which was then cut through just below. The patient recovered without much anxious symptoms, and was about again at the end of a month. She has also been delivered since, and without any trouble. In the other case there was a soft tumour springing from the sacrum, which reduced the antero-posterior diameter to about two inches. This was explored by trocar; but nothing but blood flowing, it was debated whether Cæsarean section should be performed or not. It was ultimately agreed to perforate. This was done, and the fœtus then turned. Very great difficulty occurred; but at last it was accomplished. The patient, however, died afterwards from rupture (as it subsequently appeared) of the uterus. Dr. Berry pointed out the inferences to be gathered from these cases: that, in the first, the tumours should have been tapped before the use of forceps; and, in the latter, the Cæsarean section would have been probably much the safer treatment.

After remarks by Dr. Tyler Smith and the President,

Dr. A. Hall related a case similar to the last one, where version had been adopted, and rupture of the tumour, with internal hæmorrhage, caused death shortly afterwords.

Dr. Greenhalgh read a paper on the

COMPARATIVE ADVANTAGES OF CÆSAREAN SECTION OVER CRANIOTOMY IN EXTREME DISTORTIONS OF THE BRIM.

He recited cases of difficult craniotomy; together with another case of Cæsarean section which he had recently performed, in which the patient afterwards died. After analysing the cases on record and his own, he considered that craniotomy should not be attempted where the effective antero-posterior diameter was less than two inches, considering the chances for the patient better under Cæsarean section.

In the discussion which followed,

Dr. Barnes showed a fœtus that he had drawn through a very deformed pelvis by the craniotomy forceps, bringing by it the face to present; the mechanism of which instrument had been pointed out to the Society by Dr. Braxton Hicks last year.

Dr. Playfair referred at length to the statistics of the Cæsarean section published by M. Dufeillay in the *Archives Générales de Médecine*, which showed that, where the operation had been performed under favourable circumstances, 80 per cent. of all the patients had recovered, whereas in unfavourable circumstances 17 per cent. of the operations had been successful. Even this was a better result than had been obtained in England; but if anybody would take the trouble to read over the history of the recorded cases, and would note the semi-moribund condition in which the patients generally had been before the operation was resorted to, he would be surprised, not so much at the mortality, but rather that even the small success of 11 per cent. had been obtained. Dr. Playfair did not suppose that M. Dufeillay's statistics could be taken as absolutely correct, but they at least proved that the Cæsarean section need not be the almost certainly mortal operation we were generally taught to consider it. He wished, however, particularly to refer to the question of the proper treatment of cases of labour obstructed by ovarian tumours which could neither be pushed out of the way nor punctured. He had lately collected the details of more than fifty cases of this complication, and found that more than one-half of all the cases in which craniotomy had been performed had terminated fatally. It was doubtful whether, if the Cæsarean section had been employed in preference, the mortality would have been greater; and not only would the children have been saved, but a radical cure of the disease might have been effected at the same time. Even if the patient survived craniotomy, the disease still remained, and in all probability at no distant period she would again have to undergo the risk of an equally serious operation for its removal. It might even be possible to remove the ovarian cysts, which must necessarily be small, without incising the uterus. At any rate, it seemed that the ordinary rules of practice laid down for this emergency should be considered.

Dr. Eastlake referred to one of Dr. Greenhalgh's cases, where, after the head had been perforated, the labour was left to the natural efforts. He wished to ask the author whether under such circumstances he had ever, in his experience, met with any change in the presentation of the fœtus. A case of this nature had occurred in the Rotunda Lying-in Hospital, and was recorded by Dr. Shekleton in the *Dublin Quarterly*

Journal. The patient had been delivered on two or three occasions by craniotomy, owing to great disproportion, due to a pelvic tumour. On the occasion of her last labour delivery by the Cæsarean section had even been contemplated. The majority of accoucheurs in consultation were, however, in favour of again using the perforator; the head was accordingly opened, and a large quantity of the cerebral mass evacuated. The patient was then left for a couple of hours, when, to the surprise and regret of the Medical attendants, the left arm of the child was found to occupy the narrow space in the vagina. This untoward event of the altered presentation compelled them to separate the child's arm from the body, and eviscerate and extract under the greatest difficulty. The woman died within ten minutes of her delivery. At the autopsy a laceration was discovered in the posterior wall of the uterus. The fatal issue in this instance might be justly attributed to the increased difficulty of the labour due to the altered presentation. With the experience of such a case before us, Dr. Eastlake considered that where it was thought advisable to postpone extraction after perforation it would be well to adopt some means by which the head could be fixed or tethered so as to correspond with the pelvic aperture.

Dr. Braxton Hicks thought that before the statistics of craniotomy could be fairly compared with those of other operations it was highly necessary that they should be fully revised; because he had found, on searching to the original cases of recognised statistics, that nearly all the deaths which had arisen had occurred rather from the want of the operation, or from neglecting the proper time for its performance. In many it was specially mentioned that had the operation been performed some three, four, or five days previously, the patient would probably have recovered.

Dr. Greenhalgh having replied to the several speakers the meeting adjourned.

MEDICAL BARONETS AND KNIGHTS.

(From the Observer.)

The baronetcy recently bestowed on the most eminent of metropolitan Surgeons, Sir William Fergusson, has been followed by a similar honour to the most eminent man in the whole Medical Profession, Dr.—now Sir James—Simpson, of Edinburgh. As Physician, as Surgeon, or as accoucheur, Sir James Simpson is universally acknowledged by his Professional brethren to stand pre-eminent. At home or abroad, his fame is wide-spread, and his name will add lustre to the order which he honours. Indeed, it has long been a matter of surprise that a man whose discoveries have been of such vast service to the whole human race should have been left so long without a title, a pension, or the thanks of Parliament. When we remember that it is twenty years since the discovery of the use of chloroform in rendering the most terrible Surgical operations and the most agonising of woman's natural sufferings painless was made by Dr. Simpson, every one must admit that the man who made the discovery by which so many lives have been saved, and so much pain has been prevented or mitigated in all parts of the world, has been late in receiving any reward from the State. We trust, however, that even this tardy recognition of national service, as well as the honour conferred upon Sir William Fergusson and Sir Roderick Murchison, may be accepted as some confirmation of the hope entertained by some leading men of science that the systematic neglect from successive Governments under which they have suffered will be at length redressed by the Ministry of Earl Russell. If we only compare the decorations and titles, the parliamentary thanks and grants, the places and the pensions, which reward the successful soldier, sailor, or lawyer, and the life peerages which are almost certainly obtained by any really able churchman—the rewards granted by the State to men of science are so few and disproportionate, that the injustice and impolicy of the neglect at once become evident. This view has recently been so well expressed in the *Medical Times* that we place on record what we believe to be a very general feeling in the Medical Profession. When making known how the Emperor Napoleon and the French Academy of Medicine had rewarded a successful Surgeon by a pecuniary grant and enrolment in the Legion of Honour, our Medical contemporary said—and we most fully concur in his conclusions—"It is certainly most unjust that, while national honours are heaped upon those who have distinguished themselves by military courage or by political talents, no public recognition is given to men who have been pre-eminently benefactors to humanity. A tardy and insufficient tribute has, it is true, been paid to the discoverer of vaccination; but there live at this moment men in our Profession who have done as much to deserve public gratitude as did Jenner. There are great men now alive who have robbed operative Surgery of half its horrors by abolishing its pain; and there are those who have manfully overcome every opposition which prejudice threw in their way, and have triumphantly rescued one disease from the black list marked incurable. We believe that those men are themselves sufficiently repaid by the inward consciousness of having been pre-eminently useful to their fellow men, and having added to the sum of human knowledge. But for the sake of others, and especially for the sake of those still hesitating as to the Profession which they will embrace, it is extremely desirable that some tangible evidence should be given that the nation appreciates the sacrifices daily and hourly made by those who devote their energies and their talents to the promotion of its physical well-being." We hope that all this is likely to be well considered by the Government and their advisers, and we trust that the day is not far distant when a deserving Medical man may not only look forward to a knighthood or a baronetcy as a reward of meritorious service, but—like the churchman and the lawyer—may hope for a seat in the House of Lords. Until a system of life peerages becomes recognised in our constitution and extended to the Medical Profession, it will always be less attractive to young and able men than law and divinity. This, we believe, to be a national evil. The day may be distant before it is remedied; and in the meantime we trust that the honours conferred upon Sir W. Fergusson and Sir J. Simpson may be accepted as a sign that at length Government will recognise and reward Medical men whose labours have done honour to their country, and have improved the science and art of their Profession to the benefit of mankind.

ROYAL COLLEGE OF VETERINARY SURGEONS AND THE CATTLE PLAGUE.

On Thursday, the 11th inst., the Royal College of Surgeons held a *conversazione* at the Freemasons' Hall, Great Queen-street, where Professor Simonds, of the Veterinary College, delivered an interesting lecture on the cattle disease. He handled the subject with great ability, and his remarks were listened to with marked attention.

The lecturer alluded to the outbreak of a cattle disease which occurred in the year 1712, which, he considered, so we understood him, as resembling the present one. In 1714 it was again introduced into England, probably from Holland. He quoted at some length from a paper in the Philosophical *Transactions*, by Mr. Bates, Surgeon to the household of George I. In this paper Mr. Bates speaks of the disease as contagious, and describes its symptoms and the means adopted to eradicate it. The cows first refused their food; the next day had husky cough, and voided excrements like clay, their heads swelled, and sometimes their bodies; in a day or two more there was a great discharge of mucous matter from the nose, and their breaths smelled offensively; lastly, a severe purging (sometimes bloody), terminating in death; that some died in three days, others in five or six; but the bulls lived eight or ten days; that during the whole illness they refused all manner of food, and were very hot. As to the means of stopping the disease, Mr. Bates, in his Report, recommended that all diseased cows should be killed and burnt, and that those which appeared well should be secured and kept on the grounds on which they then were, and that such of them as should sicken or die should be removed and burnt. It appears that these suggestions were adopted, and the result was, that the disease was effectually stopped. The disease again visited England in 1769, and was referred to by George III. in his speech from the Throne in 1770. Dr. Layard, who had written an essay on the cattle plague of 1744 to 1756, was applied to by the Privy Council for his advice and assistance. He was consulted in drawing up those Orders of Council and Acts of Parliament, which being put into immediate execution, stopped the spreading of the contagion, and totally extirpated it in less than six months at an expense of £3000. Dr. Layard's opinion was—1st, that the distemper in 1756 was similar to the small-pox in the human body, to be managed with the same intentions, that it was communicated in the same way as that disease and the plague; 2nd, that kill-

ing the cattle without the effusion of blood—viz., by strangling them and burying them deeply with their whole skins, and avoiding communication both of persons and beasts—was the surest way of extirpating the malady; 3rd, that, by inoculation, the sound cattle might be preserved; 4th, that the utmost attention should be paid to prevent the introduction of infected cattle, hides, straw, hay, or cloth packages from foreign countries; 5th, that the variolous affection is a different disease from the gullsey, which is a putrid sore throat, natural to, and common to, Great Britain and Holland.

He alluded to the present cattle plague, and the means by which it had found its way into this country. He did not believe in its spontaneous origin. We could only have received it from Russia. He here showed on a rough map certain districts of Russia in which he said the disease was prevalent at the time of its introduction into England, and where preventive measures were not observed. It was a remarkable fact that some cattle had been shipped at Revel, landed at Hull, were thence forwarded to London, and within nineteen days the disease had made its appearance in the metropolis. He then traced the disease from London to the various counties in which it had successively appeared, and cited facts which left no possible room to doubt that London had been the centre from which the whole country had received the infection. In each case he had discovered evidence of the transport of cattle, hides, or some other material which might contain it. He was of opinion that birds might be the means of conveying it, particularly pigeons, which were in the habit of visiting neighbouring farm-yards, and might thus convey the poison on their feet. He mentioned one case in which there was, he thought, little doubt that it had been so conveyed. He also thought that hounds passing over pasture fields might carry the infection on their feet. and thought that hunting should not be practised in infected districts. He considered that improper burial was a means of spreading the infection, and cited a case that came under his own observation where some carcases had been placed in shallow holes near a small stream of water, and that the disease had appeared subsequently along the course of the stream. As to the pathology of the disease, he agreed with the opinion of Dr. Layard, that it was variolous; but he could not say if it was identical with the variola of the human subject; he, however, referred to the case of Mr. Hancock, of Uxbridge, who had slightly wounded the back of his hand with a knife used in skinning a diseased animal; on the second day a vesicle made its appearance, which ripened into a pustule, and subsequently ran the usual course of a variolous pustule. (A very excellent drawing of the hand, with the pustule in its two later stages, was exhibited by Mr. Tuson, and it certainly looked very like variola.) Mr. Simonds thought that if the distemper was not variola it certainly belonged to the class exanthemata. He said he would just allude to another theory —namely, entozoa. He did not believe that the disease was owing to the presence of those bodies, and it was doubtful whether they were entozoa or not. With regard to the treatment, it was a subject on which he felt some disinclination to express his opinion, as it might not accord with the views of others on the subject; however, if pushed into a corner, he would say do not treat it at all. He was not aware that any special medicines could be mentioned as having power over the malady. It had been stated that some animals had recovered under the administration of mineral acids, others by diffusible stimulants, some from doses of salts, and some from simply good nursing; the latter he thought was that which would ensure the greatest amount of success, as more have recovered from good nursing than from any other treatment. The nervous centres were so paralysed that the animal was not susceptible of the effects of medicinal remedies, but that by care the system might gradually throw off the poison, and recovery take place. He was of opinion, however, that treating the affected animals was a means of keeping the disease in the country; and therefore, as a preventive measure, he should say kill all—that is, all animals stricken with the poison. He might express his views regarding preventive measures in a few words—isolation and disinfecting. Disinfecting was seldom properly carried out; it was not sufficient to apply a deodoriser to remove an offensive smell. Deodorising is not disinfecting, and therefore a sufficient quantity of lime, or chloride of lime, must be mixed with the manure or other matters to completely destroy the poison. Merely sprinkling a little chloride of lime over a large mass of manure is of no use at all.

He did not enter into the question of the post-mortem morbid appearances, but referred his hearers to the elaborate drawings and models of morbid specimens, by Mr. Tuson, exhibited in the room. These attracted a good deal of attention at the conclusion of the lecture. The models were most beautifully executed. The majority of them represented severe inflammation of the mucous membrane, with foul-looking ulcers. One specimen showed ulcers of the first stomach as large as a crown piece; another, the second stomach greatly congested, with small, deep, ragged ulcers; another of the larynx and trachea showed severe inflammation of the lining membrane, studded with foul ulcers. In a model of the upper jaw the palate was of a deep pink colour, partially denuded of mucous membrane, and partially covered by a greyish crust. One of the drawings represented a piece of lung in which pleuro-pneumonia was distinctly marked. A drawing, also, of a piece of skin denuded of hair showed marks resembling the pits of small-pox. Whatever may be the true nature of the disease, inflammation and ulceration of the mucous membrane appears to be one of its most prominent features.

OBITUARY.

DR. DAVID JAMES SIMPSON.

It is our melancholy duty this week to record the decease of Dr. David James Simpson, the eldest son of Professor Sir J. Y. Simpson, of Edinburgh. The sad news of his death has followed fast on the intelligence of the honour paid by the Sovereign to Medical science and public and private worth in the person of his father. Seldom has the mutability of human affairs been taught by a sadder lesson or been presented in a more touching example. The whole Profession, who so lately rejoiced in Professor Simpson's well-merited advancement, will unite in regret and condolence over the grave where such high hopes and the promise of so noble and useful a career lie buried. The universal feeling of sympathy with which the news will be received by the Medical brethren of Sir James Simpson, although it cannot alleviate the grief of such a bereavement, will, we may hope, help him to bear it, and, as time rolls on, may throw a softening and healing ray over the dark shadows of his loss.

Dr. David Simpson was only twenty-four years of age, but he had already shown that he was likely to prove worthy of the name he bore. The story of his Professional career was only begun, but its short page was a history of successful work, and of public duty well and honourably performed. He took his degree in the University of Edinburgh in 1863, and in the same year acquired the license of the Royal Colleges of Physicians and Surgeons. He then held the office of Resident Physician in the Edinburgh Royal Infirmary, a post in which he remained until he was called to succeed his cousin, Dr. Alexander Simpson, in assisting, conjointly with Dr. Black, Professor Simpson in his private practice. He was for a considerable period Senior President of the Royal Medical Society of Edinburgh; and his tenure of office was signalised by the delivery of an able Inaugural Address, on December 4th, 1863, which address was afterwards published as a pamphlet, and by a paper on the "Cure of Constitutional Syphilis by Syphilisation," which was read before the society on the 26th February, 1864, and published in the December number of the *Edinburgh Medical Journal* of the same year. At that time syphilisation had excited but little attention in this country; and Dr. Simpson was the first British writer who had directed attention to Professor Boeck's remarkable conclusions. In his paper he details two well-marked cases of constitutional syphilis, of long standing, which came under his own cognizance. The subjects of them, after trying various means in this country, repaired to Christiana, to place themselves under Dr. Boeck's care. The results of their treatment by syphilisation were most satisfactory, all traces of disease disappearing, and up to the date of the reading the paper, between two and three years afterwards, no relapse in either case occurred. This paper also contains an interesting summary of the views concerning the syphilitic poison held by Dr. Boeck and Dr. Danielson, of Bergen, and the attempts of the latter to substitute "tartarisation," or irritation produced by means of tartar emetic, in place of syphilisation. An analysis is also given of the records of the Christiana Hospital, comparing the treatment of syphilis by mercury, iodide of potassium, tartarisation, and syphilisation, exhibiting the decided supe-

riority of this last. Dr. Simpson, therefore, while discountenancing the employment of syphilisation as a prophylactic, as recommended by Auzias-Turenne, pressed upon the notice of the Profession its utility as a valuable curative agent.

The career thus commenced was one of the highest promise. Dr. Simpson had excellent natural abilities; and had inherited from his father a love of scientific truth and investigation, which would in all probability have led to a distinguished position in Medicine. His kind heart and affable manner endeared him to all with whom he came in contact. In fact, it would have been difficult to have found one on whom Fortune had been more liberal in the bestowal of her gifts. But all the high and well-grounded expectations which clustered round him were to be broken. A fortnight ago he was seized with icterus. At first there seemed no ground for serious apprehension; but during the eight days which preceded his death the symptoms of his attack became graver and more alarming. Insensibility supervened on Saturday, and he died on Sunday at his father's house in Queen-street, Edinburgh.

LEGAL INTELLIGENCE.

COURT OF QUEEN'S BENCH, Westminster, Jan. 11.

(Sittings in Banco, before the Lord Chief Justice, *Mr. Justice* Blackburn, *Mr. Justice* Mellor, *and Mr. Justice* Lush.*)*

HUNTER V. SHARP.

This was an action by the person describing himself as "Dr. Hunter" against the printer of the *Pall-Mall Gazette* for an alleged libel upon him in that paper. The article set out in the declaration, and read by counsel, was as follows:—

"Impostors and Dupes.—The modern system of easy advertising, and the facilities of the penny post have many advantages, but they have also their attendant evils of no little weight. One of these evils is nothing less than a curse upon English society. Occasional exposures in the law courts and the newspapers have made us familiar with the advertising practices of a certain class of Medical impostors, and with the misery they inflict upon their unhappy dupes. And now a series of recent proceedings in the Marylebone Police-office has revealed the existence of ramifications of the detestable system in question for which few ordinary readers will have been prepared. Persons who turn over the pages of the cheap newspapers in search of the curiosities of advertising will have noticed the frequent recurrence of a whole column, purporting to give a consecutive series of extracts from a Medical work on consumption by a person signing himself 'Robert Hunter, M.D.' If they have taken the trouble to read its uninviting paragraphs they will have found that they are a long rigmarole of some scientific declamation, professing to expound to the non-professional invalid the causes and symptoms of disease of the lungs, and to prove that nobody knows how to cure it except this same Dr. Hunter, whose method is one of inhalation. On the face of all this there is nothing more than the puffery of the dealers in the various pills, potions, ointments, and liniments, who rejoice in the profusion of testimonials from innumerable correspondents who bless the day that they first made their acquaintance. That any reputable Physician would thus advertise for patients is, of course, out of the question; but, although these advertisements are free from the mysterious hints and suggestions and the scarcely veiled offensive phraseology of the basest class of Medical puffs, one is led to suspect the existence of very serious malpractices by observing the length and frequency of these recommendations of Dr. Hunter and his inhalations. When a man finds it worth his while to insert a very costly advertisement in several papers, and to go on with it from day to day, or week to week, it is clear that his patients must be dupes of a very different class from the simple people who buy pills by the gross and potions by the gallon. Nor need there be any actual difficulty in putting a stop to such advertisements by Act of Parliament. It should be an indictable offence for any man to call himself a Physician, Surgeon, apothecary, or dentist unless empowered to practise by the colleges or societies recognised by the law of the land. The assumption of all foreign Medical degrees should be absolutely forbidden under the same penalties, whether claimed by English subjects or foreigners. English subjects are forbidden to assume any foreign title of rank without the permission of the Crown. But what would be the evil of permitting some foolish gentleman to call himself "count" or "baron" compared with the mischief done by scoundrels who utter this base, forged coin and claim to be respected as qualified Physicians on the strength of some diploma obtained in Canada or New York?"

The plaintiff complained that the article, in effect, imputed to him that he was an impostor and duped persons who became his patients, and that he was a scoundrel and had done something morally wrong, which might be fairly described, metaphorically, as uttering base, forged coin, by reason of which he alleged that he had been greatly injured in the way of his business as a Medical Practitioner. The defendant pleaded that the said alleged defamatory matter was and is true in substance and in fact.

Mr. H. Williams, on the part of the plaintiff, moved to set aside the plea as too general, or, at all events, for an order for particulars of the charges intended to be imputed to him. He urged that the plea was so general that it was wholly left at large what it was intended to allege and to prove, and that it might include the matters which had come before the police-court upon the charge of rape.

Their Lordships, however, concurred that the scope of the plea was the same as the scope of the libel—which was, in effect, that the plaintiff was one of those who called themselves "Doctors" or "Physicians," which would imply that they were so by British diploma or degree; when, in point of fact, they were only so by some foreign diploma or certificate which might be of little or no value, and that his letters amounted to quackery and puffery.

The application, therefore, was refused.

MEDICAL NEWS.

Royal College of Surgeons of England.—The following gentlemen passed their Primary Examinations in Anatomy and Physiology, at a meeting of the Court of Examiners on the 16th inst., and when eligible will be admitted to the Pass Examination:—

James Stothard, P. R. Littleton, John Horsfall, W. C. Bucknill, C. E. Walker, A. C. Nadin, A. H. B. Hallowes, George Tobin, F. H. Watson, and H. F. Norris, students of St. Bartholomew's Hospital; Thomas Docking, Thomas Lettis, and F. C. Lloyd, of University College; G. E. Martindale and Ernest Fussell, of Guy's Hospital; J. S. C. Yule and Charles Barlow, of Charing-cross Hospital; J. C. White and H. J. Linton, of Westminster Hospital; Jas. Walker and J. A. Hall, of the Leeds School; S. A. Lucas and William Leonard, of Dublin; Henry Estcourt, of Manchester; Edward Clarke, of Philadelphia; John Chapman, of St. Mary's Hospital; William Draper, of Middlesex Hospital; and A. R. Gray, of Aberdeen.

The following passed on the 17th inst.:—

Alfred Roworth, John Evans, and G. A. Thomas, students of St. Bartholomew's Hospital; W. A. Cox and J. L. Hobbes, of Charing-cross Hospital; M. H. Molloy and William Nolan, of the Dublin School; James Pavey and Septimus Evans, of the London Hospital; R. H. Stevens and N. E. Schömberg, of King's College; T. E. Webb and J. R. Bosworth, of Guy's Hospital; Arthur Hensman and John Waller, of University College; H. E. Lewill and William Harris, of St. Mary's Hospital; G. W. Geldart and W. W. Spencer, of Newcastle; Charles Parr, of St. George's Hospital; and Joseph Carbery, of Calcutta.

Apothecaries' Hall.—Name of the gentlemen who passed their Examination in the Science and Practice of Medicine, and received Certificates to Practise, on Thursday, January 11, 1866:—

John Thompson Dickson, Logic Lodge, Clapham-park; William Fowler Birmingham.

APPOINTMENTS.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

Barker, John, M.D., has been elected a Member of the Court of Examiners of the Royal College of Surgeons in Ireland.

Barrett, John J., M.D. St. And., has been elected District Surgeon to visit out-patients to the Royal South London Dispensary, St. George's-cross, S.

Bramwell, John B., M.D. Edin., has been appointed to the Commission of the Peace for the borough of Tynemouth.

Chaffers, E., M.R.C.S. Eng., has been appointed Assistant-Surgeon to the North Riding Lunatic Asylum, Clifton, York.

Charteris, Matthew, M.D. Edin., has been elected Assistant Medical Officer to the parishes of St. Giles's and St. George's, Bloomsbury.

Clark, T., M.D., has been appointed by J. Stuart Mill, Esq., M.P., to be his Assessor in the University Court of St. Andrew's, N.B.

Fussell, F., M.B., M.R.C.P. Lond., has been appointed Treasurer to the Brighton Lying-in Institution.

GRIFFITH, G. DE GORREQUER, L.R.C.P. Lond., has been elected Physician-Accoucheur to St. Saviour's Maternity Charity.

GWYNN, EDMUND, M.D., has been appointed Surgeon to the Holloway and Islington Dispensary.

HIGHMORE, WILLIAM, M.D. St. And., has been appointed one of the Medical Officers to the Yeatman Hospital, Sherborne, Dorset.

JONES, EDMUND, M.D. St. And., has been appointed one of H.M.'s Justices of the Peace for the County of Hereford.

MACKINLAY, JAMES G., L.R.C.P. Lond., has been appointed Resident Medical Officer to Charing-cross Hospital.

PORTER, GEORGE H., M.D., F.R.C.S.I., has been elected Surgeon to Simpson's Hospital.

RANSOM, ROBERT, M.D. St. And., has been appointed Medical Officer to the Union Workhouse, Cambridge.

RIVINGTON, WALTER, F.R.C.S., Eng., has been appointed Surgeon to the London Dispensary, Spitalfields.

SAUNDERS, WILLIAM S., M.D., has been appointed Surgeon to the B Division of the Metropolitan Fire Brigade.

SKINNER, THOMAS, M.D. St. And., has been appointed one of the Medical Officers to the Lying-in Hospital, Liverpool.

SMITH, C. J. HARDY, M.R.C.S. Eng., has been appointed Assistant House-Surgeon to the Sheffield General Infirmary.

STEELE, ARTHUR B., M.R.C.S. Eng., has been appointed Lecturer on Midwifery and the Diseases of Women in the Liverpool Royal Infirmary School of Medicine.

TATHAM, JOHN, M.D. St. And., has been elected one of the honorary Medical Officers of the Royal Pimlico Dispensary.

WILLIAMS, WILLIAM H., M.D. Lond., has been appointed one of the Medical Officers to the Yeatman Hospital, Sherborne, Dorset.

WOODFORDE, WILLIAM T. G., M.D. Lond., has been appointed Surgeon to the C Division of the Metropolitan Fire Brigade.

BIRTHS.

DAY.—On January 15, at Harlow, Essex, the wife of Robert N. Day, M.R.C.S. Eng., of a daughter.

DUKES.—On January 13, at High House, Enfield Highway, the wife of M. Charles Dukes, M.D., of a son.

HARRIS.—On January 10, at Botley, Southampton, the wife of J. C. Harris, M.R.C.S. Eng., of a daughter.

ISTANCE.—On January 10, at Risca, Monmouthshire, the wife of Richard Istance, M.R.C.S. Eng., of a daughter.

LITHGOW.—On January 6, at Royal-terrace, Weymouth, the wife of Dr. James Lithgow, of a daughter.

MACLURE.—On January 14, at 16, Hanley-street, W., the wife of Duncan M. Maclure, L.R.C.P. Lond., of a son.

MORGAN.—On January 11, at Bayswater, the wife of W. Taylor Morgan, M.D., of a son.

NEWMAN.—On December 29, at Hanover-square, Dartmouth, the wife of Dr. A. Newman, of a daughter.

OWEN.—On January 8, at Leatherhead, the wife of Francis Owen, M.R.C.S. Eng., of a son.

SANDS.—On January 10, at the Elms, Foot's Cray, Kent, the wife of Dr. J. Lee Sands, Surgeon R.N., of a son.

SKINNER.—On January 1, at Lyme Regis, Dorset, the wife of David S. Skinner, L.R.C.P. Lond., of a daughter.

SQUIRE.—On January 12, at Wivenhoe, Essex, the wife of S. N. Squire, M.R.C.S. Eng., of a son.

VIPAN.—On January 11, at Uxbridge, the wife of W. H. Vipan, M.R.C.S. Eng., of a daughter.

MARRIAGES.

DODS—CRABBIE.—On January 11, at 22, Royal-terrace, Edinburgh, George Dods, M.D., to Maggie, daughter of John Crabbie, Esq.

DUNLOP—BROWN.—On January 4, at Georgeville, Irvine, Robert Dunlop, M.D., to Mary, daughter of Captain James Brown.

HILL—RING.—On December 30, at St. Marylebone Church, Frederick A. Hill, M.R.C.S. Eng., to Bessie, youngest daughter of Richard Ring, Esq.

WHAMOND—KING.—On January 8, at Dalziel, Lanarkshire, William Whamond, M.D., to Mary Ann, eldest daughter of Thomas King, Esq.

WOODMAN—COWIE.—On January 11, at All Saints' Church, Norwood, Frederick Woodman, M.D., to Alice Emily, eldest daughter of the late Henry Cowie, Esq.

DEATHS.

DAUGLISH, JOHN, M.D. Edin., at Furze Bank, Great Malvern, on January 14, aged 42.

GROGAN, JOHN, Surgeon-Major 4th R.I. Dragoon Guards, at Brittas Castle, on January 6.

HATRICK, WILLIAM R., M.D. Glasg., at Hope-street, Glasgow, on December 30.

HULKE, WILLIAM, M.R.C.S. Eng., at Lower-street, Deal, on January 12, aged 74.

JARDINE, JAMES B., L.R.C.S. Edin., Staff Assistant-Surgeon Army, at Chatham, on January 10, aged 28.

MACGREGOR, Sir JOHN, M.D., K.C.B., late Inspector-General Army Hospitals, and Hon. Physician to the Queen, at Ryde, Isle of Wight, on January 13, aged 74.

PAYNE, HENRY, M.D. Edin., at Castle-gate, Nottingham, on January 7, aged 80.

SIMPSON, DAVID J., M.D. Edin., at 52, Queen-street, Edinburgh, on January 14, aged 24.

STUART, ANDREW P., M.R.C.S. Eng., at University College Hospital, aged 22.

TRAVERS, JAMES W. G., L.A.C., at 22, Millpond-street, Bermondsey, on January 13, aged 52.

POOR-LAW MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the last census.

RESIGNATIONS.

Buntingford Union.—Mr. Charles Gaffney has resigned the North-East District; area, 6414; population, 1847; salary, £40 per annum.

Cambridge Union.—Mr. Robert Rawsom has resigned the Second District; salary, £60 per annum.

Croydon Union.—Dr. Hetley has resigned the Norwood District; area, 2876; population, 6658; salary, £50 per annum.

Great Yarmouth Parish.—Dr. John Stephenson has resigned the South District; salary, £80 per annum.

West Derby Union.—Mr. Charles Evers has resigned the Garston District; area, 1680; population, 4516; salary, £30 per annum.

APPOINTMENTS.

Braintree Union.—Thomas Taylor, M.R.C.S.E., L.S.A., to the Booking District; John Harrison, M.R.C.S.E., L.S.A., to the Braintree District.

Fulham Union.—Nicholson Avent, M.R.C.S.E., L.S.A., to the Walham-green District.

West Bromwich Union.—William H. Hayward, M.R.C.S.E., L.S.A., to the West Oldbury District; James Beatty, M.R.C.S.E., L.S.A., to the East Oldbury District.

West Derby Union.—John James Flinn, L.R.C.P. Edin., M.R.C.S.E., L.S.A., L.M., to the Workhouse.

SIR WILLIAM FERGUSSON, BART.—The past and present pupils of this distinguished Surgeon are organising a committee to receive subscriptions to present him with a testimonial of their especial regard.

MR. SPENCER WELLS has been elected a Corresponding Member of the *Société de Médecine de Paris*. This is the oldest Medical society in France. The sittings are held in the Hotel de Ville, and have an official character.

MR. BENJAMIN TRAVERS, F.R.C.S.—There is no truth in the statement in some of the daily newspapers that the above gentleman has lately died.

THE LOSS OF THE "LONDON."—We regret to notice that among those who perished in the *London* was Mr. J. V. Faule, the Surgeon.

NAVAL MEDICAL SUPPLEMENTAL FUND.—At the quarterly meeting of the Directors of the Naval Medical Compassionate Fund, held on January 9, Dr. J. W. Johnston, Inspector-General, in the chair, the sum of £95 was distributed among the various claimants.

COLLEGIATE EXAMINATIONS.—It is stated that at the recent Primary, or Anatomical and Physiological, examinations for the diploma of Membership of the Royal College of Surgeons of England, when sixty-six candidates offered themselves, that rather more than a fourth of the number were referred back to their studies for three months. Of the sixty-six gentlemen no less than thirty-two had previously been rejected on this their Primary examination.

THE FLOODS IN DEVONSHIRE.—A SURGEON DROWNED.—The storms of last week in Devonshire were most disastrous. Many melancholy casualties have occurred in addition to those which have been already reported in the papers. Mr. Basleigh, a Surgeon of Morchard Bishop, North Devon, left his house to attend to his patients on Saturday afternoon. Some hours afterwards a horse without a rider was seen in the middle of a stream which is ordinarily a mere rivulet. Search was made, but no trace of Mr. Basleigh could be discovered until the afternoon of Sunday. His body was then found. He had been drowned in his attempt to reach the house of a patient.

METROPOLITAN ASSOCIATION OF MEDICAL OFFICERS OF HEALTH.—The next meeting of the Association will be held on Saturday, January 20, at half-past seven o'clock in the evening. Dr. H. B. Montgomery, Member of and Secretary to the Madras Sanitary Commission, will read a paper on "The Tendency of Religious Festivals and Pilgrimages in India to Originate and Disseminate Epidemic Disease; with Suggestions as to the Sanitary Precautions to be adopted to prevent Injury to Public Health."

OBTAINING POLICIES OF LIFE ASSURANCES BY FALSE PRETENCES.—We blush to have to record that a Surgeon, one Thompson Whalley, practising at Mirfield, has during the past week been convicted on two charges of obtaining policies of life assurance by false representations. One of the cases, to which he pleaded guilty, was that of a woman whom he was attending for cancer of the rectum. He insured her life in the British Prudential Assurance Company, and when her death took place he forwarded a certificate to the Company that she had died of fever, and made a claim in the name of the deceased's mother, but without her authority, for the amount insured. He is sentenced on both charges to fifteen months' imprisonment with hard labour. Of course the Medical Council will take action in this case, and by removing

Mr. Whalley's name from the Registry relieve the Profession from the disgrace of including such a person.

GAS PURIFICATION.—Experiments are being now made at the Crystal Palace District, and other gasworks, to test the practical value of a recent discovery by Dr. Letheby, who, besides his many other engagements, is now consulting engineer to several gas companies. He has found that the waste material of the soda manufacture, and known as "soda waste," is unexpectedly effective in absorbing the sulphur compounds in crude coal gas, and especially the obstinate bisulphide of carbon. The soda waste is employed in the purifiers in layers, as much as oxide of iron is now generally employed to arrest the sulphur of sulphuretted hydrogen.—*Engineering*

THE Annual Report of the Council of the Pathological Society gives a deservedly gratifying account of its prosperous condition: plenty of members, crowded meetings, interesting discussions, and a fair balance at the bankers'. One or two new regulations are brought forward for the general convenience regarding the presence of "living specimens"—*i.e.*, patients, cases previously published, incomplete cases, and microscopical specimens. The total income of the Society was £395 6s. 2d., and the total expenditure £359 7s. 3½d. The balance in hand at the commencement of the account was £87 1s. 1d. and, adding to this the excess of income over expenditure, the present balance in hand is shown to be £122 19s. 11½d. The annual income is made up of the following sums, viz.:—£39 14s. 11d. derived from the sale of *Transactions;* this item is a gratifying proof of the large demand which exists for the publications of the Society. £9 1s. 3d., dividends on £308 11s. 4d. invested in Consols; the increasing balance in hand will doubtless enable the Council to add to this investment. £28 7s. for twenty-seven entrance fees; this item again will show an increase in next year's account. Finally, £318 3s., the proceeds of 303 annual subscriptions; this number, as stated above, is the largest which the Society has ever yet attained. The items of expenditure do not call for any long comment. They include merely the usual expenses: £63 as rent for the rooms, and £229 14s. 2½d. the expense of publishing the 16th volume of the *Transactions*. This sum is greater than the expenses of the 15th volume, but the number of copies is also greater, the increased number of members having rendered it necessary to print 450 copies instead of 400.

DR. HEARNE ON THE SANITARY STATE OF SOUTHAMPTON.—Was it nothing, at the commencement of the past year, to warn the authorities that danger was looming in the distance—"That in the same streets year after year deaths have resulted from removeable causes; that of water inches deep under the floors of the houses—the level of the sewers being above the surface of the water, although, according to their own surveyor, an ample fall to remove the same; that there are houses in the town wanting both drainage and water; that other houses have no water; and that some of the houses, according to official report, have not even the convenience for water supply, and, consequently, are unfit for habitation; that, again, other houses are dependent for water on local springs, the supply from which can never be regarded as wholesome in thickly populated districts, and that that from some of the Southampton wells has been demonstrated by examination to be unfit for use; that streets remain blocked at either end so as effectually to preclude the free circulation of air, although the cost of alteration would amount to a very trifling sum—but however great the amount it would have been money well invested for the town; that privies in a crowded district have been allowed to remain unattended to for from fifteen to twenty years, and for years after having been reported upon—possibly even to the present time?"

VACCINATION AND RINDERPEST.—In the *Times* of Thursday, January 18, Mr. Wilbraham Tollemache, High Sheriff of Cheshire, gives the following account of the success which has hitherto attended his experiment of vaccinating cattle against Rinderpest:—"Having been requested by several stock-holders and others to make known, through the medium of the *Times*, the present condition of my ten vaccinated cows, I am sure, from the importance of the subject, you will allow me space to do so. My ten cows are up to this present time quite healthy and well. I made no difference in their treatment either before or after the operation. No medicine was given, no change of diet. Some of the cows were in milk, some were dry before calving, and one calved six days after she was vaccinated. My own family and household partook, and partake, of their butter, milk, and cream, without experiencing the slightest inconvenience. As the question of vaccination being a safeguard against Rinderpest is of vital importance in this cheese-making county, I may state that, after the most diligent inquiries, I have not been able to hear of one fatal case in this neighbourhood where the operation had been successful. Many vaccinated cows have died, but not one, as far as I can hear, where the vaccine had taken. I have lately been trying an experiment, which I am sure will possess deep interest with many of your readers. On Thursday morning last, the 11th, I had a thirteen months old Alderney heifer, which had been most successfully vaccinated, turned into a kind of loose place, nine feet square, in which was one calf very ill from unmistakable Rinderpest, and another calf which had just died from the effects of it. The dead calf was removed in about half an hour after my calf was put into the place. The sick calf died the following day. Since then two more calves ill from Rinderpest have been placed with my calf, and have since died from the disease. My calf is as healthy and sharp as ever she was, notwithstanding she has been kept for five days and five nights in a most fetid atmosphere, and coming in immediate contact with these four dying and dead calves!"

THE following are the last week's Cattle Plague Returns. By comparison with those of the previous week, it will be seen that there have been 8508 attacked, 5701 deaths, 588 slaughtered, and 1223 recoveries, since December 30:—

Census Divisions.	1. Attacked. Week ending January 6.	Week ending December 30.	Week ending December 23.	2. Result of reported Cases from the Commencement of the disease. Attacked.	Killed.	Died.	Recovered.	Remaining.

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

Next week we shall report an important case of traumatic aneurism following perforation of the arteria innominata, which has lately occurred in the practice of Sir William Fergusson, Bart., and which we have been unavoidably obliged to postpone.

A private letter for "Physiologicus" is waiting at our office.

Dr. Dyce Brown.—The communication shall appear.

Dr. W. Ogle.—The paper is in the printer's hands, and shall appear.

Chlorodyne.—We have received plenty of communications on this popular medicine, which we must keep till next week.

Mr Thomas Shearman Ralph, of Melbourne, has written an able pamphlet on the Parasitic Nature of the Pleuro-pneumonia in Cattle.

The *Municipal Government of London*, by a Landowner (R. Hardwicke, 192, Piccadilly, price one shilling), is a clever pamphlet, which shall be noticed next week.

A Hospital Surgeon.—There are two members of the Council senior to Sir William Fergusson for a seat at the Court of Examiners, viz., Mr. Cock, of Guy's, and Mr. Solly, of St. Thomas's Hospitals.

A Village Surgeon.—The vaccine virus should be taken directly from the cow. Vaccination of cows from children is successful in comparatively a very small proportion of cases.

Helminthologist.—The preparations of Dr. Cobbold are now displayed in the Museum of the College of Surgeons, where you can see illustrations of the disease to which you refer.

F.R.C.S. and *A Member*, Birmingham.—There is no doubt but that, following recent precedents, the name of the delinquent will not only be removed from the College List, but also from the Register.

Alleged Breach of Medical Etiquette.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—Allow me to point out an accidental error in your remarks on the case between myself and Dr. Heginbotham. You say Dr. Heginbotham had permission of the parents to "open the child." Such was not the case as given (by the parents) and admitted by Dr. Heginbotham in evidence.

I am, &c.,
A. J. W. Banks, M.D.

Evercreech, July 15.

Poor Law Medical Reform.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—Since the last report in your journal, I have received £7 3s. 6d., as the annexed list will show, which has not only placed the Association out of debt, but leaves a small surplus for future proceedings. To this surplus I trust the Poor Law Medical Officers, generally, will and their subscriptions, and thus enable the Association to take active proceedings during the ensuing session of Parliament.

There is a question now before the country to which I desire to call the attention of the Poor Law Medical Officers, viz., "the Rinderpest," which, should it be proved to be a malignant form of small pox, will compel the Government to consider the question of the compulsory vaccination of all calves, not to be killed as such, and thus prevent the spread or reappearance of the Rinderpest in the United Kingdom. Should such be the case, and the Poor Law Medical Officers not consider it derogatory to vaccinate these animals in their respective districts, a very material addition might be made to their at present miserable incomes, besides this, it would be the means of keeping up the supply of lymph for the human subject; if, however, they should decline to do this, I feel certain that those who are deputed to vaccinate the calf—a much more difficult operation than in the human subject—will, after a time, vaccinnate the infant, and thus a material reduction instead of an increase may be made in the incomes of Poor Law Medical Officers. I throw this out for the consideration of my brethren, that steps may be taken to insure the attainment of this object should they desire it.

R. Griffin, Weymouth, 21s.; H. T. Matthews, Horsham, 21s.; C. F. Lewis, Horsham, 5s.; W. Martin, Horsham, 10s.; R. Harrison, Kendal, 5s.; A. Cheeves, St. Germans, 5s.; H. E. Sargent, Launceston, 5s.; H. B. Goold, and W. B. Norman, Portsea Island, 10s.; W. A. Raper, Portsea Island, 5s.; J. S. Allnutt, Portsea Island, 5s.; J. E. Brine, Shaftesbury, 21s.; J. H. Swain, 10s.; W. H. R. Bennett, 10s.; J. S. Miles 10s.

I am, &c.,
12, Royal-terrace, Weymouth, Jan. 13. Richard Griffin.

To the Benevolent.

The case of Mr. Gregory, only son of the late Lieutenant-Colonel Gregory, 44th Regiment of Foot, is eminently deserving not only the sympathy, but the assistance of the Medical Profession, of which Mr. Gregory is a member.

His eyesight began to fail him while in Australia, which compelled his return to England.

The most eminent Surgeons in London—Mr. Bowman, Mr. White Cooper, Mr. Dixon, and Mr. Haynes Walton—have pronounced the disease to be atrophy of the optic nerve, causing an impairment of vision equal almost to complete blindness and quite incurable.

He is unable to read or write, and entirely incapacitated from practising his Profession, or, indeed, following any occupation. He is thus deprived of all power to contribute to the support of himself and wife.

His state of destitution has induced the following gentlemen to permit references to be made to them and to receive subscriptions with the hope that a sum may be collected to enable Mrs. Gregory to do something for the support of herself and husband.

The following gentlemen will answer any references made to them, or receive subscriptions on behalf of Mr. Gregory:—Barnard Holt, Esq., 14, Saville-row; Gilbert MackMurdo, Esq., 7, New Broad-street; Dr. Basham, 17, Chester-street, Belgrave-square; Dr. Hudson, 11, Cork-street, Regent-street.

COMMUNICATIONS have been received from—

Apothecaries' Society; Dr. John Whitmore; Dr. W. Ogle; Mr. F. Clowes; Dr. Dyce Brown; Mr. F. Crook; Mr. R. Griffin; Mr. Edwin Hearne; Ethnological Society; A Surgeon; A Village Surgeon; Pharmaceutical Society; Dr. George F. Duffey; Royal Medical and Chirurgical Society; Mr. G. Gaskoin; Dr. Fotherby; Doubt; Scottish Widows' Fund; Dr. C. Kidd; Admiralty, Somerset House; Dr. C. H. Marriott; Mr. Henry Viant; Mr. Thomas Stokes; Dr. A. J. Banks; Mr. W. B. Kesteven; Dr. G. H. Porter; Mr. W. Troup; Mr. A. Arthur Napper; Dr. G. Whyte; Professor Lionel Beale; Dr. C. Handfield Jones; Dr. James Russell; Mr. E. Bellamy; Dr. J. C. Gooding; Mr. Spencer Wells.

At the Royal Observatory, Greenwich, the mean height of the barometer in the week was 29·195. The reading was 29·93 in. on the morning of Sunday; it fell to 28·65 in. on Thursday, and rose to 29·83 in. on Friday. The general direction of the wind was south-west and west.

* The average weekly numbers of births and deaths in each of the above towns have been corrected for increase of population from the middle of the ten years 1851-60 to the present time.

† Registration did not commence in Ireland till January 1, 1864; the average weekly number of births and deaths in Dublin are calculated therefore on the assumption that the birth-rate and death-rate in that city were the same as the averages of the rates in the other towns.

‡ The deaths in Manchester and Bristol include those of paupers belonging to these cities who died in Workhouses situated outside the municipal boundaries.

§ The mean temperature at Greenwich during the same week was 43·2°.

APPOINTMENTS FOR THE WEEK.

January 20. *Saturday* (*this day*).

Operations at St. Bartholomew's, 1½ p.m.; St. Thomas's, 9½ a.m.; King's, 2 p.m.; Charing-cross, 1 p.m.; Royal Free Hospital, 1½ p.m.

Royal Institution, 3 p.m. Prof. Westmacott, "On the Way to Observe in Fine Arts."

22. *Monday.*

Operations at the Metropolitan Free Hospital, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 9 a.m. and 1.30 p.m.

Medical Society of London, 8½ p.m. Lettsomian Lectures—"On Certain Painful Affections of the Fifth Nerve," Lecture II., by Dr. F. E. Anstie.

23. *Tuesday.*

Operations at Guy's, 1 p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; St. Peter's Hospital for Stone, 3 p.m.

Ethnological Society of London, 8 p.m. Sir E. W. Belcher, "Remarks on the Andaman Islands, from the Notes of Lieut. St. John." Dr. Caddy, "Visit to the Patagonians."

Royal Institution, 3 p.m. Prof. Tyndall, "On Heat."

Royal Medical and Chirurgical Society, 8½ p.m. Dr. Radcliffe, "Case of Acute Uncomplicated Myocarditis." Mr. C. H. Moore, "Arterio-venous Cyst in the Popliteal Nerve; Amputation; Recovery."

24. *Wednesday.*

Operations at University College Hospital, 2 p.m.; St. Mary's, 1½ p.m.; Middlesex, 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; St. Thomas's, 1½ p.m.

Hunterian Society (Special Council, 7 p.m.), 8 p.m. Dr. Peacock, "On Some of the Hospitals in the North of Europe, and on Hospital Construction." Mr. Couper, "A Case of Deficiency of the External Ear Remedied by Operation."

25. *Thursday.*

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Surgical Home, 2 p.m.; Royal Orthopædic Hospital, 2 p.m.; West London Hospital, 2 p.m.

King's College Medical Society, 8 p.m. Mr. Welch, "On Ovarian Cysts."

Royal Institution, 3 p.m. Prof. Tyndall, "On Heat."

26. *Friday.*

Operations, Westminster Ophthalmic, 1½ p.m.

Royal Institution, 3 p.m. S. W. Baker, Esq., "On the Sources of the Nile."

ORIGINAL LECTURES.

LUMLEIAN LECTURES

ON SOME POINTS IN THE PATHOLOGY OF NERVOUS DISEASES.

By C. HANDFIELD JONES, M.B., F.R.C.P., F.R.S.,
Physician to St. Mary's Hospital and Lecturer on Medicine.

Lecture III.

(Continued from vol. ii., 1865, page 623.)

I proceed now to make some remarks on *pain*, the commonest as well as the most distressing of the symptoms to which functional nerve disorder gives rise. The purpose I have chiefly in view is to endeavour to ascertain the true character and import of this condition. One of the most eminent and respected Fellows of this College describes it as follows:—"Natural sensation," he says, "suffers offence from some cause or other, and hereupon it is altered, raised, exasperated, and so it becomes *pain;* but it is sensation still, and nothing more." The idea here conveyed is otherwise expressed by Romberg when he says, speaking of hyperæsthesia (a convertible term with him for neuralgia), "the character which these affections have in common is exalted irritability, and increased irritation of the sensitive or centripetal nerves." Mr. Paget speaks of pain as a morbid exalted sensation. It seems to me that in these descriptions, embodying, as they do, very much the notions generally entertained on the subject, the condition giving rise to pain is regarded as one of increased functional activity of the nervous tissue, increased at least in some degree, though not in a healthy and natural manner. I think it may be worth while to consider whether in the majority of neurotic pains the phenomena are not essentially indicative of depression, resulting from lowered and enfeebled vital power in the suffering tissue itself, and in the body generally. First, however, it seems to me desirable to draw a distinction between two forms of nervous pain, the types of which are very dissimilar, though they are often variously combined in intermediate instances. Hyperæsthesia, interpreting the term according to its etymology, is, I think, a real morbid state, and should not be confounded with neuralgia. The affection termed scrofulous ophthalmia, with its intense photophobia, affords one of the best instances. The retina is utterly intolerant of its natural stimulus, and this excessive irritability is evidently the essential morbid condition, and not inflammation. It is true, that as the optic is not a nerve of common sensation, we cannot show that it is liable to the different form of nerve distress which we call neuralgia, but there is no difficulty in making this distinction in other instances. Thus even in the eye photophobia appears to be sometimes dependent, as Romberg considers it generally is, on disordered action of the ciliary nerves; I have myself met with instances of the occurrence of photophobia in amaurotic individuals. Neuralgia of the eye is, however, quite a different affection, often co-exists with neuralgia of the face, and may be quite unattended with photophobia. The same distinction may be made of the nerve pains which affect the stomach. Some of them, the commonest, are typical examples of neuralgia, being attended with much sense of depression and sinking, and relieved by stimulants, as brandy and opium. In others, the phenomena are much more those of extreme sensitiveness and irritability, the epigastrium being very intolerant of pressure, the lightest ingesta immediately producing pain and often vomiting. The remedies for this latter state differ so much from those which avail in the first, that we have the clearest evidence of the great difference between the vital actions in the two cases.

The uterine neuroses present us with a third example. The affection termed "irritable uterus" can only be regarded as essentially an hyperæsthesia of the organ, especially of its cervical part; while the pangs of dysmenorrhœa are in many instances true neuralgiæ. Romberg (a) distinguishes tic douleureux from what he calls anæsthesia dolorosa of the fifth nerve, and says the important criterion by which the latter may be recognised is the insensibility of the painful surface to irritation; while in tic douleureux the parts become morbidly sensitive to the most superficial contact. The testicle and the female breast sometimes present exquisite instances of hyperæsthesia; any, even the gentlest, contact being intolerable; while many instances of true neuralgia are relieved by firm pressure and friction.

We have no certain knowledge as to the condition which determines the occurrence of hyperæsthesia rather than of neuralgia. I believe we must acquiesce in the somewhat vague statement that it is a different mode of acting in the nerve tissue itself, and is not dependent on neuritis or any discernible alteration. Hyperæmia, however, does seem in some way to be associated with hyperæsthesia, as is evidenced in those cases of neuralgia where, after the lapse of a certain time, the affected part becomes more or less red, swollen, and exquisitely tender; the neuralgia having, in fact, been converted into hyperæsthesia. Tranverse lateral division of one half of the cord in the dorsal region produces marked hyperæsthesia of the lower limb on the same side, which is referred by Brown-Séquard to paralysis of the vaso-motor nerves of this side induced by the operation. He makes the hyperæsthesia chiefly dependent on the resulting hyperæmia, the vital properties generally of the parts supplied by the dilated vessels being increased by the afflux of arterial blood. It is, however, I think, certain that hyperæmia is no necessary part of hyperæsthesia. I remember attending a lady of advanced age, who suffered, after an attack of zona, with persistent extreme hyperæsthesia of the skin of the breast and adjacent parts, quite unattended with any hyperæmia. A patient lately under my care for severe facial neuralgia had no heat or redness of the skin covering the affected part, but it was very tender. Another patient suffering in the same way obtained relief by stooping forward so as promote the flow of blood to the head. In the affection termed mastodynia, as described by Sir Astley Cooper, the local tenderness is extreme; but the colour of the skin, it is expressly said, remains unaltered, and no trace of inflammation is visible. The same is true, I believe, of most of the cases of irritable testis; Graves says(b) of a case attended with excruciating agony that there was no fever, and not the slightest appearance of local congestion or inflammation.

Hyperæsthesia, like neuralgia, may be of reflex origin. Mr. Erichsen states that this condition of the testis may be dependent on local irritation, as that produced by external piles, and may cease after these have been removed. The affection termed painful subcutaneous tubercle is often attended with most marked hyperæsthesia. Romberg says that during the paroxysm the skin is so excessively tender that the most superficial and gentlest contact increases the pain, which is not the case in the intervals. It is remarkable that the nerve disorder in these instances rarely takes a centripetal, but usually a peripheral direction. Foreign bodies or wounds of the nerves produce much the same effect as the painful tubercle. Wardrop relates a case in which the thumb, after being wounded, became constantly painful and extremely tender to the touch, with severe reflected pains extending over the whole hand, arm, neck, and even down to the back. Immediately after complete division of the nerve above the injured part, the thumb which he could not allow to be touched a minute before he could now roughly handle, and all pain left the other fingers and hand. In this case, as in others, the hyperæsthesia was unattended by any hyperæmia, and temporary relief was even afforded by copious general bleeding. The production of hyperæsthesia by such causes as have now been mentioned is surely significant as to the nature of the symptom. They can act no otherwise than in the way of deteriorating and injuring the nervous tissue.

While insisting, however, on the distinction between hyperæsthesia and neuralgia as a point of some practical importance, I would not omit to note the affinities between these two states;—both are essentially neuroses, both commonly have their origin in causes which impair the strength and tone, and heighten the mobility of the nervous system, and both are often ameliorated by means which improve general and nervous power. Of these as of many other conditions we may say—"Facies non omnibus una, nec diversa tamen."

With respect to neuralgia, there seems to me much to support the view that it is the result of depressed and not of increased nervous power; that though it must be regarded as a form of sensation, it is an impaired and deteriorated, and not in any wise an exalted, and that it betokens an approach to sensory palsy and anæsthesia rather than to a higher manifestation of functional power. One very significant and interesting feature in the ordinary instances of neuralgia is the intimate connexion between the pain and the coexisting general debility. Whatever improves the general health and strength usually amends the neuralgia, and whatever lowers it will assuredly be speedily

(a) Romberg, vol. i., p. 49.

(b) Graves, p. 83.

followed by increased suffering. Even a moderate amount of bodily exertion, by the expenditure of nervous energy which it involves, will aggravate or reproduce a neuralgia which was ceasing under treatment. In one instance a male under my care, convalescent from severe facial neuralgia, found that he was rendered sleepless at night by pain in his arms if he worked at his trade of shoemaking during the day, but he had no pain if he kept at rest. Mental effort has the same effect;—a Medical man suffering with nervous exhaustion from overwork and neuralgic headache, told me that he found any amount of close thought induce actual acute pain.

The state attendant on neuralgia is essentially one of depression, which does not appear to be merely the result of the suffering, but to be in a measure itself the root-malady. The brain is inapt for mental effort, and its functional power sometimes fails in a very marked manner. The parts affected are often quite numb; I have especially observed this when the hands and fingers were attacked. Moreover, the muscles supplied by the suffering nerves are sometimes distinctly paralysed, and there is usually more or less weakness and impaired mobility in the limb. Paresis of vaso-motor nerves sometimes accompanies that of the sensory. I well remember, when suffering some years ago with an annoying throat neuralgia, both the great depression with which it was attended and the very troublesome salivation. The latter was doubtless a secretion flux dependent on a semi-paralysis of the nerves of the salivary glands. The beneficial influence of appropriate electrical stimulants may also be cited as indicative of the quality of the morbid action, and so also may the nature of the local applications, chloroform, opium, turpentine, ammonia, etc., as well as of the internal remedies which we often employ with advantage. Now, it may be fairly argued that when the signs of nerve debility are so apparent, and have such a distinct relation to the particular symptom, this must be itself of the same essential character. When the vis nervosa generally is feeble, the brain languid, the affected nerves anæsthetic or tingling, as after pressure has been made on them, the colligated motor and adjacent vaso motor semi-paralysed, and when all these aberrations from the healthy state are corrected by a tonic and nutrient treatment, the conclusion seems inevitable that the disorder is essentially one of lowered vital action, and that we must employ such terms as irritation and the like, with the full understanding that such is really the case.

I have hitherto been speaking of non-organic neuralgia, especially that which does not depend on any material cause of irritation, but on some undiscernible primary alteration in the state of the affected tissue. What is true in this case holds good also, I believe, in the other. Pain essentially depending on some local lesion is aggravated by fatigue, mental anxiety, bad food, and the like; and is relieved by restoratives which improve the general strength. Dr. Brinton says "there are hundreds of people walking about London the diseased nerves of whose carious teeth would be speedily roused into severe neuralgia by two or three nights of sleepless watching and anxiety, or by two or three days of insufficient nourishment, or of violent and exhausting exertion of mind or body. And conversely, I am sure that a generous diet will often relieve the agony arising from sheer involvement of nerves in a cancerous deposit." Dr. Anstie, describing his personal experience of neuralgia of the vasal and frontal branches of the fifth dependent, apparently, on a tight stricture of the upper end of the nasal duct, says, "The attacks of pain are invariably caused by fatigue of body or mind, and are preceded or accompanied by pallor of the face, weak pulse, and a general sense of depression. Ammonia, hot tea, and local blistering are the most effective means of relief." The *conditions* which give rise to pain, so far as we can take cognisance of them, are such as can only affect the nervous system in an unkindly injurious manner. Carious teeth, hard cancer growths, renal and biliary calculi, stone in an inflamed bladder, a piece of lead imbedded in a nerve are, it is true, nerve-excitants; but their action we can pronounce *à priori* can be no other than depressing and exhaustive. Nerve excitants, which act beneficially, are, we know, of a very different sort. The *effects* of pain are notoriously exhausting and depressing, and may even lead to a cessation of all vital action. Dr. Latham mentions a case in which death ensued from the agonising pain of a gall-stone.(c)

(e) I am glad to find that Dr. Anstie in his able work has taken the same view that I have, and developed it more completely. I have no doubt that his opinions were arrived at by independent investigation; but that I may not appear to any to be guilty of plagiarism, I will mention that in my paper on the nature, etc., of neuralgia, published in the *Lancet*, September, 1859, I took almost the very same ground that I do now.

Although the above evidence seems to me tolerably conclusive as regards the true nature of pain, I may refer incidentally to two or three other instances which seem to me to admit of an explanation very confirmative of the view I have taken, and which are in themselves of some interest. The usually trifling disorder of sneezing seems to afford some evidence of the paralysing influence of pain. It is quite certain that the profluvium which is poured out so suddenly and rapidly is not produced by the expiratory air blast; for we expel none such by the strongest voluntary imitation of the process. The act commences with pain, and it appears that when this attains a certain intensity it conditionates in some way paralysis of vaso motor nerves, in consequence of which the mucous membrane becomes flushed with blood and exudation takes place. The pain is a neuralgia, and as such is associated with motor paralysis, as is often observed in brachial and other neuralgias. Copious sweating is often the result of pain, doubtless from inhibitory paralysis of the arteries of the cutaneous glands. The lacrymation attendant on photophobia is an instance of the same kind; and so also is pyrosis, where the gastralgia gives rise by reflex relaxation to the watery effusion which is then rejected.(d) The pain occasioned by the descent of a renal calculus is often associated with numbness of the corresponding thigh, giving us, as it were, an interpretation of the true character of the pain.

From all the above it is tolerably evident that in the sensory department of the nervous system paresis must be of very frequent occurrence, much more than it is in the motor. A multitude of common pains occur in the way of direct primary failure of functional nervous power, but very many also are the result of reflex irritation, and therefore belong to the category of inhibitory paralysis. Some of the cases related by Sir B. Brodie read, *mutatis mutandis*, exactly like histories of reflex paralysis—*e.g.*, the man whose painful foot was cured by dilating a stricture in his urethra, and the female in whom a like pain was removed by the cure of piles. This theory referred to seems thus to derive material confirmation from a due estimate of the true nature of pain.

Hyperæsthesia at first sight appears to present much more resemblance to a state of increased functional energy than neuralgia does. On closer examination, however, it becomes pretty clear that such is not really the case. A true increase of functional energy would surely imply that the tissue was more capable of fulfilling its proper work, was able to put forth more power than it could before. The sensory nerve ought to be more discriminative, more quick at perceiving minute differences, not merely more sensitive, so much so as to be actually shrinking from the contact necessary to the exercise of its function. The organs of special sense, when trained to their highest degree of efficiency, are, we know, in a very different state to that which they present when their nerves are hyperæsthetic. There is a wide difference between the condition of the retina in the photophobic patient and in the Indian who recognises the footprints of some particular individual where the untrained eye can discern nothing at all. So also the wonderful delicacy of touch which the blind acquire is a very different quality from the hyper-sensitiveness of the hysterical. The power which a practised taster possesses to judge of flavours has nothing in common with that most refractory and distressing disorder, lingual hyperæsthesia. The fact seems to be that hyperæsthesia of a sensory nerve is a state strictly analogous to undue excitability of a motor nerve, such as exists in chorea, and in a variety of states of debility. The excitability, the mobility of a motor nervous apparatus, if excessive, is so far from being the same thing as increased functional capacity of that apparatus that the two are always developed in inverse ratio. The strong organs are tranquil in their strength, as all really strong things are; the weak, on the contrary, are prone to make a fidgetty display of imperfect action. It is just the same with the sensory organs: a certain amount of strength is necessary for the due fulfilment of their function, and from this hypersensitiveness the offspring of debility incapacitates them.

It may add to the force of the above remarks if we take some instances of hyperæsthesia, and consider the attendant circumstances. With regard to photophobia, nothing can be more evident than that the fundamental condition is in most cases one of marked debility, and that the analeptic and tonic regimen is urgently needed. Acoustic hyperæsthesia is a much rarer phenomenon. Dr. Watson mentions the case of

(d) I beg to direct the reader's attention very especially to Bernard's paper (*J. de l'Anatomie und de la Physiol.*, September, 1864) "On the Influence of Paralysing Reflex Agencies."

a gentleman who was taken suddenly ill, and died in a few hours of an irregular form of cholera. When seen, he was pulseless; his skin was cold; he was evidently dying; but his intellect was entire, and his hearing was so painfully acute that he was distressed even by the whispered conversation of his attendants. Under such circumstances, an increase of functional power seems out of the question. The condition of the general health in the affection termed "irritable uterus" is certainly indicative of impaired vital power, and the local disorder is evidently inconsistent with the due function of the part. The same must be said of gastric hyperæsthesia, whether it originate primarily in the organ itself, or be of reflex origin. A patient under under my own care suffered with exceeding pain after eating, so that she went without food to escape it. Any exertion made her worse. Her pulse was very feeble. Her head she described as being in such a "very queer state" that, if left alone a short time, she felt lost. With nitrate of silver and lactic acid she benefited very much. The depression of nervous power in this case was well marked, and it is usually so in most instances of the same kind. With regard to cutaneous hyperæsthesia, it seems to me that the phenomena of itching and creeping (formicatio), which are described by Romberg as disorders of this kind, are not really and properly such. By hyperæsthesia, as we have above employed the term, we imply a condition in which the part concerned is intolerant of pressure or of any kind of excitement. Such is not at all the case in pruritus and formicatio, which invite pretty rough manipulation, and herein show more affinity to neuralgia than to hyperæsthesia. The former of these—dysæsthesiæ—it may be remarked, is by no means closely connected with a depressed state of vital energy, but rather the contrary. I have several times had occasion to observe that the subjects of lichen, though suffering considerably from the annoyance of the eruption, were in a rather vigorous state of health. A recent writer(e), speaking of the prickly heat in India, says that it prevails at that time of the year when sickness is least prevalent, and is usually associated with excellent health. True cutaneous hyperæsthesia is often observed in facial neuralgia, and is, I am sure, by no means limited, as has been asserted, to the declining period of the disorder, when vascular injection of the skin occurs. I have found it present when the surface had quite its ordinary appearance. In the graphic description which Dr. Fuller has favoured us with of his personal experience of infra-mammary pain, he remarks that the disorder first attacked him in the month of June, when he was thoroughly exhausted by incessant Professional work, and enervated by want of active out-of-door exercise. The disorder was chiefly a neuralgia, but when severe was accompanied by superficial tenderness, so acute as to be aggravated by the slightest pressure, but of much more limited extent than the pain. Improvement of health by means of country air seems to have been the chief means of procuring recovery. Here the connexion between neuralgia and hyperæsthesia, as well as their dissimilarity, is sufficiently marked; and the conditions under which both occur are plainly those of nervous exhaustion. The following instance is much to the same effect:—A lady, who is by no means subject to neuralgic affections, was convalescing very prosperously from her fifth confinement, and nursing her infant. At about the end of the second week she was attacked one day with sensations of incipient catarrh, and with considerable tenderness of the right breast. The left breast was a little painful, but much less. On the second day of this evidently influenzal disorder the tenderness of the right breast was extreme; it could hardly bear the least pressure, even its own weight was distressing; pain shot up towards the axilla and scapula. Pain was felt when the breast was not touched,—sharp, pricking, shooting, and aching; giving suck increased the pain, and put her into a bath of perspiration for a time, but the breast got easier afterwards. There was no inflammation. Quinine was given, and the suffering was at an end in five days. The influence of pain in this instance in causing vaso-motor paresis of the perspiratory glands is noteworthy. Cutaneous hyperæsthesia is a very marked feature of the earlier period of catarrhal fever, as I can testify from personal experience. I have suffered from this disorder the last two years at about the middle of July; it continues about a month, and is certainly no mere febricula, nor has it any relation to hay-fever. The symptoms are languor, mental and bodily, prostration, chilliness, complete anorexia, pharyngeal and nasal catarrh. While suffering with the chills and slight rigors of this fever, I was forcibly struck with the perverted state of the cutaneous sensibility; the cool breeze which would have been most grateful during the summer heats being now actually distressing. The peculiar co-existing prostration of mental and muscular power rendered it quite impossible to regard this hyperæsthesia in any other light than as a sensory paresis, and it was also evident that the vaso-motor nerves of the upper part of the air-passages were similarly affected.

(To be continued.)

ORIGINAL COMMUNICATIONS.

NOTES ON SYPHILIS, WITH SPECIAL REFERENCE TO ITS TREATMENT BY SYPHILISATION.

(Extracted from the *Norsk Magazin for Lægevidenskaben*, xix. Bind, 11 Hefte, Christiania, November, 1865.)

By WILLIAM DANIEL MOORE, M.D. Dub., M.R.I.A.,
Honorary Fellow of the Swedish Society of Physicians, of the Norwegian Medical Society, and of the Royal Medical Society of Copenhagen; Examiner in Materia Medica and Medical Jurisprudence in the Queen's University in Ireland.

The following notes are extracted from a report on the Section of the Royal Hospital in Christiania for Diseases of the Skin, from October, 1863, to the end of 1864, drawn up by Hr. Owre, Physician Extraordinary to the Hospital, and published in the number of the *Norwegian Magazine of Medical Science* for November last. From the report, it appears that, in the above space of time, 511 patients—of whom 270 were males and 241 were females—were treated in the division of the Hospital just mentioned, and that of these 511 patients, almost exactly one half—viz., 257—were affected with syphilis.

Of the 257 individuals so affected, 34 presented primary symptoms alone, while 223 laboured under constitutional affections.

Of the 34, 9 (1 male and 8 females), had before been under treatment for general syphilis; the average duration of treatment for these patients was 22⅓ days; the other 25 (19 males and 6 females) were now for the first time in Hospital for a syphilitic affection, and the time of treatment for these was, on an average, 41 days. The cause of this difference in time is, no doubt, to be found simply in the fact that public girls, who are subjected regularly to inspection twice a-week, are taken into Hospital immediately on exhibiting ever so slight excoriations or ulcerations of a suspicious appearance on the genitals, particularly those who have recently been treated for general syphilis. All the eight women who had before laboured under constitutional syphilis were also prostitutes. They were in Hospital in the last quarter of 1863, and after that time such affections did not come under treatment, principally because public girls, as has already been stated, are no longer received into the Royal Hospital.(a)

The period of treatment for those not previously syphilitic, forty-one days, is about the same as Professor Boeck has assigned as the average time for a total of several hundred individuals treated with simple local means. (See "Recherches sur la Syphilis," pp. 57 and 58.)

The treatment of all primary sores, whether soft or hard, has been exceedingly simple, nothing else having been employed than plain external applications, as water dressing, slightly astringent solutions, and occasionally the application of lapis infernalis. Where the sore has not been easily accessible—for, example, on account of considerable phimotic swelling of the prepuce—it has been kept clean by ordinary injections with a long-pointed syringe; sometimes the prepuce has been divided to admit of the ulcer being treated, and this method is highly to be recommended, especially in simple large indurated ulcers, which might otherwise require many months for cicatrisation; laid bare after division, they in general heal very quickly. That the syphilitic sore may extend over the preputial lobes—nay, may even destroy the whole prepuce—has, indeed, occurred, but extremely rarely, and this risk can, at all events, not justify us in abstaining from a proceeding which spares the patient great pain, shortens his stay in Hospital, and must be regarded as free from danger.

(a) From the preceding part of the Report, it appears that, since the commencement of 1864, sixty beds have been appropriated in the Municipal Hospital (Kommunesygehuset) to such patients.—W. D. M.

For that a portion of the prepuce, or perhaps the whole, should be lost is not any great misfortune.

Suppurating buboes occurred very rarely.

Of primary sores in unusual places we may remark :—An indurated ulcer in the umbilicus of a man, in whom the indurated ulcer on the inside of the prepuce had given rise to a phimosis like that just mentioned, and had ulcerated through the prepuce ; out of this perforating ulcer pus flowed in great masses at the time of his admission into Hospital, or two months after connexion. He could give no information as to the origin of the umbilical sore, but it must undoubtedly have arisen by self-inoculation from the sub-preputial ulcer ; it was quite characteristically indurated, penetrated rather deeply, and did not heal until after the lapse of about three months.

Labial chancres in two adult girls.

Ulcers on the mammæ in four, namely :—

1. G. M. N., aged 28, admitted on November 11, 1863, with constitutional syphilis. She had in the spring given suck to a strange diseased child with ulcers on the lips, trunk, and anus ; subsequently an ulcer was developed on the left nipple, where there is now a tolerably large, rather hard cicatrix. Later a sore (mucous tubercle) presented itself in the middle of the tongue, after which there was a distinct scar ; an affection of the throat and large mucous tubercles became developed in the course of the summer and autumn. The lymphatic glands in the left axilla, neck, and groin were swollen and indolent. At the same time her own male child, aged 15 months, was admitted with general syphilis. Her husband was healthy.

2. L. J., aged 34½, was admitted on April 1, 1864, with constitutional syphilis. Shortly before Christmas she gave suck to a child which was subsequently certainly known to be syphilitic. In the course of January she remarked a small ulcer on the right nipple, which, notwithstanding constant Medical treatment, refused to heal, but on the contrary regularly spread, so that on her admission into Hospital the right nipple was found to be considerably enlarged, uneven on the surface, ulcerated, of an intensely red colour, feeling hard throughout its whole mass and tender to the touch. The corresponding axillary glands were swollen and indolent. In addition there were secondary phenomena on the trunk and in the throat. On May 21 she was delivered of a putrid child in the eighth month.

3. S. H., aged 41, admitted on May 7, 1864, quite healthy, with her male child, aged 15 months, who had copiously secreting ulcers in the nose and mouth and on the chin, besides other secondary symptoms. On May 26 she called our attention to the fact that during the last few days an oblong ulcerated surface had been developed one-third of an inch from the base of the right nipple, which surface was covered with a thin crust, beneath which the ulcer was red, shining, and rather elevated. Subsequently there were fugitive pains in the loins, indolent glandular enlargements, particularly in the right axilla and along the posterior margin of the left sterno-cleido-mastoid muscle, with iritis of the left eye.

The child was infected by a woman labouring under secondary syphilis who sometimes took care of it.

4. A. E. L., aged 30, admitted on May 11, 1864, with her syphilitic child, exhibited on both mammæ a dry superficial ulceration, of the size of a bean, without any hardness, near the nipple. Constitutional symptoms were gradually developed, and on June 1 she was put under treatment.

The child, who had been infected many months previously by sucking a strange woman, whose child was syphilitic, had large ulcers on the lips and in the angles of the mouth.

Two little boys, the one aged 4, the other 10 years, came in with primary indurated sores on the penis ; they did not belong to the same family. As their cases have been detailed in the present volume of the *Norsk Magazin*, pp. 87, *et seq.*, I shall merely refer to them.

Before passing over to the constitutional cases, I shall mention that in 18 experiments we succeeded six times in inoculating the indurated chancre on the individual, and that in one out of five we obtained a positive result from mucous tubercles.(b)

Of the 223 constitutional cases, 212 were so-called secondary and 11 tertiary ; of these 212, 188 were new cases—partly acquired and partly hereditary syphilis—and 24 relapses. The 188 may be divided into the following six classes :—

1.	Treated by derivation	53
2.	,, syphilisation	97
3.	,, one of these methods, but supplemented by the use of iodine .	11
4.	,, without any special treatment (expectant) . . .	7
5.	To the City Hospital (improving or uncured)	19
6.	To continue the syphilisation out of Hospital	1
		188

1. Derivative treatment is employed only in Dr. Hjort's clinique, and consists in the application to different parts of the body of stibiate plasters (c) of the size of a visiting card, followed, when good pustules are developed, by the use of poultices. We begin with the back (above between the scapulæ), then pass to the upper arms, and subsequently to the thighs, which occupies about a month or a little more in the first round. This differs somewhat in different persons ; but the longer we continue the method, the shorter is the round—in other words, the sooner does the plaster act. This is quite constant ; while the first plaster may require one or sometimes two weeks for the formation of pustules, the third may, for example, in the same place, or in its immediate neighbourhood, produce good pustules in from one to two days.(d)

But it is true that at the same time all cases of ulceration, as ulcers on the tonsils and in the cavity of the mouth, as well as mucous tubercles, etc., are treated locally with caustic and poultices.

The period of treatment for these fifty-three patients, taken together, was 5936 days ; consequently for each on an average the time amounted to 112 days with eleven drawing plasters (the longest time was 255 days with 15 plasters, the shortest was 38 days with three plasters).

This mode of treatment is by no means free from pain, and is used only for adults.

2. Syphilisation was on the whole employed in ninety-seven cases (thirty-four in Dr. Hjort's and sixty-three in Professor Boeck's clinique), with a total period of treatment of 14,898 days—that is, on an average, $153\frac{57}{97}$ days, the longest time being 283, and the shortest 74. The proper inoculation, which is always continued until immunity is obtained—that is to say, until the time when no kind of syphilitic matter any longer takes effect—occupied 13,798 days ; that is, $142\frac{24}{97}$ days for each ; but as all syphilitic symptoms had not invariably disappeared on the occurrence of this condition, several patients were obliged to remain in Hospital after the cessation of the inoculations, in order to have the remaining phenomena removed by caustic and baths. This occupied 1100 days, and as fifty-eight persons required this local after-treatment, it amounts to $18\frac{34}{58}$ days for each ; but divided among all the syphilised patients (ninety-seven), it gives $11\frac{33}{97}$ days over the average time of treatment stated in the above calculation.

As during derivation, so also during syphilisation, were caustic and astringent topical applications made to the syphilitic ulcerations and vegetations.

Syphilisation is more painful than derivation, and exhausts the patient's strength in a much greater degree, particularly during the first two months, while all these inoculation sores, some of them deep and wide, are most active. Then every movement of the body is extremely incommoded, sleep at night is disturbed, and the copious suppuration wastes the frame. But when the second or third month is well over, and the inoculations no longer produce so violent an effect, the suppuration being at the same time limited together with the artificial ulcerations, the organism often easily regains its lost tone and

(b) Much as the dualists may laugh at the favourite mixed chancre of Rollet, the auto-inoculability of the infecting chancre cannot be argued away. While this is being written, there lies in the Hospital a case particularly instructive in this respect. A man was admitted nearly three months ago with ulcers as large as a half-skilling piece on the outside of the penis (one towards the root of the penis, the other on the prepuce, both genuine *chancres parcheminés*) ; inoculation from them was attempted, but unsuccessfully. They were stimulated with savine : the inoculations continued without result. For a fortnight nothing was done with the sores ; fresh inoculations then yielded a positive result in the patient for many days, and from the pustules so produced both he and several other generally syphilitic individuals were inoculated with positive results through many links. This patient, shortly before admission, infected two girls, who are now labouring under secondary syphilis.

(c) The "emplastrum stibiatum" of the Norwegian Pharmacopœia is prepared by accurately mixing extemporaneously one part of powdered tartar emetic with three parts of adhesive plaster melted with a gentle heat.—*Translator.*

(d) In the face of this incontestable fact, which has now been observed in hundreds of cases in this Hospital, it is, in truth, surprising to find one after the other stating that the skin by frequent irritation loses its power of reaction—for example, after stibiate plasters—is always added. Dr. Joh. Björkén, in one of his "Letters on Syphilis" in the November number of the *Hygiea* for last year, calls this artificial condition "weariness of the organism."

fulness, and the patients towards the end of the treatment generally look very thriving and happy.

No particularly dangerous ulceration occurred as the result of syphilisation, and it would appear as if we have a certain limited power over such cases by beginning first on the chest and abdomen, then passing to the upper arms, and finally to the thighs. The ulcerations are never so great in this way as when we proceed in an inverted order. But wherever we begin, we must always remember to let the punctures be removed somewhat from one another (for example, an inch), particularly in the commencement, for the ulcerations are then largest; if the single inoculations are placed near together, the sores coalesce, and we then have rather deep and large ulcers. This has often been the case abroad, where syphilisation has been tried, and just for this reason forthwith given up. Such was the case, at all events, according to the testimony of an eye-witness, in Vienna with Professor Sigmund.

According to this method both adults and children were treated, and for the last without any difference, whether their syphilis was acquired or hereditary, except in a couple of cases among the latter, where the patients were evidently so weak, that it was not thought advisable to employ syphilisation with them.

In the children with inherited syphilis the symptoms disappeared under syphilisation in general tolerably readily, except in

A. L., aged 14 months, admitted into Hospital on October 9 in good condition, with a slight papulo-pustular exanthema on the trunk and thighs. The inoculation on the whole gave no particular result, which circumstance is generally observed in the papular and pustular syphilides.

December 23.—Two rather elastic swellings (gummata?) have been gradually developed on the glabella (space between the eyebrows) and somewhat farther up and to the left on the forehead.

31st.—A similar swelling on the back of the left hand, apparently proceeding from the middle metacarpal bone.

January 4, 1864.—A similar tumour appeared on the left zygomatic bone, and on the 5th another on the right.

7th.—The upper third of the right radius and the metacarpal bone of the first finger of the right hand were thickened.

March 19.—A number of small cutaneous abscesses have latterly successively formed on the nates and on the posterior surface of the lower extremities.

June 12.—A fresh eruption of papulo-pustular syphilides.

August 18.—A fresh tubercle on the right zygomatic bone externally and inferiorly.

October 23.—A swelling on the first metacarpal bone of the right hand.

December 1.—A similar protuberance superiorly on the right radius.

All these tumours extended widely, became fluctuating, were cut into, yielded pus copiously, suppurated long, presenting everywhere denuded necrosed bone, great destruction with contractions and ectropium (produced by sinking and perforation of the eyelids from the tumours on the forehead and zygomatic bones). The condition of the sufferer was miserable; there was tedious diarrhœa with excessive emaciation. There was no effect from syphilisation. And yet the little patient recovered.

In infants with hereditary syphilis the method of inoculation was employed in six cases, of which one ended fatally. As in such patients we often find this peculiarity, that we cannot propagate one and the same matter through long series of inoculations, just as in persons with the acquired form, we must frequently introduce fresh matter, which is then always taken from other individuals under similar treatment. In the following note upon these six cases will be found mentioned the age of the child upon admission, the duration of the treatment, and the number of times that inoculations with fresh matter were made:—

1. A. M. K., aged 7 weeks; 113 days; 38 fresh matters.
2. O. S., aged 2 months; 208 days; 111 matters. Admitted again on June 13 with a relapse; he remained 80 days, and was inoculated with 21 fresh matters.
3. A. O., aged 3 months; 107 days; 16 matters.
4. E. L. O., aged 3 months; 118 days; 36 matters.
5. M. E. P., aged 2½ months; died after 47 days' treatment with 12 matters.
6. P. P., aged 3 months; 97 days; 18 matters. (In the note-book it is, however, stated that the syphilitic symptoms had disappeared at the end of 40 days' stay in Hospital.)

(To be continued.)

ON THE EARLIEST PHYSICAL SIGNS OF PNEUMONIA.

By H. FEARNSIDE, M.B. Lond.,
Member of the Royal College of Physicians of London.

Attention has been lately drawn to the subject of the earliest physical indications of pneumonia by the paper of Dr. Waters, read before the Medical and Chirurgical Society of London on the 12th ult., and by the important discussion to which it gave rise.

It so rarely occurs that an opportunity is presented of witnessing the onset of an attack of pneumonia, and of testing the signs by which it is characterised, that I watched with great interest such an example, which fell under my notice a few weeks ago. An outline of the case, so far as it bears upon the points under consideration, may not be uninteresting to the readers of the *Medical Times and Gazette*.

In the early part of November I was requested to see a young woman who was suffering from acute renal congestion,—apparently the result of exposure to the influence of the poison of scarlatina. On my first visit she had no pulmonary symptoms, and I satisfied myself, by careful examination, that the lungs and heart were in a normal state. She was directed to remain in bed, and was (very unadvisedly) placed in a cold room. In the course of a few hours she was seized with rigors, followed by a sharp pain in the lower part of the left side of her chest. She began to cough, and her breathing became embarrassed. The dyspnœa gradually increased until it amounted to orthopnœa, and the cough became incessant, but was not at first accompanied by any expectoration. I saw her on the following morning, and found her respiring 60 times to the minute, and with a small pulse of 120. On examining the condition of the lungs, it was seen that the movements of the left side of the chest were less free than those of the right side, and the stroke sound over its upper part seemed slightly impaired. On auscultation over the upper lobe of the left lung, the respiratory sounds were found exceedingly feeble,—almost annihilated, in fact; over the lower lobe they were harsh; on the right side the respiration was universally loud and puerile.

Feeling both interested and anxious respecting my patient, I visited her again in four hours, and then found that over the whole of the upper lobe of the left lung there was audible a fine, dry, crepitant râle, of the most perfect type.

The dyspnœa continued, but she had begun to expectorate a fluid largely mingled with blood.

It is needless to record the subsequent progress of the case beyond stating that the evidence of condensation of the affected lung speedily became more marked, and that, under a supporting regimen, the patient made a good, but slow recovery.

Preston.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

GUY'S HOSPITAL.

CASES OF CONTRACTED MITRAL, IN WHICH THERE WERE PRÆ-SYSTOLIC OR AURICULAR-SYSTOLIC MURMURS OVER THE LEFT SIDE OF THE HEART.

For many years it has been a question as to how far we are able, with any degree of certainty, to say that the mitral orifice is contracted or dilated. Dr. Stokes (in his standard work, page 144) says—when it is asked, can we say whether the disease of the mitral valve is a narrowing or a dilatation—"we must answer in the negative."

Dr. Walshe observes:—"We learn that a contracted mitral may be diagnosed by means of a diastolic murmur, of maximum force, heard immediately above and about the left apex, and conducted in the same direction, though less extensively, as the systolic murmur of the same seat." (See Walshe on "Diseases of the Heart," p. 104.) Moreover, it is stated that a diastolic murmur at the left apex may be produced either by the mitral valve being roughened on its auricular surface, and the orifice not at all affected, or be produced by the contraction of the left auricular ventricular orifice, with or without

roughening of the surface of the mitral valves. Skoda states that when the orifice is contracted, the second sound of the heart, heard over the left base—that is, over the pulmonary artery—will be greatly intensified, whereas, when the mitral valve is simply roughened, no sueh intensification of the second sound will be produced.

Dr. Walshe further remarks (p. 104):—"This murmur is generally spoken of as diastolie in rhythm, but, in point of fact, it is rather post-diastolie or præ-systolie than preeisely coincident with the diastole.

Dr. Gairdner, in his admirable elinieal leetures, has called attention to some cases of contracted mitral, in which there was, or had been, a præ-systolic murmur over the left apex. Dr. Gairdner appears to consider that when sueh a murmur is present, it is by no means difficult to recognise it. The evidenee below, as will be seen, confirms Dr. Gairdner's experience; and from what we ourselves have heard, we cannot but admit that we do not consider it by any means difficult to reeognise such a bruit; on the contrary, onee heard, it is easy again to distinguish it.

In a previous number of the *Medical Times and Gazette* we brought forward some interesting remarks on this disease by Dr. Wilks.

A CASE OF CONTRACTED MITRAL ORIFICE, IN WHICH THERE WAS A LEFT AURICULAR SYSTOLIC BRUIT.

(Under the care of Dr. G. O. REES.)

For the following particulars we are indebted to the able report of Dr. G. Mickley:—

William C., aged 49, admitted in Guy's Hospital December 13, 1865, a pale, sallow-looking man, who states he has never been very strong; always liable to repeated colds. He says that about fifteen years ago he awoke one morning with a peeuliar indescribable sensation, and found that he was incapable of moving his left arm, and that he soon lost the use of the leg on the same side. His faee also was paralysed. He soon, however, recovered the use of his limbs, and now there is no remaining evidence of paralysis. He has suffered with shortness of breath for the last six or seven years, but more so the last twelve months. The last month he has had pain over the heart, and not been able to walk more than a few yards at a time without resting. He has a troublesome cough, and has spat blood the last four days. Has never had rheumatie fever.

On admission.—He is suffering with great dyspnœa, so mueh so that it is only with great care that he ean be moved in bed. On examining his chest in front, the inspiration is puerile, and the expiration markedly prolonged; also sibilus and rhonchus all over the chest. Posteriorly, dulness on pereussion over both bases; also crepitation, rhonchus, and sibilus over the upper part of the chest. The heart: The area of cardiac dulness is bounded above by the lower margin of the third rib; below, by the upper margin of the sixth rib; to the right, by the mid-sternal region; and to the left, by a vertical line half an inch to the left of the left nipple. The rhythm of the heart is very irregular, and there is heard a prolonged, running-up-to sound between the second and first sound of the heart. It is a feeble, although a harsh sound. It is more distinctly heard about two inches below and a little to the left of the nipple. It is exceedingly faintly, if at all audible in the left axilla. The first sound over the base of the heart is exceedingly feeble. No visible impulse. The liver is enlarged. No ascites or œdema of the arm or legs. Very slight œdema of the walls of the chest. Slight puffiness of the lower extremities. Urine scanty, high coloured, loaded with lithates, sp. gr. 1025, a doubtful trace of albumen. The expectoration is tenacious, sprinkled with bright red blood, also a few minute pellets of blood. It is suffieient for our purpose to state that his breathing gradually got more laboured, and he died rather suddenly December 20, 1865.

The post-mortem examination, conducted by Dr. Moxon, showed the pleuræ free from adhesions, and a quantity of fluid in the cavity of the right pleura. The lungs were very much engorged; and in both lungs there were several patches of apoplexy. The pericardium contained three and a-half ounces of yellow fluid. The left ventricle appeared normal, but the left auricle was seen to be very much dilated; its museular walls hypertrophied, and the lining membrane of the left auricle was thickened, white, and opaque. The auricular appendages were enlarged and open. The right ventricle also much dilated. The right auricle also was considerably dilated. The mitral orifice was very mueh contracted—so mueh so, that the end of one finger could with diffieulty be introdueed. The great diminution of the orifice was seen to be due to the extensive thickening and induration of the fibrous tissue of the mitral orifice and at the roots of the mitral valves. On the auricular surface of the valves were some minute vegetations, whieh could be readily removed. The chordæ tendinæ were thiekened, and the capsule of the liver was thiekened. On seetion the liver showed the ordinary nutmeg appearance; intestines healthy; spleen very firm. Kidneys weighed 11 ozs.; the right showed on its posterior surfaee a transverse depression, which was seen to be due to an irregular band of fibroid tissue. The kidneys were slightly granular on their surfaces.

Dr. Rees remarked, when speaking of this ease:—The eonclusion I arrived at on first examining the patient was that he was suffering from a contraction of the mitral orifice. I was led to express this opinion, for it was elear to me that the second sound over the left base was greatly intensified, which led us to eonclude that the pulmonary valves were unduly stretehed by the increased pressure of the blood on the pulmonary artery. In fact, that there was some impediment to the flow of the blood through the lungs. Now, although the lungs were believed to be in an emphysematous condition, yet they did not appear to be so highly so as to account for this great obstruetion. Further, on listening two inches below and a little to the left of the left nipple, a murmur was heard—faintly, it is true, still it eould be heard with very little care. It was a rough, prolonged sound. The first sound of the heart was so exceedingly feeble that it was very difficult to say in what relation this murmur stood to the first sound of the heart. The loudly marked seeond sound, however, was readily heard, and immediately afterwards this rough prolonged sound. Yet this murmur was not continuous with the second sound. It appeared to occupy almost the entire ordinary period of silenee, and also where the first sound ought to have been heard. It was, however, more the quality of the murmur (just such as I have heard in other eases of eontraeted mitral) that led me at onee to express the opinion that it was an auricular systolic murmur produeed by the blood passing through the narrowed aurieular ventrieular orifice. Nevertheless, I could not but notiee that the murmur was heard in a very unusual situation; for the experience in this Hospital, at all events of late, has agreed with what is generally taught—that the situation in which such a murmur is usually heard is, in eases of contracted mitral, immediately above or immediately around the nipple. I was therefore led to ask whether the murmur might not be exocardial, and not endoeardial. Our diffieulty was inereased owing to the fact that there was no visible impulse of the heart, nor eould apex beat be felt. The sounds of the heart, also, were so extremely feeble that it was impossible to define the exact situation of the apex of the heart. Nor was percussion of much assistance; for although we were led by the site of the dulness to think the apex was carried to the left of the left nipple, and in the fifth and sixth interspaee, yet the dulness was not so well marked that we could say how far the emphysematous condition of the lung interfered with the precordial dulness. Again, it is usual to hear this auricular systolie murmur immediately adjoining the nipple, because the apex of the heart is usually raised in cases of contracted mitral. Owing to the impediment in the mitral orifice, the quantity of blood entering the left ventricle is diminished, and in eonsequence the ventriele wastes and diminishes in size. In this case, however, if our diagnosis of the position of the apex was eorrect, the ventricle had not diminished in size, but rather inereased. There was, however, no discoverable aortie valve disease, and no positive evidenee of kidney disease, to aecount for the size of the ventricle; and to explain why, if this was a ease of long-standing contraction of the mitral orifiee, the ventricle had not diminished in size, as it usually does in such cases. I was, therefore, led to state that this murmur might prove to be of exocardial, not of endocardial, origin, and the left side of the heart be in a state of dilatation, with its walls attenuated and no valvular disease at all be present. This was rendered still further probable when we remembered the age of the patient, the presence of the emphysema, the history given of what appeared to have been an apoplectie attack, the absenee of any history of rheumatic fever, the inereased area of dulness, the great irregularity of the heart's beat, and the extreme feebleness of the first sound of the heart; all of which eonditions are found in the eases of dilatation with attenuation of the left ventricle. The autopsy, however, made it all clear, and showed that our first opinion was eorreet. The apex of

the heart was carried to the left, owing to the greatly dilated right side of the heart. The left ventricle, although not larger than a ventricle in a normal condition, yet it was not diminished in size, and in consequence ought to be considered as equivalent to being hypertrophied and dilated, and this due to the granular condition of the kidneys.

This case has appeared to me well worthy of attention, and has taught me in future to rely on the rhythm of the murmur alone, and it clearly shows that the position of the apex will determine the exact spot over which the murmur will be heard. Therefore, if there is a murmur pre-systolic in rhythm, the mere fact of its being heard in an unusual position should have no weight in determining that it is not due to contraction of the mitral orifice, unless the position of the apex can be clearly defined.

A CASE OF CONTRACTED MITRAL ORIFICE IN WHICH THERE WAS AN AURICULAR SYSTOLIC AND A TRICUSPID MURMUR.

(Under the care of Dr. GULL.)

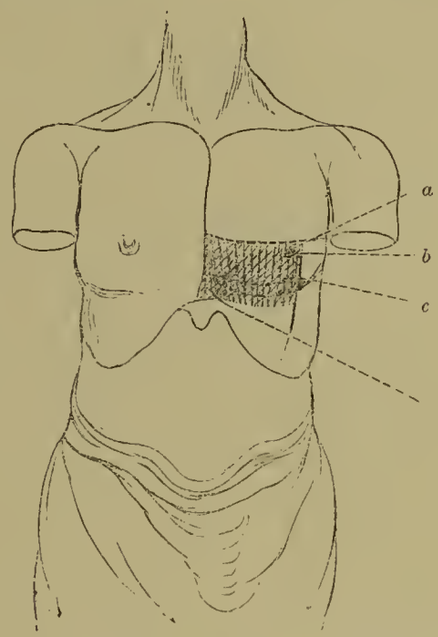
Sarah C., aged 32, married. States that she had always enjoyed very good health and considered herself strong until she was married. Her health first began to fail her during her first pregnancy. She has had six children born alive and one miscarriage. She felt weak while pregnant, but had at that time no particular illness. Five months ago, while pregnant, she noticed her feet and legs began to swell. Three months ago she was confined, and has never recovered since. She noticed that her abdomen did not diminish in size, and ever since it has gradually got larger. Her breath has been very short in exertion for some months past, but she cannot say definitely how long. She has never had rheumatic nor scarlet fever to her knowledge, and there is no reason to think she has had syphilis.

Her abdomen is very much distended with fluid; her legs and feet are not swollen. The liver can be very distinctly felt below the ribs. Her breathing is quick, and she states it has been much worse than it is now. Her face is distressed looking. No lividity, but an anxious look. Her pulse is slow, irregular, at other times regular, feeble, very compressible, but not the small pulse usually felt in mitral obstruction. The area of cardiac dulness extended from the fourth rib above, bounded on the right by the mid-sternal line, and on the left a vertical line drawn one inch outside the left nipple. Over this space there was marked dulness. The apex beat was felt half-an-inch below and one inch to the left of the nipple. The impulse was sharp and sudden, not heaving. Directly under the nipple a somewhat harsh sound was heard, between the second and first sound of the heart. The heart's action being slow it was very readily made out. The click of the second sound was heard, although feebly and immediately afterwards the rough, slow murmur continued until it reached the first sound. The murmur gave the impression as if the apex of the heart was labouring to get over a roughened spot on the pericardium. Although the murmur came immediately after the second sound, and almost filled up the entire ordinary period of silence, yet it did not occupy the entire period. On careful listening the sound was heard, then an appreciable period of silence, and thirdly the murmur. The area over which the murmur was heard was very limited. No murmur was heard in the middle of the axilla nor at the angle of the left scapula. On carrying the stethoscope from the left nipple towards the sternum, when about midway, a soft systolic bruit was heard. On tracing it still nearer to the sternum it was heard more distinctly, and the point of greatest intensity was a little to the left of the left margin of the sternum. The latter bruit was not conducted up the sternum. No murmur was heard over the base of the heart during the first two weeks of her residence in the Hospital, but the week before she died a murmur was heard over the base. The second sound over the left base was markedly intensified. The rhythm of the murmur just over the apex beat led Dr. Gull to decide that it was auricular systolic, and that taken with the much intensified second sound over the pulmonary artery showed there was contraction of the mitral orifice. The murmur over and near the sternum Dr. Gull considered to be due to tricuspid regurgitation. Although the apex was carried to the left by the distended right side, yet the apex of the heart was to some degree displaced, also by the large quantity of fluid in the abdomen.

While in the Hospital this patient became insane, and unfortunately committed suicide.

In order not to make this communication too long, it will be probably sufficient to say that the autopsy, conducted by Dr. Moxon, showed the mitral orifice very much contracted, and a good example of a so-called "button-hole" mitral; that the left auricle was greatly dilated, the right ventricle dilated also, but its walls markedly hypertrophied, the right auricle also dilated; the aortic valves showed signs of recent endocarditis.

The adjoining diagram will render the position of the murmurs still more clear.



a. The fourth rib. The dark, shaded portion shows the position o t dulness.

b. The left nipple.

c. Apex beat, between the fourth and fifth ribs; and here a pre-systolic murmur was heard.

d. Here a soft systolic bruit was heard.

Dr. Gull observed: If a murmur similar to this one be heard about the left apex, and if the second sound over the pulmonary valves be intensified, there can be no doubt that the mitral orifice is contracted; but it happens now and then that no such murmur is present. Then the diagnosis is difficult. I remember a case in this Hospital in which such a murmur was present. The case was well watched, and the bruit was noticed to grow less and less distinct, until it became quite inaudible, and the most careful examination failed to discover any. The patient died, and the post-mortem examination showed the left auricle immensely dilated and also hypertrophied, and the left auricular-ventricular orifice to be a mere slit-like opening. It was contracted to an extreme degree.

A few weeks ago there was under Dr. Gull's care in the same ward a girl with imperfect mitral. The question was raised as to whether the orifice was dilated or contracted. It was certain there was no auricular-systolic or pre-systolic bruit. A systolic murmur was heard over the left apex; it was also heard in the axilla, and over the angle of the left scapula. The murmur was prolonged, and seemed to occupy the entire period of the first sound. But the period of silence was distinctly marked. It appeared to be a case of imperfect closure of the mitral orifice and regurgitation through it.

The autopsy showed that the mitral orifice was contracted, but not to an extensive degree. It allowed of the admission of the two first fingers up to the first joint, but with difficulty. The curtains of the mitral valves were much thickened and rigid, also the chordæ tendineæ thickened and apparently shortened. It was thus clear that there were all the conditions favourable for regurgitation, while the orifice appeared not sufficiently contracted to produce a direct murmur.

On referring to Hope "On Disease of the Heart," p. 388, it will be seen that he alludes to such cases. Speaking of the diastolic mitral murmur, he says—"I have found this murmur absent unless the contraction of the valve was considerable; for the blood had still sufficient room to pass with tranquillity; and I have also found it absent when the contraction was great—when, for instance, the aperture admitted one finger only, or merely a quill, provided that the canal was preternaturally weakened by softening, by extreme dilatation of the heart, or by both."

ST. BARTHOLOMEW'S HOSPITAL.

SUBCUTANEOUS ULCERATION.

EXTRACT FROM A CLINICAL LECTURE BY MR. PAGET.

Among the frequent effects of inflammation are, the separations of adjacent layers of different tissues. Some of these deserve special notice for their practical importance. The simplest examples of this dissevering process are those in which one finds the capsule of the kidney more than usually separable, or the periosteum too easily stripping from the bone. In these cases there may be no more morbid change than that of softening of the walls of vessels, and the small quantity of connective tissue, which naturally hold together the two parts. A greater change is effected when articular cartilage can be stripped from bone; for here the separation is not possible till after the ulceration or extreme softening of one or both of the adjacent layers. In some of these cases it is observable that the disseverance of the bone and cartilage is without apparent formation of pus, or other morbid fluid. The cartilage, usually ulcerated on its under surface, can be raised from contact with the ulcerated bone, or the thin layer of granulations covering the bone, and no pus visible to the naked eye lies between them. This manner of disseverance by ulceration of bone and cartilage is generally known; it is a common result of acute inflammation of the joints. A similar process sometimes separates the subcutaneous fat from the subjacent fascia. It may fairly be called subcutaneous ulceration, to distinguish it from that with which it is mostly confounded—namely, the diffuse suppuration of the subcutaneous fat. There are truly several points of resemblance between the two processes, as there are between all instances of suppuration and ulceration; but a manifest difference is in this—that in the one the suppurative, in the other the ulcerative, process is greatly preponderant. In the diffuse suppuration, the pus forms an evident collection of fluid more or less widely separating the layers and upraising the skin; but in the ulceration, the separated layers remain in contact, or with only a little fluid between them. With these differences, others equally marked coincide in the general condition of the patients, and in the course and necessary treatment of the local disease. In the girl now under treatment, the disease appeared, when she was admitted into the Hospital on August 15 of last year, as an ill-defined patch of mottled, dusky redness, larger than one's hand, across the front of the lower part of the thigh. This patch of diseased integument was scarcely raised above the surrounding level. To the touch, it felt firm and brawny, but unequally so in different parts. It was hot, but not very painful, and at only one or two points tender upon pressure. Higher up in the outer part of the thigh were two scars, said to have been formed after similar disease there. The patient's general condition was that of mere debility, and that not extreme. She had no fever, no hectic, no rigors, and, except after a slight attack of pneumonia, she scarcely lost weight or strength. A variety of different modes of treatment were all equally useless for the remedy of this state. Complete rest, blisters, ointment of iodide of mercury, and the internal use of iron, iodide of potassium, cod-liver oil, had no sensible effect. At length, one of the places at which tenderness had been long observed was found soft as if with pus. This was opened, and in a few days later the opening was found to lead to a large space, in which the subcutaneous fat was completely separated from the fascia. The skin over this space was not upraised by any collection of fluid, and when the space was freely laid open by incision scarcely any pus flowed from it.

Within the last two years you have had opportunities of seeing three other cases of this kind under my care, and from them you may have been able to gather a general description of this disease. All the cases, you may have observed, have been in young persons of pallid complexion, with very feeble health; thin, and with very little muscular power. They might be called strumous, although they have not all the distinctive features of struma. In all of them the disease has been near the knee, where it is certainly most frequently seated, and in all the subcutaneous tissue, after feeling for a time firm and brawny, as if with inflammatory infiltration, has softened in one or more parts, and then has been widely undermined by slowly extending ulceration, with very little formation of pus. In the patient now in the Hospital the skin is much more evidently and widely diseased than in the others; in them much of it, even when undermined, has appeared nearly healthy, neither elevated, nor tense, nor reddened; but some part of it, after slowly softening and then ulcerating, or being punctured, has let way into the ulcerated subcutaneous space. In all, this space at the first laying open has yielded very little pus; in none has any slough or tuberculous matter appeared; but all the surfaces after exposure have suppurated freely, though thinly, till near their healing. In no instance has the skin itself ulcerated widely, however far the subcutaneous ulceration might extend. In all alike the only effective treatment has been such a thorough laying open of the ulcerated spaces, and of all bays and channels leading from them, as has completely exposed their surfaces, and permitted them to be dressed by packing. By this alone has the ulceration been either stayed or healed. Till this has been done the ulceration has always gone on extending subcutaneously, and its exposed surfaces have shown no signs of healing. Drainage tubes, setons, injections, compressions, and many other means have alike failed. In all the cases the ulcerated surfaces thus exposed have healed slowly, forming large thin tender scars, easily breaking down or ulcerating; but finally all have recovered. Moreover, none of these patients has had any acute constitutional disturbance, and none of the medicines given them—tonics, iodides of potassium or iron, cod-liver oil, or others of the same classes—has appeared to have any really or directly remedial influence. To those who were before in poverty the Hospital diet has seemed to do little good till the local disease has been brought towards recovery by the incisions; and after nearly complete healing the complete and firm scarring has been delayed till change of air has given renovated health.

KING'S COLLEGE HOSPITAL.

TRAUMATIC ANEURISM, RESULTING FROM PERFORATION OF THE INNOMINATA ARTERY—DEATH—AUTOPSY.

(Under the care of Sir WILLIAM FERGUSSON, Bart.)

Remarks.—The following case is one of great interest, from the great difficulty experienced in accurately diagnosing, in the first place, what vessel was the seat of aneurism originally, and, consequently, which had given way, thereby causing the effusion of blood into the surrounding parts, and secondly, of accounting satisfactorily for the aperture in the innominata artery, as seen on post-mortem examination. Spontaneous rupture of the arch at the commencement of the innominata is very improbable, and the existence of aneurism of this vessel would have been detected long before the fracture of the collar bone took place. In all probability, however, the arch was slightly dilated at the time of the accident, and the sharp inner extremity of the broken clavicle gradually made its way through its coats, which would otherwise have escaped injury had it been normal in size. The absence of the usual physical signs of aneurism of the innominata or subclavian were further confirmed by the application of the "sphygmograph," and the result of the observations made with this instrument seemed to point to the aorta as the seat of disease. Sir William Fergusson did not consider the case one for any operative measures, owing chiefly to the doubtful position of the aneurism.

Michael W., aged 43, an English sailor, fell overboard, October 1, 1864, while in a voyage to India, striking against the ship's bowsprit in his fall, and so injuring his right arm as to be unable to use it. Nothing was done to the injured limb at the time, except that the whole of the shoulder and the portion of chest adjoining it were closely enveloped in a pitch plaister, on the removal of which, by a Surgeon at Aden, about six weeks after the accident, the right collar bone was found to be fractured about two inches from the sternum. The fracture had not united; but a small pulsating tumour was now discovered to exist near the sternal end of the clavicle, about two inches above that bone. The tumour was at this time painted with iodine. On the ship's arrival at Bombay the patient was admitted into the Hospital, and he states that he heard the Surgeon there say that the tumour was an aneurism of the innominata. The tumour steadily increased in size, and on his return to England he was admitted into King's College Hospital, about twelve months after the accident.

On admission (October, 1865), a large pulsating tumour was seen to bulge forth from the upper part of the chest, in front, on the right side, the bony structures in the position of the right sterno-clavicular articulation having apparently disap-

peared. In the upward direction the pulsation extended to the parotid region; downwards it reached to the level of the third rib; internally it extended to the sterno-clavicular joint of the opposite side, and externally it seemed close upon the acromion process. Over the tumour generally the skin was of a light red tint, except at the spot (on the clavicle, and about two inches to the right of the sternum), where it was of a dark purplish colour; and at this point the wall of the tumour felt decidedly thinner than at any other part. There was no œdema of the neck and face, no hoarseness or other alteration of voice, no difficulty of swallowing, and but little affection of the breathing. Vision unimpaired in both eyes, the pupils were equal, there was no arcus senilis, no giddiness, noises in the ear, or, indeed, any affection of hearing. No bruit was audible over the cardiac region, and the heart sounds normal both at apex and base, but they could be distinctly heard over the tumour in the situation of the right sterno-clavicular joint, though somewhat later, as it were, than over the heart itself. The right forearm was a little œdematous, and the right pulse at the wrist slightly smaller than at the left. With regard to the state of the pulse, it ought to be mentioned that it was carefully examined by the "sphygmograph" by Dr. F. E. Anstie, who found so little difference between the pulse wave at each wrist as to lead to the inference that the subclavian artery could not be the seat of the aneurism.

After admission the tumour gradually increased in size, and showed a disposition to spread outwards and backwards towards the shoulder.

On November 17 the skin over the spot previously alluded to had a tendency to ulcerate, and about six weeks later (January 2) the tumour burst at this point, but the resulting hæmorrhage was promptly stopped by the nurse placing her finger upon the opening until the arrival of the House-Surgeon (Mr. Howells) who completed its arrest by the application of a graduated compress soaked in solution of perchloride of iron, without any marked aggravation of symptoms. The patient lived for three days longer, when a further hæmorrhage occurred from beneath the compress, and although the House-Surgeon again succeeded in preventing any great loss of blood, death took place about twenty minutes subsequently, the tumour appearing to subside under the pressure applied, and leading to the inference on the part of those around the bed that its contents had found their way into the pleural cavity. It should be stated that subsequently to the rupture of the tumour a patch of discolouration made its appearance on the point of the right shoulder (about the outer angle of the supra-spinal fossa), which induced fears lest a second opening should occur in the situation.

Post-mortem Examination Sixty-six Hours after Death by Dr. Conway Evans.—On examining the body after death, all appearance of swelling in the upper part of the right side of the chest had disappeared—the hollow, indeed, above the collar bone being deeper than usual. About two inches to the right of the top of the sternum was an aperture in the skin about the size of a sixpence (from which the blood had escaped during life), and through this opening could be seen the inner end of the fractured clavicle lying immediately behind and in contact with it. On laying open the aneurismal sac (after the removal of the platysma, sterno-mastoid, and other structures above the clavicle), though in great measure empty, it was found to be of considerable size, and capable of holding, when full, about two or three pints of blood. Forming a portion of the anterior wall of the sac towards its lower part was the right collar-bone (the fracture being situated about five inches from its outer walls), the fractured surface projecting somewhat on its posterior aspect into the aneurism so as to be bathed in the blood current passing over it. The right sterno-clavicular joint had entirely disappeared, and with it the inner portion of the broken collar-bone. One or two spiculæ of bone, adherent to, and embedded in, the inner surface of the sac immediately over the situation, were the only remaining vestiges of these structures. The posterior surface of the upper end of the sternum was likewise much eroded, and formed a part of the anterior wall of the aneurism, being also freely washed by the blood current. The sac itself appeared to be in great part formed by a condensation of the surrounding structures (muscle, fascia, and areolar tissue); but, in fact, also consisted of layers of fibrinous material (more or less decolourised), evidently deposited from the blood which had passed through it. Outwards and posteriorly the condensation of surrounding tissues became less and less marked, in such a manner that the sac walls became gradually lost in the neighbouring muscular structures (chiefly deltoid and trapezius) so as to lead to the inference that latterly, at all events, no distinct aneurismal sac had existed in this direction, considerable coagula of pretty recent formation having forced their way among and between the muscular structures of these parts. The outer end of the clavicle, indeed, seemed almost surrounded by these coagula, and in great measure, if not entirely, separated from the acromion process of the scapula. In its inner extremity and lower side, nearly opposite the eroded posterior surface of the upper end of the sternum, the aneurismal sac communicated with the aorta, through an opening of about the size of a sixpence (but more triangular in form) which was situate in the anterior wall of the innominata somewhat above the point at which this vessel springs from the aortic arch, the upper margin of the aperture being about seven eighths of an inch below the angle formed by the division of the innominata into subclavian and common carotid; a little below this opening the anterior wall of the aorta was firmly adherent to the posterior surface of the sternum. The right common carotid lay behind the aneurism and to its left side, the subclavian artery was situate behind and beneath it, the pneumogastric nerve also passed down behind it, but its recurrent branch wound backwards beneath the subclavian, and appeared to have escaped material compression. The left brachio-cephalic vein crossed the aortic arch in front, and must probably have been considerably pressed upon; both the superior cava and right phenic nerve, descending along its right side, did not seem to be much compressed. The right and left chambers of the heart, and also the aorta, were quite empty. The heart itself was normal in size, but the aortic arch was enormously dilated—to such an extent, indeed, that a line drawn along the base of the heart and the upper part of the arch measured upwards of $1\frac{1}{2}$ in., while the transverse measurement of the aorta in front exceeded $3\frac{1}{2}$ in. On the extreme left, in front, the aorta was dilated into an aneurismal pouch capable of containing a small walnut, and the walls of the artery were unusually thin in this situation; on the right side, on the contrary, the dilatation of the aorta was general; internally the aorta was somewhat puckered, and its surface was studded with numerous patches (greater or less in size) of atheromatous deposit. The cardiac valves on both sides were sound, except that those of the aorta, and also the mitral, were more opaque than natural and slightly thickened. The thoracic aorta, and indeed the common carotid and the subclavian arteries were unusually large, and this was particularly the case in respect of the last-named vessels on the right side. The lungs were pale, containing very little blood, but not collapsed, and the upper lobe of the right lung, at its highest point, was adherent at the spot which corresponded to the under surface of the aneurismal sac for a space about the size of a crown-piece. These adhesions were of recent formation, and readily broken down. The liver, spleen, and other abdominal viscera were congested, but in other respects apparently healthy.

These notes were afforded us by Dr. Conway Evans, who kindly placed them at our disposal.

DR. CORRIGAN'S BARONETCY.—Dr. Corrigan, formerly President of the Royal College of Physicians, to which office he was repeatedly elected by his brethren, has received from Her Majesty the dignity of baronetcy. Sir Dominick Corrigan is Physician in Ordinary to the Queen in Ireland. He is the author of the pamphlet on education to which I referred in a letter a short time ago, and in which he, as a Roman Catholic, deprecated the establishment of denominational colleges and a chartered Catholic University. For the last six years the Medical Profession in this country has not been honoured by a dignity of this kind. Sir Henry Marsh, Physician in Ordinary to the Queen, died in 1860, and Sir Philip Crampton, Surgeon in Ordinary to Her Majesty, died in 1858. That branch of the Profession will no doubt expect a similar distinction, but there may be more difficulty in selecting the most worthy man to receive it among the Surgeons than among the Physicians. A morning journal remarks that "the honour thus graciously conferred on our distinguished fellow-citizen by the Queen will, we are certain, be acceptable to the country generally, not only as an acknowledgment of the eminence he has won in his Profession, but as a dignity bestowed on an Irishman who has been ever identified with the people and the advancement of their interests."—*Times' Dublin Correspondent.*

Post-office Orders and Drafts on Army or Navy Agents, should be made in favour of Mr. James Lucas, 11, *New Burlington-street, W.*

Medical Times and Gazette.

SATURDAY, JANUARY 27.

THE NATURE OF THE RINDERPEST.

Vaccination of cattle is being extensively carried out, and its protective powers against Rinderpest put to the proof. Several cases have been made known, principally through Dr. Murchison, who so energetically advocates the small-pox hypothesis of cattle plague, and who loses no time in publishing accounts as they are sent in to him. Results, however, to be satisfactory need more time for their acquirement than has yet been allowed. Vaccination has already firm believers in its efficacy, but so have many other modes of treatment had which have since been proved to be of no value.

The case reported by our correspondent, Mr. Fairmann, is of the greatest interest, leading, as it does, to the conclusion that cows can take Rinderpest in all its severity a few months after suffering from cow-pox. One case of this kind tells with more weight in deciding the effects of cow-pox upon cattle plague than very many others in which animals having suffered from cow-pox escape from cattle plague. For in the former case there is direct proof that vaccination failed to protect against Rinderpest; while in the latter cases, until they become very numerous, we may fairly entertain doubts as to whether the facts that cows having had cow-pox have not taken Rinderpest are not merely coincidences, since many cattle which have not had cow-pox have also not taken cattle plague.

Nevertheless, the facts published by the High Sheriff of Cheshire in the *Times*, and others communicated by several gentlemen to Dr. Murchison, are such as to inspire us with the hope that in vaccination we may find the means, if not of preventing the spread of this distemper, at least of disarming it of its virulence.

Should it be established that previous vaccination really influences the action of the *materies morbi* of Rinderpest upon cattle, even to a prevention of the disease, an important advance will have been made in our knowledge of pathology, for we shall then have proof of how closely allied as to causes are the manifestations of different diseases. But it may be disputed whether such a relation of the two diseases will by itself justify us in regarding the two as modifications only of one disease. We feel that we ought to have proof of the kind which Mr. Hancock's case is believed to furnish—that is, of the production of the genuine cow-pox or of small-pox in other animals; otherwise, we can only assert that the one disease has had such an influence on the organism as to have altered its behaviour when exposed to the exciting causes of other diseases.

But Mr. Hancock's case is not only unsupported by any other case, but cases which militate against the belief that cattle plague virus can produce cow-pox or small-pox in man or sheep may be said to be numerous. Repeatedly have persons been inoculated with this virus, either by accident or design, but in no case have specific spmptoms followed. And more than this, one gentleman, well known for his investigations of Rinderpest, has, after having again and again purposely inoculated himself with the matter of the disease without result, had himself vaccinated with full success; thus showing the fitness of his system to take on the vaccine disease, and the incapability of the virus of cattle plague to produce it. And, again, as regards sheep, these animals take Rinderpest from cattle, but do not modify it so as to exhibit the symptoms of ovine small-pox, but return the disease to other oxen unchanged in form or virulence.

Further, concerning Mr. Hancock's case, we have to contemplate a startling, though not impossible conclusion, if the system of this gentleman has really manifested cow-pox in consequence of inoculation with Rinderpest matter. This conclusion is *that the small-pox (Rinderpest) virus of the bovine species acts upon the system of man just as the small-pox virus of the human species acts upon the system of the ox.* For if we inoculate a cow with the human small-pox matter she has cow-pox, and gives, in return, cow-pox, and not human small-pox, to a human being inoculated with the lymph of her disease. And, on the other hand, if we inoculate a man with bovine small-pox (Rinderpest) matter, he has also "cow-pox," and gives cow-pox to cattle in return if they are inoculated with the lymph of his disease; so that the vaccine disease is producible in two ways—namely, in the cow by inoculation with the virus of human small-pox, and in man by inoculation with the virus of bovine small-pox (cattle plague). In the latter case, cow-pox deserves to be called by a name indicating that it is the human modification of cattle plague. Such a conclusion is far too remarkable to be accepted without much further evidence. Yet when we have refused to believe that the Rinderpest matter produced cow-pox in Mr. Hancock, we are almost obliged to admit that the cow he was inoculated from had cow-pox and cattle plague simultaneously, and so far, therefore, the non-protective power of the former against the latter disease. Bearing on this point is the case reported by Dr. Vaughan, of Crewe. On the third day after being vaccinated by him a cow took Rinderpest, and yet the cow-pox ran its course, only that its progress was retarded.

One argument against the probability of cattle plague producing in man the disease which human small-pox produces in oxen is furnished by the behaviour of the sheep to the ox in respect to cattle plague and small-pox. The sheep has small-pox disease, yet cannot communicate it to the ox, but only to its own species. On the other hand, the ox communicates its supposed small-pox (Rinderpest) to the sheep, and takes it again from the sheep unchanged in nature; so that between these animals there is no common expression by symptoms of the reputed small-pox of the one when transmitted to the other such as there must be in cow-pox between man and the cow, if cattle plague caused cow-pox in Mr. Hancock. The ox will not take ovine small-pox, and the sheep, though it takes bovine small-pox (Rinderpest), does not modify the character of the disease.

Concerning the character of the affection of the skin, we believe that the assertion that it is identical with that of small-pox is almost given up. Even Dr. Murchison himself has admitted that there is "an absence of well-developed pus corpuscles," and an absence "in most cases of a distinct vesicle preceding the pustular stage." These assertions have greater import when we find Dr. Sanderson still persisting most firmly in his denial of the existence, so far as he can discover, of "patches of roseola, pustules, or petechiæ." He states that the crusts, which are by far the most common appearances presented, appear at an early period, and are only formed of sebaceous secretion; that hyperæmia, which communicates a red colour to the skin when it is thin and transparent, forms the so-called roseola; and that the

papules never yield any liquid juice or serum, are never surrounded by an areola, never assume a vesicular form, and have not the most distant resemblance to the papules of small-pox.

We see, also, that Dr. Bristowe states that he has no hesitation in asserting that the eruption, though resembling superficially that of small-pox, is essentially different from the eruption of small-pox, as that eruption has hitherto been known to him by observation and by reading, and is essentially different, too, from the eruption of vaccinia. He agrees generally with the description of it which Dr. Sanderson has given. He has never yet seen a vesicle; he has never yet seen a pustule; he has never yet seen that destruction of the surface of the skin which in small-pox leads to pitting. He inclines decidedly to the belief that cattle plague is distinct from small-pox, though he is "very far indeed" from asserting that it is so.

We are disposed to think, therefore, that should cattle plague be proved eventually to be a form of small-pox, it will not be correct to say that its anatomical characters indicated that such was the case.

"A WRETCH OF A CORONER."

The office of Coroner is one of those anomalies which can exist nowhere save in England. An officer appointed to protect the interests of the Crown, including therein the lives of all the Queen's subjects, and yet elected by popular suffrage, perfectly independent as a judge, and having a fixed salary, so that there is no inducement to anything like an excessive or officious discharge of his duties for the sake of the fees, is, if a decent and conscientious man, able to afford a vast amount of protection to the most helpless of the helpless classes. In this country, where no system exists of inspection or verification of the fact and cause of death, where anybody may register anybody as dead, and where no certificate is necessary from a regularly qualified Practitioner, there is many a murder, or case of murderous neglect, brought to light by the Coroner's agency, and it is reasonable to believe that many a crime is prevented by the fear of an inquest. Still more, the power of making inquiry into causes of death may drag to light many a scandalous instance of neglect, although it may be that no human laws have yet branded such cases with the name of crime.

Now, it so happens that Dr. Lankester held an inquest last week on the case of a boy who died of typhus fever in St. Marylebone under circumstances detailed in the following evidence of the parochial Surgeon:—

"The last three weeks I have had twenty-five cases of typhus and typhoid fever in the neighbourhood of Providence-place, which contains twenty-four houses and 198 inhabitants. There are three rooms to each house—one below and two above. I believe the cause of the spread of the fever is from the inhabitants drinking the water from a tank placed in the centre of the yard, and close to which is a sink where they empty their slops and excreta of the children and other persons. The tank is a square one, and the water which fills it is obtained from a pump, and from the West Middlesex Water Company. I should think that the water is impregnated with a portion of the refuse daily thrown around the tank, and that water would therefore become a fruitful source of disease, and capable of communicating fever to any person drinking the water. The excess of the water filters itself back into the well, and, in doing so, it mixes with the excreta and other noxious matters surrounding the surface, thereby impregnating the well with all sorts of poisonous matters, and it is the great cause of the spread of disease in that neighbourhood whenever the epidemic breaks out. Before this present epidemic of fever, Providence-place was comparatively a healthy place. The room in which deceased died would contain about 1000 cubic feet of air; but it was about one of the smallest rooms in Providence-place. Four other persons slept in the same room."

It appeared by evidence subsequently given by Dr. Whitmore, and various officials of the Marylebone Vestry, that so soon as the state of things was brought to the knowledge of the local authority they issued notices, caused the houses to be cleansed, the tank to be emptied (which had not been done for fourteen years), and new drains and pavement to be laid down. But this inquest will not be without its fruits. The coroner intimated that if the landlords who owned the property did not obey the orders of the Vestry and of the Medical Officer of Health, and another death occurred through neglect of adopting necessary sanitary measures, such landlords were liable to be indicted for manslaughter. He also took the opportunity of asking whether it were true that the Vestry discouraged their Medical officers in their efforts to improve the healthiness of the dwellings of the poor, and received the most satisfactory answers in the negative.

Now, an inquiry such as this could harm no one and must do good. It tended to protect the poor labouring man, urged the small house proprietor to keep his premises clean, encouraged the Medical officers to do their duty, and gave an opportunity to one of the Vestries of showing the groundlessness *now* of an accusation which their conduct in times gone by may have invested with a certain degree of probability. Of course, such inquiries are troublesome, and make enemies of small ratepayers; and we must give Dr. Lankester this bit of serious advice—viz., that if he hopes ever to become M.P. for a metropolitan borough he had better not be too active as coroner. Still, we should have thought that every reasonable person who is not an owner of "weekly property" would have applauded Dr. Lankester, and bid him go on and hold more such inquests.

Not so, however. One member of the neighbouring Vestry of St. Pancras actually is reported to have said in that august assembly that "*the wretch of a coroner for Middlesex*" sought by all means in his power to bring Vestries into contempt. Now, we have seen lately somewhere a list of the avocations of the Vestrymen of St. Pancras, which are some of them humble enough. What think you then, reader, is the station in life of the member who was not ashamed to speak thus in a public assembly? Is he a butcher? cabman? publican? Do you give it up? Then he is a Doctor of Medicine, and his name is Collins.

THE STARTING POINT OF CHOLERA.

It is unnecessary for us to do more than call attention to the admirable paper by Dr. Montgomery which appears in our columns this week. It is seldom that we have read a paper more full of facts and more sound in its inferences. A perusal of this paper will clear away all the scepticism sometimes professed as to the real noxiousness of those agents which sanitary people affirm to be the common generators of pestilence. Here, in this climate, no doubt, scattered instances arise from time to time which serve the purpose of the sceptic. Some undrained places may go on for years without fever. Some cases of typhoid or cholera may be found, of which the exciting causes are not clear. Hence, argues the sceptic, filth is not a poison; disease comes from accidental or irresistible causes, and preventive medicine is a myth. The remedy for this state of mind is to study the subject on the large scale, and Dr. Montgomery's paper will furnish the material for such study.

THE WEEK.

ANOTHER MEDICAL BARONET.

Dr. Corrigan, of Dublin, has been selected by Her Majesty's advisers as the Irish representative of Medicine to be honoured with the dignity of baronet. We are sure that the selection will give satisfaction to the Profession in the sister island and throughout the kingdom. Dr. Corrigan is known as a Physician of the highest social standing, great Medical and scientific acquirements, and as possessing the entire confidence of his

Professional brethren. He has been several times elected to the Presidency of the King's and Queen's College of Physicians, and is the representative of the Queen's University of Ireland in the General Medical Council. We heartily congratulate the Profession in Ireland on an event which is a fitting recognition of their public worth and services.

We trust, however, that the creations of the last few weeks are but the first drops of a more plenteous fall of similar distinctions on members of the Medical Profession. Those selected for the honour have all been right worthy recipients, but there are Professional names in each of the three kingdoms which will present themselves immediately to the minds of our readers as having deserved hereditary distinction equally with those hitherto chosen. No such honour has as yet descended upon a Fellow of the Royal College of Physicians of London. The present Government appears to wish to acknowledge the claims of Medical science on public reward. But it is surely an anomaly that the first Medical Corporation in the kingdom should be passed over in a distribution of State honours.

THE CASE OF THE WOMAN WINSOR.

We are very glad to see that it is not likely there will be a miscarriage of justice in the case of the woman Winsor, who, it will be remembered, was convicted on the clearest evidence of pursuing infanticide as a profession. If capital punishment is to be inflicted for murder in any case, we believe that this one of Winsor would justify it. Whether she undergo the last penalty of the law or no, the confirmation of the legality of her second trial and of the sentence then pronounced insures that she will be henceforward dead to society. The circumstances of the discharge of the jury on her first trial, the postponement of the second to the next assizes, the admission of her accomplice as evidence against her, whilst they cannot in the least influence the question of her guilt, yet, involving as they do some nice points of law, may be made a ground for appeal to the Royal mercy to commute her sentence. But as far as she is concerned, the lapse of time between her first and second trials, and that gained by the issuing of a writ of error, affords no real ground for commutation, for it has been practically a respite from death for many months, and may be supposed to have benefited the prisoner. The only plea, it appears to us, for the interference of the Home Secretary is suggested by the questionable admission of her accomplice Harris to give evidence against her at her second trial, Harris having been charged with the same crime, and having been jointly indicted with her at the first trial, and then neither acquitted nor found guilty. It was argued with some force by the prisoner's counsel that the fear of impending punishment, and the temptation to try to obtain immunity for herself, might have influenced Harris to give false testimony against the prisoner. But the guilt of the latter was independently proved, and it does not appear that, in her evidence, Harris made any attempt to exculpate herself at the expense of Winsor.

FROM ABROAD. — THE PARIS FACULTY OF MEDICINE — THE CATTLE PLAGUE — AN EXPLANATION OF BOLD ENGLISH SURGERY.

Matters do not seem to be working very smoothly with the Paris Faculty of Medicine. The students' row, which the martinet stupidity on the part of the authorities produced, has been effectually put down by the aid of the police, and the more popular Dean, Tardieu, has been replaced by M. Würtz, Professor of Medical Chemistry, supposed to be a more pliable personage. But that arch enemy to the quietude and comfortable existence of all corporate bodies, reform, is knocking for admission at the door of this pleasant monopoly ; and a commission has been appointed having for its object the consideration of what remodelling will render the present Faculty better able to meet the wants of the period. Great dissatisfaction has long existed at the monopoly of teaching it is in the possession of, and the little scope there exists for the employment and development of rising talent. Something analogous to the *privat docentes* of the German Universities, or the extra-academical teachers of the Edinburgh University is evidently wanted ; but any such innovation has hitherto been, and probably will continue for some time yet to be successfully resisted by the present holders of power. In the meantime, the prolonged retention of their posts by Professors (however eminent these may have been in their day) safely guarded from the stimulus of competition is unjust to those entering the Profession, entitled to the benefits of its newest teachings, and detrimental to the progress of Medical science. The separation of the examining from the teaching bodies is another reform much desired, but somewhat difficult of accomplishment.

M. Auzias-Turenne, in a communication to the Academy of Medicine, observes that the cattle disease named by Guersent in 1815, and in our own day by Bouley and Leblanc, contagious typhus of horned cattle, was as long ago as 1776 designated by Vicq d'Azyr as the *peste varioleuse ;* while the fact of its occasional extension to other animals — as dogs, cats, pigs, and fowls, has been testified to by the same writer as well as by others. Attempts at prophylactic inoculation were also made under the auspices of Vicq d'Azyr, Haller, Camper, etc. ; and recently M. Auzias-Turenne has discovered a pamphlet by a M. Billard, of Vesoul, without date, but supposed to be published about 1820, in which this preventive inoculation is said to have been performed with great success by Professor Salchow, of Maldorf, in Holstein. Minute directions are given for the application of the virus by means of a seton, and its preservative power is said to have been complete. M. Reynal observed that in Russia, while the trials of vaccination had failed, the inoculation of the virus itself had been more successful, and is the prophylactic usually resorted to.

The gravity with which a Frenchman can launch forth a preposterous assertion, especially when this is in self-glorification, is something astounding. Here is one of the last specimens we have met with. M. Desgranges, addressing the Lyons Academy of Science and Belles Lettres the other day upon "Public Assistance in France and England," thus explains the bolder character of English as compared with French Surgery :—

"We Frenchmen appreciate as of equal value every human being, to whatever rank of society he may belong, whatever may be the place he occupies in the social scale, and whatever may have been his services. As Surgeons, we watch over with equal solicitude the infirm pauper destined to inactivity after his cure as the workman whom our care may restore to-morrow to his labours. In England this is not exactly the case, for there, amidst that devouring activity, that feverish passion for the useful, the human being is regarded for little more than what he will bring in. Thus, when disease has rendered him unproductive, his right is not recognised of refusing to submit to the boldest enterprises proposed by art in order to restore to him his social value as an instrument of labour. Can we, then, feel astonished that this mode of viewing the matter, in which is displayed the national character of our neighbours, favours these bold adventures which have borne far and wide the scientific renown of their Surgery?"

"Listening to this judicious and philanthropic interpretation," says the reporter of the *Gazette Médicale de Lyon*, "puts me in mind of an anecdote of Bérard, which is quite in point. In 1835, when he succeeded the old Lallement as Surgeon of the Salpetrière, he was burning with ardent operative zeal, for the gratification of which that Infirmary hardly furnished the material. He therefore set about in search for cases of operation, and amidst the four or five thousand pensioners there was no want of cases of complicated cataract, pannus, prolapsus uteri, and vesico-vaginal fistula. But none of these desired to be cured ; it was their infirmities which had gained them admission into the *hospice* and kept them there, and their infirmities they wished to keep. Neither

entreaties, promises, exhortations, nor insinuations prevailed against the resistance of these obstinate incurables. In this extremity, the Anglo-Saxon spirit inspired Bérard with a strategem which he believed for an instant would prove successful. Despairing of being able to persuade his patients, he had recourse to the Hospital administration, and plainly put the question—Is a pretended incurable, who I affirm I can cure by operation, at liberty to refuse to submit to that operation? The administration hesitated not an instant, furnishing, thirty years in advance, a striking confirmation of the principles which M. Desgranges has so eloquently termed the characteristics of French Public Assistance. It refused to sanction this *compelle intrare* the operating theatre of Salpetrière, and Bérard did not insist on a proposition, of which it only required a short period for his generous soul to recognise the harshness."

REVIEWS.

Saint Bartholomew's Hospital Reports. Vol. I. Longman. 1865. Pp. 327.

The members of St. Bartholomew's have made an admirable beginning. From the first page to the last will this volume be read with interest; and in order to show the Profession what sort of volume it is, and what they may expect who propose subscribing to the series now commenced, we propose to accord to it a full review, noticing more or less every paper that it contains. We believe that in doing this we shall be meeting the wishes of our readers halfway, while the task will be as agreeable to us as profitable to them. The contributions, then, are as follow:—

1. *Cases of Chronic Pyæmia.* By James Paget, F.R.S.—Six cases are recorded. The first succeeded ligature of the subclavian artery, and death occurred on the sixty-fifth day; the second after lithotomy, and the patient recovered. Then comes a case following acute necrosis of the os calcis; the symptoms here extended over three years. It is in this connexion that Mr. Paget tells us that he has observed the duration of the pyæmia most extended. The least severe cases have been those associated with disease of the urinary ograns or catheterism, and he narrates cases that recovered, one after catheterism and one after lithotrity. His sixth case followed a small puncture made into some inflamed inguinal glands. He thus sums up his conclusions:—"It is not rare to meet with examples of disease presenting the essential characters of pyæmia, but much slower in progress and much less severe and perilous than those from which pyæmia is usually described. These cases are frequent enough to justify the general use of the names 'chronic' or 'relapsing' pyæmia. They are more rare among the instances of pyæmia following wounds than among those occurring in disease. The local evidences of chronic are, more often than those of acute pyæmia, seated exclusively or chiefly in different parts of the same tissues; they are more frequent in the trunk and limbs than in internal organs, and when seated in the veins are most frequently found towards the close of the disease. The nearest affinities of chronic pyæmia are with rheumatism, through gonorrhœal and urethral rheumatism; with simple or single abscess formation after fever; with hectic fever; yet with very scarce exceptions the diagnosis from all these is in practice clear. The prognosis in chronic pyæmia may usually be very favourable. . . . The usual treatment of chronic pyæmia may be with good food, patient nursing, a moderate use of stimulants and tonics, and an abundance of fresh air."—P. 12.

2. *On the Diagnosis of Systolic Endocardial Murmurs, whose Point of Greatest Intensity is at, or near, the Left Apex of the Heart.* By James Andrew, M.D.—The murmurs principally treated of are the ventriculo-auricular (regurgitant) and the ventricular—*i.e.*, produced within the ventricle (onward). Dr. Andrew dwells especially upon the diagnostic value of murmurs heard posteriorly near the inferior angle of the scapula as indicating the regurgitant lesion. His conclusions are,—"1. That of systolic murmurs, audible at or near the apex, a large number, 34 per cent., do not indicate mitral regurgitation, or for the most part any very serious lesion. 2. That the decision as to the regurgitant or non-regurgitant character of a murmur rests principally upon its presence or absence posteriorly. 3. That intensification of the second sound in the pulmonary artery as a gauge of the obstruction of the blood stream on the left side of the heart is of great value, but that in estimating it there are certain precautions to be taken. 4. That the occurrence of a non-regurgitant systolic murmur may be explained by changes on the inner surface of the ventricle, or by dilatation of its cavity leading to undue tension of the chordæ tendineæ."

3. *Brief Notes of the Surgical Practice of the Hospital.* By Geo. W. Callender and Alfred Willett.—These notes relate to ordinary cases of disease of bones and joints, injuries of them, cases of cancerous disease, etc.

4. *Hypertrophy and Prolapse of the Tongue occurring during Convalescence after Scarlatina; Removal of the Protruding Portion with the Ecraseur and Seissors, with ultimately a good Result.* By Bowater J. Vernon.—Two operations were necessary in this case, since the stump exhibited a tendency to resume excessive growth. The deeper parts of the portion removed seemed composed of coarse bundles of muscular fibres. After the second operation (with scissors) there was still the tendency to excessive growth observed, but it consisted only of an apparently purposeless development of epithelium, which was shed and reproduced.

5. *Practical Observations upon Tumours of the Pelvis and Neighbouring Parts, Complicating Pregnancy, and Impeding Labour, with Illustrative Cases.* By Robert Greenhalgh, M.D.—The nature of the cases recorded, and the results, are as follows:—"One case of thrombus of the labium and vagina; four cases of tumours of the ovaries; four cases of tumours of the uterus; one case of tumour of the rectum; one case of tumour of the kidney; four cases of extra-uterine fœtation. Eight of the patients reached the full period of uterine gestation; in the remaining seven, pregnancy terminated at some period between three and seven and a-half months of gestation. In four cases labour set in spontaneously; in two cases labour was induced artificially; four patients were delivered by the natural efforts at the full period, one at the third month; in fourteen cases the labours lasted for periods varying from five to thirty hours. Of the fourteen children, eleven presented with the head, one by the feet, one by the arm, and another by the breech. Twelve were males, four females. Turning was had recourse to in four cases, but was completed only in three, the fourth being subsequently terminated by the Cæsarian operation. Two were delivered by the forceps. Five of the mothers and eight of the children were lost; of the former, three died from exhaustion, and two from hæmorrhage."—P. 93. The remainder of the paper is occupied by a consideration of the changes occurring in the form of the abdomen in healthy pregnancy, and some general remarks upon morbid growths in and about the abdomen and pelvis.

6. *Restoration of the Lower Jaw after its Entire Removal.* By Thomas Smith.—The title of this paper does not fully explain its character. It is a record of a case where a necrosed lower jaw was removed, prior to which the foundation of a new one had been laid by the efforts of nature. The opinion of the author is that the soft tissues furnished the material out of which the new bone was constructed, and that the periosteum took no part in the process. We may be pardoned for doubting the accuracy of the author's conclusion.

7. *On the Local Effects of Blood-Poisoning in Relation to Embolism.* By William Savory, F.R.S.—This paper consists of a record of experiments consisting in the injection of various matters into the veins, and, either after spontaneous death or after killing of the animals, of the appearances presented by the lungs. The matters injected were disintegrated fibrin and oxide of zinc suspended in distilled water, a filtered putrid infusion of muscular flesh, filtered putrid liquor amnii, olive oil, fresh pus, the thin fluid filtered from fresh pus, and fluid filtered from putrid pus. The result of the experiments is thus stated by the author:—"That spots and patches of congestion and stagnation, with perhaps ecchymosis in the lungs and other organs, may be produced by the injection into the veins of minute particles of solid matter suspended in water, which can undergo in the blood no decomposition or induce any chemical change, and consequently can only act mechanically; of putrid fluids which have been previously carefully filtered, and so deprived of any solid particles; of pus. That in either case the local effects are the same. The most critical examination fails to detect any distinction in the engorged portions of tissue produced by these different means, except that when solid particles which undergo no change are employed they may be discovered in the midst. The action of fresh pus in producing these effects is mechanical. Either its cells or the clots which it may form in the blood become impacted in the capillaries. When putrid it no doubt acts in both modes. Pus, then, has no peculiar or specific action when present in the blood. If putrid, it will act like putrid matters generally

*

do; or its globules may, under certain circumstances, like other foreign particles, become arrested in and block up the capillaries, producing effects already described. In these experiments abscesses were not more readily induced by the injection of pus than of simple fluids or even of solid particles. The chemical relation of pus to the production of pyæmia appears to be this:—Suppuration is a common occurrence either on the surface of wounds or ulcers or in internal parts. Pus, as pus, cannot be absorbed—that is, its solid particles, its corpuscles, cannot enter the circulation except through some lesion of the bloodvessels. Pus may pass into the circulation through an orifice in a vein; this occurrence, however, must be extremely rare. But the fluid part of pus may be absorbed. If this be not putrid no mischief will supervene. Even if healthy pus should by some rare chance find its way into the circulation, no secondary abscesses would perhaps be, under ordinary circumstances, produced. . . . But pus may become putrid, more especially if exposed to air in a wound, and the putrid fluid may be absorbed, and this, like any other putrid fluid, will produce the effects to which the term pyæmia is applied."—P. 134. Why, considering the frequency with which wounds are bathed in fœtid fluids, is not pyæmia more common than it is? Mr. Savory's answer is, that the membranes with which they are in contact may deny passage to some such fluids, and that when they do pass through them they may be eliminated so fast as to equal the rate of absorption, and thus no sufficient accumulation of poisonous matter occurs in the blood. The paper is an important one.

8. *Two Cases of Poisoning by Mercuric Methide.* By George N. Edwards, M.D.—They occurred in the persons of two of the laboratory assistants, and similar, though less severe, symptoms were felt by all working in the laboratory at the time and inhaling the poisonous vapour. Mercuric methide, $HgMe_2$, may be regarded as the analogue of corrosive sublimate, $HgCl_2$, in the methyle series of salts.

9. *Cases in which Large Arteries were Tied during the year* 1864. By Alfred Willett.—"All vessels of less magnitude than the brachial and all amputation ligatures are omitted. The cases are arranged in two groups, the first includiug those in which the operation was performed for disease of the vascular system, one only being for disease other than aneurism; the second comprising those in which the operation was necessitated to suppress hæmorrhage." Altogether ten cases are recorded.

10. *The Minute Structure of the Human Kidney.* By Reginald Southey, M.B.—Dr. Southey considers "the tortuous or glandular tubes proper as signified by their structure, contents, and intimate annexation with blood supply, to be that portion of the tubes in which the separation of the more solid constituents of the urine and its colouring matter takes place; but we regard the Malpighian bodies themselves neither as the especial seat of water filtration, as assumed by Bowman, nor as that of urea secretion, as Dr. Isaacs, of New York, has from his experiments surmised; but rather, as their position and structure appoint them, as blood regulators." This paper deserves careful study.

11. *Remarks on the Operation of Excision of the Knee-Joint.* By Holmes Coote.—He says at the conclusion of his paper,—"The result of my own experience in the treatment of knee-joint disease, especially in the young, is adverse to the operation of resection. I feel more confidence in the treatment by long-continued rest and the application of those principles comprehended by the term Orthopædic Surgery. And this opinion seems in consonance with the feeling of the upper classes, among the children of whom I have not yet heard of one instance of the performance of 'resection.' When the disease is so far advanced as imminently to threaten life, amputation is the preferable operation. To this rule the exceptions are, I believe, very few."—P. 196.

12. *Report of a case of Ichthyosis, with Congenital Malformation of the Aorta.* By William Church, M.B.—"The chief points of interest in the foregoing case appear to be,—First, the evidence afforded by it of a correlation of growth existing between the derma and the teeth; secondly, the proof that some cases, at all events, of ichthyosis spuria or sauriderma are due to an alteration and hypertrophy of the papillæ of the corium and their epithelium, and not to desiccation and altered sebaceous substance, as stated by Mr. Erasmus Wilson; thirdly, the limitation of the disease to the left side of the body; lastly, the absence of any cyanosis or marked cardiac symptom, notwithstanding the patency of the foramen ovale and the malformation of the aorta."—P. 200.

13. *On Tumours Containing Fluid Blood.* By. W. Morrant Baker.—Those only are considered in this paper in which the blood is variously altered and not spontaneously coagulable. The following propositions are severally discussed:—"1. That although the coagulation of blood extravasated in the cellular tissue, or in cysts or hæmatoceles, is probably delayed, yet it does occur after a longer or shorter interval more or less completely. 2. That in many cases the whole of the blood does not escape at once or within a short time, but that the hæmorrhage continues for a considerable period, although the loss of blood is only small—too small to allow the disintegration and absorption of that which has already escaped to proceed at a quicker rate than does the effusion of fresh blood. 3. That the fluid obtained from these tumours is, in many cases at least, not simply uncoagulated blood, but a mixture of serum (derived, probably, not only from extravasated blood, but secreted also by surrounding parts) with blood cells, diffused colouring matter of cells, and disintegrated fibrin. 4. That besides the constant but small effusion of blood, there is a constant absorption, though not sufficient to keep pace, or do more than keep pace, with the effusion."—P. 206.

14. *Observations upon some Points in the Anatomy of the Supra-renal Capsules.* By Dyce Duckworth, M.D.—The following are the matters treated of in the several sections of this paper:—1. The naked eye appearances of the supra-renal capsules, as modified by age and other apparently normal circumstances. 2. The appearances presented on section. 3. Nature of the expressed juice of the cortex. 4. Arrangement and nature of the cortical columns. 5. Structure of the accessory supra-renal capsules. 6. The relation between the cortical and medullary portions of the supra-renal capsules. 7. Nature of the expressed juice of the medulla. 8. The medullary matrix and its contents. The paper is illustrated by well-executed coloured plates.

15. *Cases recently under Treatment.* By Thomas Wormald.

16. *Cases from the Wards.* By Robert Martin, M.D.

The above two papers contain some interesting records.

17. *Case of Acute Necrosis of the Tibia.* Death from Pyæmia. By W. I. Savory, F.R.S. This is a sort of addendum to Mr. Savory's paper above noticed.

18. *Note on Hippuric Acid.* By W. Odling, M.B. A paper of purely chemical interest.

Fractures Injuring Joints. Fractures interfering with the Movements at the Wrist and with those of Pronation and Supination. By George W. Callender.—The object of the paper seems to be to show that while the unfavourable results of such cases "are frequently referred, in some measure at least, to the treatment which has been adopted," yet "it will not be difficult to show that a great number of these hurts must have a comparatively unfavourable issue, however good the management which is bestowed upon them. Still, there remain many cases in which the recovery is not so good as it might have been if only the original injury had been accurately determined, and the right plan of treating it properly carried out.

20. *The Hospital Registration.* By George N. Edwards, M.D. A short paper descriptive of the registration arrangements in operation at St. Bartholomew's.

Altogether, we congratulate the staff of the Hospital on the success of their first endeavour thus to utilise for the whole Profession the experience of this noble foundation.

Professor Huxley, F.R.S.—This gentleman will commence his course of lectures in the theatre of the Royal College of Surgeons on Friday, the 2nd proximo, and will deliver twenty-four lectures on the Structure and Classification of the Mammalia, in continuation of his course of last year, and will be followed by Professor Hancock, who will deliver six lectures on the Anatomy and Surgery of the Foot. The lectures will be delivered on Mondays, Wednesdays, and Fridays, at 4 o'clock.

Dr. Mapother, Medical Officer of Health for the City of Dublin, Dr. Tucker, medical officer, Sligo, Dr. Foot, lecturer on anatomy, Trinity College, Dublin, Dr. Hayes, lecturer on anatomy, of the Catholic University, Dublin, were appointed by the lord-lieutenant to proceed to London to inquire into the nature and treatment of the Rinderpest. This is a step in the right direction in Ireland to consult medical science on this formidable pestilence. It affords an argument in favour of the necessity for a special State minister and department of public health.

GENERAL CORRESPONDENCE.

THE PRELIMINARY SCIENTIFIC EXAMINATION AT THE UNIVERSITY OF LONDON.

Letter from Dr. Ebenezer Watson.

[To the Editor of the Medical Times and Gazette.]

Sir,—Your last number for 1865 (December 30) contains three articles which are deeply interesting to most members of our Profession, and certainly to all teachers of Medicine. I refer to your own editorial article "Pity for Poor Students," the circular from the University of London, and Professor Beale's letter on Medical education.

With much in all of these papers I heartily concur. I highly appreciate the efforts of the University of London to elevate the standard of preliminary education in candidates for Medical degrees; but I also agree very warmly with you in thinking that this laudable desire has been carried too far in the present instance. It seems to me that a little "pity for poor students" would open the eyes of the University authorities to the fact that even a moderate proficiency in all of three sciences so extensive as Botany, Zoology, and Chemistry ought hardly to be expected from young men entering on the study Medicine. We do not find that even men devoted to the pursuit of science for its own sake, excepting in a few rare cases, have aptitude for all these different branches of knowledge. I dare say among the examiners themselves instances of this may be found; for the most eminent botanist may have little knowledge of chemistry or zoology, and, *vice versa*, the chemist or zoologist may not be much skilled in botany. Why should it be different with students? Would it not be better to give them the choice of one or other of these sciences as subjects of preliminary examination, which, in fact, is done at most licensing boards?

Perhaps with the mere University regulation, however, the general Profession have little to do; yet with the subject of the preliminary qualifications of entrants upon Medical studies we all have a deep interest, and those who have experience in teaching may be allowed to express their opinions frankly and freely, in order that improvement may follow, perhaps by the interference of the General Medical Council. Hence it is that I trouble you with this letter.

Like Professor Beale, I have some knowledge of the difficulty of grounding students in the elements of general anatomy and physiology, and I certainly have always found that those who most readily understood and most profitably retained what I brought before them were the youngest students, fresh from their early education with minds made ready for, but not yet encumbered by, the minutiæ of scientific truth. A good ordinary education, as it is now to be had in every well-organised academy, including some knowledge of Latin and Greek, is all that, in my opinion, should be required from students entering on their Medical curriculum, and I do think that requirements such as those of the London University are very injudicious, and must be felt to be an insuperable bar to the entrance upon their studies by the majority of young aspirants to the Medical Profession. I hope, however, that this will not be the case with those who were unfortunate at the recent examination; for I do believe that many of the forty-three rejected students would have made, and I hope will yet make, even more satisfactory progress in Medical studies than their more fortunate compeers on the occasion referred to.

There is another point in regard to which I wish to express a very decided opinion in accordance with that of Professor Beale—viz., that it is impossible for any student to profit by Hospital attendance without a knowledge of physiology. This must be obvious to any one who takes the trouble of thinking on the subject for a few minutes; and yet it would seem from Professor Beale's letter that students, even in England, rarely have the necessary knowledge of that science before commencing their Hospital studies. With us in Scotland they never have, or can have; for they are not required by any Scotch Licensing Board, or by the Royal College of Surgeons of England, if educated in Scotland, to have more than one course of fifty lectures on physiology instead of the two required from students educated in England; and this course of physiology they almost invariably attend during their second winter session, at which time they begin to attend the Hospital. It follows, therefore, that during that winter session, or the greater part of it, they cannot benefit from the Hospital attendance; and we all know that if students are not getting benefit in such circumstances they are growing in the worst of habits—habits either of ill-timed frivolity or of vague, objectless walking of the wards.

I agree with Professor Beale that it is time some remedy were devised for this defect in the arrangements of the curriculum, and perhaps that remedy will be found in a modification of the first-half examination. For I think with him that it would be advisable to have three Professional examinations—one at the end of the first year upon the elements of anatomy, chemistry, and physiology, without passing which no student should be allowed to enter the Hospital; the second, at the end of the second or third year, on more advanced anatomy and physiology, with materia medica and Surgery; and the third, at the end of the fourth year, upon practice of physic, Medical jurisprudence, and midwifery.

This would imply an equalisation of requirement as to attendance on physiology in England and Scotland; for I do not see why students should be exempted from an attendance here which is enacted in England, and I am sure that every one who knows the difficulty and importance of the study of physiology will agree that the English arrangement is better than the Scotch; that, in fact, the student ought to be kept to the study of physiology for the first two years of his curriculum. I am also quite confident that the Scotch students themselves would consider this as no hardship, while they all regard the preliminary requirements, even though much less stringent than those of the London University, as somewhat oppressive, and perhaps unnecessarily severe. They can all of them be persuaded of the necessity for a thorough understanding of the principles of their Profession; but many of them have no taste for literature, in the highest sense of that word, or even for the cultivation of general science; and, while it may seem very desirable that the members of a learned Profession should be all learned, yet no sensible man can refuse to acknowledge that the pecuniary emoluments and the social circumstances of many Medical Practitioners are little suited to the possession of such acquirements, and but little in accordance with the mental refinement which they are calculated to produce.

I am, &c.

Glasgow, January 5. Ebenezer Watson.

EPSOM COLLEGE.

Letter from Mr. John Propert.

[To the Editor of the Medical Times and Gazette.]

Sir,—I hasten to announce to my Professional brethren, through your widely circulating journal, that our much esteemed friend, Sir William Fergusson Bart., has most kindly consented to devote his first public exertions in advocating the cause of those, who, alas! have not been as fortunate in life as himself, by taking the chair at the fourteenth anniversary festival of the Royal Medical Benevolent College, on Thursday, April 26 next, at Willis's Rooms; when I hope—nay, confidently anticipate—that every member of our noble Profession will—who can—gladly and immediately enrol his name as a steward, to support our much respected friend on that interesting occasion.

The first list of stewards will very shortly be published.

I am, &c.

John Propert, Treasurer.

New Cavendish-street, January 23.

CENSURE BY A CORONER'S JURY.

Letter from Mr. F. Harry Hume.

[To the Editor of the Medical Times and Gazette.]

Sir,—A few days ago I heard quite accidently from a friend that there was an account in the *Islington Gazette* of an inquest held by Dr. Lankester, at which, with the verdict returned, was coupled a vote of censure against myself.

I could scarcely believe it to be true, never having been informed of the occurrence calling for an inquest, or that my presence would be necessary in order that I might give an explanation.

The facts of the case are these:—On Sunday, the 7th inst., at nine o'clock a.m., my servant informed me that a woman wished me to go immediately to see a person who was dangerously ill. I sent back word that they must go to the Workhouse to obtain an order or must pay for attendance.

My excuse for asking payment is this: I must have found a substitute, who would have been obliged to supply medicine, the Workhouse Dispensary not being opened until midday, and then only for an hour.

The woman returned in about twenty minutes, and stated that she had applied for an order, but was refused, and told at the same time to inform me that I must go to the case. Now, it so happened that I could not do so, as I had several cases to attend which I had promised to see first thing in the morning, they being very urgent. When I returned home from seeing them, I received a message to go immediately to Holloway to attend a midwifery case, at which I was detained for the rest of the day. No further message had been brought from the case in question when I arrived home in the evening. Supposing that I was in fault, will you suffer me to ask what is the propriety of censuring a man in his absence, and without sending for him to give an explanation? This is more surprising when a Medical Coroner presided at the inquest. I naturally wrote, asking for an explanation, in the following letter:—

"8, Angell-terrace, Islington, N., January 17, 1866.

"Dr. Lankester,—Sir, I am surprised to see the report of a case of a sudden death in a local newspaper in which my name is introduced, I having had no notice of the occurrence or of any inquiry which would necessitate my bringing forward evidence to clear my character.

"Moreover, I had never heard, excepting through my servant, of the very existence of the case, I having been hard at work during the day.

"I must beg for an explanation as to how the jury arrived at the vote of censure, and why I was not made acquainted with the case. "Yours, very truly,

"F. Harry Hume, M.R.C.S.

"Dr. Lankester."

To which I received the following reply:—

"January 18, 1866.

"Sir,—I am directed by the Coroner, Dr. Lankester, to acknowledge the receipt of your note of yesterday, and to say you can have a copy of the depositions taken at the inquest referred to by paying the customary charge for the same of 10s. 6d. "I am, Sir, your obedient servant,

"F. H. Hume, Esq. "J. H. Murrey."

I leave this with you and your readers, and inquire if this is the treatment which the Medical Profession is to expect from the hands of a Coroner.

I am, &c. F. Harry Hume, M.R.C.S.

8, Angell-terrace, Islington, N.

[We have received this letter since writing the leading article in to-day's *Medical Times and Gazette*. We should be glad to have a copy of the verdict returned by the jury, together with the exact terms of the censure of which our correspondent complains. Certainly, to condemn a man unheard is contrary to the principles of English justice. We think there must be some mistake in the newspaper report. It is but just to Dr. Lankester, meanwhile, to direct attention to his tone at an inquest held on a man who had died at St. Mary's Hospital under the effects of chloroform. He distinctly protected the Medical men from an imputation of want of care.—Ed.]

THE ACUPRESSURE CONTROVERSY.

[To the Editor of the Medical Times and Gazette.]

Sir,—It appears from his communication in your last that Dr. John Brown wishes his Professional brethren to understand that he does not disapprove of Mr. Syme's (so-called) "public execution" of Sir J. Y. Simpson's pamphlet on Acupressure; although the motive of such a disclaimer, addressed to any body of gentlemen, is not very obvious. Dr. Brown regrets "his (Mr. Syme's) taking such a step" only because it "was liable to misrepresentation." I venture to bid him make himself easy on this score,—the "step" admits of but one construction; and not all the ingenuity of principal and second in the affair combined can give it any other than a very ugly aspect. Dr. Brown's attempt to justify it as "the deliberate reply to an imputation on his (Mr. Syme's) fidelity as a teacher, and not as an expression of dissent from the proposed substitution of needles for ligatures" is simply absurd, and can mislead nobody. As a bit of special pleading, it may take rank with the defence in a certain trial for assault in which it was admitted that the panel struck the blow, but alleged that he did it merely in a parliamentary sense! But for the after-boasting of Mr. Syme, with this "evidence as a witness," the scene in the operating theatre of the Edinburgh Infirmary might have passed as a transient ebullition of wrath on the part of the self-constituted High Priest against the invader of those sacred mysteries the "Surgical principles," deserving ridicule rather than grave reprehension, and destined soon to be forgotten; but a studied indignity,—as the sequel shows this to have been,—offered "with the most perfect coolness" (Dr. Brown assures us) by an operating Surgeon of note to Sir J. Y. Simpson, has, unfortunately for the doer, the elements of perpetuity of remembrance in it:—

"Is it not as if this mouth
Should tear this hand for lifting food to 't?"

In the practice of not a few Hospital Surgeons, and teachers of Surgery,—to say nothing of the obscure provincials with their "penny trumpets," all playing the same tune,—acupressure has approved itself most emphatically the reverse of "useless and injurious;" and the evidence in its favour of competent judges, who have employed it, is daily accumulating. Who, then, is Mr. Syme, that his condemnatory *dictum*, wholly unsupported, as it is, by personal experience, should be set against the approving depositions of such a cloud of witnesses, many of them his equals in authority, even if his judgment on the point were a mature and dispassionate one?

I think, however, the time has arrived when Sir J. Y. Simpson may safely leave this, his latest great invention, to recommend itself, and an opponent like Mr. Syme to his own devices.

I am, &c.

January 16, 1866. A Surgeon

REPORTS OF SOCIETIES.

METROPOLITAN ASSOCIATION OF MEDICAL OFFICERS OF HEALTH.

Saturday, January 20.

Dr. Druitt, President, in the Chair.

At this meeting the following paper, by Dr. H. B. Montgomery, Member of the Sanitary Commission of Madras, etc., etc., was read:—

ON THE ORIGIN AND PROPAGATION OF CHOLERA IN INDIA BY MEANS OF RELIGIOUS FESTIVALS AND PILGRIMAGES.

To grapple successfully with epidemic disease, we must prevent its primary development, and in doing this we shall more easily attain success than in endeavouring to limit its extension. There has, hitherto, been too much attention given to the cure rather than the prevention of epidemic disease; but now, under the awakening sense of the value of hygiene, we may hope that we will henceforward have our attention directed to the laws of its propagation. I shall in the following paper discuss the possibility of checking those periodical ravages which are effected by epidemics, more especially in intertropical latitudes. I desire here, however, to guard against an error which might possibly arise from the title prefixed to this communication, and may briefly explain that it is intended to show not that special and exceptional laws regarding the origination of epidemic disease are in force in India, but rather that certain fixed causes of epidemic disease exist all over the world, and that in India we are able to identify cause and effect: while the teachings of our experience may not be quite without value in other countries.

The argument, in fact, is one from the "particular" to the "general"; and the application of any conclusions at which we may arrive regarding causation or prevention must be modified only by considerations of local peculiarities, as to the habits of the people, or the character of the disease. I should, however, notwithstanding the interesting nature of the inquiries upon which I am engaged, have hesitated to bring this subject before the Society if it did not possess a direct and practical bearing upon public health in this country. At a time when epidemic disease of a most formidable cha-

racter is threatening us, it may be worthy of inquiry whether or not there is evidence to connect the late epidemic of cholera in France, and even its appearance in England (as the ultimate scene of its contagious propagation), with its previous appearance among pilgrims and religious devotees resorting to Mecca.

The task of tracing out evidence on this point is, I believe, now engaging the attention of a member of this Society, and the following observations were in the first instance prepared for his information:—The first point for consideration—and really that upon which the whole question depends—is as to the actual facts regarding the liability or otherwise of large collections of people to cause the primary appearance of epidemic disease. It may here be well to state that the epidemics most usually witnessed in India are cholera, small pox, and fevers of a contagious character, or of that class which is attributed to malarious influence. (By the term malaria, I would, however, imply in its fullest acceptation the effluvia or noxious emanations arising from decayed animal or vegetable matter.) Now, all the diseases named are generally accepted as contagious, and any influence which will tend to their production will equally aid their extension. If, then, it can be shown that the influences most potent to originate and disseminate contagious disease are present in the case of large collections of natives in India, and, next, if further experience places beyond doubt the occurrence of diseases coincident with the presence of these concurrent causes—if, moreover, disease of an epidemic character can be traced back from various points of its development to one common centre of production, then the argument which points to this as the real place for action and prevention becomes irresistible.

Although fevers, whether exanthematous or otherwise, may, and doubtless are frequently, propagated by collections of people assembled in great numbers, and although they are justly recognised as fruitful sources of disease and death among the population of India, it is perhaps better, for closeness of argument and clearness of investigation, to limit our present inquiry to the one topic of cholera. I propose this course because the contagious character of variola, typhus, &c., is almost an admitted fact, and also because the period of incubation of these diseases is less fixed than that of cholera, and consequently greater difficulty exists in tracing the former to their true and immediate origin. In all contagious affections illustrations of deferred propagation of disease may occur, as by clothing contaminated by unhealthy or morbid secretions; but these must be regarded as exceptional, and, while they are admirable and conclusive evidences of contagion, they somewhat tend to erroneous conclusions regarding the date of origination of these forms of disease.

In our endeavour, then, to account for the frequency with which cholera is witnessed during or subsequent to festivals, or among bodies of pilgrims, it is desirable that we should appreciate the predisposing and immediate causes which tend to produce it. These may be classed as follows:

(1) Undue exposure to the vicissitudes of climate, and the occurrence of certain atmospheric phenomena, including frequently absence of ozone.

(2) Physical fatigue and nervous depression from prolonged travelling, mental apprehension, sorrow, or fear, more especially of this disease.

(3) Undue abstinence or deprivation of food, or the presence of injurious properties in it.

(4) Excess in eating, drinking, and licentiousness.

(5) Vitiated atmosphere from miasmata.

(6) Direct exposure to the contagion of the disease.

As regards the first of these causes, I may observe that the most unhealthy seasons in India are those before the commencement, and at the close, of the rains. These, technically called the monsoons, rapidly chill the air, and predispose to fevers and bowel complaint (due probably in great part to checked or arrested cutaneous exudation) at their onset; while their termination, marked as it is by the subsidence of swollen floods and the renewed exposure of decaying and wet animal and vegetable matter to the influence of a tropical sun, tends to the origination of all diseases whose existence is referable to miasma.

As regards atmospheric phenomena, I may direct attention to the first appearance of true Asiatic cholera in 1817. This year was from its commencement uncommonly moist, and the annual rains began in Bengal some three weeks before the usual time. The delta of the Ganges was soon flooded so as to become one vast sheet of water, and the rains exceeded the average of ordinary years by some 33 per cent. Jessore, the station from which the disease originated, was especially exposed to these injurious influences, lying as it did in a dense jungle, and surrounded with stagnant water. The disease in its mitigated form was not, however, absent from other parts of Bengal, and more especially from Calcutta, which was then, and is now in some places, one of the dirtiest cities in the world. How far true Asiatic cholera owed its presence in Calcutta to dissemination of the original disease from Jessore or not is now a matter of historic doubt. But it is beyond all question that with appalling rapidity the disease spread through the different cities of Bengal, passed up towards the source of the Ganges, and extended its ravages to the west of the Jumna. The territories of Oude and Rohilcund, lying on an elevated tract of land, would, however, not appear to have suffered in the first instance, though they did subsequently. Within two or three months of the first appearance of the disease it was brought to the camp of the Marquis of Hastings, which was then moving slowly through the low and unhealthy district of Bundelcund. A reign of terror followed the appearance of this new foe, and the army became temporarily "demoralised." The epidemic only lasted eight days, but during that time 8,000 native followers and 764 of the troops died. The sudden disappearance of the malady allowed the progress of the army, and the health of both officers and men became rapidly re-established. Similarly in many other parts of India atmospheric phenomena seem to have borne an active part in the organisation of epidemic disease. But the consideration of this subject is beyond the limits of the present inquiry.

Of the second cause predisposing to cholera—namely, physical fatigue and nervous depression—I need only now add that experience has conclusively shown that individuals proceeding on long journeys or after their conclusion are markedly subject to be attacked. The admirable report of Dr. Lorimer, formerly Secretary to the Medical Board at Madras, has conclusively shown, from well-framed and reliable statistics, that the probability of cholera may be estimated as being in the direct ratio of the number of men composing, and the distance to be travelled by, bodies of troops marching.

Of the effects of mental or nervous depression it is needless to speak, as it is a recognised source of danger to all persons liable to the influence of this epidemic.

3rd. Undue abstinence, during which the absorbent system is unusually active and the nervous system labours under the hypersensibility induced by depressed vital power, will tend to predispose to either the origination or development of the disease, and this more particularly if any of the food used is of an improper description, either as directly producing intestinal irritation or as wanting in nutrition.

To the importance of this latter source of cholera too much attention cannot be given. My own personal experience has taught me that certain articles of diet have certainly been the immediate and exciting cause of cholera, capable of proving fatal itself and of being propagated. Certain vegetables (more especially of the natural orders of Cruciferæ and Cucurbitaceæ) cause many of the symptoms of the disease, and apparently are capable of originating the disease, or at least of developing it where the seeds of it have been latent. Water melons are conspicuous among these articles of diet, and are consumed by natives in enormous quantities, more particularly when they are travelling, and during the hot season, when pilgrimages are, for agricultural and personal considerations, usually made; and the first appearance of cholera is by some referred to the diseased rice used by troops.

4th. Equally if not more injurious than insufficient or improper food is excess, and this is frequently exhibited in the use of alcoholic and narcotic stimulants, and extreme venery to an amount that would be hardly credited among European nations, but which is common enough among natives, particularly at festivals.

5th. Of the evil effects of overcrowding in houses and of the influence of miasma, in the extended sense in which I have accepted it, it is not necessary to say much; but the imagination of an English mind could never depict the extent to which causes for miasma are allowed to exist in native towns, and there seems little reason to doubt that the evil effluvia arising from decomposing animal and vegetable matter is as deadly a poison as any more material one within our knowledge. Mere humanity itself can, as we know, poison the surrounding air; and not only so, but the effluvia thus arising may act as truly as a blood poison as any distinct

and special morbific element. Just one hundred years ago the few survivors of the Black Hole in Calcutta suffered from consecutive fever almost without exception, and if time allowed I could multiply illustrations of the ill effects of crowding in barracks, Hospitals, and other houses. In these cases cholera is not of necessity produced *per se*, but a fruitful ground is prepared where its seeds will germinate and bear their evil fruit with awful productiveness.

6th. Lastly, among the immediate and direct causes of individual seizures of cholera stands the exposure to its poison. To avoid an imperfect, and consequently unsatisfactory, consideration of the question of contagion, I shall merely assert this cause, without assigning for doing so any especial reasons.

The foregoing brief summary of causes, generally recognised as affecting all classes in India, and, among them, predisposing to the development and the propagation of cholera, would scarcely need any augmentation had it been intended as a sketch of the conditions surrounding or affecting pilgrims on the march, or during the celebration of their festivals. They are subject, not to one of these influences only, but to four out of the six of necessity, and frequently to the other two—namely, the first and last. In fact, all the evil conditions noted must belong to the undertaking upon which they are engaged, and these very conditions, be it remembered, are all co-existent, or follow close upon one another.

A brief sketch of the mode of travelling adopted by the various classes of native travellers is needful to the comprehension of the physical and mental condition in which they have to make their prolonged journey. Either on foot walking almost incredible distances under a burning sun, or closely packed in a stifling cart which is crammed to suffocation by human beings, and from which every breath of air is as carefully excluded as it is possible to do, they struggle along indifferent roads, or no roads at all, slowly dragged by miserable, half-starved, and all over-worked bullocks. Their food, indifferent in quality at the best, is cooked under the shade of a tree, or under the cart in which they travel, and after it they drink pernicious arrack, or fermenting toddy, or tank or well-water scarcely less pernicious. At night they sleep in the foul conveyance in which they have travelled, or lie exposed on the ground to be chilled by dews or damp, or subject to the influence of the land wind. If they stop at a native town, they crowd into the closely-packed bazaars, and sleep, perhaps, in some filthy choutry, or travellers' rest-house,—seldom little more than a shed enclosed on two or three sides—and they lie packed as close as they can, with, perhaps, a thermometer at 70 to 80 degrees at the lowest.

Can it be wondered that they are unhealthy? Can we feel surprise, if they do manage to reach the goal they seek, that when they mingle with others influenced by similar injurious surroundings, and meeting in a densely-crowded native town, without conservancy, with water defiled by cattle and the washing of carts and clothes, and the bathing of crowds of human beings, they fall victims to miasma? Would not the wonder be if they escaped from disease?

That they do not—that thousands annually perish—is undoubted; but this is not the sole evil, although even its magnitude is appalling. In preference, however, to theorising, let us examine a few well-marked examples of the direct origination of cholera at religious festivals, and of the subsequent development of the same disease as the result of pilgrimages. In order to avoid a needless repetition of facts well known in India, but the details of which are not easily attainable in this country, I will confine my observations to the effects of the causes under consideration as influencing the vast population of the city of Madras, and others as affecting large sections of the army of the same presidency while marching in a distant part of it. These illustrations of immediate and remote effects are equally important.

Situated at a distance of forty-five miles from Madras, and on the western boundary of the collectorate of Chingleput, is a native town called Conjeveram. "It is large, pretty, and regularly built; the streets are broad, and planted with cocoanut trees, and a small stream runs along its western side. The soil is clayey from decomposition of felspar, which abounds in the granite, and proves very fertile; the river and surrounding tanks are favourable to cultivation. The inhabitants are chiefly ryots" (cultivators of the soil) "and weavers. Many Brahmins reside here, and the large Pagoda or Temple at Conjeveram is greatly famed in heathen mythology. It is one of the strongholds of Hindooism in Southern India."

Here, then, we have an example of a sacred shrine, which in some respects is favourably influenced for the existence and maintenance of public health. Many of the inhabitants, more especially those attached to the temples and also the leading cloth merchants of the place, are wealthy. It occupies a somewhat secluded position, and the mode of construction of the town, with a view to the passage of large processions along its leading streets, is favourable to ventilation. The occupations of the people are healthful, much of the weaving (which might seem an unhealthy occupation) is carried on out of doors, and the general health of the people is satisfactory. The festival is comparatively of short duration, and held in the month of May, which is a hot weather month, and not unhealthy, in this part of India. Yet with all its advantages the annual feast at Conjeveram is almost as regularly the means of introducing cholera into Madras. Scarcely a year up to 1863 passed without an outburst of cholera during, or immediately subsequent to, the festival, and its appearance in Madras a few days subsequently was directly traced, in many instances, to the visitors returned from Conjeveram.

A better marked example of the deadly effect of these festivals could scarcely be found. On the one hand we have a town naturally tolerably salubrious, with a population independent and healthfully employed, and yet we find that cholera appears with the aggregation of strangers, even although the majority of them have come a comparatively short distance, and their stay is limited.

The causes likely to predispose these people to disease have been already detailed as they influence even individuals, but to these others and equally suggestive ones were added as affecting the mass when aggregated together. Up to the festival of 1863 no provision of any kind of an hygienic nature was made. No places of public convenience were erected, and an indiscriminate collection of men, women, and children, bullocks, horses, and cattle of all kinds, crowded and defiled the public streets. Pigs, the natural scavengers of an Indian town, devoured the foul and decomposing excreta festering under a tropical sun, and were subsequently slaughtered to supply pork to Madras. Mad revelry by day and night, when the tumult rendered sleeping a matter of difficulty even to a native, excited to a preternatural degree the religious zeal of the Hindoo, and excess and debauchery prostrated his energies and made him an easy prey to disease. The effluvia arising from decomposing excreta polluted the air, and in this foul atmosphere the inhabitants of the town had to live, with an additional supplement of some 200,000 strangers who attended the feast. The carts in which they came to the feast—if they were of the better classes—became saturated with the poisonous atmosphere. The clothes of the poorer,—tainted by prolonged wear, and the various contaminations likely to arise during an orgie of days,—wrapped round the wearied limbs of these miserable devotees, and sent them back to Madras, each of them perhaps a nidus for future epidemic disease. Exhausted, weary of excitement, with all the sustaining hope of religious zeal to support them gone, they hastened back to the Presidency town—itself notorious for indifferent conservancy,—and the life of every European, East Indian, and native in that great city was perilled. How these adverse conditions have been partially mitigated, with the happiest effect, by the efforts and on the advice of the Commission to which I have the honour to belong, I will shortly detail.

In contrast to the foregoing facts regarding the condition of a town, itself the scene of a religious festival, we will next turn to an example of the effects left behind by bands of pilgrims traversing the land. Some of these come from Bhopaul, the territory of Bundelcund, and the provinces of Central India, collecting from distant stations in bands more or less numerous, but sometimes amounting to thousands. Many of these, poor, ill-fed, and diseased, start on their weary journey of some 1500 to 2000 miles in length. Passing by Nagpore, and occasionally by Hyderabad and Bellary, the miserable caravan wends its way through the Ceded Districts, and Kurnool, Cuddapah, Salem, and Trichinopoly come in their route, which, for obvious reasons, is that of the grand trunk roads of Southern India. Visiting the sacred shrines of Trichinopoly, weary and exhausted, they still pass on, and visiting Saringum at length their hearts are gladdened and their courage is revived by the longed-for sight of the sacred island of Ramieseweram, from which they feast their eyes upon the distant site of the mythical Lunka, the holy or resplendent island of Indian song and story—the Ceylon of modern writers. At Ramieseweram they visit the sacred spots commemorated in the great epic poem of the Rama-

yanam. Visits to the island Ramieseweram and bathing in the sacred water where the two seas mingle are supposed to free from sin and give a passport to immortality.

I allude to this belief because it, in part, explains the strong motive that impels the resort of these pilgrim, who, so long as their religion lasts, will continue to flock to Ramieseweram, and to be a constant souree of disease if stringent measures are not adopted to check the evils they give rise to.

To reach the shrine of their devotion, many thousands start each year from the distant regions of Upper and Central India.

Ten years ago the population of the island was under 5000, and no less than 130,000 pilgrims annually arrived to worship. To this a goodly addition must be made if we would account for all who originally started on the journey. The hearts of many have failed them; the money of others has fallen short; possibly at some native village where they halted disease has sprung up and checked the adventurous travellers; and thousands of graves unseen, because unmarked, exist on these trunk roads of the travels of these votaries of religion.

But perilous as has been the route to reach the sacred land, the dangers of it are, perhaps, less urgent than those of the return. When their ceremonies have been performed in due course, and when the strong feelings of religious enthusiasm have been gratified, they soon take their staff in hand, or yoke the travel-worn cattle, and turn their faces homeward once again. Now it is that disease asserts her illimitable power. No longer upborne by excitement, the object of their lives now fully attained, wearied, poor, and with no hope to cheer them on their way, they start on their return journey. How many of their companions may have fallen by the way—how many are never to see their homes again,—who can tell? On the return journey, all the influences, physical and moral, which endangered them are multiplied in number and intensified in power. They seek on their return the camping ground before defiled by themselves. They listlessly occupy the same vehicles which brought them all this long journey; they are depressed at the dread that spoilation of their property at home may have occurred, and they are in a strange country, speaking an almost unknown tongue. Forced marches knock up both man and beast, and foot-sore, down-hearted, and ill-fed, they fall an easy, unresisting prey to epidemic disease.

But it would scarcely be just that all our sympathies should go with the people of India as sufferers for the faith they possess, if I failed to remark that more worldly objects than those noticed are equally cogent to compel long and dangerous journeys. The great fair of Biginugger (more commonly called Humpi) collects annually thousands of native traders, and, like that of Hurdwar, at the issue of the Ganges from the Himalayas, is equally with Conjeveram and Ramieseweram a source of injury to public health; and from these centres cholera almost always accompanies the homeward-bound trader. Serious, however, and lamentable as are the results of festivals and pilgrimages to those who are personally concerned in them, there are other and far more important consequences likely to follow them. The gradual dispersion of the religionists, while it is favourable to their own freedom from the eventually depressing effects of the assemblies in which they have taken part, is also, unfortunately, the immediate means of propagating disease if it has seized them. The villages in their route are visited, and, as free intercourse with the villagers, and easy access to the crowded and unhealthy bazaars, are inevitable and eannot be controlled, the extension of disease results.

Hence the public thoroughfares beeome dangerous, and troops or private travellers are exposed to risk. We have but to recall the numberless instances of cholera imported into moving camps, or attacking private individuals, to recognise the facility with which passers-by are soon found to succumb under this eontagion. In both instances supplies have to be obtained from villagers, and even the slight amount of intercourse thus arising may implicate the safety of those *en route*.

But in addition to this explanation of seizures of cholera among troops, and independent of the predisposing causes which travelling itself originates, it is no fancied conclusion to infer that if troops pass near, or rest upon, tainted encamping ground, they may become the victims of disease. Of this latter point a sad proof was given within the limits of the Madras Presidency, or, at least, as affecting some of its troops. On the breaking up of the Saugor division in 1860, many of the regiments, returning to their own stations, crossed the route of the pilgrims who had gone to, and returned from, the Island of Ramieseweram, and in numerous instances they were attacked with cholera. This was no rare eoincidence, but occurred with such precision that it must be deemed a natural effect of an undoubted cause.

Again, in the previous year, Inspector-General Macpherson records, a detachment of 74th Highlanders were attacked with cholera from passing within 100 yards of the camp of the 35th Regiment M.N.I. when suffering under an epidemic of that disease.

The former gallant regiment were brought down to Madras to embark for England in 1864, and being most improperly encamped on ground defiled by previous occupation for weeks of 76th Foot, were attacked with cholera, and a good number of deaths ensued. Now in the latter instance the first occupants of the encamping ground had not suffered from this disease.

In all these instances the troops were in high health—those from Central India had passed through a glorious campaign. They had won a large amount of booty, but had not an opportunity of spreading it, and they were under the Professional charge of Medical officers of experience, thoroughly competent to adopt any possible measure to guard the lives and health of the men in their charge. Nothing that skill could do or money could ensure was left undone, and yet they fell victims to an atmosphere, and probably camping grounds, tainted by religious pilgrims. The case of the 74th at Madras was a proof of the innate power of malaria to generate epidemic disease, and in this instance the disease was brought from the camp (six miles distant from Madras), and it rapidly took root, and spread in a densely-populated portion of the city, remarkable for its want of ventilation and conservancy. Analogous to the experience of the detachment of 74th Highlanders, who contracted cholera near Bellary from an affected camp, by which it passed but where it did not halt, was that of a wing of the 43rd Regiment of Europeans, who, passing through a village near Palmanair—one of a number of small native villages skirting the frontier border of the Mysore table-land, and some 2000 feet above the level of the sea—were seized with cholera and brought into Madras dying by scores, some of whose dead bodies lay among the living for miles of their miserable railway journey. If it were necessary to multiply proofs of the ill effects of native encampments and of native habits of travelling, I could easily from my own experience show that there is no more fruitful source of epidemic disease than is here to be found.

The city of Madras abounds in cart-stands, where native travellers' vehicles are encamped—places uncared for apparently by any one, and they are for the whole year round the nuclei of epidemic disease. The large up-country railway stations—as, for example, Coimbatore and Salem—are found to prove perfect nests of cholera, the virulence of which is maintained by an almost total absence of conservancy.

No language that I could use would be too strong to deprecate the wanton risk to human life which is needlessly allowed to cause such dire results; and no exertions should be spared to save the life and protect the health of the general population of India from influences the evil effects of which are, to a degree, inevitable. A review of the observations I have made will point out some remedial measures of importance, and the good effect of which is not merely hypothetical. I think I shall be in a position to prove that very simple measures may suffice to ward off much of the danger now threatening pilgrims and those who attend religious festivals, and that if attention is once directed to the subject, it may be possible, by timely warning, to enable the commanding and Medical officers of troops on the mareh to guard their men against the injuries of contagion.

We shall first consider, then, the steps to be adopted at the festival itself. Here, in accordance with the rest of this paper, I will confine myself within topics of which I am personally cognisant.

I have before spoken of the Grand Feast of Conjeveram, and of the injurious results so often consequent on it. These were brought to my notice personally (not officially) about a week before the feast of 1864 by a most intelligent Medical subordinate, since appointed a sub-Assistant-Surgeon. Mr. Kinsley solicited that the matter might be submitted to the Sanitary Commission, but time did not allow that it could be considered by them in regular routine in sufficient time to promote the necessary action before the commencement of the festival. The Hon. Mr. Ellis, the President of the Commission, however, took immediate steps in the matter, and by his active exertions, and in consequence of urgent letters written by me to officials, we were able to accomplish something.

Cattle were as far as possible removed from the strict limits of the town. Public places of convenience were erected, and their contents removed twice a-day. The main streets were swept and watered, and supplies of good water were made available near places of public resort for the use of the native visitors.

As regards the result of these measures, I prefer to quote from an official report kindly furnished to me by Captain Cloete, Superintendent of Police, who was present during the festival, and who had the most ample means of information at his disposal. He says:—

"In 1862 and 1863, at this festival the effluvia arising from the hedges and ditches on the side of the main street was so offensive as to make it quite sickening to walk in the streets in the morning. In 1864 I walked from Kisna Cunchi to Siva Cunchi, a distance of about two miles, at daylight, and experienced no more disagreeable smell than is to be experienced in the bazaar on ordinary occasions. The contrast to the previous years was most marked. In 1862 and 1863 human excrement was to be seen in the main streets at every step; this year I saw none at all. Not one case of cholera occurred during the festival; but it seldom or ever happens that cholera does not break out either in Conjeveram itself or among the people returning from the festival, or in Madras after this feast. I have not heard of one case in which the seeds of the disease are traceable have been sown in Conjeveram. It, and the adjacent villages have been singularly free of cholera since the festival, and, to the best of my belief, Madras has been unusually so."

In this conviction Captain Cloete was perfectly correct, and, humanly speaking, Madras was spared from an epidemic by the very simple and inexpensive arrangements proposed by the President of the Madras Sanitary Commission, and acted upon by Mr. Kinsley and the Tasildhar of Conjeveram, who were, by Mr. Ellis's exertions and authority, supplied with funds and the requisite carts and scavengers. Here I may note that, of the particular caste or race of people who alone will sweep the roads and remove human excrement, not one is to be found in Conjeveram, and we had to send them from Madras, a distance of forty-five miles.

One of the natural consequences of this utter absence of the sweeper caste (analogous to scavengers in London) is, that accumulations of rubbish, house refuse, and excreta remain piled in the yards attached to the private houses, even of the wealthier classes. Thus, although I have spoken of this town as being in some respects favourably circumstanced, as compared to other Indian towns, it must be held as requiring—eminently on account of the access to it annually of such a multitude of people—those improvements in conservancy which can alone be relied on as likely to conduce to an improved sanitary condition. Mr. Kinsley, to whom I have before alluded, furnished a very interesting account of the measures adopted during the festival, and thus concludes his report:—

"In concluding these brief remarks, it may be mentioned that during the ten days of the festival the town remained free of cholera, and no cases occurred during the year. The whole of Southern India, it is true, remained singularly exempted from the epidemic during the past year, but this fact cannot be made to detract from the ability and efficiency of the sanitary measures put into force at Conjeveram, during the annual festival, for it is doubtful whether many of the towns were placed under the same favourable circumstances for starting an epidemic, as this usually is, during the May festival—and it is impossible now to speculate as to what the results would have been on the dense masses congregated here, had these measures been neglected. Tradition testifies to the fact that ever since cholera was first known in India it has never failed to make havoc amongst the Hindoo population present here during the grand festival of May. So notoriously was this the case that, it is said, people from distant places, before starting out to come here for the feast, always took a more than usually solemn leave of their friends in anticipation of their never returning; and the result justified these anticipations in hundreds of cases."

Similar precautions were adopted in 1865, and with an equally favourable result, although the year was notoriously unhealthy. But I need scarcely say that what happened so often before, and is so likely to happen again, should be prevented, if prevention be possible.

I have endeavoured to demonstrate that, from various causes, pilgrims and the visitors to native festivals and fairs are especially liable to suffer from epidemic disease, and that with a full knowledge of the frequent fatality attending these journeys they still undertake them, and will doubtless continue to do so until their idolatry has been eradicated.

It is also undoubtedly necessary that native and European troops must, for many years, continue to traverse the country on change of station, or for political exigencies or the purposes of war, and that during their march they are liable to be the victims of disease, either directly acquired from tainted encamping grounds or from contact with infected villagers; and no exertion should be spared to save them from the risk of a disease often more deadly than the most gallant enemy. It is equally plain that, although in 1864 and 1865 the simple means adopted at Conjeveram were followed by a most gratifying condition of public health, yet something more is required. We must devise some means to protect the religionist on his journey, more especially on his return home, and prevent those bands of pilgrims or traders from carrying with them the seeds of disease along the public thoroughfares.

To do this is hopeless, unless two conditions are fulfilled. 1stly, the careful conservancy of the places of chief resort; and, 2nd, a careful supervision of the travellers *en route*.

I have shown that they go from one end to the other of the presidency of Madras, and that they pass by, and frequently touch at some of the important stations for European troops, and where an European population is gradually springing up in the civilians' lines; and to any of these they may bring disease.

At present, sanitation in India is more a theory than a science, and, like most other theories, has few supporters, and many most serious opponents, even among the classes whom education and experience should render the most capable to appreciate hygiene, its teachings and its object. We have to combat the prejudices of a people with whom the habits of the past are accepted as the precepts for the present, who resent innovation with open hostility, or impede it with passive opposition, and who are naturally utterly devoid of habits of cleanliness or—I may almost add—of decency; who will, if allowed, resort to the public thoroughfares for the purposes of nature, and who will construct cloacæ under the rooms where they live and cook by day and sleep by night. A people they are who are listless and wanting in energy to shake off disease, and who are especially liable to all the nervous influences that render disease fatal. Can we wonder, then, that disease stalks through the land, and hurries thousands to the grave annually, and that their pilgrimages, intended by them as passports to eternity, frequently prove so, though, perhaps, in a more material manner than they anticipated, or wished for?

I think not; nor can we, seeing how others suffer, and how our army may be paralysed and the best interests of our rule in India be perilled, any longer leave this matter to be simply a topic of inquiry and report, rather than the subject of active interference.

The Commission to which I belong has not been inactive in this matter, and has promulgated a scheme which would do all that is needful, and almost all that is possible, at a cost absurdly small as compared with the advantages hoped to be attained. Under the provisions of it, officers of public health would be appointed at all military stations and civil towns. Conservancy establishments would be instituted, and regular statistics of births and deaths collected. The importance of these as indications of the condition of public health among the urban and rural population cannot be overstated. Among the more prominent officials of the scheme would be officers of experience, who would be the media of transmission of the district returns, and whose attention would be by them directed to any place, whether a village or an encamping ground, or a public road, where epidemic disease might be present, and advice regarding, or caution against, access to such places would be afforded to travellers or bodies of troops.

In case of disease prevalent on trunk-roads, the rules advocated by the late Commander-in-Chief, in India, Sir Hugh Rose, should be observed; and when bodies of travellers are attacked with disease, they should alter their course, and travel at right angles to the prevailing winds.

The conservancy of native towns would be directly supervised by the local health officer, and intimation of disease among travellers would be systematically conveyed to this officer by his immediate superior. The latter officer should, in my opinion, be authorised to direct the route of all bodies of people traversing his district; and he should similarly,

in concert with the military authorities, suggest the route to be observed by troops of all kinds.

The conservancy of encamping grounds well situated, protected from undue exposure either to sun or water, should be promoted, and sites, well removed from public thoroughfares, should be established for cholera and fever camps, not only along the general line of the high roads of traffic, but within moderate distance of the more important towns.

An analysis of the drinking water of all wells and tanks likely to be resorted to by pilgrims, or troops, should be made, and the necessary instructions given to prevent the defilement of these by cattle.

Public health officers should also, I think, be authorised to enforce the observance by pilgrims of those rules regarding encamping which experience shows to be salutary. The separation of carts occupied as means of carriage by day and sleeping places at night, the removal to a distance of all cattle employed by travellers, and the construction of sewage pits close to, but to leeward of, all encampments.

The expenses attendant on these arrangements need not be great, and could be in many cases defrayed by the travellers themselves.

Public health officers should, I am of opinion, be authorised, through their establishment, to enforce the periodical washing of all carts used by traveller, and the cleanliness of the clothing of all persons component parts of such large assemblies of people.

They should also be empowered to cause the division, into two or more sections, of parties so numerous as to be likely to have disease engendered among them, for the proclivity to disease of bodies of men is now conclusively shown to be in the direct ratio of these numbers.

Care should be taken that ground once used for encampment should not be again so employed until it has been exposed to the full action of one monsoon, and ground formerly the scene of epidemic disease should be as far as possible thereafter avoided.

I believe that by the adoption of some such measures as these, and by these alone, can the origination and propagation of epidemic diseases be prevented; and I bring the matter to the notice of this Society in the hope that the experience of some of those present may be able to suggest other and more efficient means of protecting public health.

For any such suggestions, I may add, I shall myself feel grateful, and it is of importance to me, as in some degree representing, however humbly, a new department in the organisation of the Madras Executive, that all the expedients that science can suggest, or experience can prove the value of, should be freely discussed by us this evening.

I confess that I, for one, do not shrink from the task of making the attempt to check disease, if I can only commence the task with a full conviction that the principles of action are well founded, and likely to conduce to a favourable result.

In India we are lamentably behind the age in sanitation. In this, as in everything, we can only follow England; but we look to the example of such societies as this to teach us, and I think I may promise that we will endeavour to be willing and patient students.

Our object is, at all events, a noble one. We hope to gain increased security—or, to speak more suitably, less risk to human life—and in this one common aspiration of humanity we are prepared for some failure, much discouragement, and opposition, but the pain of these will be well endured if they eventuate in time in the ensurement of success.

THE PATHOLOGICAL SOCIETY.

TUESDAY, DECEMBER 19.

DR. PEACOCK, President.

(Continued from page 78.)

Mr. HUTCHINSON exhibited a specimen of

DWARFING OF THE RADIUS AND ULNA AFTER INJURY TO THE CARPAL EPIPHYSIS OF THE RADIUS.

It had been removed from an adult woman who had died in consequence of an accident about twenty years after the injury to her wrist. She stated that she had dislocated her wrist at about the age of eight. The whole forearm and hand were smaller than those of the opposite limb, but the chief dwarfing was that of the radius itself. This bone was a full inch shorter than the ulna, and the carpus was drawn upwards, so that the semilunar and cuneiform bones were in apposition with the radial border of the ulna. There was considerable distortion during life, the styloid process of the ulna projecting. The radius was very small in all its proportions, and just in front of its carpal extremity there was a remarkable hollow. Its carpal end was very short. The head of the radius showed one side bevelled off. Mr. Hutchinson suggested that probably the original injury had been only to the carpal extremity, and that the condition last mentioned was probably secondary and due to attrition. The history which the woman gave of an accident in childhood made it probable that detachment of the carpal epiphysis had been the injury to which the dwarfing was due.

Mr. HUTCHINSON also showed a

CAST OF A COMPLETE DISLOCATION AT THE KNEE-JOINT.

The tibia was thrown forwards in front of the femur, and there was three-quarters of inch of shortening. (This case has already been mentioned in the *Medical Times and Gazette* for December 9, 1865, page 629.)

Mr. HOLMES did not recognise in the radius the characters of separation of the epiphysis. The injury to the bone appeared to him to be above that position, and suggested rather the idea of fracture. It reminded him, indeed, of one of Mr. Curling's cases of fracture through the medullary canal, which he believed might, perhaps, lead to shortening of the bone.

To Mr. WM. ADAMS' mind the idea suggested by the specimen was rather that of congenital dislocation of the head of the radius. This part alone of the bone seemed abnormal.

Mr. CALLENDER remarked that there were very few well authenticated cases as yet bearing upon the question of the effect of separation of the epiphysis upon the growth of bone. It would be very desirable to have a further examination.

Mr. HEATH said it had been discussed both in America and in Paris whether in injuries to the forearm in children, in which the hand was forced back and impairment of growth followed, the seat of the mischief was the lower or upper end of the bone. The majority seemed to incline to the latter. The present specimen was, therefore, of the greater interest.

Mr. HUTCHINSON willingly accepted the Committee, but could not expect much light to be thrown upon the nature of the injury after the lapse of twenty years. The elbow joint was perfect and in perfect use. There was no malformation of humerus. The apparent wearing away of the head of the radius was not seen till after dissection. He only inferred the separation of the epiphysis from the history and its known effect in arresting growth of bones.

Mr. Callender and Mr. Wm. Adams were appointed a Committee.

Mr. NUNN exhibited drawings

ILLUSTRATIVE OF THE PROCESS OF SYPHILISATION.

Fig. 1 showed the results of a series of inoculations with pus from the chancre of a patient with an indolent bubo in a case of constitutional syphilis in its earliest stage, the patient having taken no mercury, nor having been submitted to any other treatment. The sores produced by the artificial inoculation diminished progressively in size, from that of a threepenny piece to that of a millet seed. Fig. 2 was taken from a complicated case, the patient having been treated in April last for constitutional symptoms with mercurials; the constitutional symptoms had returned. The results of the artificial inoculation were all but negative, very small vesico-pustules only being produced, with some surrounding redness. Simultaneously with the inoculation, the ointment of protoiodide of mercury was being applied to some painful sores about the anus. The sores healed, and the pustules produced by the inoculations also scabbed over, leaving but, as was shown in the drawing, only the slightest indications of their situation. The date of the inoculation in the first-named case was November 15, of the second, November 17; the date at which the drawings were made, December 4. Mr. Nunn stated that he brought the drawings forward with a view of possibly removing prejudices that, he believed, did exist with regard to the process of syphilisation,—prejudices which he thought might prevent a just appreciation of the merits of the system. He abstained from expressing any opinion on the merits of syphilisation, as he did not consider the place fitting,—investigations, as was well known, being still carried on, the results of which would in due time be placed before the Profession. The drawings showed that the local effects of the artificial inoculation on the plan of Professor Boëck (to whose kindness Mr. Nunn

wished to say he owed much) were not severe nor especially repulsive.

Mr. Nunn next showed drawings of two cases of

CONTRACTING CANCER OF THE FEMALE BREAST.

Mr. Nunn said that practically cancers of the breast might be arranged into two classes, the one comprising cancers that, inflaming, sloughed, the other, cancers that, atrophying, contracted. In giving a prognosis in cases of cancer of the breast, according to some statistics, one might on the average say that a cancer left alone would end fatally within a little less than three years, that a cancer operated on would not end fatally until a little more than four years had passed. The drawings shown were taken in 1862 from two patients of the Middlesex Hospital. *Case* 1.—E. T., admitted in 1859 with contracting cancer involving the nipple and region of the areola. The disease had commenced in 1850, and the patient did not die until June, 1864. *Case* 2.—E. H., admitted June, 1862, with contracting cancer of the lower lobes of the right breast. The disease commenced 1861. The patient died June, 1865, with acute effusion into the right pleural cavity and with secondary deposits in the lung. The disease in the breast gave but little inconvenience, and the death of the patient might almost be said to be not due to the cancer, although doubtless the existence of the cancerous "*boutons*" on the pleural surface of the lung determined the occurrence of the pleuritis.

Dr. Ogle exhibited three specimens of

TÆNIA REMOVED BY MALE FERN.

One of the worms was the tænia canellata, and its head had become decolourised by the spirit.

Dr. Ogle also showed a portion of the

ARACHNOID CONTAINING CYSTS,

from each hemisphere of a lunatic who had been under the care of Dr. Boyd. The lunatic was 49 years of age, and epileptic. The membrane was thickened and contained cysts full of a fluid like that found in the cysts of the choroid plexus. This condition was considered by Dr. Ogle to be a rare one. Dr. Ogle had not had time to examine this specimen minutely, but had rather expected to find that the cysts were formed from dilatation of veins in which calcareous matter had been deposited of the nature of phlebolithes.

Dr. Ogle showed also

DRESSINGS FROM WOUNDS OF A DROPSICAL LEG.

A middle-aged woman suffered from Bright's disease, and ulcers of considerable size formed on the legs, from which the escape of fluid greatly relieved the dropsy. Three weeks before death, however, this fluid began to produce a stain of a beautiful carmine colour, indelible by washing; and this continued for several days. The colour suggested a production of murexid, from changed urate of ammonia; but the chemical tests did not quite accord with this view. Dr. Ogle had been able to hear of two similar cases only—one was related to him by one of the nurses of St. George's Hospital, the other by Dr. Hawksley. Dr. Bence Jones had told Dr. Ogle that he had seen traces of a similar colour in the sweat from the forehead and axillæ in one case.

At a previous meeting, Mr. Ernest Hart showed the parts involved in an

ENCEPHALOID TUMOUR OF THE ORBIT.

The chief interest in this preparation lay in the considerable increase in length of the optic nerve, associated with the downward pressure of the eyeball, and its expulsion from the cavity of the orbit. There was no derangement of the visual power until a day or two before death, when the cornea became affected by exposure to the air. There was actual growth of the nerve. The tumour had been painless. Cancer was here coincident with scrofulosis, and the apparent symptoms of scrofulosis had attracted the attention of the Surgeon long before there was any reason to suspect that a cancerous tumour was developing itself. The patient was under the care of Mr. J. B. Walker, of Clifton-gardens, with whom Mr. Hart had seen the patient during life, and to whom he owed the opportunity of making the post-mortem examination. Mr. Hart gave further details of a second case of cancer of the eyeball, which contrasted with this instructively. When the child, a patient of Dr. Fyfe, of Brompton, was first seen, a small tumour was detected by the ophthalmoscope springing from the edges of the optic disc; but as the history was one of sudden loss of sight from a blow, the parents refused to allow the eyeball to be excised, and another Surgeon undertook to cure it by leeching and mercury. Subsequently the tumour grew; excision was performed when no longer useful; the pain became almost immediately afterwards intense; and the patient died. In addition to the clinical interest of the contrasted histories, Mr. Hart called attention to the different histological characters of the two tumours. Both were pathologically classed as encephaloid; but the encephaloid in the one case springing from the nerve tissue displayed an abundant cell growth, which might be expected; while in the first-named case, which sprang from the dura mater, there was but little of the characteristic cellular element, and an abundance of old fibres and small non-nucleated granules.

MEDICAL NEWS.

Royal College of Surgeons of England.—The following gentlemen, having undergone the necessary examinations for the diploma, were admitted Members of the College, at a meeting of the Court of Examiners on the 23rd inst.:—

Ridgway Robert Syers Christian Codner Lloyd, Bury St. Edmunds, Jas. Haslam, Reading, Berks, George John Muriel, Ely, Algernon Ewen, L.S.A., Long Sutton, and Frederic Edward Manby, L.S.A., East Rudham, Norfolk, students of Guy's Hospital; Frederic Evans Chambers, Camdentown, Charles Thomas Ennals, St. Neots, and Henry Lissmore Shaw, South Mimms, of the Middlesex Hospital; John Waller Melson, B.A. Univ. of Lond., and L.S.A. Birmingham, and Edward Bousfield, Mansfield, Notts, of the Birmingham School; John Lea Molyneux, Wigan, and John Wickham Legg, L.S.A., Alverstoke, Hants, of University College; Frederick Earle, Edgeware, Middlesex, and Napoleon Bisdee Major, L.S.A., Hungerford, of St. Mary's Hospital; Herbert Wood, L.S.A., Ashton-under-Lyne, of the Manchester School; Edward Horne, L.S.A., Isleworth, of the Charing-cross Hospital; Antonio Lorenzo Chiappini, M.D. Edin., Cape of Good Hope, of King's College; George Edgelow, Kensington-square, of St. George's Hospital; and William Henry Plaister, Bristol.

The following gentlemen were admitted members on the 24th inst.:—

John Henry Simpson, Fore-street, William Henry Ellis, Willingham Cambs, Arthur Jackson, Sheffield, George Christopher Tayler, Trowbridge, John Chamberlin Eaton, Ancaster, and William Alexander Slater Royds, Bedford, students of St. Bartholomew's Hospital; Thomas Percival, Geo. Ackroyd, John Bywater Ward, and William John Mountain, all of Leeds, Henry Cecil Smith Bayswater, William Evatt Wright, L.S.A., Brixton, and Frederick Everard Hunt, Shortlands, Kent, of Guy's Hospital; Richard Hewetson, Bayswater, and Paris Bradshawe, of King's College; John Lawrence, Clifton, and Arthur John Farr, Newport, Monmouthshire, of the Bristol School; William Nolan, M.B. Trin. Coll. Dub., Athbay, Frederick John Wadd, M.B. Univ. of Aberd., Kilburn, of St. Thomas' Hospital; Herbert Ridley, Newcastle, Joseph McCarogher McWilliams, Omagh, and James Inglis Ransford, Sydenham, St. George's Hospital.

Apothecaries' Hall.—Name of the gentleman who passed his Examination in the Science and Practice of Medicine, and received a Certificate to Practise, on Thursday, January 18, 1866:—

Benjamin Chaston Gowing, Lowestoft.

APPOINTMENTS.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

Anderson, Alexander D. M.D., Edin., has been nominated a Director of the Glasgow Royal Lunatic Asylum.

Barlow, Mr. J., has been elected Dispenser to the Salop Infirmary.

Canton, Alfred G., M.R.C.S. Eng., has been appointed Assistant-Dental-Surgeon to the Dental Hospital of London, Soho-square.

Clarke, Joseph, L.K.Q.C.P.I., has been appointed Surgeon to the Constabulary, Bacheborough, Co. Cavan.

Fussell, Edward F., M.B., M.R.C.P. Lond., has been appointed Physician to the Brighton Dispensary.

Hoffmeister, William, M.D, has been elected one of the Surgeons to the Cowes Dispensary.

Hopkinson, W. L., M.D., has been appointed Consulting Physician to the Stamford and Rutland Infirmary.

Lyon, William, M.D. Glasg., has been nominated a Director of the Glasgow Royal Lunatic Asylum.

Newman, William, M.D. Lond., has been appointed Surgeon to the Stamford and Rutland Infirmary.

Oxley, C. F., L.R.C.P. Edin., has been appointed Resident House Physician to the Westminster Hospital.

Pagan, John, M.D. Edin., has been re-elected a Director of the Glasgow Royal Lunatic Asylum.

Redwood, T. H., L.R.C.P. Lond., has been appointed Senior Assistant-Surgeon to the Rhymney Iron Works, Monmouthshire.

Roberts, Frederick T., M.B. Lond., has been appointed Lecturer on Comparative Anatomy and Zoology at the Liverpool Royal Infirmary School of Medicine.

Shore, O. Bohun, M.D. Edin., has been appointed Physician to the Stamford and Rutland Infirmary.

Winterbotham, W. L., M.B., to be Assistant-Surgeon Second Administrative Battalion Somersetshire Rifle Volunteers.

BIRTHS.

BETHUNE.—On January 5, Mansion House-road, Grange, Edinburgh, the wife of N. Bethune, M.D., of a daughter.

BROWN.—On January 18, at Eastwood, Notts, the wife of Edward A. Brown, M.D., of a daughter.

CAMPBELL.—On January 14, at 104, Lansdowne-road, Kensington-park, W., the wife of Dr. A. Campbell, late of Darjeeling, of a daughter.

DUNCAN.—On January 22, at 83, Gower-street, the wife of Dr. A. Duncan, of a son.

FREEMAN.—On January 18, at Bracknell Lodge, Hartley-row, Hants, the wife of Thomas A. Freeman, M.R.C.S. Eng., of a son.

HACKETT.—On December 17, at Berbice, British Guiana, the wife of J. S. Hackett, M.D., of a son.

MARSHALL.—On January 23, at Mitcham, Surrey, the wife of Edward Marshall, M.R.C.S. Eng., of a daughter.

SMITH.—On December 14, at Ootacamund, Madras, the wife of Colvin Smith, M.D., of a son.

SOPER.—On January 13, at Stockwell, the wife of William Soper, M.R.C.S. Eng., of a daughter.

TUKE.—On January 10, at Charlotte-square, Edinburgh, the wife of J. B. Tuke, M.D., of a son.

WAGGETT.—On January 18, at 4, Stanley-terrace, Kensington-park-gardens, the wife of Dr. Waggett, of a son.

WATSON.—On January 11, at Calder-bank, Midcalder, the wife of W. Watson, M.D., of a son.

MARRIAGES.

BELL—SPARKES.—On January 22, at Christchurch, Clapham, James V. Bell, M.D., F.R.C.S., to Susannah Charlotte, youngest daughter of the late E. M. Sparkes, Esq.

WATSON—MAIR.—On January 23, at St. George's, Bloomsbury, W. Spencer Watson, F.R.C.S. Eng., to Georgiana Mary Jane, eldest daughter of G. J. J. Mair, Esq.

DEATHS.

BAILEY, WILLIAM, at Gurtadda House, Co. Limerick, on December 31, formerly Surgeon, R.N.

CHAILLY, HONORE M., one of the most celebrated of the Paris accoucheurs and author of the best Obstetrical Manual, has just died after a prolonged illness.

CLARKSON, EBENEZER, M.D. Edin., at Selkirk, N.B., on January 9.

DALGAIRNS, Dr. WILLIAM, late of the Bombay Army, at Woodcot, Dollar, on January 18, aged 70.

DUNNE, JAMES R., F.R.C.S.I., of Moymore, Co. Clare, at Mountjoy-square, Dublin, on January 4.

HALL, Sir JOHN, M.D., K.C.B., Inspector-General of Hospitals, at Pisa, Italy, on January 17, aged 72.

MACINTYRE, PETER, M.D. Edin., at 56, Canning-street, Liverpool, on January 19, aged 69.

WRIGHT, GEORGE E., M.D. Edin., R.N., at Sierra Leone, on December 24, aged 24, Assistant-Surgeon H.M.S. *Rattlesnake*.

POOR-LAW MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the last census.

RESIGNATIONS.

Chesterfield Union.—The Bolsover District is vacant; area 10,366; population 2402; salary £20 per annum.

Dewsbury Union.—Mr. Thompson Whalley has resigned the Mirfield District; area 3548; population 9263; salary £30 per annum.

Haslingden Union.—The Edenfield District is vacant; area 5259; population 4723; salary £12 10s. per annum.

Leominster Union.—Dr. J. Davies has resigned the office of Medical Officer for the First District; area 36,641; population 10,740 and the Workhouse; salary £200 per annum.

Neath Union.—Mr. James French has resigned the First Central District; population 12,935; salary £65 per annum. Also the Workhouse; salary £30 per annum.

Stoke-upon-Trent Parish.—Mr. Goddard has resigned the Lougton District; area 1369; population 16,742; salary £35 per annum.

Watford Union.—Mr. Henry Lewis has resigned the Rickmansworth District; salary £35 per annum.

Witney Union.—The Eynsham District is vacant; area 16,618; population 5237; salary £113 per annum.

APPOINTMENTS.

Blandford Union.—Edward Monro Spooner, M.R.C.S.E., L.S.A., to the Second District and the Workhouse.

Worksop Union.—William Latimer, M.R.C.S. Edin., to the Auston District.

WE are happy to learn that Mr. Henry Thompson has been appointed "Surgeon Extraordinary" to His Majesty Leopold II., the King of the Belgians.

MR. CHARLES SHARP, Librarian and Assistant-Secretary of the Pharmaceutical Society, and co-editor of the "Year Book of Pharmacy," has been elected Secretary of the Liverpool Institute and of Queen's College, Liverpool, in the room of Mr. Astrup Cariss.

THE MIDDLESEX HOSPITAL.—The munificent sum of £20,000 was presented yesterday to the above institution, through the hands of Mr. Michael Smith, the Chairman of the Weekly Board, who stated that it came from an anonymous donor.

EPSOM COLLEGE.—It will be seen from a letter from the indefatigable founder of the Epsom College, which we publish in another column, that Sir William Fergusson has consented to preside at the next anniversary dinner of the College. We hope a very large attendance of Medical men will bear witness to the estimation in which the first Medical charity is held, and to show respect to the great Surgeon whom Her Majesty has so recently singled out for honour.

CHOLERA IN PARIS.—From the final report of the sanitary department of the Préfecture de Police, it appears that the total number of deaths from the recent epidemic amounted to 6383.

ACADEMIE DES SCIENCES.—M. Charles Robin has just been elected a Member of the Section of Anatomy and Zoology, receiving 34 votes, M. Lacaze-Duthiers, the rival candidate, receiving 21.

FISKE FUND PRIZE QUESTIONS.—The trustees of the Fiske Fund announce as the subjects for the Prizes for 1866: 1. "Vaccination: why does it ever fail to give perfect protection?" 2. "Pyæmia: its causes, pathology, and treatment." For the best dissertations on either subject 100 dollars will be given. The dissertations to be forwarded with mottoes free of expense before May 1, 1866, to Dr. Arnold, Secretary of the Trustees, Providence, U.S.

SPURIOUS VACCINE.—An anonymous correspondent of the *Times* states that a mixture of collodion with croton oil or tartar emetic is being manufactured for supply to the agriculturists as vaccine lymph.

DEATH OF SIR JOHN HALL.—Sir John Hall, M.D., K.C.B., Inspector-General of Hospitals, died at Pisa, Italy, on January 17, aged 72. Sir John Hall served the campaign of 1815 in Flanders; served the campaign of 1847 in Kaffraria, as head of the Medical Department under Sir George Berkeley, and was thanked in general orders (medal). In 1858 he accompanied Sir Harry Smith across the Orange River, as principal Medical officer of the force employed against the emigrant Boers; was present at the battle of Boem Plaatz, and specially mentioned in Sir Harry's despatch for services on the field, and subsequently thanked in general orders. Was principal Medical officer of the army in Kaffraria, under Sir Harry Smith, during the campaign of 1851, and thanked in general orders on his being ordered to India. Served as principal Medical officer of the Eastern Army from June 18, 1854, to July 5, 1856, without being absent from duty for a single day; was present at the affairs of Bulganac and Mackenzie's Farm, battles of Alma (mentioned in dispatches), Balaklava, Inkerman, and Tchernaya, capture of Balaklava, siege and fall of Sebastopol, taking of the Rifle Pits and Quarries, assault of the Redan on June 18 (medal with four clasps, K.C.B., officer of the Legion of Honour, third class of the Medjidie, and Turkish medal).

DEATH FROM CHLOROFORM.—A patient died last week at St. Mary's Hospital from the inhalation of chloroform. As so often happens, the operation for which chloroform was given was comparatively a slight one—the removal of an ingrowing toenail. It was proved that the Surgeon who administered the chloroform had had ample experience in the operation, having given it in above 400 cases. Nevertheless, the jury wished to add a sentence to their verdict, to the effect that chloroform should only be administered by the senior members of Hospital staffs. But Dr. Lankester interposed by saying that it would be difficult to obtain a gentleman of greater experience in the administration of chloroform than the Surgeon who had given it in this case. Unfortunately it was not quite clear that the patient's consent to the anæsthetic had been obtained before its administration.

A CAUTION.—At the Thames Police-court on January 18, Mr. Healey, a Medical Practitioner, of No. 2, Devon's-road, Bromley, applied to Mr. Partridge under the following circumstances:—The applicant said a few days since a lady and gentleman, who gave the name of English, entered his house in a state of great alarm. The woman had just been taken in labour, and they craved his assistance. The lady was put to bed, and in a short time she gave birth to a female child. She remained in his house for a week. Last Saturday the lady went out for the first time since her accouchement, and said she was going to Bow to make some purchases. She had never returned, and the child had been left with him. He had received only 10s. for his Professional attendance, and 5s. for a week's rent. He had been to the relieving officer at Bow, and he had directed him to come to this court. He had no

idea who the mother and father of the child were. Mr. Partridge said he could not interfere in the case at all. The maintenance of the child must fall on the parish where it was born. If a full description of the parties was given to the relieving officer, it was very probable they would be traced and punished. He would advise Mr. Healey to be very careful how he acted in relation to strange ladies calling at his house in future.

Discovery of Stone Coffins.—Several weeks ago some human bones were found in a sandhill about a mile from Torphichen, Linlithgowshire. On Saturday last the hill was examined by Professor Duns, New College, Edinburgh, Mr. J. R. Martin, of Bridge-house, and a couple of workmen. A partial examination showed that many cists are probably contained in the mound. One had very recently been exposed in the course of carting away sand for building purposes. Another was opened on Saturday, and found to contain a human skeleton. Dr. Duns took possession of the skull found in each. The character of the crania gives the chief interest to the discovery. They have evidently belonged to full grown individuals; yet both are comparatively small. The bones of the eyebrows are largely developed, and those of the forehead sharply recede. The cists had been placed at the depth of about two and a-half feet from the surface. The bodies must have had the legs bent up at the knees, as in both cases the bones of the feet were found near those of the hands, lying beneath the thigh bones. The sandhill in which these cists were discovered is about 100 yards from one of the stones which mark the boundary of the ancient "refuge" connected with the "commandery" of the Knights of St. John at Torphichen.—*Scotsman.*

Vaccine Virus from France and Italy.—Dr. Brent, of Woodbury, Devonshire, believing that vaccination would be of benefit in arresting the progress of the cattle plague, during the past month had various animals in his herd vaccinated with the ordinary lymph from the human species, and in every instance it failed. He thereupon addressed a letter to the Vaccine Establishment in London, requesting a fresh supply of the vaccine matter for the purpose, and received as answer the intimation that the quantity of lymph for disposal was "barely sufficient to answer all demands for the legitimate purposes of the establishment." Dr. Brent, therefore, applied to her Majesty's Minister for Foreign Affairs, and suggested that in Italy the cattle are periodically vaccinated, and that it would be an easy and simple way of getting it through his department. The reply was as follows:—

"Foreign Office, January 13.

"Sir,—I am directed by the Earl of Clarendon to acknowledge the receipt of your letter of the 8th inst. on the question of vaccination as applicable to the cattle disease, and requesting that steps might be taken with the object of procuring from Italy a supply of pure vaccine matter for further experiments in the vaccination of cattle in this country.

"I am to state to you that Lord Clarendon considered it desirable to communicate on this subject with the Council Office, and that his Lordship has received a letter from that department, stating that the Lord President of the Council attaches great importance to this subject and to the expediency of further experiments in the vaccination of cattle being carried out in this country, and, in accordance with the President's suggestion, her Majesty's representative at Paris as well as at Florence has been instructed to endeavour to obtain a supply of pure vaccine matter for such experiments.

"I am, Sir, your most obedient humble servant,

"G. Hammond.

"R. Brent, Esq., M.D, Woodbury, near Exeter."

The excellent ladies who superintend the *Mater Misericordiæ* Hospital, Dublin, have started the scheme of a monster lottery for the benefit of the institution. The tickets are so low—viz., sixpence each—that none of our readers ought to resist the temptation, more especially our younger readers; for the fortunate possessors of the prizes offered will be able incontinently to marry and set up housekeeping. The first prize is a light sociable landau (newly built), and a pair of splendid horses, with silver-mounted harness to suit; value £200. Second prize, a boudoir "Alexandra" piano, sweet-toned and highly finished. Third prize, a beautiful oil painting, view of the banks of "Allan Water;" a rare work of art, now on view at Mr. Lesage's, 40, Lower Sackville-street. Fourth prize, a suite of drawing-room furniture, in Italian walnut, richly upholstered in green damask and silk cord, consisting of couch, table, two easy chairs, and six small chairs; value twenty guineas. Fifth prize, a mauve-coloured Irish poplin dress, same as worn by the Princess of Wales. Sixth prize, a lady's diamond ring, of great value and brilliancy. Seventh prize, a valuable short-horned Durham cow; value £20. Eighth prize, a complete dinner service in ancient china; value £40. Ninth prize, a rich velvet carpet, with border to match, for a room 20 ft. by 17 ft. Tenth prize, a valuable gold watch, by Donegan; now on view at his establishment, 32, Dame-street. Eleventh prize, a Limerick lace shawl, suitable for a bride. Twelfth prize, a Killarney arbutus davenport, beautifully inlaid with views of Irish scenery; exhibited at Mr. Egan's stand in the International Exhibition. Also 456 additional prizes, varying in value from 5s. to £10. Tickets, sixpence each. The drawing, which will be on the plan of the Art Union, will take place on February 7, and the winning numbers will be published in the *Irish Times*, *Freeman's Journal*, and *Evening Post* of February 9; London, Manchester, and Glasgow papers of February 10. A list of the winning numbers will be forwarded on February 9 to those who will make a request for same when returning the duplicates. All the prizes, with the exception of the landau and horses, will be delivered to the winners, carriage free, immediately after the drawing takes place. Apply to the Sisters of Mercy, Mater Misericordiæ Hospital, Eccles-street, Dublin, on or before February 2, 1866.

The Late Sir John M'Gregor, M.D., K.C.B.—Sir John M'Gregor was the second son of the late Mr. Duncan Macandrew, of Culross, county Perth, N.B., by Mary, daughter of Mr. John M'Dermott, of Perth. He was born October 20, 1791, and educated at the University of Edinburgh. Entered the medical department of the army 1809; served in the expedition to Walcheren 1809, and was present at the taking of that island and the forts of Terbeer and Ramakins; present at the siege of Flushing, and served with part of the army in South Beveland, General the Earl of Chatham commanding; served in the Peninsula under his Grace the Duke of Wellington from 1811 to 1813, and was present at the siege of Badajos, and in all the cavalry actions against the French in Lord Hill's advance to Merida, and the retreat from Burgos, as well as in various other operations of the second division of the army in Spain and Portugal; was appointed surgeon to his Royal Highness the Duke of Sussex, February 1, 1819; served in the Presidencies of Madras and Bombay, twice in Bengal and the island of Ceylon; was present at the capture of Fort Minora and the surrender of the town of Kurrachee in Lower Scinde; was senior medical officer of the army sent to the relief of the forces employed against the fort of Kujjuck, Upper Scinde, February 21, 22, and 23, 1841; present during the investment of Kandahar, end of 1841, beginning of 1842; senior medical officer of the force sent under Brigadier Wymer for the relief of Kelat-i-Ghilzie, May 1 to June 7, 1842; present during the second Afghanistan campaign, 1842, and with the army on its return to the British provinces, through the Khoord, Cabool, and Khyber Passes, August 1 to December, 1843, and was present at the following actions fought during the foregoing period:—The battle of Kallee Shuck, January 12, 1842; present at the actions of Runga Ruck, Pangwaria, and Zilla Ostracy, March 7, 8, 9, and 10, 1842; present at the battle of Baba Walla, March 25, 1842; battle of Gowine, August 30, 1842; at the capture of Ghuznee and the storming of the heights of Bellool, September 5 and 6; present at the affairs of Bene Bedam and Mydam, September 14 and 15; present during the attack on the rear guard from Skoorab to Gundamuck (Khoord Cabool Pass), October 19; affair with the rear guard from Lundekama to Ali Musjid (Khyber Pass), November 4 and 5, 1842; was principal medical officer with the Kandahar field force during the whole of these operations under the command of Major-General Sir W. Nott; present and acted as principal medical officer of Queen's troops at the battle of Maharajpore, in the dominions of Scindia, December 29, 1843, General Lord Viscount Gough commanding; served a second time in the island of Ceylon, and was senior medical officer in the Kandian provinces during the rebellion in 1848. Was three years principal medical officer in Hongkong, China, 1850 to 1853; three years as deputy inspector-general and principal medical officer at Madras, 1853 to 1856; one year and two months as inspector-general in Bengal, and travelled during the latter period in the performance of his duties 4,462 miles. Served in the north-west provinces of India during the mutiny of the native Bengal army. Was present at the siege of Delhi, and at the storming and capture of the city on September 14, 1857. Sent as prineipal medical officer with the army

proceeding to Lucknow under the command of Sir C. Campbell, and was present at the capture of the city in March, 1858. Recommended for promotion by Lieutenant-Colonel Hibbert, commanding the 40th, and Major-General Sir W. Nott, for services performed as chief medical officer of the Kandahar field force in Beloochistan, Scinde, and Afghanistan. Recommended for promotion by his Excellency the Commander-in-Chief in India for services performed at the battle of Maharajpore, but was the only officer at the head of a department in Sir W. Nott's army not promoted on its return to India. As before stated, he entered the medical department as Hospital assistant June 27, 1809; became Assistant-Surgeon February 15, 1810; Regimental Surgeon April 30, 1822; Staff Surgeon July 7, 1846; Deputy Inspector-General, 1853; Inspector-General, 1856. Sir John was made an honorary Physician to Her Majesty in August, 1859, and was, in recognition of his eminent Professional services, created a Knight Commander of the Bath in the same year. In August, 1863, he assumed the name of M'Gregor instead of his patronymic, the family being descended from the M'Gregors of Rora, the name having been changed after the rebellion in Scotland in 1745. He died at Corstorphine Lodge, Ryde, Isle of Wight, on January 13, 1866, at the age of 74. He was buried at the cemetery in that place.

THE following are the last week's Cattle Plague Returns. By comparison with those of the previous week, it will be seen that there have been 12,199 attacked, 8199 deaths, 876 slaughtered, and 1740 recoveries, since January 6 :—

THE

CATTLE PLAGUE COMMISSIONERS ON VACCINATING AGAINST RINDERPEST.

THE Commissioners, whilst asserting that the efficacy of vaccination is not yet proved, have issued the following memorandum as to the performance and results of the operation for the guidance of persons who may wish to make the experiment :—

I.—MODE OF PERFORMING THE OPERATION.

The vaccination of the cow with the lymph naturally and casually developed on the species is, in general, a successful operation, but unfortunately such lymph is rarely procurable.

The retro-vaccination of the cow with humanised lymph is a different affair, and to insure but a moderate amount of success, when indiscriminately performed, needs more attention to many particulars than is generally supposed.

In the first place it is necessary to shelter the animal from cold and wet.

In the next place it is desirable to employ recent liquid lymph, conveyed in capillary tubes, or contained in well-developed vesicles on a child's arm.

It is important also to select certain regions for the operation.

Those regions are the most eligible which possess the thinnest skin, are void of hair, not likely to be subjected to friction, and yet afford facility of access in operating and inspecting.

In the milch cow the back part of the udder, the thin lax skin on each side of the vulva, or in close proximity to its cutaneous margins, are parts most eligible. In the dry cow and in the female calf the teats and udder will be available, although the parts above mentioned are more convenient of access. In the male the perinæum and the scrotum afford the best sites. But in individuals difficult to manage the inside of the ear, or some part of the neck, or behind the shoulder, denuded of hair, and possessing some of the above-named requisites, may be chosen.

The modes of operating, like those on man, vary, each having its advocates and advantages :—

First —By incision.

Secondly.—By puncture.

Thirdly.—By scratching or abrading the cutaneous surface.

1. Incision has advantages as regards celerity of execution and facility of introducing the infecting, as well as abstracting the resulting, lymph. It may be effected by a small scalpel or short bistoury, or, still better, by the Danish vaccinnator.(a)

The incision should be made from half to three-quarters of an inch in length into the skin, just deep enough to make the edges of the wound slightly to gape. Wait till the oozing of blood has ceased, then supply the lymph into and upon the edges of the incision. The Danish vaccinator resembles a small "Valentine's knife," or the steel pen usually found in a pocket case of mathematical instruments—only this has a cutting edge. The instrument being well charged by applying its point to the liquid lymph discharged from the capillary tube, or oozing from the punctured vesicle on the child's arm, is made to penetrate the skin to the requisite depth, not drawing much blood. The lymph by this means is deposited at the time of making the incision. With a little practice, half-a-dozen incisions are quickly made and charged.

2. *Puncture.*—This is best suited to the practice of inserting the end of a doubly-charged vaccine point, which may be broken off from the shaft, and allowed to remain in the puncture for a quarter of an hour.

3. *Scratching.*—This is tedious, but in thin skins is often advantageous for the application of lymph preserved in large or small ivory points. The lymph, previously moistened, is rubbed off the point into the scratched surface. From four to six clusters of scratches should be made. These, if executed by a large modification of Weir's vaccinator, are done with much more celerity than with a single-pointed instrument.

II.—RESULTS OF THE OPERATION.

About the fourth or fifth day after the operation a slight redness and elevation, with some hardness and heat, may be discerned. These phenomena gradually, but not uniformly, increase till the sixth or seventh day, when a small central crust fills the incision and plugs the punctures.

On the scratched surface the exuded and dry lymph occupies the furrows, or more or less overspreads the abraded surface.

The vesicles now become more and more elevated and extended till the tenth or eleventh day, when they flatten and rapidly decline, more or ess covered with a thick blackish-brown crust.

Unless the skin be thin and very fair, no areola is visible, but the margin of the vesicle is felt hard and tense. When the areola is visible on a fair skin it is often not more than three or four lines in width.

Although the vesicle assumes the form usual in man, as determined by the mode of operating, its margin is, from the thickness of the skin of the animal, solid, and if punctured will yield only blood. Lymph can be procured rarely before the ninth or tenth day, and then only by removing carefully the central crust, and waiting patiently for its exudation through the original puncture.

Vesicles raised by very slight punctures or superficial abrasions of the cutis resembles more closely those on man and yield lymph earlier, but they are liable to earlier rupture or abrasion, and yield but a scanty supply of turbid lymph.

It not unfrequently happens that the stage of progressive papulation is indistinctly marked or apparently arrested, so as to lead to the apprehension of failure, when suddenly the characteristic form of the vesicle appears, and it advances to maturity.

It is not rare, however, to find among several papulæ some of them arrested in their progress, and prove abortive. When this event befalls the major part or the whole of the punctures or incisions, a repetition of the operations in the same site may nevertheless succeed.

During the progress of the disease scarcely any constitutional symptoms are observed; sometimes an acceleration of the pulse may be detected.

The retro-vaccine lymph obtained from these operations, little as it is, should be used as far as possible for other vaccinations.

RUSSIAN CONCLUSIONS ON CATTLE PLAGUE.

THE following despatch has been received at the Foreign Office from Her Majesty's Consul-General at Odessa :—

Odessa, January 8, 1866.

My Lord,—The following important information respecting the cattle plague has been kindly supplied to me in answer to a series of questions I addressed to Prince Manoukbey, and the principal landowners and cattle breeders of Bessarabia. As it differs materially from the information transmitted to your Lordship from the province of Kherson in my despatch dated November 24, 1865, and as I can depend on the facts stated being in every particular the result of actual experience, I lose no time in submitting them to your Lordship's attention :—

1. The Bessarabian cattle owners and breeders state that the plague during the last few years has been permanent in Russia. It exists sometimes in one district, sometimes in another, of that vast country. Up to the present nothing is known with certainty either of the true cause of the disease, or of the proper means of treatment for its cure. On one point only there exists no doubt—it is certainly contagious.

2. No remedies which have been yet tried, neither fumigation, friction, bleeding, nor medicine, have met with enough success to warrant their recommendation. From time to time a few beasts recover, and each person attributes their cure to the remedy he has employed, but general experience has not confirmed such assertions in any case.

3. One opinion only appears to merit serious attention, and is now under anxious consideration. That opinion is in favour of vaccination, which the Imperial Government has undertaken to introduce throughout the infected districts by competent Veterinary Surgeons employed for that purpose. Time only can decide whether vaccination will afford a sure protection from the disease; but at present it seems to promise more satisfactorily than anything else which has been tried.

4. Effective means may be taken to restrain the plague from spreading. For this purpose it is advisable, as soon as it is found to exist in an

(a) An instrument in general use in Denmark, procurable at a small expense in London.

district, that all communication with other places should be strictly prohibited.

5. Dead animals should be buried as soon as possible, and in no case should it be allowed to skin them previously for their hides. They should be buried in the state they die.

6. Great care should be taken not to suffer diseased beasts to drink out of the same troughs as healthy cows.

7. Healthy cattle should be separated at once from the diseased, and immediately any beast falls sick among them the healthy cattle should be taken away and transferred to other pasturage. By these means large herds have been entirely saved.

8. These facts are indisputable. But there is still to be mentioned a probable theory as to the origin of the malady.

9. It is to be observed that the disease rages more violently in the south of Russia than in the north; that it generally breaks out in autumn, and not during the great frosts. Therefore it seems clear that cold is not only far from being the first cause of it, but has not even any influence over it. It is well remembered that before the year 1846 (when free trade in corn began with England), and when Odessa exported much less grain to foreign countries than now, this disease was very rare; but it appeared always after every campaign in the wars with Turkey. Now, these wars occasioned a great deal of cartage for the commissariat of the army. The waggons used by the commissariat were drawn by bullocks, who were thus forced to make long journeys during the great heats of summer across arid steppes, where no pasture or wholesome water could be found, the plague soon seized them, and they rotted and died in great numbers.

The same cause will continue to operate in a greater or less degree until the establishment of railways puts an end to the transport of merchandise for long distances by oxen. Until then it is more than probable Russia will be always devastated by this terrible malady.

Oxen are principally employed on the hardest service during three or four weeks of the hottest part of the year, during which they have no other food than the withered herbs they can crop by the roadside.

Every year more than a million waggons, each drawn by two oxen, coming from different parts of the country, arrive at Odessa alone. As they draw nearer and nearer to their journey's end their food grows more and more scanty and worse in quality, so that they are reduced for several days following to feed upon the meagre roots of grass, which they swallow mixed with dust, and quench their thirst with the muddy liquid which remains of the stagnant water left in ponds and puddles by the roadside.

10. This seems to be really the sole cause of this terrible disease, and the waggons returning to their several homes spread it throughout the country.

11. On examining an ox attacked by the plague, it will be found that it first becomes dull and spiritless; it ceases to ruminate, it eats with difficulty, and its sufferings manifest themselves by a violent diarrhœa. This is a proof that the disease lies in the digestive organs, and probably springs from improper nourishment.

The opinion of French Doctors that this sickness may be caught by men from diseased cattle is not warranted by experience in Bessarabia, no case having been ever known to have occurred there.

The plague does not appear either to be caught by sheep, who have a disease of their own also contagious, but which differs very much from the cattle plague among oxen, and it may be remarked that these two diseases very seldom exist at the same time and place.

I have, &c.

E. C. Grenville Murray.

The Right Hon. the Earl of Clarendon, K.G.

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

Dr. Radford's letter has been received. The great pressure on our columns has hitherto prevented its appearance.

Inquirer.—The treatment of disease by compressed air is described in a pamphlet on Bronchitic and Peptic Asthma, by Dr. W. McLeod, of Ben Rhydding.

A Night in a Casual Ward.—It is said that Lord Eustace Cecil is the hero of this adventure, and author of the account of it.

A. B.—The vaccination question shall have all attention. We are aware, meanwhile, of the activity of some persons in "getting up" evidence in support of the small-pox theory, and of the kind of terrorism established in some bucolic circles against any Medical men who presume to doubt.

The First British Writer on Syphilisation.—In reference to a passage that occurred in our obituary notice of Dr. David Simpson, we are reminded by a correspondent that Dr. Simpson was not the first who introduced the subject of syphilisation to the Profession in Great Britain, a paper entitled "Syphilisation in Norway," by Dr. Lauder Lindsay, having appeared in the *Edinburgh Medical Journal* for November, 1857.

Dr. Trayer.—Some allowance must be made in the case of sudden and unexpected demands on a public office. The Privy Council have announced that they are endeavouring to obtain original vaccine in France and Italy. In the meanwhile, we recommend our correspondent to apply to Mr. Badcock, of Brighton, or to Mr. F. Crook, Vine Cottage, Forest-hill.

Vaccinating a Blistered Surface.—A correspondent of the *Times*, signing himself R. E., and dating from Sloane-street, recommends the following mode of vaccinationg, and thiuks it applicable both to babies and cows:—

"For many years past I have ceased to use the lancet in vaccinating, and I proceed in the following way:—I touch the arm with a minute drop of a fluid in common use in our Profession, called 'Liquor vesicatorius:' this is allowed to dry, and in a few hours a little bead-like blister, the size of a pin's head, appears on the spot. With a very fine-pointed penknife this little blister is then cut, the drop of serum wiped away, and the ivory point, charged with fresh vaccine lymph, is slipped under the thin skin. After lying there for a minute it is withdrawn and the layer of cuticle pressed gently back. The result is an almost unvaryiug success. It is only by a rare exception that this mode fails of communicating the virus, and mothers (and probably the baby, if it could express itself) are generally thankful to escape the dreaded lancet."

The Vaccination of Cattle.—Mr. Griffin, of Weymouth, has written a letter to the Privy Council, in which he recommends the general vaccination of cattle throughout the country. He suggests that "it should be made compulsory that all calves should be vaccinated before they are three months old—a time sufficient to allow all those not intended to grow up to be killed as calves. In order to facilitate this measure and do away with any objection by the owner to vaccination on the plea of expense, let similar arrangements be carried out as are now in force for vaccinating the human subject, and the parish or union will then have to defray the expense. It is now, I believe, a parochial charge, and if the district Medical officers of unions, parishes, and incorporations would consent to become the vaccinators, then you will at once have a staff in England and Wales of over three thousand Medical officers fully competent, with a few general instructions, to carry out the plan. A similar course might be ordered for Ireland and Scotland." He also recommends that the fee for vaccinating animals and certifying should be larger than in the case of children, inasmuch as the operation involves more labour.

Erratum.—In Mr. Spencer Wells's 72nd Hospital case of ovariotomy, published at page 63 of our last number, *for* "four tappings," *read* "seven tappings." Dr. Brabant tapped the patient four times after her discharge from the Hospital, and before her readmission.

The Griffin Testimonial Fund.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—The following subscription has been further received on behalf of the above fund:—Heynes Hardwicke, Esq., Hempnall, 5s. Amount previously announced, £132 14s. 3d. Received at *Lancet* Office, £9 9s.

I am, &c.,

Robt. Fowler, M.D., Treasurer and Hon. Sec.

145, Bishopsgate Without, January 24, 1866.

Inoculating Animals with Variolous Matter.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—I am informed that a gentleman in this immediate vicinity is having all his cattle inoculated with and from the small-pox, which is in the neighbourhood, but not close. Is this right? Does the act against human inoculation apply to cattle? I am, &c.,

Bagshot, Surrey, Jan. 23. J. H. Blount.

*** It is illegal to inoculate a human being with small-pox, but we doubt whether the act extends to animals. The experiment should be performed with the greatest precaution.

Recurrent Swelling of the Tongue.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—A patient of mine, but not at the time under my care, has recently suffered from sudden swelling of the tongue, which the friends feared would cause suffocation. There was at the same time a general appearance of urticaria. There have been other, but slighter, attacks.

This may give a hint to your correspondent for the treatment of his case.

Reading, January 23. I am, &c. B. A.

Influence of Climate, &c., on the Horse.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—Will you enable me to obtain information, through your column of "Notes and Queries," as to the correctness of the following statement, which I recently met with in Mr. Macdonald's "Hints on Farming and Estate Management." At page 409 of the edition just issued, he says:—"The diminutive Shetland pony when transported to England loses this peculiarity of form in the course of a few generations, and approaches the native horse in bulk and general characteristics. The noble Arabian degenerates in England, and the English dray-horse, noted for its heavy limbs, if carried to Arabia, acquires in time the symmetry, grace, and speed of the native."

The latter statement is certainly a startling one, and I, for one, should be glad, in the interests of veteriuary ethnology, to hear of facts which may substantiate it. I am, &c. Inquirer.

Treatment of Rinderpest by Sulphites.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—It should be plainly stated, for the information of those who are inclined to make trial of the sulphites in the cattle plague, that it has never been the pretension of Dr. Polli that morbid products are neutralised or in any degree lessened in their toxic effects on the system by the agency of these chemicals. The sulphites paralyse and arrest the fermentative act and thus check the growth and accumulation of morbid matters in the blood, but it is only through the great emunctories that the morbid products already formed may be got rid of, unless we have faith in other medicines which may, if we choose, be simultaneously employed. Less modified is the view Dr. Polli takes of their efficacy in prophylactic treatment; that the employment of the sulphites is not unfavourable to nutrition is proved by sufficient experience. They are opposed to any primary deviation from the normal processes—by way of fermentation, at least—and in this point of view a full trial of them is recommended. From their slower action, the hypo-salts are to be preferred in prophylaxis; and if there is any fear as to disturbance of digestion, they may be administered as much as possible apart from the food.

I would not hazard an opinion as to the pathological character of cattle plague, yet I may say, in comparing it with small-pox, that I think there is an error in regarding the cutaneous eruption as the most essential feature of variola. In days of inoculatiou for small-pox I believe the fever was always considered to be the main point, and provided it occurred at the right time, the amount or even the presence of the eruption was not considered to be of the first consequence, and the immunity was as complete.

Skin manifestations, moreover, are wont to vary much, no less from individual susceptibility than from diversity of seat or structure, of which instances may be quoted in the dark varieties of mankind, who present peculiarities under the infliction of small-pox which are not witnessed among Europeans. I am, &c.,

3, Westbourne-park, January 17. G. GASKOIN.

ARMY MEDICAL DEPARTMENT.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—I trust you will permit me to warn the Profession of a danger which may possibly have escaped notice; it is this: There is to be an examination of candidates for the Medical department of the Army on March 19, and if a sufficient number can then be obtained to fill the vacancies which exist, we may justly fear—judging from past experience—that the labours of the Committee which has recently been sitting will bring forth no fruit. We know that advantages are conferred on Medical officers merely when necessity compels the authorities to do something to procure candidates; therefore, if vacancies can be filled up without the concession of the privileges and advantages which the sanguine anticipate, then may we assuredly bid adieu to all hope of improvement.

Various rumours are afloat regarding the recommendations which the Committee will make, many of which are doubtless much exaggerated by the sanguine, and by persons who desire to recruit the department by means of empty promises; and it will be advisable to forewarn gentlemen of the evils which may be expected to ensue if they are unwise enough to enter the service until the improvements which have been asked for are actually conceded and in operation. Do not let us place any faith in promises; and let it also be remembered that there is a wide difference between the recommendations of a Committee and the issue of regulations giving effect to such "recommendations." Let us also remember how well the department was recruited after the issue of the Warrant of 1858, and how soon after the advantages then conferred were withdrawn.

We cannot too strongly urge young Surgeons to be cautious, and not to respond too eagerly to the invitation for March 19. I am, &c.,

DOUBT.

POOR-LAW MEDICAL REFORM.

Mr. Griffin requests us to state he has received the following subscriptions towards the funds of the Association:—

Davison, J., Boston, 5s.; Johnson, O., Newark, 5s.; McMaster, J., Portsea Island, 5s.; Frank, P., M.D., late 80th Reg., Mentone, 60s.; Bury, G., Whetstone, 10s.; Hands, B., Edmonton, 10s.; Brett, A. T., Watford, 10s.; Terry, H., jun., Hardingstone, 5s.; Dudley, E., Hardingstone. 5s.; Percival, W., Northampton, 5s.; Bryan, J. M., Northampton, 5s.; Willis, J. H., Tavistock, 5s. Mr. Prowse, of Amersham, has received the following:—Brent, R., St. Thomas, 20s.; Kelly, H. Uxbridge, 10s.; Dickenson, T., Chelsea, 21s.; Herswill, R., St. Germans, 5s.; Wrench, E. M., Bakewell, 5s; Brooks, H., Bridgewater, 10s.; Burton, J., Walsall, 20s.; Buckley, N. Rochdale, 20s.; Wilson, W., Chesterfield, 42s.: Wright and Allen, Basford, 5s.: Hemborough, J., Caistor, 10s.; Buckell, E., Winchester, 10s.: Griffith, W. R., Hinckley, 10s. 6d.; E. G., 10s.; Bell, Dr., Cockermouth, 10s.; Bryden, R., Tiverton, 5s.; Claremont, C. E., St. Pancras, 10s.

METEOROLOGY.

From Observations at the Greenwich Observatory.

Mean height of barometer	29·740 in.
Mean temperature	46·9
Highest point of thermometer	53 2
Lowest point of thermometer	39·1
Mean dew-point temperature	42·3
General direction of wind	SW, WSW, W.
Whole amount of rain in the week	0·62 in.

BIRTHS and DEATHS Registered and METEOROLOGY during the Week ending Saturday, January 20, 1866, in the following large Towns:—

Boroughs, etc.	Estimated Population in middle of the Year 1866.	Persons to an Acre. (1866.)	Births Registered during the week ending Jan. 20.	Deaths. Corrected Average Weekly Number.*	Deaths. Registered during the week ending Jan. 20.	Temperature of Air (Fahr.). Highest during the Week.	Temperature of Air (Fahr.). Lowest during the Week.	Temperature of Air (Fahr.). At the Royal Observatory, Greenwich, the mean height of the barometer in the week was 29·740 in. The barometric pressure fell to 29·53 in. on Tuesday, rose to 30·09 in. on Wednesday, and fell to 29·43 in. on Saturday. The general direction of the wind was south-west.

* The average weekly numbers of births and deaths in each of the above towns have been corrected for increase of population from the middle of the ten years 1851-60 to the present time.

† Registration did not commence in Ireland till January 1, 1864; the average weekly number of births and deaths in Dublin are calculated therefore on the assumption that the birth-rate and death-rate in that city were the same as the averages of the rates in the other towns.

‡ The deaths in Manchester and Bristol include those of paupers belonging to these cities who died in Workhouses situated outside the municipal boundaries.

§ The mean temperature at Greenwich during the same week was 43·2°.

APPOINTMENTS FOR THE WEEK.

January 27. Saturday (this day).

Operations at St. Bartholomew's, 1½ p.m.; St. Thomas's, 9½ a.m.; King's, 2 p.m.; Charing-cross, 1 p.m.; Royal Free Hospital, 1½ p.m.

ROYAL INSTITUTION, 3 p.m. Prof. Westmacott, "On Art Education."

29. *Monday.*

Operations at the Metropolitan Free Hospital, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 9 a.m. and 1.30 p.m.

MEDICAL SOCIETY OF LONDON, 8½ p.m. Lettsomian Lectures—"On Certain Painful Affections of the Fifth Nerve," Lecture III., by Dr. F. E. Anstie.

30. *Tuesday.*

Operations at Guy's, 1 p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; St. Peter's Hospital for Stone, 3 p.m.

ROYAL INSTITUTION, 3 p.m. Prof. Tyndall, "On Heat."

31. *Wednesday.*

Operations at University College Hospital, 2 p.m.; St. Mary's, 1½ p.m.; Middlesex, 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; St. Thomas's, 1½ p.m.

February 1. Thursday.

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Surgical Home, 2 p.m.; Royal Orthopædic Hospital, 2 p.m.; West London Hospital, 2 p.m.

HARVEIAN SOCIETY OF LONDON, 8 p.m. Mr. Victor de Meric, "On Syphilisation."

ROYAL INSTITUTION, 3 p.m. Prof. Tyndall, "On Heat."

2. *Friday.*

Operations, Westminster Ophthalmic, 1½ p.m.

ROYAL INSTITUTION, 8 p.m. The Earl Stanhope, "On the Influence of Arabic Philosophy in Mediæval Europe."

WESTERN MEDICAL AND SURGICAL SOCIETY, 8 p.m. Mr. C. Hunter, "A Case of Stricture of the Œsophagus, with Remarks."

ORIGINAL LECTURES.

LUMLEIAN LECTURES
ON SOME POINTS IN THE PATHOLOGY OF NERVOUS DISEASES.

By C. HANDFIELD JONES, M.B., F.R.C.P., F.R.S.,
Physician to St. Mary's Hospital and Lecturer on Medicine.

Lecture III.

(Continued from page 87.)

The view which I have advocated respecting the essential nature of neuralgia and hyperæsthesia is strongly supported by the occasional occurrence of acute pain and tenderness in limbs affected with embolism of the main artery. Motor and sensory paralysis are constant, but in some instances there is also pain and hyperæsthesia. A case is recorded in the *Dublin Quarterly Journal of Med. Sci.*, May, 1862, of embolism of the right common iliac, femoral, and lower arteries. The symptoms were sudden acute pain in the calf of the leg, which was so tender that the patient shrieked when it was touched, loss of motion in the limb, and loss of sensation from the knee downwards, with remarkable diminution of the temperature. In the case of a female, recorded by Dr. Fuller, who died in thirty-five days with gangrene of both lower limbs, depending apparently on spontaneous coagulation of fibrine in the arteries and veins, which were healthy, the first symptom was acute pain, which set in suddenly without obvious cause. The whole limb, it is said, was so exquisitely tender that the slightest touch caused intolerable pain; it presented, however, no unusual appearance, and no difference could be detected between the two limbs. Even a week later all that could be observed in the painful limb was a slightly greater fulness of the superficial veins, and a somewhat lower temperature; the difference, however, in colour and temperature was so slight as hardly to attract attention. Mr. Erichsen describes arteritis as attended with excessive sensitiveness of the surface, so that the patient cannot bear the finger to be laid upon it; the pain is of a smarting and pricking character, and is always associated with more or less loss of muscular power. The inordinate sensibility continues, he says, after the limb has become cold, livid, and pulseless, but yields to complete anæsthesia as gangrene advances. The examples I have cited afford, it appears to me, quite sufficient evidence that both neuralgia and hyperæsthesia in their purest forms occur under conditions of lowered vital and nervous power, and that hyperæsthesia is quite independent of any increase in the blood-supply of the suffering part. That a state very similar to hyperæsthesia often occurs also as the result of inflammation is, I think, certain, but it is to be ascribed, not to the local afflux of blood, but to the lowered vitality of the parts involved in the morbid process, which, as is now well known, always implies a tendency to degeneration and decay.

Besides the morbid modifications of sensibility already noticed, there are various common derangements of this property, such as itching, formication, burning, trickling of cold water, and the like. These are often regarded—at least, some of them, viz., pain, temperature, and contact—as being the result of impressions made on different nerve-fibres; and this view is supported by the fact that the consciousness of one of these impressions may be lost, while it is retained of the others. The great multiplicity of separate nerve-fibres which would be required on this hypothesis has always seemed to me a weighty objection against it; and I do not see any more difficulty in comprehending that one and the same fibre may be capable of conveying different impressions than there is in the fact that the same wire may convey to the hand vibrations, caloric, and electricity. The phenomena of colour-blindness seem to militate against the theory. Considering the great variety of colours, and the very varying degrees of this defect, it would seem impossible to suppose that there can be different fibres in every part of the retina, for all the colours and tints which some persons are unable to distinguish, and for which, in them, according to the theory, the perceptive media would be wanting or paralysed.

With regard to this subject I have been favoured with the following communication by Dr. Southey Warter. He states that about four years ago he was studying the spots on the sun through a telescope, having previously shaded the eye-piece with a double layer of smoked glass. He was not conscious at the time that the eye had received any damage, but subsequently he has found that there is a considerable difference between the right and left eye in the faculty of appreciating colours, the normal tints as viewed with the left eye being replaced by duller and dirtier shades in the picture conveyed by the right. Strange to say, however, the right eye, which gives such false representations of colour, is the best for the definition of objects; he can read better with it than the left. The right pupil is slightly larger than the left. He has favoured me with the accompanying tableau of the differences in colour perceived by the two eyes, but states that the differences in the colours of flowers and of painted windows are much more striking than he can depict on paper. Sometimes he fancies that with the right eye he can see colours properly with the very oblique rays, while all the direct ones give a false image, as if one central spot in the retina where the image of the sun rested was alone affected. An ophthalmoscopic examination detects nothing abnormal in the eyes.

It appears in this case that the retinal fibres, at least in the central area, have suffered a paresis as respects their power of appreciating colours, while in other respects their functional capacity is unimpaired. It is impossible to believe that there exist different fibres for coloured and for white lights.

Dr. Basham has kindly communicated to me the case of an artist who, during convalescence from fever, found that all reds appeared to him as greens; the perception of the latter was not altered. Under the use of quinine and iron his retinæ regained their normal state. Here there was evidently a paresis of the nerve fibres with regard to a particular kind of impression.

There is no doubt that the sense of taste is ministered to by more than one nerve; the glosso-pharyngeal, the gustatory, and the palatal branches of the fifth are all capable of conveying impressions of this kind to the sensorium; and all these nerves are also fitted to convey impressions of contact, and the glosso-pharyngeal the peculiar one of nausea besides. Again, the great variety of impressions which the nerves of taste convey has a bearing on this question. To my own mind, there seems little room for doubt that one and the same nerve-fibre is capable of being thrown by different excitants into different states which affect the sensorium with different impressions. If this be true of the peripheral nerves, it probably is true also of the nerve-centres. To this point we shall return.

The actual *seat* of neuralgia and hyperæsthesia is, in many instances, a matter of great uncertainty. We know well that these disorders may depend on a central lesion, but it is often no easy matter to determine whether such is the case or not. Even where there is no organic alteration, the morbid action may be central, or perhaps both central and peripheral, extending along the nervous cords in their whole length. Such appears to be the case when the pain darts up and down the nerve, as it does in some cases of sciatica, or as in other instances where it radiates in a reflex manner from the nerve first affected to various others. Indeed, as we have every reason to believe that the nervous influence is propagated along its paths by molecular change passing instantaneously from particle to particle it seems, that we can hardly speak of nervous disorder as limited to the centre or periphery, except in those less frequent cases where a manifest cause of irritation is discovered in some part of the tract. If a tumour, a decayed tooth, or the like, vex and irritate a sensory nerve, we may say the morbid action originates at the periphery, but we cannot say this in a case of gouty or malaria-engendered neuralgia, where as nerve and centre are alike exposed to the toxic influence contained in the blood it is reasonable to conclude that both suffer simultaneously. The centre involved in most instances is the inferior one, where the nerve appears to be directly implanted, but it is interesting to observe that in cases of great severity other centres become engaged, first those giving origin to other nerves and then the superior, the emotional, or intellectual, as evidenced by the occurrence of hysterical disorder or delirium. The widely-diffused hyperæsthesia of hydrophobia affecting the skin, the mucous membrane of the throat, the eye, and the ear is in all probability central as well as peripheral.

It is of some practical interest to have correct views as to the seat of neuralgia and hyperæsthesia, especially with regard to the use of local applications. I am by no means sceptical as to their frequent efficacy, but I think it is very doubtful whether they act, as they are often supposed to do, directly on the nerves affected. It is too much to suppose that an external application of belladonna or aconite should make its way through thick layers of skin, fat, and fascia—

not to say muscle—to reach and act upon the sciatic nerve, and if it did, beyond all question grave toxic effects would ensue. Still, we find ourselves, as it were, instinctively applying our remedies as near as may be *loco dolenti*, and I am not prepared to say that this is not right. Assuming, however, that it is, I think the benefit produced must be ascribed to the influence exerted on the cutaneous nerves to which the remedy is directly applied, and which is propagated from thence to the region of the cord where the roots of the suffering nerve are implanted. It is certain that the nerves of the surface acted on must be affected, and that the subjacent trunk cannot be directly; so that there seems no other mode of accounting for the beneficial effect except that suggested. This *modus operandi* would be the beneficial homologue of the reflexion of pain. Just as a morbid stimulus, an irritant, applied to one part generates pain in a remote by being reflected on to its nerve, so a beneficial stimulus being propagated in a like way may annul a morbid condition set up in a centre by impressions transmitted to it from a focus of irritation. It is, however, very conceivable that this result is more likely to ensue when the nerves, stimulated with a curative intention, have their central terminations near those of the nerve fibres which are in a morbid state. A very interesting paper by one of the Προμαχοι of the host of scientific inquirers, Dr. Lionel Beale, sets forth grounds for the view that the caudate nerve cells are not the points from which nerve currents radiate in different directions along single fibres, but rather the common points where a number of circuits, having the most different distribution, intersect, cross, or decussate. The so-called cell is part of a circuit, or rather of a great number of different circuits. If this be the case, it adds much to the probability that an agent operating upon one nerve may affect thereby other filaments continuous in the centres with those of the former. It is remarkable that even neuralgic pain depending on organic lesion may be relieved by remote applications. Mr. Tomes mentions that a mustard poultice or ammonia applied behind the ear will be effective in some few cases of toothache, and may be tried with considerable hope when other remedies have failed. Mr. Little testifies from personal experience to the great efficacy of chloroform applied to the temple in two severe attacks of rheumatic inflammation of the eye, in which the pain came on periodically with extreme severity. The chloroform is applied in a watch-glass, so as not to evaporate, and produces a burning sensation locally. He praises its efficacy in a great variety of neuralgias. Dr. Weber tells me that he has repeatedly witnessed the good effect of chloroform applied to the ear in stopping a toothache for a time. It is clear that in both these instances the remedy acts as a local stimulant, exerting an influence on the nerves of the surface to which it is addressed, which modifies the condition of other connected nerves.(a)

It is scarcely digressing from my subject if I allude shortly to the *modus operandi* of general applications made to the whole surface. The recreating influence of warm baths, sulphur vapour baths (as especially remarked by Mr. Green), and Turkish baths appears in all probability to depend on a beneficial stimulus being made on the cutaneous nerves, and by them conveyed to the centres. The result of Bencke's observations is, that the beneficial effect of the bath consists in an elevation of depressed nervous power. For this, he says, the stimulus of the bath must be duly proportioned to the individual; if it is too great the action is depressing, and the vital power and bodily weight is lowered. Karner takes nearly the same view; he thinks that the temperature of baths should be regulated not by the thermometer, but by the sensations of the individual. The action of the temperature is determined by the sum of the excitation of all the peripheral nerves, and its propagation to the nervous centres. The result is modified by many circumstances, as the receptivity of the cutaneous nerves, the mode of life, the being or not being accustomed to the bath, etc. That the great nervous centres are capable of being thus beneficially influenced by means of peripheral impressions is a truly remarkable fact, and scarcely, I think, sufficiently considered. It is clear that it is quite of the same kind as that on which I commented previously—viz., the production of a depressing or paralysing effect by inhibitory impressions. The injurious effect of "*frigus nervis inimicum*" is counteracted by the beneficial agency of caloric, properly applied; but both influences seem to act through the same channels, and in analogous ways. The point which I have before insisted on—that the action of an excitant applied to a sensory surface is determined to a great extent whether it shall be beneficial or otherwise by the state of the nervous power in the nerve centre—is quite borne out by the conclusions which the German observers just quoted have arrived at, and by our own experience. We know, indeed, that a bath at the same temperature which refreshes one man may induce in another dangerous syncope.

The question seems to me well worthy of consideration how far we may regard the great spinal and encephalic nervous centres as susceptible of such affections as neuralgia and hyperæsthesia, apart from any such disorder in the peripheral nerves. Romberg seems to have no doubt on the subject; his fifteenth chapter is entitled Hyperæsthesia of the Spinal Cord and of the Brain, and he speaks distinctly both of spinal and cerebral neuralgia, though he applies the latter term to hemicrania, which most of us, in spite of his protest, regard, I suppose, as a neuralgia of the upper division of the fifth.

With regard to the hemispheres, we know that the grey and white matter of which they are composed is quite insensible to pain—at least, such as can be excited by mechanical injury. As, however, almost all organic diseases of the brain are attended with pain, which sometimes corresponds exactly with the seat of the lesion, and which may occur when the membranes remain perfectly sound (Andral), it seems to me unquestionable that some parts of the encephalic mass, quite apart from the nerves, must be capable in conditions of disease of being so affected as to give rise to pain, or some equivalent dysæsthesia. The case which Romberg gives of a tumour involving the root of the fifth nerve contains a description of marked phenomena of facial neuralgia, quite unlike any suffering which appears to be seated directly in the head. But even though we admit that pain is not so readily to be produced in the brain as in the nerves, it does not follow that the cerebral tissue may not, in its own special way, express its resentment of the operation of the cause which gives rise to neuralgia in the peripheral nerves. It cannot be questioned that malaria, for instance, does actually affect the nerve centres as it does the nerves. It is, however, very possible and probable that the symptoms will differ in the two localities. Our examination of neuralgia led us to conclude that this morbid state essentially consisted in a lowering or deterioration of nerve-power. Now, supposing the hemispheres to be invaded by the influence which produces neuralgia in nerves, they would express their suffering by a failure or disorder of the special functional power which belongs to them. Numbness is a common symptom in peripheral neuralgia, and I think there is much reason to believe that the white fibres of the hemispheres may be affected in a very analogous way, and that an alteration of this kind has much to do with the phenomena of certain pernicious agues attacking the head, as well as of other obscure cerebral disorders. The following case recorded by Torti is, I think, worth our attention. G. J., an eminent lawyer and privy councillor, was attacked with a simple tertian. After two paroxysms he was bled on a free day on account of plethora, and the red, thick, and scanty condition of the urine. The third attack came on about noon the next day. He then began to speak in a broken manner unusual to him; soon after he had difficulty in expressing his thoughts, which he was aware of, but was unable to correct his mistakes, while continually he used one word for another. At last he began to sleep so soundly that he could with difficulty be aroused, and when he was he answered in a random manner, and fell off again into sleep. When the paroxysm was at its turn the sopor diminished, but the tremors of the hands and the twitchings of the tendons showed that the sources of the nervous force in the head were gravely affected. The fourth paroxysm came on with formidable symptoms. Although ʒvi. of bark had been given the previous night, there was manifest delirium, with tremor of the hands and tongue, invincible lethargy, insensibility to any amount of pain, convulsive movements of the limbs and of the whole body, and especially in the course of the attack a frequent and troublesome hiccup. Bark was again administered after the paroxysm, and in three days he was well. Andral relates a remarkable case (p. 86), of which the following is a summary:—A woman, aged 63, who generally had good health, was attacked one morning with great illness, vomiting, and a violent pain of the head. After the lapse of a quarter of an hour, she uttered a loud scream and fell,

(a) Perhaps the popular faith in warm plasters to the loins and chest is warranted by the same principle. Pogonotrophy, I believe, has been found useful to prevent relapses of sore throat. The intention of the oriental khummerbund is similar. In these and such like instances the protection of a sensory surface or its gentle stimulation by uniform temperature acts beneficially through a nervous centre on the nerves and vessels of certain co-ordinated internal parts.

deprived of consciousness. Half an hour later Andral found her plunged in profound coma, pupils large and motionless, scarce any reflex contraction of orbicularis palpebrarum, face injected, not distorted, all the limbs in a state of complete relaxation, and insensible. Pulse strong and not frequent; heart beating strongly. In spite of venesection the coma continued till 6 p.m., when all the symptoms disappeared. A second similar paroxysm occurred the second day, and lasted till the middle of the third. A third paroxysm continued for thirty-five hours. Quinine was then administered very freely, and the next paroxysm was retarded in its arrival, and was much less severe. The patient had violent headache without vomiting, shivering, which had been absent previously, some convulsive movements of the face, coma for only two hours, after which she remained for some time as it were benumbed. The treatment was continued, and no further disorder occurred. Andral views this case as one of intermittent cerebral congestion, and some may be disposed to take the same view of Torti's case. I cannot but dissent from this opinion, because the symptoms seem to me quite unlike those of active cerebral hyperæmia, and because there was nothing to produce a state of passive congestion. When active hyperæmia exists, the brain, like all other organs in a like state, becomes excited and stimulated, the patient is delirious—sometimes maniacal—is restless, and extremely sensitive to light and sound. This state may be succeeded, if it be of great severity, by stupor and coma, but then these symptoms never come on or disappear suddenly, inasmuch as they depend upon effusion or other organic changes. An opposite condition, one of anæmia, is very likely to produce some such cerebral symptoms as occurred in the two foregoing instances. Anæmiating arterial spasm is now regarded by many as the immediate cause of the unconsciousness and convulsions of the epileptic paroxysm, and it is possible that anæmia of the hemispheres might have caused the coma in Torti's and Andral's cases. I reject this view, however, because in Torti's case the attack did not come on with the suddenness of spasm, but in a more gradual way, and the coma was attended with manifest delirium, and because in Andral's case it is expressly said the face was injected, and the duration of the coma in the third paroxysm was so prolonged that it seems unlikely the brain could have tolerated so long a deprivation of blood and yet recovered its function so rapidly. Kussmaul and Tenner appear to consider that two minutes is the longest period that the brain of the rabbit can remain deprived of arterial blood without losing its capability of again performing its functions upon the renewal of the circulation. I am quite inclined to believe that anæmiating arterial spasm may be the essential condition of single paroxysms of epileptic vertigo and epileptic convulsions, but I think it quite impossible to make this view applicable to all cases, especially those where the attacks are very prolonged, or evidently depend on direct cerebral irritation, as in tubercular and exanthematous disease. In the above-cited and in similar cases I believe the condition of the brain to be very analogous to that of a nerve affected by neuralgia, and which is in that state which Romberg denominates anæsthesia dolorosa. I coincide very much with the opinion expressed by Trousseau, when he recognises in eclampsia and the various forms of epilepsy two distinct things—viz., 1. A peculiar modification or modality of the nervous tissue of unknown nature, which annihilates in a moment all the manifestations of animal life, and which is far the most important element of the disorder. 2. A secondary cerebral congestion, which in rare instances may amount even to capillary apoplexy or meningeal hæmorrhage. I adopt also the proposition which Trousseau lays down as the sequel of his first—viz., that the same modification of the encephalon which causes the epileptic or eclamptic convulsive attack produces also the apoplectic stupor which succeeds it. The anæmial theory seems to me quite to fail to account for the consecutive stupor, which is sometimes extremely profound. Kussmaul's and Tenner's rabbits recovered their cerebral functions speedily after the readmission of blood to the organs, and so ought the human brain to do also.

(To be continued.)

HOSPITAL LIBRARIES.—The Council of the Royal College of Surgeons of England has presented complete sets of the illustrated catalogues of the Hunterian Museum to the libraries of our metropolitan and provincial Hospitals.

ORIGINAL COMMUNICATIONS.

REPORTS AND LECTURES ON ORIGINAL RESEARCHES IN SCIENTIFIC PRACTICAL MEDICINE.

By BENJ. W. RICHARDSON, M.A., M.D., F.R.C.P.,
Senior Physician to the Royal Infirmary for Diseases of the Chest.

I.—ON A NEW AND READY MODE OF PRODUCING LOCAL ANÆSTHESIA.

SOME years ago I published in the columns of the *Medical Times and Gazette* some researches for the production of local anæsthesia by a process which I designated voltaic narcotism. Those researches, very much praised on the one hand, and very rudely and unfairly attacked on the other, failed in the end in leading me directly to any practical means of producing local insensibility applicable to Surgical proceedings. The causes of failure were threefold. The apparatus required was cumbersome; the application was painful; the result was uncertain. In the course of the past year a similar series of experiments have been made by an Italian Physician; but whether in imitation of my previous labours or in ignorance of them, I do not know: they have proved equally unsatisfactory.

The researches on voltaic narcotism, although practically of little value, were not in reality without their use. Previously to making them I was quite conversant of the fact—indeed, I learnt it from Snow—that all the narcotics produced anæsthesia by the process of arresting oxidation; but I had still to learn what Snow himself had not reached, that arrest of oxidation meant, in the end, arrest of motion; and that anæsthesia, in truth, means the temporary death of a part influenced—*i.e.*, inertia in the molecules of the part.

Learning this, I discovered that voltaic narcotism had at its base a fault. My idea in it was, that by quickening the circulation of a part by galvanic stimulus, and by applying over the part where circulation was quickened a narcotic solution which the blood could absorb, I could so charge the blood locally with narcotic substance as to produce local insensibility. In feeble subjects, as the result proved, local narcotism could, in this way, be temporarily set up; but it was always attended with a certain amount of disorganisation. In strong subjects it failed altogether, because such of the narcotic as might be absorbed was carried rapidly into the general circulation. In plain words, by the use of the galvanic current, I was committing the paradox of applying a form of motion for the indirect production of inertia.

The failures I experienced at the period referred to in no degree lessened my efforts to find a practical means for producing local insensibility. They simply caused me to think more on the whole subject, and to invent new methods of inquiry. I came at length to the conclusion that Dr. James Arnott's plan of using extreme cold was the first true step in the progress of discovery, and that if it could be made easier of application, and at the same time could be combined with the use of a narcotic fluid, an important advance in therapeutics would necessarily follow. For full four years this truth has been before my mind, and I have made numerous experiments with the view of demonstrating it. At one time I tried to freeze parts by the application of ice and salt, and then to inject by the hypodermic plan narcotic solutions into and beneath the frozen tissue. These experiments were never sufficiently satisfactory to allow of their publication. At last I hit upon a method which I am now about to describe, and which, although admitting of very considerable improvement, is sufficiently important to justify me in laying it before the Profession.

THE ANÆSTHETIC SPRAY PRODUCER.

When the toy for diffusing eau de cologne in fine vapour over the skin, in the form of spray—which some time ago found its way into our drawing-rooms—first came before me, it struck me at once that it might possibly be applied to the production of local anæsthesia; and I set to work to try its applicability in this respect. I was soon afterwards assisted largely in my labours by taking advantage of Siegle's apparatus, with the hand-ball spray-producer invented by my valued friend Dr. Andrew Clarke, and supplied by the manufacturers, Messrs. Krohne and Sesemann, of Whitechapel-road.

With this apparatus I set myself to determine the degree of cold that could be produced by the vaporisation of all the known volatile liquids, and I determined the fact that the intensity of the cold produced held a definite relationship to the boiling-point of the fluid used; the rule being that the lower the boiling point the greater was the amount of cold exhibited. In these inquiries I employed a very delicate thermometer, directing the spray upon the bulb from half an inch to an inch and a-half from the point of the jet. By these means I learnt that with rectified sulphuric ether I could bring down the thermometer within 10 degrees Fahr. of zero, and that by directing the jet on the skin I could produce a certain definite and marked degree of local insensibility, but not sufficient for Surgical purposes.

I next got Mr. Krohne to construct for me a hollow cylinder of thin metal, six inches long and three inches in diameter. In the circumference of this cylinder was a chamber one-eighth of an inch in diameter for containing ether. The ether communicated with a tube which was joined to an air-tube, as in Siegle's apparatus, and the centre of the cylinder was filled with ice and salt mixture. In this way the ether was reduced to zero, and when vaporised gave spray which brought down the thermometer six degrees below zero, and produced on the skin such entire insensibility that I could pass a needle through the part without sensation. On the 11th of December, 1865, I applied this process for the first time on the human subject for an operation. The patient was a lady, who required to have five front teeth extracted. I had previously administered chloroform to this lady for a tooth extraction, but the inhalation had produced so much irregularity in the action of the heart and other disagreeable symptoms, that I considered it inadvisable to repeat chloroform, and she herself was only too ready to give the local measure a trial. The extraction was performed by my friend Mr. Peter Matthews. On directing the ether spray first at a distance and then closely upon the gum over the first central incisor on the left side, we observed, at the end of fifty seconds, that the gum had become as white as the tooth itself, and quite insensible. I then directed the vapour upon the tooth for twenty or thirty seconds more, and on the patient intimating that she did not feel, I suggested to Mr. Matthews to proceed. He extracted a very firm tooth without the slightest expression of pain. The process being continued in the same manner, he extracted three other teeth with the forceps. The fourth gave way, and had to be removed by the lever; but in all cases the result was equally good. Not a drop of blood was lost; there was no painful reaction; and the healing process proceeded perfectly. Our patient, who was exceedingly intelligent, was specially requested to note every step of the operation, such as the applying of the forceps, the insertion of the blades beneath the gum, the loosening process, and the removal. She told us that in two of the extractions she felt nothing; that in one it seemed as though the jaw altogether were being pulled downwards, but without pain; that in another she was conscious of a kind of wrench or loosening but without pain, and that the introduction of the lever was attended with a momentary dull ache, just perceptible. On the whole, the process was quite as painless as when she took chloroform.

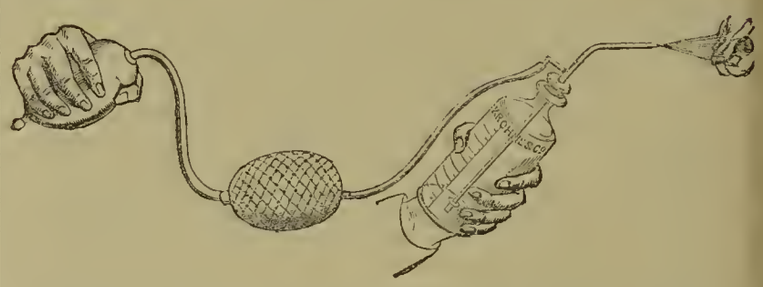
On December 13th I applied the local anæsthetic to the same lady for the further extraction of nine teeth, Mr. Peter Matthews again operating. The results were equally good with the first seven, at which point, unfortunately, the apparatus partly ceased play. At the eighth tooth pain was felt, and at the ninth, the apparatus being out of play, the operation caused great pain. We regretted this much, although it gave us the information of the perfect action of the process when no mechanical obstacle interfered with it. The reason why the apparatus stopped play was very singular, and could hardly have been foreseen. It arose from the condensation of water derived from the air in the air tube, and from the blocking up of the fine jet with a little portion of ice.

In the next step of research I got Mr. Krohne to make for me an apparatus with two spiral tubes, one the air tube, the other a tube for ether; and I immersed these spirals in a closed chamber filled with ice and salt. The degree of anæsthesia at first produced was most intense, and Mr. Spencer Wells was good enough to allow me the opportunity of applying the process in a case where an operation was required for closing a perineal rupture. Unhappily the apparatus, from the very same cause as before, ceased to yield a current; water condensed and became frozen in the air-tube. The apparatus itself was also found to be too cumbersome for practical purposes; I therefore, in this trial, failed to obtain any result.

By this time I had been led, very reluctantly, to the fact that the use of ice and salt for reducing the ether was a failure when the plan came to be tried in practice, nor could I see any ready way of preventing the difficulties that were brought before me. Added to these difficulties there was another, which has always attended my friend Dr. Arnott's plan, viz., that of getting the ice and salt readily for operation. To succeed, therefore, it was requisite to dispense with ice and salt altogether.

In considering how this object could be achieved, it occurred to me that if a larger body of ether than is supplied by Siegle's apparatus could be brought through the same jet, by mechanical force, in the same interval of time, and with the same volume of air, a proportionate increase of cold must necessarily be produced. The theory was one of pure physics, admitting even of arithmetical demonstration, and running parallel with the lessons which had been taught me with respect to the cold produced by liquids having different degrees of boiling point. The theory was put to the test at once, and proved correct to the letter. By driving over the ether under atmospheric pressure, instead of trusting simply to capillary action—or to suction, as in Siegle's apparatus—the spray evolved brought the thermometer within thirty seconds to four degrees below zero—the result that was desired.

Ascertaining this truth, I instructed Messrs. Krohne and Sesemann to construct the very simple apparatus depicted below.



The apparatus consists simply of a graduated bottle for holding ether; through a perforated cork a double tube is inserted, one extremity of the inner part of which goes to the bottom of the bottle. Above the cork a little tube, connected with a hand bellows, pierces the outer part of the double tube, and communicates by means of the outer part, by a small aperture, with the interior of the bottle. The inner tube for delivering the ether runs upwards nearly to the extremity of the outer tube. Now, when the bellows are worked, a double current of air is produced, one current descending and pressing upon the ether forcing it along the inner tube, and the other ascending through the outer tube and playing upon the column of ether as it escapes through the fine jet. By having a series of jets to fit on the lower part of the inner tube, the volume of ether can be moderated at pleasure; and by having a double tube for the admission of air, and two pairs of hand bellows, the volume of ether and of air can be equally increased with pleasure, and with the production of a degree of cold six below zero.

By this simple apparatus, at any temperature of the day and at any season, the Surgeon has thus in his hands a means for producing cold even six degrees below zero; and by directing the spray upon a half-inch test-tube containing water he can produce a column of ice in two minutes at most. Further, by this modification of Siegle's apparatus he can distribute fluids in the form of spray into any of the cavities of the body—into the bladder, for instance, by means of a spray catheter, or into the uterus by an uterine spray catheter.

When the ether spray thus produced is directed upon the outer skin, the skin is rendered insensible within a minute; but the effects do not end here. So soon as the skin is divided the ether begins to exert on the nervous filaments the double action of cold and of etherisation; so that the narcotism can be extended deeply to any desired extent. Pure rectified ether used in this manner is entirely negative; it causes no irritation, and may be applied to a deep wound, as I shall show, without any danger. I have applied it direct to the mucous membrane of my own eye, after first chilling the ball with the lid closed.

I have now employed this mode of producing local anæsthesia in four cases on the human subject. The first case was the extraction of a tooth from a lady, the operation being

performed by my friend and neighbour Dr. Sedgwick, on January 24th of this year. On the 29th of the same month I used it again on the same lady for the extraction of three very difficult teeth, Dr. Sedgwick again operating. The results were as satisfactory as in the previous case, where the ice and salt ether apparatus was used.

I have used the apparatus also in connection with my friend Mr. Adams, who had a case at the Great Northern Hospital of deep dissecting abscess in the thigh of a young woman. In the abscess there was a small opening, which just admitted the director. I first narcotised around this opening, and the director being introduced, Mr. Adams carried his bistoury nearly an inch deep and one inch in the line of the director. I then narcotised the deep-seated parts, and enabled him to cut for another inch and a half in the same direction. The director was then placed in the upper line of the abscess, the process was repeated, and the incision was carried two and a half inches in that direction. The patient was entirely unconscious of pain, and after narcotising the whole of the deep surface, Mr. Adams inserted his fingers and cleared out the wound without creating the slightest evidence of pain.

Afterwards, in the case of a lacerated wound, six inches long, in the arm of a boy, who had been injured with machinery, I narcotised while six sutures were introduced by Mr. Adams. The first needle was carried through without the anæsthetic, and caused expression of acute pain; the remaining eleven needles, after a few seconds' administration of the ether spray, were passed through painlessly. The twisting of the wire sutures gave no pain.

These results are so interesting that I make no apology for bringing them at once before my Medical brethren. I wish it to be distinctly understood that at the present moment I only introduce the method here described for the production of superficial local anæsthesia. It is, I believe, applicable to a large number of minor operations, for which the more dangerous agent chloroform is now commonly employed—I mean such operations as tooth extraction, tying nævus, tying piles, incising carbuncles, opening abscesses, putting in sutures, removing small tumours, removing the toe-nail, dividing tendons, operating for fistula, removing cancer of the lip, and other similar minor operations which I need not mention. The process may also be applied to reduce local inflammation.

In course of time, and guided by experience and the advancement of science, we may, however, expect more. If an anæsthetic fluid of negative qualities, as regards irritation of nerve, and which has a boiling point of 75° or 80°, can be obtained from the hydro-carbon series, the deepest anæsthesia may be produced, and even a limb may be amputated by this method. It may also turn out that certain anæsthetics may be added to the etherial solution with advantage, such as small quantities of chloroform, or some of the narcotic alkaloids, if they could be made soluble in ether. A solution of morphia and atropia combined, if they could be diffused through ether, which at present seems impossible, could thus be brought into action so as to cause deep insensibility. In operating on the extremities it would be good practice to stop the current of warm blood by making pressure above on the main artery.

Reaction from the anæsthesia is in no degree painful, and hæmorrhage is almost entirely controlled during the anæsthesia.

One or two precautions are necessary. It is essential, in the first place, to use pure rectified ether; methylated ether causes irritation, and chloroform, unless largely diluted with ether—say one part in eight—does the same.

The *modus operandi* of this process is exceedingly simple. It acts at first merely by extracting force, and afterwards, when the nervous filaments are exposed, by preventing the conveyance of force through them. To be plain, sensation means the conveyance of force or motion from the extreme parts to the brain. The motion is communicated by the blood in the form of heat: it is communicated to the nervous filaments, and by them is conveyed to the sensorium. This is passive sensibility. When we irritate a nervous fibre, as by a cut, we communicate more motion rapidly along that fibre and cause pain. This is active or exalted sensibility. To remove sensibility, therefore, we must adopt one of three processes: we must remove or render inert the sensorium; we must stop the evolution of force generally by arresting oxidation of blood; or we must rob the body locally of its force beyond that with which it is constantly being renewed. We see the first of these proeesses in action in cases of pressure on the brain, as from injury or effusion of blood; we see the second whenever we produce general anæsthesia by charging the blood with chloroform or other analagous anæsthetic; and we see the third when, by means of extreme cold, we rob the local part of the force that has been brought to it by the blood.

The problem of local anæsthesia will consequently be quite solved when by a rapid process we can exhaust the natural force of a part as fast as such force is evolved in the local structure; and especially when with this we can combine the action of a substance which for the moment controls, as by compression, the conducting power of nerve matter. These two latter objects are to a large extent carried out by the method I have described above.

I cannot conclude this paper without expressing my thanks to Messrs. Krohne and Sesemann, the makers of the anæsthetic apparatus, for the industry, the perseverance, and the skill with which they have carried out all my designs. I feel that without their ready hands it would have been difficult indeed to have conducted the numerous and delicate operations through which the results I have described have been so far brought about.

NOTES ON SYPHILIS, WITH SPECIAL REFERENCE TO ITS TREATMENT BY SYPHILISATION.

(Extracted from the *Norsk Magazin for Lægevidenskaben*, xix. Bind, 11 Hefte, Christiania, November, 1865.)

By WILLIAM DANIEL MOORE, M.D. Dub., M.R.I.A.,

Honorary Fellow of the Swedish Society of Physicians, of the Norwegian Medical Society, and of the Royal Medical Society of Copenhagen; Examiner in Materia Medica and Medical Jurisprudence in the Queen's University in Ireland.

(Continued from page 89.)

A SIMILAR state of unsusceptibility of syphilitic action is, as I have said, rarely met with in adults, and then, for the most part, only in individuals with scaly, papular, or pustular cutaneous forms of disease; but such forms occur with us only seldom in comparison to the maculated exanthema. By the latter, the inoculations are almost never prevented; and yet the one case, which I shall now mention on account of its unusual want of reaction after the numerous punctures, is precisely one with roseolar eruption.

C. J. B., aged 23 years, admitted on October 9 with a rather bright roseola on the lateral portions of the chest and on the back. Syphilisation had a good effect until November 20 (1½ months) with a single matter, but from that day we no longer succeeded in obtaining a positive result with a single matter, notwithstanding that fifty-three different sorts were employed; and I sometimes tried, if possible, to increase the reactive power of the skin by applying dry cupping glasses immediately before the inoculations, which were made upon the part drawn up, but in vain. The patient remained quite unsusceptible, consequently immune, and was dismissed cured on March 9, 1864, the syphilitic phenomena on the skin and mucous membranes having disappeared. But so soon as June 7 he was again admitted with a well-marked maculo-papular exanthema over the trunk and extremities. This time we did not succeed in getting a positive result after a single inoculation with twenty-two different matters. On July 19 the eruption had disappeared, and the patient left the Hospital well. He subsequently continued in good health.

Such unsusceptibility is, as I have said, rare; but in a slighter degree it has been observed in not a few cases during the last fifteen months. I will, however, mention only one example of this kind.

In K. M. H., a girl aged 8 years, who was admitted on July 11 with "a number of scattered, reddish-brown papulæ of the size of a pin's head, on the chest and back," and, moreover, slight secondary symptoms, seventy-two different matters were tried in the course of 170 days. She, however, remained in Hospital ninety-one days after this time to undergo local treatment for iritis of the left eye and lymphatic abscesses on the right side of the neck and in the left popliteal space.

This inactivity in the skin in presence of the local irritation is very singular, and the curative effect of these missed

inoculations upon the system is quite inexplicable; Professor Boeck has, however, expressed his opinion in reference to this point that a kind of action takes place under these circumstances by absorption of the syphilitic pus through the punctures.

3. Of the 11 patients who, either on account of intercurrent new diseases or of very slowly subsiding syphilitic forms, were subjected to a somewhat varied treatment, and whose average stay in Hospital was $228\frac{8}{11}$ days (the longest time being 304, the shortest 130 days), I shall describe the following three a little more in detail:—

a. H. P. O., aged 31 years, was admitted on June 2 with an extensive papular and partly desquamating exanthema on the face, forehead, and trunk, large mucous tubercles on the scrotum and penis; debilitated aspect; tremor of the hands. No regular account to be had of the duration and origin of the disease. For two years there has been a papular eruption on the face and chest, which continued notwithstanding the employment of various lotions and ointments, but disappeared in the course of about a year under the use of a mixture containing iodide of potassium, reappearing in spring, and gradually becoming developed to the above degree. Two and a half months ago the affection on the genitals began.

Syphilisation was employed and took well until August 14. Nothing is to be found in the journal respecting the patient's health until the 16th of that month, when it is stated that he had for several days complained of pain and of a sensation of weight in the whole head. In the afternoon of the same day there were spasms in the left arm and shoulder; the left side of the face was drawn upward; articulation was laboured and thick. The day after the patient was somewhat confused, his movements and speech were unsteady, but he could be understood. The pulse was regular. In the afternoon a fresh attack of spasms. August 18.—The right side of the face was flaccid and pendulous, the left angle of the mouth was drawn upwards, the tongue when protruded turned to the right. . . . Under the use of antiphlogistics and of iodide of potassium the pains in the head diminished, but some weakness in the tongue remained. On October 7 iritis supervened in both eyes, with copious exudation and adhesions posteriorly, both pupils being only slightly dilated and in a very angular manner by the application of atropia. Great pain in and around the eyes. Vision imperfect.

After some fluctuation in the state of the eyes, during which the irido-chorioiditis became constantly worse, the power of vision diminished, so that the patient could not go about alone. He was dismissed on November 30. The exanthema had not disappeared, but was less. The cerebral disturbance had not returned during the last two months, but some slowness of apprehension and difficulty of speech remained.

b. M. J., aged $36\frac{1}{4}$ years, had on admission on July 28 a faintly red, macular eruption on the body, many large mucous tubercles upon the genitals, indolent glandular swellings in the neck and groins. The disease had lasted at least three months. Derivation was established September 12. The eruption is distinctly papular.

December 9.—The eruption is somewhat levelled; iodide of potassium.

May 28.—The patient was dismissed, but the spots after the papulæ were still very distinct.

Notwithstanding the "derivation" and the iodide of potassium, the eruption disappeared only extremely slowly, and seemed on the whole not to be particularly affected by the treatment.

c. A. M. H., aged 20, on November 20 exhibited secondary symptoms. Syphilisation was established, and proceeded favourably until March 4, 1864, when the patient gave birth to a dead fœtus of the seventh month. Subsequently pelvic cellulitis, of considerable extent, nearly filling up the right iliac fossa, set in, with highly febrile symptoms and with persistent tenderness in the hypogastrium. More than three and a-half months elapsed before the cellulitis was resolved, and then all the syphilitic symptoms had disappeared. The patient was dismissed on June 23, 1864.

4. Among the seven patients who were treated solely with topical applications for their fresh secondary syphilis was a girl, two months old, with hereditary disease, whose treatment required 61 days. The average time for all was $65\frac{2}{7}$ days. These patients got a warm bath occasionally, and the ulcerations were touched with nitrate of silver.(a)

(a) This mode of treatment I have now practised for two and a-half years on about fifty private patients with particularly satisfactory results.

5 and 6 require no special mention. Of the 24 secondary relapses were previously treated with—

		Average time of treatment of the relapse.
Derivation	6	$38\frac{1}{2}$ days.
Syphilisation	7	$49\frac{1}{7}$,,
Mercurials	11	44 ,,
	24	

Of the 11 tertiary cases were treated with—

		Average time of treatment.
Derivation	2	28 days.
Syphilisation	3	$53\frac{1}{3}$,,
Mercurials	2	$58\frac{1}{4}$,,
Sweating cure	1	48 ,,
Not treated	3	$82\frac{2}{3}$,,
	11	

The two subjected to derivation were:—

J. S. L., admitted on January 22 with superficial ulcers on the calves of the legs and coloured scars after similar ulcers on the forearms and calves of the legs; commenced six weeks ago. The patient was treated by derivation for his secondary syphilis from October 24, 1862, to May 11, 1865. And

O. B. O., who was admitted on May 28 with a large tuberculo-serpiginous ulcer on the right buttock, near the fissure, which had been developed within the last two months. She was subjected to derivation for perfectly fresh secondary symptoms from December 17, 1862, until July 23, 1863. She then went out before complete cicatrisation; so the period of treatment above stated is in fact short. This time both got iodide of potassium.

The three subjected to syphilisation were:—

1. H. H. H., admitted on October 7 with a round, accurately-defined, quasi-fluctuating swelling of the size of a silver dollar piece, with a hard contour, and of the normal colour of the skin, under the left tuber frontale; painful on strong pressure. At first he was unable to assign any cause for the tumour, but, after repeated inquiries, he stated that once in the course of last spring he had got a blow on the forehead, which, however, was so slight that he paid no further attention to it, and could not now point out the place. Professor Boeck, nevertheless, considered this to be the exciting cause.(b) Four months ago the patient began to feel pains in the part now attacked, in which the swelling at the same time began to show itself. The pains went and returned at different intervals, and were always most violent at night. For the last few days he has been free from pain. He was treated by syphilisation in the summer of 1859. He now got iodide of potassium, the tumour was painted with alkaline solution of iodine, syphilisation was tried anew during a period of five weeks, without any particular result being obtained from the inoculations. Pustules were still sometimes produced, but they did not proceed to ulceration, formed no crusts, and the whole soon dried off.

After about five weeks' stay in the Hospital, the patient got iritis of the right eye. On November 19 he went out, "the iritis removed, the swelling on the tuber frontale gone. There remains only a slight elevation of the bone."

This result of the inoculations is usual in those who have once been syphilised to immunity.

In one of the above-named seven patients with relapse of a secondary nature after treatment by syphilisation,

M. J. H., who had been syphilised from July 29 to November 14, 1859, the same treatment was now again tried for sixty days. The result of the inoculations was about the same as in the foregoing cases; the effect was, to be sure, a little more persistent.

But the long series of inoculations from one and the same matter sometimes witnessed in those not previously treated,

(b) Thus I have often read and heard that external influences acting on a universally syphilitic individual may give rise to characteristic local phenomena. It has never yet fallen to my lot to see anything of the kind either after the numerous stibiate plasters employed in the treatment by derivation (they never produce any other than the usual "variolous sores," and I have never succeeded in exhibiting any specific syphilitic action with their contents; inoculations with them do not give rise to the most distant reaction), or after incisions, or after spontaneous openings in abscesses or furuncles, or in ruptures after delivery, in teething, or in the edges of the wound made in dividing the prepuce in phimosis with chancres. In this case it may be, as I have already mentioned, that the lobes—nay, sometimes the whole prepuce—ulcerate away; but this occurs merely by an extension of the original sore or sores to the retro-preputial flap, not at all by the formation of any fresh ulceration in the edges of the wound effected by the knife. In a word, I have never seen any characteristic (specific) syphilitic local affection arise after external influences acting upon a patient labouring under constitutional syphilis.

and especially in the commencement of the cure, are never observed in those who have passed through the treatment by syphilisation. In the latter has occurred a peculiar, but inexplicable immunity of the skin of great physiological interest. That this immunity—four years after the first treatment—is no longer as perfect as it was at the termination of the treatment, will be seen from the respective histories of the cases of these two patients. And the question whether the immunity is permanent, or lasts only for a certain limited time, has not as yet been solved; it would appear, at least from these two cases, as if it is gradually lost.

2. M. E. S., had on the outside of the calf of the right leg two sharply-edged, foul, shallow ulcers of the size of a silver half-dollar; the surrounding parts were unaltered. Developed during the last three months without any known cause. Catamenia regular. Treated by syphilisation from April 25, 1857, to January 6, 1858. After forty-three days' local treatment and keeping her bed, the sores healed.

3. G. K., had on admission swelling of the left testicle and epididymis, which was developed, without any cause known to him, in the course of the last three or four months; a few crusts of ecthyma on the inside of the right thigh and on the left side recently formed; an ulcer two lines in length and one and a-half in breadth on the anterior surface of the right leg, developed after a blow received three months previously; hoarseness for the last six months without pain in the throat.

He was treated by syphilisation for secondary symptoms from July 17, 1861, to January 2, 1862; came in again on July 8 in the same year with deep ulcers on both sides of the scrotum, mucous tubercles around the anus and on the tongue, for which only local treatment was employed during three week's time.

The tertiary symptoms disappeared under the use of topical applications, and of iodide of potassium, after seventy-five days' stay in Hospital.

To these three belongs properly as a fourth,

M. K., admitted on October 14 with several ulcers on both legs and cicatrices after similar previous sores. Was treated by syphilisation from January 25 to May 21, 1862, in which period, however, she suffered from pneumonia; intercurrent febrile attacks are found to render syphilisation less certain in its results. She was transferred after eighty-six days' stay in Hospital to the Municipal Hospital.

(To be continued.)

REPORTS OF HOSPITAL PRACTICE
IN
MEDICINE AND SURGERY.

THE LONDON HOSPITAL.

RESUME OF A WEEK'S ADMISSIONS.

BEING THE SUBSTANCE OF A CLINICAL LECTURE DELIVERED WEDNESDAY, JANUARY 10.

(Cases under the care of Mr. HUTCHINSON.)

[Reported by Mr. WAREN TAY.]

GENTLEMEN,—Our week which ended yesterday has been one of unusual interest. As regards numbers admitted, we have had the usual average, and our mortality has not been heavy; some of our single cases, however, furnish unusually tempting materials for detailed clinical study. The following is our list:—

Strangulated inguinal hernia reduced *en masse* (operation), 1; injury to the head, 2; rupture of kidney, (?) 1; dislocation of the astragalus, partial, 1; retention, from organic stricture, 1; compound dislocation at the ankle-joint, 1; synovitis of knee-joint, 3; periostitis of tibia, 1; necrosis of tibia, 1; phymosis, 1; burn, 1; lacerated scalp, 1.

Fractures (simple): of tibia and fibula, 5; tibia only, 1; fibula only, 3; femur, 2; humerus, 2; ribs, 3; (compound): phalanges of fingers, 1; metacarpus and carpus, 1; first metatarsal bone, 1.

Inflamed arm, 1; hand, 2; elbow, 1; leg, 2; foot, 1; gland, 1. Contusions, 11.

Ulcers, 3; hydrocele (injection of iodine), 1; amaurosis (white atrophy), 1; carcinoma, epithelial, back of hand, 1; encephaloid of tibia, 1; syphilitic disease of larynx, etc., 1; syphilitic double orchitis, 1; gangrena senilis, 1; tumour, fatty, 1.

Total, 62.

Chief amongst our interesting cases have been two of injury to the head.

HEMIPLEGIA AFTER INJURY TO THE HEAD FROM A FALL.

On January 2, a man, aged 56, was brought in who had fallen from a ship's mast whilst at work in the rigging. He had sustained a severe fracture of several ribs on his right side, and his symptoms were chiefly referable to his chest. He was in collapse and had much difficulty of breathing. On a subsequent day, however, we noticed that his mouth was drawn somewhat to the right side, that he protruded his tongue towards the left, and that he had partially lost the use of his left arm and leg. He was quite conscious, could hear well, answered all our questions, but spoke thickly and mumbled his words. Now, we could find no traces of injury to the scalp or skull, excepting a trivial cut over the right eyebrow; there was no swelling anywhere, and he had had no bleeding from ear or nose.

Let us concentrate our attention upon this symptom of hemiplegia, and ask how it is to be explained. During the last three or four years, in connexion with the Astley Cooper Prize, I have been paying especial attention to injuries to the head, and one of the most interesting results which I have arrived at has been the observation that lacerations of certain parts of the surface of the brain cause paralysis of the opposite side. Lacerations of the brain surface in connexion with falls or blows on the head are tolerably common, and in a considerable series of cases where such laceration involved the middle of one hemisphere, I found more or less of hemiplegia on the opposite side. When the anterior lobes are lacerated, hemiplegia does not result; respecting the posterior lobes I can say nothing, for it is very unusual to find them much injured. Cases of cerebral laceration from injury are usually complicated with more or less effusion of blood, and those who believe that local effusion of blood within the skull can produce symptoms of local compression, might hold that the hemiplegia which results was due to the compression rather than the laceration. Physiologists have, I believe, been sceptical as to the possibility of producing hemiplegia by damage to the surface of the hemisphere, and hold that it is necessary that the more central parts should be implicated.

This result of clinical observation was, therefore, somewhat at variance with the doctrines of the day. At length, however, two almost conclusive cases occurred. In each a man was admitted with a severe compound fracture of one parietal bone, retaining his consciousness, but hemiplegic on the opposite side. In each I trephined the skull, removed large portions of bone, and left the dura mater exposed, so that there was no longer any possibility of local compression. In each case the hemiplegia persisted, and in each we had a post-mortem, and found, as expected, that the damage consisted in extensive laceration of the brain surface. We have had several cases in which patients showed this symptom of partial hemiplegia after severe blows on the head, and recovered from it in the course of a few months, and in these I have ventured to diagnose laceration of the middle or sphenoidal lobe. There is a very important feature characteristic of this form of hemiplegia, and it is this, that both motion and sensation are involved. In the common forms of apoplexy, in which usually the corpus striatum or thalamus is lacerated by extravasation of blood, hemiplegia, as is well known, results, but the hemiplegia usually involves motion to a very much greater extent than sensation. In fact, some Physicians have, I believe, doubted whether in common hemiplegia from apoplexy sensation is involved at all. You will see that the essential feature of difference between traumatic lacerations of the brain and lacerations from disease is that the one are almost always on the surface and the other usually near the centres.

To return from this digression to the case before us. Is it probable that this man has sustained a surface laceration of his right hemisphere, to which the symptom of hemiplegia is due? He fell a height of twenty-five feet, and, although there is no contusion of his scalp, we know from abundant experience that the brain within may be smashed by injuries which do not show themselves externally.(a) It is therefore very possible that his hemiplegia may be traumatic. My diagnosis is that it is not so. I suspect rather that the man had apoplexy while in the ship's rigging, and fell in consequence. The hemiplegia which he presents much more nearly resembles that which occurs from apoplexy than that which we meet with in our Surgical wards in connexion with injuries. His sensation is very slightly impaired. On the two sides of his face we cannot make out that there is any difference. The mumbling way in which the man speaks is

(a) See, for example, the next case.

exactly that of Medical apoplexy, but I think there is yet a more trustworthy reason for doubting the existence of traumatic laceration. It is not likely that a blow on the head sufficiently violent to inflict a severe laceration of one hemisphere should not at the same time so shake the rest of the cerebral mass as to induce the symptoms commonly, and I think quite correctly, ascribed to general concussion. These symptoms are, after the first stage of collapse has passed off, a stupid, sleepy condition, with great disturbance of the intellect, with a hot surface, and often with a good deal of restlessness alternating with the sleepiness. Now of these symptoms our patient has shown not one. He has slept at nights, and kept awake in the day; he has taken his food; he has always been able and willing to answer questions, and has shown not the slightest irritability of manner.

There is yet one other hypothesis in explanation of his hemiplegia which I must endeavour to dispose of; that, namely, which would suggest local compression by effused blood. I have no belief whatever in the possibility of permanent paralysis resulting from local compression of the brain; such paralysis being restricted to one part, and not implicating the nervous system generally.

A temporary paralysis may result from a local effusion of blood, but the brain mass is so yielding and can accommodate itself so readily to intrusion of other matters within the cranial cavity, that hemiplegia from this cause never lasts long. Of this we had a capital example about six weeks weeks ago. A man had hemiplegia, incomplete, but well marked, on the day of his admission, and on the next day he had none whatever. We proved at the post-mortem that this symptom had been due, as we conjectured at the time, to effusion of blood between the dura mater and the bone from laceration of the middle meningeal artery. Whenever you find lasting hemiplegia, whether of face, of limbs, or both, or paralysis of any single nerve or single set of nerves, the patient showing no symptoms of general damage to his nervous system, you may be sure that the paralysis in question does not result from local compression, but from some structural lesion, most probably from laceration.

FRACTURE OF OCCIPITAL BONE AND LACERATION OF ANTERIOR LOBES OF BRAIN.

We have had this week another most interesting head case, one which at first puzzled us a good deal, because we had an incomplete history, but which, when looked at by the light of the post-mortem, is very characteristic of an important group. When the man was first admitted some conjectured that he was intoxicated; afterwards we had to entertain the hypothesis of fever or of arachnitis. The man himself, from the first, was in a state of stupor. Just after he came into the Hospital he managed to tell the nurse his name; but after that we could never get him to speak. He was admitted about Wednesday noon, and he died on Saturday. During the whole of this time he had lain in a stupid condition, without speaking; capable of resisting vigorously when we disturbed him, but never speaking. His tongue and lips were dryish, but he would never put his tongue out. His face was flushed and bloated; his surface temperature varied very much. When he was covered his skin got hot; but when he kicked the clothes off, as he often did, he rapidly became cold. His pulse was steady, and usually about 65. We could not make out that he was paralysed in any part; he moved all his limbs when we pricked them, and screwed up his eyes when we tried to open them. His pupils were of medium size. He was more or less restless, frequently tossing the clothes off and turning in bed. He could rouse himself when the bladder was full, and would then get out of bed, stagger to the next patient's bedside, and make water against it. No friends came to see him, and the only history which had been obtained from those who brought him was, that he had had a fall of a few feet, and that he was a very drunken man. There was no contusion to be discovered about any part of his head. He had had no bleeding from ears or nose, nor was there any ecchymosis of his eyes. We could find no fever spots on his body. After remaining three days in the condition I have described, getting gradually more and more stupid, he had, on the morning of the third day, a succession of convulsions, each one weaker than the preceding, and after which he died.

In discussing the diagnosis of the case, I had remarked that on the whole I was inclined to think that he had sustained some severe injury to the head, and I pointed out that it was unusual in cases of mere concussion that we should be unable to rouse the patient to speak. I stated, also, that the circumstance that he could rouse himself when the bladder was full was quite in keeping with what we often notice in concussion, very often a patient who is in a stupid sleep at all other times will rouse himself to make water, then go to sleep again. The absence of paralysis seemed to show that the patient had no extensive injury to the middle parts of his hemispheres, and it was also, to my mind, tolerably conclusive that he had no surface arachnitis. I will explain my reasons for thinking so at a future lecture. On the day of the man's death we obtained an account of his accident from the foreman of the yard where he had worked. He had, whilst sober, fallen backwards from the cart which he was loading, and struck the back of his head. He was stunned, and was picked up by the bystanders. Soon afterwards, he regained consciousness sufficiently to tell them that "he felt very bad, but hoped he should be better soon." He was at once conveyed to the Hospital, and the rest of the case I have already given you. The height which he had fallen was eight or nine feet.

Now, let us ask what are the usual consequences of a severe blow on the occiput such as this man had received? Very often there is, in the first place, a fissure fracture of the bone where struck, and a slight contusion of the cerebellum above it; but the most important lesion is to the anterior lobes of the brain. These are driven violently forwards against the skull, and very frequently they are lacerated (laceration by contre-coup). Not unfrequently there is further evidence of the effects of contre-coup in a few linear fissures in the thin plates of the frontal bone on each side the ethmoid and in ecchymosis beneath it. Connected with the laceration of brain, there is always the effusion of more or less blood into the bruised brain-substance, into the meshes of the pia-mater, and into the arachnoid cavity. These were precisely the lesions which our patient had sustained. I show you in this sketch the direction which the line of fracture had taken.

The symptoms which the man had presented fitted very well with the conditions found at the post-mortem. The case was essentially one of very severe concussion of the entire brain, plus laceration of the anterior lobes, plus a certain amount of general compression by effused blood. The compression had probably a good deal to do with the immediate cause of death. The convulsions no doubt very much hastened his death, and they might have been due either to the laceration or to the compression. I have known a series of convulsions precede death in a case of pure and uncomplicated compression.(b)

We have had two or three other head cases, but not calling for special notice. In one case of slight concussion, the patient is a young man who had fallen from a waggon on to his head. In another the patient is a delicate infant only ten months old, whom, we are assured, had fallen, or been thrown, from a window thirty feet high. This child presents no serious symptoms. Its head is hydrocephalic, the fontanelles are large, and the whole of the sagittal suture gapes. This condition of yielding parietes would tend very materially to diminish the risk of injury to the brain.

(To be continued.)

BIRMINGHAM GENERAL HOSPITAL.

ILLUSTRATIONS OF THE CAUSES OF DEATH IN BRIGHT'S DISEASE OF THE KIDNEYS.

(By JAMES RUSSELL, M.D.)

(Continued from vol. ii. 1865, page 708.)

III.—COLLAPSE OF THE LUNGS, THE CONSEQUENCE OF EFFUSION.

Case 16.—*Acute Dropsy.*

A. B., aged 4 years. Scarlet fever without sore-throat, about a month ago; exposure and neglect. Anasarca three days ago in upper extremities, face, and trunk; retching. Urine at admission smoky; ¼ albumen. Uric groups; blood and exudation-casts. Next day, pulse 160; rapid, catching, and irregular breathing. Cough, with expectoration. Clear intellect. Dulness over right base. Puffed hands and face. Urine very scanty; ½ albumen; more smoky. Death in the night.

Sectio Cadaveris.—Considerable effusion in each pleura, some in pericardium and abdomen. Heart contained blood. Partial collapse of entire lungs, complete of right and left lower lobes; inflation of the edges and of particular lobules. Not much mucus in the tubes. Pulmonary artery

(b) See London Hospital *Reports*, vol. ii.

free. Coarse injection of kidneys; very anæmie cones; granular cells; opaque tubes. Some bloody coils.

In the preceding case the fatal effusion was probably brought on by exposure in bringing the child to the Hospital. A condition amounting to the same state may be induced in the adult by rapid increase of fluid within the chest in the course of the chronic form of Bright's disease, the lungs being already crippled by coexisting disease. Such was no doubt the cause of death in the following case. The fatal event was quite unexpected at the particular time when it occurred.

Case 17.—*Granular Fat Kidney, Early Amyloid.*

E. S., aged 24. Delicate constitution; very sedentary habits. Permanent impression on his health from typhoid fever eight years ago. Excessive masturbation. Bone abscess. Cough and some hemoptysis four or five years. Health declining a year. Œdema six months; dry skin; liability to vomit; diarrhœa lately; scanty urine; advanced anæmia; considerable anasarca; constant diarrhœa. Some amendment, with considerable diminution of anasarca. Increasing rapidity of pulse; retching. Death took place with much rapidity, and was not anticipated. Urine averaged 26 oz.; specific gravity, 1036; very ammoniacal; albumen from $\frac{1}{3}$ to $\frac{1}{2}$; intracellular hyaline casts.

Sectio Cadaveris.—Considerable ascites; very copious effusion in right pleura compressing the lung (the more healthy one); copious miliary tubercles through the lung. Left lung upper third cirrhosed; adhesions half inch thick. Effusion in the pericardium. Heart 12 oz.; fat on each ventricle; fascicles healthy. Spleen waxy; 16 oz. Liver, $4\frac{1}{2}$ lb. (avoir.); not unhealthy. Kidneys, 16 oz.; excellent specimen of the granular fat kidney; much blood in the larger vessels; general hypertrophy of the arteries; resplendent tufts. Ulcers in the ilium.

CARDIAC DYSPNŒA.

Case 18.—*Chronic Desquamative Disease.*

J. N., aged 49.—A hard drinker of ale; had been exceedingly stout; once "rheumatic gout." Ailing fourteen years; severe fit of vertigo; three epileptiform fits, the last two years ago, ending in prolonged delirium. Then steadily progressive anasarca, loss of flesh, constant cough and expectoration. Shortness of breath amounted at last to orthopnœa; when visited by me had passed five or eight nights in his chair. Copious anasarca; advanced anæmia.

Orthopnœa relieved. As he mended urine amounted to fifty to sixty oz. in twenty-four hours; specific gravity, 1007-9; very albuminous, and containing granular casts. Subsequently, after ten days' suspension of treatment, was found with complete suppression of urine for three days; increased dyspnœa; dulness; pupils natural; had constant vomiting; bowels refused to act; cerebral oppression increased. He died early on the fifth day; one stool, and only a few ounces of urine.

Sectio Cadaveris.—Fluid in the pleural cavity; condensation of right lung; œdema of both lungs. Hypertrophy of left ventricle of heart; fatty growth encroaching on the fibre of the right; tissue flabby and brown. Kidneys advanced in chronic desquamative disease, and contained cysts.

Case 19.—*Chronic Desquamative Disease.*

Mr. S., aged 39. Has a son diabetic. He has had the symptoms of the same complaint for four years. Special failure of health six months,—debility, emaciation, irritability of bowels, some dyspepsia and tendency to vomit; frontal headache, severe vertigo; occasional slight epistaxis; anasarca for some time, considerable for three months, with known albuminous urine.

Nineteen days before death extreme dyspnœa, very intolerant of movement, aggravated by paroxysms of spasmodic character; during this entire period sat up in bed, or with head resting on a table. Sleep only obtained by snatches, and patient became greatly exhausted, worn, and haggard. Spasmodic cough, dry, or with scanty expectoration. Pupils small, little dilatable; intellect entire till last four nights. Physical signs in chest normal throughout, except feeble impulse of heart and depressed apex by descent of diaphragm.

Anasarca very copious, and though relieved by profuse discharge from punctures—the serum soaking the bed and forming pools on the floor—soon reappeared. Finally intense restlessness and frequent delirium.

Urine fell the first day of my attendance from very large quantity to 88 oz., sp. gr. 1013; then to 30—40 oz. sp. gr. 1011. No trace of sugar. Albumen $\frac{1}{5}$ [1] Large number of granular casts up to $\frac{1}{300}$th inch diameter. Some large waxy casts.

DEATH FROM SUPPRESSION OF URINE.

Suppression of urine may occur at any period of the disease. It may constitute the one main symptom of an acute attack, and be the direct cause of death; or it may prove fatal through the intervention of some organic change. It may present itself during the course of a chronic case, and may be relieved, or may prove fatal, exhibiting in its fatal operation the same variation as in the acute form.

Again, the symptoms to which suppression may give rise, even when it remains uncomplicated by any organic change, may present remarkable variations; they may involve the intellectual faculties, or may leave them intact; they may present a decidedly typhoid aspect, or may be free from this characteristic, retaining, however, always, a manifest tendency to asthenia; irritation of the gastro-intestinal tract may be present or absent; anasarca may be copious, or there may be none at all; and hæmorrhage may take place from the mucous membranes, or this accident may never occur at all. Once more, life may be extinguished rapidly, or may be surprisingly prolonged.

Some of these variations admit of explanation, by peculiarity in the patient, and by changes in the blood; some by the particular manner in which nature endeavours to establish a compensating excretory process; but more, no doubt, by the success with which this subsidiary elimination is performed.

The length of this paper forbids my entering into further details; the two following cases, though unfortunately without post-mortems, strikingly exhibit some of these contrasts:—

Case 20.

Master W., aged 13. He had mild scarlet fever, and was out on the fourth day. Eight days after renewed submaxillary swelling, soon subsiding, and severe paroxysmal pain in the abdomen. Vomiting set in next day; he then passed some deep red urine. No fever; tendency to doze. Whole illness lasted twelve days; absolutely no urine, with the following exceptions:—Twice one ounce, twice one drachm; densely albuminous. No anasarca throughout; no eruption, except for one day a few purple specks. Great difficulty in acting on the bowels; only once copious dark fæcal stools: twice stools of very fetid blood. Not much perspiration.

Incessant vomiting from first to last of green or yellow fluid; twice of "coffee-ground" matter; quantity asserted much to exceed ingesta; entire impossibility of administering food or medicine by the mouth.

Breath very urinous, and strongly alkaline, and at last surface of body also. Tongue dry and glazed. Intellect remarkably clear; only some drowsiness towards last; slept at night. Pupils only exhibited some tendency to contraction as the case advanced; pulse 100, feeble, and became thready; respiration 14; temperature normal. Emaciation proceeded rapidly, and great depression came on. Sounds of heart feeble; respiratory sounds clear.

Three convulsive fits in last three hours of life; died after the third. Every endeavour was made without success to introduce fluid by mouth or rectum.

Case 21.

Mr. S., aged 26, after a doubtful throat affection, with abscess in tonsil, during which urine was very scanty; urine became almost entirely suppressed. Suppression of urine continued through six days. During that period profuse watery purging, at first from medicine then spontaneously; some perspiration. Steady pulse at 80; very dilated pupils; clear intellect; troublesome wakefulness. Severe paroxysmal pain in abdomen through these six days, with tension, at last necessitating an opiate stupe; it gave great relief, but pulse fell at once to 40, with some dulness and diminished dilatation of pupil.

On the next day, from the fall of pulse, reappearance of urine, which soon reached a pint in twenty-four hours; sp. gr. 1013, increasingly albuminous. On the eleventh day a very thick erythematous eruption over entire surface, much like measles, and twice copious hæmoptysis; and next day several malænous stools. The symptoms then became decidedly typhoid; sordes, dry tongue and throat; apathy; feeble voice; proneness on the back; intellect clear; pulse rising slowly to 68 on fifteenth day, and 93 on eighteenth day; on that day renewed hæmoptysis. (The blood did not contain urea.) The pulse had now assumed a peculiar state of irregularity by groups of beats, once fell to 38; respiration 22.

Typhoid symptoms continued with dry, sticky tongue and

fauces. Patient slowly emerged, but never perfectly. He died rather suddenly, having been encouraged, by commencing improvement, to leave for his country house, insisted on with obstinacy which savoured of delirium. The last few days' excess of urine above normal standard; albumen ¼; hyaline casts. The eruption only left within a week of death. The day preceding death pulse was 130. Entire absence of œdema throughout, and surprising absence of emaciation.

SATURDAY, FEBRUARY 3.

THE NEW PARLIAMENT.

The assembling of a new and untried House of Commons awakens a lively sensation of interest in all classes who have anything to lose or anything to gain by legislation. About one-fourth of the members of the new House take the oaths of allegiance for the first time, and it is not unreasonable to suppose that so large an infusion of untried strength or untried weakness will give a new character to their deliberations and a fresh impetus for good or evil to the political life of the country. As we are not politicians except in the narrow circle of Professional interests, we are spared the necessity of prophecying on the fate of the Ministry, the character and scope of the Reform Bill, the Fenians, Jamaica, the American claims, and a host of other topics which a hard fate imposes on our contemporaries. But there are several subjects which bear directly on the interests of the Medical Profession, or which affect the economical condition, and therefore the physical welfare, of the people, which must be discussed by the new Parliament, and are legitimately within the pale of the Medical journalist. Foremost amongst these is the manner in which the present Government has met the disaster of the importation of Rinderpest. We shall hope to hear from the lips of Her Majesty's Minister the reasons for many things which at present appear inscrutable. First, we shall be curious to know why the disease was allowed to exist and spread for many weeks before the Government, although repeatedly warned and urged to exertion, thought fit to institute a Commission of Inquiry into its nature and the mode of arresting it. It will also be a satisfaction to learn what sum of the public money was placed at the disposal of the Committee to enable them to institute experiments and collect evidence. The temporising and hitherto inadequate measures of the Government, the manner in which they have shifted the responsibility of carrying out the only certain method by which the plague may be arrested from their own shoulders to those of local and irresponsible Boards, will afford a subject of debate in which the skill of fence possessed by the Ministry must be severely tested. The recommendations of the Commission appointed by themselves, backed by the prayer of the whole agricultural interest, by the advice of every competent scientific authority in the country, and by the universal experience of Europe, have been disregarded with such disastrous results that it will be at least satisfactory to learn on what grounds Her Majesty's advisers have virtually refused to put a peremptory stop to the transmission of the poison by living cattle. Another subject of importance to the Profession is the present working of the Poor-law. Recent events have proved so incontestably the abuses which exist in the relief both of the resident and casual poor, and the evils flowing from the be-lauded "Anglo-Saxon" system of local unpaid government by boards of guardians, that we may hope some improvement may be ventured on. The Profession well know the necessity for Poor-law Medical reform, and we trust that they will be sufficiently alert to introduce some substantial measure when the management of the poor is before the Legislature. The question of increased Hospital accommodation for fever and small-pox in London and other large towns is another subject on which Government have promised to deliberate and decide. The reports of the Committees on the state of the Army and Naval Medical services, and on the prevalence of Venereal Diseases in the two services, will, we hope, be thoroughly discussed in the Senate. These are some of the subjects of public moment in which our Profession is directly interested. As in previous years, we shall take care to furnish our readers with a weekly condensed report of all the matters discussed in Parliament which bear on their own interests, or on the physical and social condition of the population. From the party zeal which the death of Lord Palmerston has let loose we may predict that the next session will be of far more political importance than its immediate predecessors. We hope that it will also bear more fruit in the advancement of those interests which are identified with the Profession of Medicine.

THE NATURE OF RINDERPEST.

Vaccination has proved itself to be no preventive against Rinderpest. At this result we are scarcely, if at all, disappointed, much regret though we feel at the loss of so incalculably great a boon as a preventive power in vaccination would certainly have been. We have seen, and have pointed out to our readers, how slender and how unsatisfactory are the grounds upon which the identity of cattle plague and variola has been asserted. Hence, we felt what little reason there was for anticipating that vaccination would afford any immunity against infection by Rinderpest. But cases were adduced in which vaccinated cattle seemed to be exempt from it. So we hoped, without feeling more convinced that Rinderpest was small-pox, that in vaccination we had hit upon, by a piece of good fortune, a prophylactic against the disease. Still we pointed out how uncertain was the evidence which even many apparently successful cases could afford from the fact that many cattle not treated at all had escaped an attack of the disease which might have been expected to take it.

In our numbers for January 13th and 20th there appeared letters from Mr. John Fairmann, of Hanley, Staffordshire, in which he stated that in a large herd in which cow-pox had prevailed last autumn, fifteen animals had been attacked by the plague, of which number five had died, and that more than half the number attacked had had cow-pox. This was the first case reported of the non-protective power of vaccination, and doubts were expressed by the advocates of the small-pox hypothesis as to whether the autumn attack of this herd was true cow-pox, although Mr. Fairmann had observed on the udder of one of the cows affected with Rinderpest the marks of the cow-pox.

Since then, however, the correctness of this gentleman's observations has been fully borne out by other observers. Mr. Tollemache, so hopeful as to the value of vaccination, placed an Alderney calf, which had been very satisfactorily vaccinated, in a confined space with four other calves that had Rinderpest for five days and nights, commencing on the

11th. It was then removed, being still free from signs of Rinderpest. On the 17th it was, however, attacked with the disease. In the *Times* of last Saturday there appeared a letter from Mr. Tollemache, announcing the result of what he felt was the *experimentum crucis* of the power of vaccination: on the 25th "the calf succumbed to the disease, after being ill eight days."

Further on in his letter to the *Times* of Saturday last, Mr. Tollemache states that he has also one vaccinated cow ill from the disease, and another cow, also vaccinated, that he has great misgivings about. Some vaccinated cows on the farm of this gentleman's bailiff have also been seized with Rinderpest.

In the *Times* of last Tuesday Lord Airlie states that in order to test the efficacy of vaccination as a preventive against the cattle plague he sent two successfully-vaccinated animals and one not vaccinated to an infected farm on the 15th inst. He had just heard at the time of writing that one of the vaccinated animals was dead, the other apparently quite well, and the unvaccinated one ill, with no hope of its recovery. He also mentions that on his farms he has not had a single case of disease, although one farm is surrounded by infected farms—a result which he attributes to rigid isolation and liberal use of disinfectants.

In the *Times* of the same date also appeared a letter from Mr. George Okell, of Over, Cheshire. He says in it that he has vaccinated at least 500 head of cattle; and gives the following instance, selected from among others, in which cattle have been attacked with Rinderpest and have died, although they had been successfully vaccinated:—On January 3 he vaccinated twelve cows belonging to his father, Mr. Okell, of Gorstage, Cheshire, and on the 10th the remainder of the stock, fifteen in number. In all, except two, a cow and a bull, the operation was successful. None of the cows were ill at the time. But in a few days several of the herd became affected with Rinderpest, so that by the 27th, nineteen head of cattle had been attacked with the disease. Eight cows had then died, and five of these had been successfully vaccinated at least fourteen days before they showed symptoms of Rinderpest. Four cows were recovering, and singularly enough, he says, the bull and the cow in which the operation for vaccination was unsuccessful were quite well.

Mr. Harper, of Holbeach, has also found vaccination to fail in preventing infection by cattle plague. In the *Times* of Wednesday, he writes that two heifers which he had successfully vaccinated, and then separately exposed to the influence of diseased beasts, have both taken the plague and died of it.

We also are informed that at the Albert and at the Royal Veterinary Colleges vaccinated animals have taken Rinderpest. At the Albert College the cow-pox was well-marked, and several children were actually vaccinated from the vesicles.

Little room for comment presents itself in these cases. Any one of them, the correctness of which is not disputed, is sufficient to show that vaccination is but poor protection, to make the best of it, against the contagious influence of cattle plague. Whether or not cattle plague is small-pox modified remains undecided. It can hardly be said to be disproved that it is such by the failure of vaccination in preventing it. For it seems that *vaccinated* cows take cow-pox, and that, according to Lord Airlie, inoculation does not seem to be more successful than vaccination in preventing an attack of cattle plague. Lord Airlie states that a stock-owner in the neighbourhood of Forfar has had seven animals inoculated with the virus of diseased cattle, and that four out of the seven are dead.

At the same time, we are almost at a loss to understand on what grounds the believers in the small-pox hypothesis support it. The skin affection can hardly be asserted ever, if at all, to have the characters of that of small-pox; the lesions of the mucous membranes, though closely like those in some cases of small-pox, can hardly be said to be peculiar to these diseases; and lastly, small-pox in any of its forms has not been shown capable of producing Rinderpest, or Rinderpest, small-pox. We must only wait for those who have still a confidence in this hypothesis of the nature of cattle plague to set forth some fair grounds on which to claim our assent to its probability, if not truth.

SANITARY SCIENCE AND OUR PUBLIC SERVICES.

People are very apt to be deceived by the amount of talk upon a subject, forgetful that it is talk and nothing else. What appears to exhibit a good deal of energy is in reality often only a dreary sham—the dreariest and saddest of shams when you get to the bottom of it, and discover the little earnest work it conceals. It is so much easier to let energy evaporate in words instead of converting it into actions. Hygiene, sanitation, and so on—all their equivalents and derivatives—are words found often enough on people's lips; they edge their way into all the newspapers and journals, and you go to sleep over their endless repetition through the pages of a Blue Book. The Government, however, like Gallio, cares for none of these things, after all. It may be necessary to hoodwink the public by now and then putting the right man in the right place, without any intention of giving heed to the right advice when given. Sanitary science means an outlay of money, when it ceases to be mere talk; and what chance is there for her claims in a conflict with the penurious, cheese-paring policy of the present Government?

The late loss of 220 human beings in the *London* struck most people with dismay, but our unfortunate troops may be decimated by disease—by disease such as ordinary foresight might have anticipated and prevented—and there is perhaps a leader in the *Times* only to mark the date of its occurrence.

Let any candid person peruse the account of the late epidemic of yellow fever at Bermuda, and he may convince himself that the insanitary state of that station was such as to have rendered it a hot-bed, well manured, and admirably adapted for "forcing" the seeds of disease. The principal mercantile port of the colony is the town of St. George, and a truly pleasant place it appears to be! It is said to resemble certain villages of the West of Ireland, the advantages of the comparison being greatly, however, upon the side of the Irish. Here is the sanitary picture from Surgeon-Major Barrow's capital report in the last Army Medical Blue Book:—A town seated in a hollow, composed of the narrowest streets, ingeniously cut off from winds, redolent of offensive odours from cesspools and the filth thrown into the streets (which are unscavengered); no sewers, no drains, but cesspits, which are rarely emptied; the water supply being rainfall, and the houses, overcrowded at all times, becoming excessively so during the American war—the population rising from 900 to 1500.

So far for the town; and the barrack buildings are very much on a par with it. These are defective in the sites and low levels they occupy; in their ventilation, light, drainage; in the close proximity of crowded out-buildings and privies—often placed to windward of them. At St. George, which is the head quarters, there is overcrowding also. The average strength of the garrison of the Bermudas is about 1150 men, while the barrack-room, at 750 cubic feet of air per man, only admits of 606.

We need not test the reader's patience with the other details, such as the account given of the Hospital—intended for forty-eight patients, but, allowing 1500 cubic feet for each individual, only capable of accommodating twenty-four—*with large store-rooms and pack stores occupying its basement floor!*

There are striking features of similarity between many epidemic diseases. The three factors for the cultivation of cholera, says Dr. Richardson, are:—1. A centre of pollution for its cradle; 2. a ship for its transport; 3. a number of

*

cities and towns properly prepared for its reception and development.

En passant, we may state that Dr. Barrow argues strongly in favour of the local origin of this epidemic of yellow fever, and against its importation into the colony. The first and second true cases of the disease, however, appear to have occurred in the persons of men who had arrived from Nassau, which is a significant fact to our minds. Be this as it may, in whatever way we view the facts we arrive at one result, viz., the abominably insanitary state of the town and garrison of St. George. Now comes one of the most extraordinary pieces of official hardihood. The 2nd Queen's, on its arrival from Gibraltar, was encamped near the town of St. George. The civil Physician warned the commanding officer of the great danger the troops were incurring, recommending their immediate removal; in spite of which a large body of these unacclimated troops was kept for fifteen days in the same dangerous locality. One would have thought the authorities were actuated by a spirit of dogged indifference, but for the totally inadequate efforts which they subsequently made. The troops were not only moved too late, but this removal was rendered very ineffective when it did take place. The General Hospital establishment, commissariat, purveyors, ordnance stores, etc., had been allowed to remain in the town, or its close proximity, necessitating the constant exposure of a great many men to the same pestiferous locality. Of course no one can now say of what kind, or how many, were the representations made by the Medical officers; but we are bound to state that the writer of the report from which we quote acted with great energy and discrimination. The spread of the disease was at last subdued, not without entailing a fearful loss of life among officers and men alike, including a, relatively, very large number of military Surgeons.

Now let us turn to China, for the latest, as well as the saddest exhibition of an utter want of foresight in preventing, and the most reprehensible mismanagement in dealing with the evils when they did arise. The story appears to be a simple one. The Government had determined upon reducing the army expenses on the China station, and no sacrifices must stand in the way, we presume, when the Government has made up its mind. The Indian allowances were to be withdrawn in order to effect this reduction, although Hong Kong is about the dearest station in the world. To do this, the native Indian troops were to be removed and replaced by British troops. Indian soldiers can stand the Chinese climate and exposure to night air much better than British ones. So far, then, there was some risk in the measure, but this was very far from being all. The barrack accommodation at Hong Kong is bad at the best. It is insufficient for *one* regiment, much less for two; indeed, it is so limited as to be in reality only adequate for *one wing of a regiment*. We know what China is: there is no lack of evidence in proof of fever, dysentery, and cholera being endemic there. On a previous occasion the 59th Regiment was well nigh destroyed by disease.

The late season proved to be a very unhealthy one, and the Government authorities seemed determined that nothing should be wanting on their part to place the garrison in the most unfavourable and inviting condition. We have heard that when the steam-transport conveyed the 11th Regiment there no provision was made for their reception. Their arrival was premature and unexpected. The unfortunate soldiers, and their more miserable wives and children, were lodged almost anywhere and anyhow—that is, they were encamped during the wet season in close proximity to an old burial ground. The items making up the bill of mortality and disease are—(1) an unhealthy season and climate; (2) overcrowding, impurity of air, and insufficiency of rest. The soldier actually did more night duty, and was infinitely worse off as regards accommodation and rest in this pestilential climate than he would have been in the worst barrack in England. How many poor fellows now sleep in the burial ground known as the "Happy Valley," how many more have had their constitutions shattered, will appear from this table, taken from a correspondent's letter in the *Standard* of the 17th ult.:—

Return of Losses to the Garrison from Death and Sickness between June 1 *and October* 31, 1865.

	Officers.	Men.	Women.	Children.	Total.
Died	4	87	9	52	152
Invalided	8	223	47	57	335
Total	12	310	56	109	487

On June 1 the strength of the garrison was 93 officers and 1871 men.

Many of the survivors, the convalescents, and the women and children were despatched to Japan for change of air. As to what happened *there*, we have no need to tell. It was a repetition of the same blundering unpreparedness. The *Times* of the 20th ult. supplies us with the latest facts:—

"The lists of death and disease have been already given in these columns; but as the tale is not yet told, and we have yet to learn who died at Hongkong, who at Yokohama, to which the 11th Regiment was removed, and who in the further wanderings of the plague-smitten battalion, we will only quote at present a very brief announcement in our yesterday's columns. In our Naval and Military Intelligence we read what must be almost the last act in this strange and miserable history: 'The transport *Gresham*, from Hongkong, arrived in Simon's Bay, December 7, bound to England. On departure she had on board 280 invalids, principally military from the 2nd, 9th, and 11th Regiments. Forty-two are reported to have died on the passage to the Cape; 12 of the worst cases were transferred to the Naval Hospital; 50 of the sick were sent to Seringapatam, and 68 others were placed under canvas at Simon's Town.'"

Exaggerated some of these accounts may be; disgraceful they unquestionably are.

Now, who is to blame for all this want of precaution and miserable mismanagement? The public debit it to the account of the Doctors; and if it really belongs to them there can be no mistake about the verdict they deserve, and will most certainly get. Dr. Dick was the senior Medical Officer at Hongkong, and he must have been in the condition of the Pharisees—seeing he did not see, hearing he did not hear, and, we will add, smelling he did not smell—if he did not protest against the authorities sending an additional regiment to Hongkong. We can know nothing positive of course, but we have heard and believe *that he did repeatedly, earnestly, and emphatically protest against it;* and, what is more, he prognosticated the evils that have actually ensued. We cannot understand it. There were healthy stations near: Singapore is one of them, Japan is another. At the former place there are said to be magnificent barracks, never yet occupied. How comes it that the local authorities did not take upon themselves to post the new regiment there when the danger was so imminent? Mr. Bright and a host of politicians manifest their sympathies with the much-injured black in Jamaica in very impassioned and eloquent terms; can none of these men find a voice for their own countrymen? The matter must be sifted to the bottom. Dr. Dick is to be relieved directly, we understand. We believe and hope, for the credit of the Medical Department and the Profession generally, that it will be proved that every effort was made to point out and avert the calamities which have befallen our troops in China.

THE WEEK.

CHARGE OF "MANSLAUGHTER" AGAINST THE ASSISTANT OF A POOR-LAW MEDICAL OFFICER.

We fear that fresh proof of the risk of confiding the care of patients to an unqualified assistant is afforded in the case of one of the Medical officers of the Stockton Union. Mr. John Richardson is the Medical officer for the Middlesborough district, and it appears that his assistant was attending

a man named William Jenkinson, since deceased. From the evidence taken at the coroner's inquest it did not appear that the assistant possessed any qualification. The post-mortem examination proved that death resulted from stricture of the urethra, apparently of long standing. No effort was made to relieve the bladder until the man was *in extremis*, and his death was caused, in the opinion of Mr. Jonathan Dickinson, who made the examination, by extravasation of urine from bursting of the urethra in consequence of retention. From the evidence of those who were in attendance upon the deceased, he appears to have repeatedly asked during his illness that an effort should be made to relieve him. The jury returned the following verdict:—

"We find that the death of the deceased has been caused through the want of competent skill and proper caution on the part of Mr. Simpson [the assistant to the Medical officer], and it is to be regretted that Dr. Richardson [the Medical officer] did not take the opportunity of seeing the deceased earlier."

This being in effect a verdict of manslaughter, Mr. Simpson was committed for trial. We cannot but think that were Union Medical officers to take greater pains to acquaint themselves with the requirements of the regulations prescribing their duties, they would avoid even the risk of appearing accessory to circumstances causing inquiries of this painful character.

THE MENTAL CONDITION OF EPILEPTICS.

Mr. W. A. F. Browne, Commissioner of Lunacy in Scotland, has lately published a lecture, delivered to Professor Laycock's class of Medical psychology, on the question, "Is every epileptic of unsound mind?" which affords some valuable observations on the question of the responsibility of at least one class of the criminal insane. He nowhere hints that all criminal lunatics, or supposed criminal lunatics, are epileptic; and we therefore need not discuss with him the question of moral responsibility in its relation to the great bulk of offenders in whose defence it has been raised. In fact, his theory of the non-responsibility of epileptics supposes a loss of consciousness and memory during the attack the existence of which must be at once negatived by the proof of any preparation for committing a criminal act or endeavour to justify it or to conceal it after its commission. He writes:—

"There is a portion of each epileptic's moral life during which he has not lived, of which he has no record nor experience, such as other men have; not even of transactions, and these of grave importance, in which he has shared, or seemed to share."

Again:—

"We have often compared the fury of the epileptic maniac to the rush of a runaway locomotive. It is not only that he throws himself headlong against all opposing objects and forces, regardless of himself and them, overturning, crushing, destroying, but that he is endowed with strength which is as irresistible as his murderous instinct is dangerous. At large he would be a destroyer; in a padded room, doors, walls, fall before his force and fury. André and others have related cases where the orgasm was manifested in a sudden start and race forwards, in a straight line, until the patient was brought up by a wall, or a ditch, or by exhaustion; and then, however marred and mutilated he might be, deep unconsciousness prevailed. I have seen only one case of this kind. An epileptic is the most powerful as well as the most dangerous of lunatics. The mania is almost invariably destructive, often homicidal. Georget and Bucknill have adverted to the frequency of the association of epilepsy with the homicidal impulse. Trousseau, rushing into the region of hypothesis, holds that the mere commission of a motiveless, aimless, unpremeditated murder 'est *presque certainement* le résultat du choc epileptique.'"

Great wits to madness are allied; the author shows that epilepsy is not seldom the connecting link. Julius Cæsar and Napoleon I., Bossuet and Molière, Newton and Madame de Stael, Pascal and Mahomet, are all ranged to support his belief that epilepsy, even when it only amounts to the recurrence of *petit mal*, is always attended by important modifications in the mental and moral condition of the patient.

THE ISLINGTON INQUEST.

We have received a copy of the verdict pronounced by the Coroner's jury in the case of the woman Margaret Scollard, to which Mr. Hume referred in the letter we published last week. The verdict was one of "death from natural causes"—"inflammation and effusion of serum into the bag of the heart;" but in addition the jury appended the following resolution:—

"The jury empanelled on the 11th day of January, 1866, at the Earl of Essex, Essex-street, Islington, to inquire into the cause of the death of Margaret Scollard are of opinion that she ought to have had Medical attendance, and that she ought not to have been refused an order at the Workhouse, and that Dr. Hume, the parish Medical officer, ought to have seen her when sent for."

The evidence went to show that the deceased was a woman of 40 years of age, that she was addicted to drinking, and that she had been ill for a long time, having attended as an out-patient at the Royal Free Hospital for four months. On Sunday, January 7th, she was worse, and sent for Mr. Hume, who asked for an order to attend her from the relieving officer. The messenger applied to the workhouse authorities, who refused to give the order, it being Sunday; but told her to go back to the parish Medical officer and tell him "that he must come." Mr. Hume's servant said he could not come, and Mr. Hume stated in the letter which we published last week that he was then at a midwifery case. The woman died at 5 o'clock on the 7th. Mr. Hume heard nothing more of the matter until he saw in a local newspaper that he had been censured by a coroner's jury.

We certainly think that Mr. Hume has a just right to complain. It was not incumbent on him to go to any patient without an order from the relieving officer of the parish. This he never received. When the second message arrived at his house he was absent on Professional duty, and it was impossible for him to attend. He was not allowed to give exculpatory evidence before the Coroner's jury or even informed that an inquiry was to take place, and yet a verdict of condemnation was registered against him. We hope that the verdict did not meet with the approval of the Coroner.

M. GOUNOD'S "TOBIAS."

We may remind our readers that a grand *function*, as the Spaniards would say, will be held at St. James's Hall on the evening of February 13, in aid of the funds of University College Hospital. Several unpublished works of M. C. Gounod, the author of "Faust," and of that most charming *méditation* on Bach's first prelude, which is or ought to be heard in some shape or other in every drawing-room, will be presented for the first time. There will be a good chorus and full orchestra, under the bâton of M. Benedict; that is, unless the composer himself shall conduct in person, which is possible. The second part of the performance is to consist of an entire new sacred drama on the well known and affecting story of Tobias. There is a kind of additional *prestige* conferred on some of the compositions of Handel by the fact that their earliest public performances were consecrated to the cause of charity. It will be a thing of good augury for the future fame of M. Gounod's "Tobias" that it was first performed for the benefit of a Hospital, in which so much sound work and good teaching has been done; and it will be creditable to the Medical Profession that they give a hearty support to a performance at which the most tender precepts of ancient charity will be combined with the highest flights of modern music, and applied to the cause of science and humanity. To such of our readers as like to vary the dull realities of Physic with speculation of an antiquarian turn, we may commend a study

of the original story with a view to the unravelling of the Medical problems contained therein. What was the foundation in fact of the story that Sara had strangled seven successive husbands, each on his nuptial night? Assuming that *seven* may stand for any number more than one, and knowing the prevalent ideas of the demoniacal character of epilepsy, is it possible that she had in an excess of epileptic fury strangled one or more husbands on the nuptial night? Are any similar cases on record? We have heard of one, well authenticated, which gives a shadow of probability. We believe that pinches of snuff, or other strong diffusible stimulant, may turn the scale against an epileptiform attack. Had the empyreumatic vapour of burnt fish a similar virtue in this case? Again, was old Tobit's blindness due to opacity of the cornea? Has the gall of a crocodile or other animal any virtue in causing absorption? Suffice it to say that the machinery of this tale may interest the Medical philosopher, whilst M. Guonod's music fascinates the ladies of his family.

FROM ABROAD.—THE STOMATOSCOPE—RESPIRATORY THERAPEUTICS—POPULAR LECTURES ON MEDICAL SUBJECTS.

A NEW instrument, to be termed the *stomatoscope*, was exhibited last week to the Paris Surgical Society by its inventor, Professor Bruns, of Breslau. A platinum spiral wire (enclosed in a box-wood cup, to prevent the transmission of heat), brought to a red heat by the passage of an electric current from two of Middeldorps' elements, is placed in the mouth behind the teeth. The light reflected by a very small mirror is sufficiently intense to render the jaw transparent, so as to allow of the vessels proceeding to the roots of the teeth, the smallest specks of caries, etc., etc., becoming visible. By reason of the transparency, even the labial coronary artery may in some subjects be seen at the level of the commissure, and its course followed. The instrument is therefore likely to form a useful means of exploration in dental affections.

M. Sales-Girons, encouraged, we suppose, by the favourable reception which his plan of administering pulverised liquids in a limited class of affections has met with, seems disposed, after the manner of over-sanguine inventors, to convert it into a hobby, to be ridden on all occasions. In a note accompanying a memoir sent into the Academy of Medicine, entitled "Respiratory Therapeutics," he attempts to generalise this plan of treatment, declaring that the bronchi, and not the stomach, are the proper channel for administering the principal medicinal substances. It is true he has only one solitary case to bring forward at present, but his object is to call attention to the subject.

"If there is a fact," he says, "which may be affirmed by the best proofs of modern physiology, it is certainly the preference which should be given to the respiratory passages over the digestive organs as the means of administering medicinal agents. Organic susceptibility, excellence of tissue, a position in the primary centre of hæmatosis, a special contiguity to the blood globules, a superior aptitude for absorption, cleanness of surface,—all these advantages of the bronchial mucous membrane contrast with the opposite conditions of the gastric membrane as a means for the good administration of medicines. It is true that the respiratory passages do not present the facilities of introduction and dosage enjoyed by the digestive canal; but, if a cure can be better operated through the former, the indication is furnished, and it will be attained by the means of art and practice. Until better contrivances can be devised, we offer the pulverisation of liquids as a means of introducing medicinal substances into the bronchi, as all those of which we now have to treat are soluble in liquids. Until we have clinical proofs, I am aware that the best physiological warrants are but favourable presumptions; but, if these presumptions will induce clinical researches, my end will be answered, for, persuaded that sooner or later the recommendations of physiology will lead to favourable results, my ambition counts only in hastening these on. I have only one case at present—that of an obstinate intermittent fever treated and cured by a pulverised solution of quinine."

The popular lectures on scientific and literary subjects, which have so long formed a feature amongst our own educated classes, have recently taken root in Paris, and have spread through the chief towns with something like enthusiasm. As might be expected, many of these have been characterised by great ability, and their delivery is likely to be of utility. This last remark cannot be predicated, however, of a series now in course of delivery by M. Marchal de Calvi, who, we feel certain, will never find imitators in this country, at least amongst persons of the same stamp as himself. An accomplished orator, and holding himself a high position in the Paris Medical body, he has been addressing immense audiences of ladies and gentlemen in the *Salle Valentino* upon Medical topics, taking cholera, small-pox, vaccination, etc., for his subjects. How difficult such a task must be to accomplish with tact, delicacy, and efficiency before a mixed assemblage of this kind need not be explained, any more than the necessary incompleteness and uselessness of the results which must, after all, attend its execution. If this were all, we might pass the matter by as a mere foolish undertaking; but, when it is stated that the orator has condescended to flatter in place of combating the prejudices of his auditors, and amidst salvos of applause held up what he chose to consider the shortcomings of the Profession to the gaze of a mass of persons totally unfit to entertain an opinion on the matter, one can only regret the right of holding public assemblies in France, which has been so often withheld for so many useful objects, has been granted on this occasion for one so destitute of utility and so fraught with mischief.

THE PERFECT CURE!

(*From a Correspondent.*)

Two hapless calves are down with the disease, and by dying they teach us that vaccination affords no protection against cattle plague. Thus has the small-pox fancy, falsely spoken of as the general opinion arrived at by scientific men, and puffed into publicity, suddenly collapsed. Soon, indeed, has the vaccination bubble burst—too soon for some who thought to find by it a short and easy road to scientific fame.

The Veterinary Surgeons have so far gained little credit, but they have at least exhibited wisdom in keeping silence and candour in confessing their inability to cure or prevent this frightful malady. Long ago, indeed, did many of them most strongly advocate the pole-axe, and to the pole-axe, wasteful as it seems, shall we come at last. Had this course been resorted to in the first instance how much would have been saved to us which is now lost! We know no more at this moment concerning the nature of cattle plague than we did when the first case occurred in this country. Thousands of pounds have been spent, and we have arrived at the safe conclusion that cattle plague is an "eruptive fever" of a very fatal character; but precisely how it kills, why it kills, and what it is that kills, have we yet to learn.

Now that the work of the Commission is pretty nearly over and those working for it have nearly completed their reports, it is little use suggesting the importance of further scientific investigation. Probably the Government is tired, the Commission tired, and the scientific men tired of the cattle plague; but let us not therefore conclude that all that could be done has been done. A few thousand pounds judiciously spent in experiment would have taught us far more than we now know, not only concerning cattle plague itself, but as regards the nature of some of the most important morbid changes occurring in man and the higher animals. It will be almost a disgrace to the scientific energy, to the wealth and to the persevering nature of Englishmen, if we do not learn the exact nature of this disease before it is effectually stamped out of the country and the opportunity for ever lost. We say *for ever*, for it is quite certain cattle plague will never again be permitted to ravage our herds as it has done for some time past and continues to do at this present time. We wonder

that before this there has been no association established for the discovery of the nature of cattle plague, and we strongly recommend enthusiastic veterinarians to take the matter up, get all the scientific assistanee they can, and thus gain credit for themselves, for science, and for the country.

SENSATION SCIENCE.

(*From a Lecturer.*)

Never, perhaps, in the history of British scienee did things look more dismal than at this time. A few persons with considerable scientific influence, power, and attainments, seem determined to make science appear ridiculous in the eyes of thoughtful men, and it is difficult to decide whether their acts should be condemned as resulting from vulgar taste, from intense conceit, or from bad judgment. There was a time when men worked at scienee from a love of it and a desire to find out what was unknown before. The discovery of a new truth was their highest ambition; the admiration of their fellow-workers their greatest reward. Teaching what they had themselves learnt afforded them income and brought them renown, and their pupils spread their fame. Quietly they lived and worked; quietly each one contributed his elaborately-carved stone to the ever-rising temple, well knowing how little his life's labour would really advanee the great work, but hopeful because he knew others would eontinue the task when his generation had ceased to work.

But now how different! The scientific of this age speak as if they stood upon some lofty pinnacle and looked down, with something akin to pity, from a vantage ground peculiarly their own, upon seientific work past and to come. Science, or rather that which has been wrongly called science, is to be dragged into vulgar notoriety. Things not yet proven, but of vast interest to thoughtful men, are forced before the public long before they have assumed a form in which they can be either interesting or intelligible. Crude theories are advanced and taught as if they were well-ascertained facts, and are replaced in a few months by new theories as crude and as ill-founded as themselves. Thus the public laugh at the last new thing in seience, and come to see the last new man who is brought forward for their amusement, as they come to see the last new giant or the last new conjuror. Surely it is time for those who think at all, to consider if science can be advanced by thus being dragged through the dust. What may not the whole body of scientific men lose, and what can the individual popularisers themselves hope to gain?

Some scientific men, not satisfied with the vast field of nature in which to work, would constitute themselves the directors of the general education of youth. Continually changing seience is to be forced into the place of fixed and settled branches of human learning, proved by ample experience to be at least good, and employed for training in our schools; as if every boy's mind were as capable of mastering the last new atomic theory or the Darwinian hypothesis as the elements of Latin and Greek. Nay, there are some teachers of science who, not eontent with all this, must exalt the teachings of (*their*) science above those of Christianity itself. Plain men are tortured with the so-called scientific truths and the wonders of the universe and the omnipotence of solar energy and the physies of intelleetual action, until they feel giddy and begin to loathe the very name of science. *Punch* and little boys will soon laugh at the pretentious boastings of vain-glorious seienee, and scientific theories will become bye-words. Plain fathers find a scientific authority condemning prayer as useless, and ask themselves with humble anxiety how this man eomes to know so much more than they. Then, again, they tremble lest, after all, the confident assertions of modern science should not prove to be true, and, after having seen their sons lured away from the roek on whieh they fain would have them rest, as they themselves have rested, they find them recklessly abandoned on an ever-shifting sand, which cannot become a resting-place within the time allotted to men to live. To them it seems that the present tendeney of seience is to destroy all faith, for no scientific man has hitherto stated in plain words what he does believe, or the grounds of the belief he may have. Still, men must have and will have beliefs, and there are some now living who perhaps remember with horror something about a feast of a Goddess of Reason. Some avow that nothing is to be believed save that which ean be distinctly demonstrated, and that all that cannot be understood by existing human intelligence is to be regarded as mere fable or the creation of fancy. Sensation scientific thought and work still tend almost unopposed in the same direction.

A scientific man lecturing on a Sunday evening in St. Martin's Hall, looked with horror upon the impious and blasphemous imprecations of the cix. Psalm, and appeared to think that it was his mission to educate the public mind on these matters, concerning which the mouths of the ministers of religion were closed or capable only of utter perversions.(a) After the enuneiation of modern scientific dogmas concerning the antiquity of man, the organ peals forth, and the incongruous entertainment is brought to a close. Thoughtful hearers are simply confounded, and wonder what relation there can be between the music of Handel and the antiquity of man. Poor Handel! No one knows better than the scientific men who have thus made themselves eonspicuous that no real good whatever can result from such scientific teaching. Of all thorough useless work, the delivery of a sensation scientific discourse must be the most useless. They know by experience that it is impossible for any one to learn science in one or in many scientific lectures, and smatterings of few branehes of knowledge are so injurious as smatterings of advanced speculative science, for they necessarily make men more conceited without necessarily making them them more profound.

But if some of those whose stern duty it is to jealously guard the honour and to protect to the utmost the interests of British science, and, above all, to preserve her purity, pandering to the desire for popular notoriety, choose to devote their talents and energies to pleasing and amusing the public, and exalting beyond measure one-sided scientific theories, there is no reason why Medical scientific men should follow. We have no great scientific victories to eelebrate or grand discoveries to proclaim. Little by little we may learn more of disease; but how very little we really know, our daily work tells us in language we cannot mistake. The method pursued by Harvey and Hunter is the method which a man must follow if he would advance Medicine. Quietly and submissively working on from year to year, he may, if he live long, succeed in adding something to existing knowledge. Grandiloquent boastings are, however, occasionally met with in modern Medical writings. Assertion sometimes takes the place of research, and the admiration of unthinking and irresponsible writers not unfrequently forces into notoriety that which fair and not too searching criticism would show to be of little real worth. Our reviews often give friendly praise instead of honest criticism; and tact in coming before the public has, perhaps, more to do with mere scientific or Professional success in these days than sober merit or thorough work. If, however, Medicine is to retain the respect of the public, our scientific men must avoid the sensation tendencies of the age in which we live, and if those among us who are aspirants for seientific fame feel tempted to leave the sequestered paths of quiet, steady, unobtrusive scientific inquiry, and ply for short-lived notoriety, let them reflect upon the fate of some of the

(a) See an article on "The Sunday Science Movement," *London Review*, January 27, 1866. The true philosopher is usually a man of modesty and good taste. Compare F. W. Newman's eulogies on the Psalms, the Soul, etc., etc., quoted in Stanley's second series of leetures.

most recent and most favourite theories recently advanced, forced into short-lived popularity and refuted in a few short weeks, and then reflect how differently Harvey and Hunter thought, and worked, and hoped.

The days of true work seem past. There was a time when scientific men loved their laboratories and workshops as they now seem to love amusement halls and large audiences; when, instead of forcing their ideas down the throat of a public already suffering from the nausea caused by scientific repletion, they met together, discussed the last discoveries advanced, and encouraged one another to work on. But fashion has already established a new order of things; new sensation scientific articles must enliven the pages of our evanescent, but overwhelming weeklies, and new favourites will be forced into an artificial but fatal notoriety, first petted and spoilt, and then ruthlessly abandoned to fate, or laughed at by the very caterer for novelty who seduced them to emerge from a happy, but useful, obscurity and honest work to serve the trumpery purpose of the hour. S. P. E.

REPORTS ON THE EXISTING CONDITION OF TOWN AND COUNTRY,

AND

THEIR STATE OF PREPARATION AGAINST THE INVASION OF CHOLERA.

(By our own Special Commissioners.)

No. IV.—ST. PANCRAS.

The parish of St. Pancras, with a population (by the last Census) of 198,788, and an area of 2700 statute acres, contrasts favourably with some and badly with other London parishes. Thus Hackney, with scarcely a third of the population, contains 4000 statute acres, whilst Bethnal-green has a population more than half as great, yet a superficial area of only 760 acres. Bordering towards the west upon Regent's-park and Highgate, and easterly upon St. Giles's and Clerkenwell, it contains slums that might almost vie with Bethnal-green and Webber-row; and near to its west end, yet acquiring no tincture of decency from proximity to fashion and society, is the most disreputable court in the whole parish. At the east end is the terminus of the Great Northern Railway, and the "Midland," which crosses here, will, by its proposed alterations, turn nearly 10,000 people out of doors, and at the same time clear away many obnoxious places.

The avocations of the people are very various—costermongers, artificial flower makers, small shop-keepers, stablemen, day labourers, and cabmen, form the chief part of the lower orders. The number of mews is large, and most of the hay-lofts are turned into dwellings. Those who delight in "mazes" may find scope for their ingenuity in exploring these upper regions, in ascending to which, after first passing the hind legs of several horses, you climb a staircase (provided, or not, with a hand-rail, according to the demand for hockey-sticks by the stable boys), and then, if not quite stifled by the smell of hay and horse-dung, you may try to find your way, being lucky if your hat and legs meet with no accidents. Yet the people who live up here are, as a rule, healthy, perhaps because the drains and dung-heaps are looked to once or twice a week for the sake of the money got from the sale of the latter. The "arterial" system of drainage is perfect, as any one may see who will view the plans of it at the Board of Works, where the green circles pointing out the openings into the mains, and the small figures in red and black showing the depths of the drains below the surface at different points, testify to the labour bestowed. To make a summary statement, all the sewage *north* of the main drain running eastwards goes down to Barking Creek with a constant fall, whilst that to the *south* goes to Old Ford, from which level it is pumped into a reservoir to acquire a fall for carrying it to the outlet. In the sub systems of drainage, however, many faults lie, and choked-up drains running under dwellings, broken traps, and drains built of brick, so that the sewage escapes through the crevices, are the causes of much that is bad. Unless these smaller evils be attended to, the means for good may become the seeds of pestilence, since when the traps of the drains leading into the mains are broken, an air-shaft is actually formed leading from the main, and conducting noxious vapour into the yards intended to be made healthy.

The deaths in St. Pancras from *all* causes amount to 22 per 1000, and those from typhus in 1864 amounted to 128; in Bethnal-green, for the same year, they were 138, with a population, as has been shown, of scarcely more than half that of the former. In St. Pancras, the deaths from typhus in 1865 were 135, according to the Registrar-General's Report, showing an increase on the previous year, though slight considering the heat of last summer and the greater crowding.

In point of filth and destitution, I do not think that any dwellings can be found in this parish so utterly bad as those described in the Reports on Bethnal-green and Southwark; and such is the opinion of those who have had opportunities of comparing them; yet still I managed to single out some dreary abodes, and one of the very worst was *Mary-place*, a blind alley situate between Hampstead-road and Clarence-gardens. About twenty cases of typhus have been lately taken into the Fever Hospital from this spot, and it was to accommodate some cases from this place that room was made in the Workhouse. Among them were the patients from whom the late Mr. Roberts contracted his fatal attack of typhus. A policeman to whom I spoke described the inhabitants of *Mary-place* as "thieves, prostitutes, and costermongers," and the aspect of the place seemed suited to the description of its inhabitants. A court paved with flags, much below the level of the street, and slanting downwards at its further end, with a row on each side of dirty two-floor cottages, first met the eye. Lots of begrimed, half-clad children were playing about, some singing "Jolly Dogs," and apparently as happy as they said they were. Other slatternly girls and women lolling out of the windows reminded one strongly of the "March to Finchley." Two whitewashed houses on the right side contrasted strongly with the filthy exterior of the others.

I entered one of the houses where fever had been, and found it to have just such dirty, plaster-stripped walls, with broken floors and ceilings, as were described by your correspondents in the other districts. No traps in the back yard but "five-hole" drain-tiles, and the inevitable oil-butt metamorphosed into a water-tub; the rooms small, from eight to nine feet square, very low and ill-ventilated. I could not smell any effluvia from the drains, but a blear-eyed woman said that the Medical Officer had been there the day before and had told her to scatter some chloride of lime around the apartment. All complained of the bad smells in the summer time. I asked how many slept in the rooms at night, and was told "only three or four." The policeman, however, assured me that as many as eight or twelve slept there. Another house into which I went was much after the same style, enough to show that so long as places exist such as *Mary-place*, we shall not see the last of typhus. I was glad to get away from this locality, and so seemed the policeman, who said—"You see, Sir, we never go there except when we are obliged."

In "Bellford-place," close by, the houses had, I think, the smallest modicum of stairs for descent that I ever saw; there were no traps for the drains, and actual ordure was piled up in one corner close to an over-filled dust-bin.

In *Brook-place*, Munster-square, were broken and wet flags, with a broken closet seat, and a heap of rubbish reaching nearly up to the top of the wash-house. The yard next to this consisted mainly of some puddly soil called a garden, with a small half-dead fir-tree in it, planted round with oyster-shells, the mementoes of last "grotto-day." In this quarter are several more small streets, dirty and forsaken-looking and ill-paved. Wending my way towards the east end of the parish, I came to *Little Pancras-street*, a small thoroughfare near a mews, paved with large round stones slanting down to a gutter in the middle of the street, and well adapted for accumulating rain and sundry fluids ejected from the houses. One of the houses here, No 7, stands prominent in the black books as a fever den. There has been no fever in any other part of this street, so that the circumstances under which

No. 7 is placed are noteworthy. One of a small number of two-storied cottages, it has been innocent of paint and whitewash for at least three years; the walls are plastered with filth, and the ceilings of the rooms displayed the laths in various parts. The state of the backyard was disgraceful even for a pig-stye; the tiles broken and covered over with water; a pool of greenish, milky mixture receiving the drainage from the roof; the water-tub exposed, dirty, and the water in it muddy; the dust-bin so choked up that an accessory dust-heap was made in one corner of the yard; the privy foul and the seat broken; no traps to the drains, but five-hole tiles substituted for them. Close up to this yard were men working in a timber-shed, and to these the proximity cannot have been agreeable. In-doors things were just as bad; the back-cellar was uninhabited, and had been converted into a temporary dust-cart, for here were thrown last summer's accumulations; the smell of it was strong; the woman who dwelt in the front cellar—a low, dark, wet place—said that all during the last summer the stench had been insufferable, yet she paid two shillings a week as rent for the room, such as it was. Six cases of typhus have been sent from this house to the Fever Hospital, and one of these patients died in the Hospital last week but one. I went up-stairs to the room in which the fever broke out. The look of it was melancholy; disorder and dirt were supreme. The length of it was 10 ft. 8 in, the breadth about 9 ft., and the height 8 ft. 4 in., giving 800 cubic feet of air for six people. The mother had taken the fever first, then the father, then the woman who nursed him, and after her it had spread to the front room. The rent for these rooms was from 2s. 6d. to 3s. per week; the only ventilation in them was from broken panes of glass. The drains from the next three houses, if not stopped up, emptied themselves in that of this house. True, the people here were very dirty and slovenly, but whether as a cause or a consequence of the state of their domiciles is open to question. A woman at the rag-shop a few doors lower down said that the house (No. 7) had been ill-looked after for a long time; but she vindicated the healthy condition of her own back-yard, though the dust-hole in it was full to the top. She likewise plunged her arms up to the elbows into the heap to satisfy me that it was "quite clean dust."

More dwellings as bad as those in Mary-place and Little Pancras-street are not easily met with, but I think that the rank next to them may be filled up by *Compton-place*, bordering on St. Giles's parish, and close to Little Coram-street, which has lately figured in the papers as a fever den. *Compton-place* and *Hunter-place* are tolerably well paved, only one part near to the houses, but unoccupied by any, being destitute of any kind of flags or stones; this free ground is, however, a nuisance, since unused cabbage-leaves, stones, and dirt are all thrown upon it. The people who live here are mostly Irish, and destitute enough do some of their children look—"Kays" of the future and presidents of swearing clubs to come, in all probability. The houses vary from two to three stories in height, and are more dirty than they ought to be. A great evil in nearly all of these houses is the placing of the privies inside the lobbies just under the staircase, and as the water-cistern is put either on the top of the privies, or close in apposition to them, it is clear that the chance of pure water is out of the question. Many of the houses have *no yards at all*, so that drains, privies, water tubs, etc., are crammed into corners right under the noses of the tenants. Some of the sleeping apartments are, as it were bedrooms off bedrooms, getting thus only secondary light, which, dim originally, becomes exceedingly glum at last; yet for some of these rooms six shillings a week are paid. At No. 17 there was no back-yard, the closet very dirty, six or seven persons sleeping in a small upstairs room, and great complaints were made about the smells from the drains. Some urinals at the entrance to the court are rather a nuisance in hot weather.

One of the offshoots of Judd-street, which latter is one of the best streets in the parish, is *North-place*, where the abusive and disgusting language of the district seems to be concentrated; whitewash and plaster are unknown here, and the ricketty stairs, sloppy yard, and untrapped drains show as little regard to cleanliness as the indwellers do to godliness. In one of these back yards a breeze which was blowing was operating on a large dirt-heap in the corner, and carrying the particles into the top of the uncovered water-tub, there forming so complete a dusty layer that the nature of the fluid underneath it could not be determined. The cellar was 2s. 6d. a-week, and two dark and dismal rooms on the ground floor 4s. a-week. Great complaints were made of the difficulty in getting the dustmen to come if there were no chance of any beer for them.

In *Catel-place*, Cromer-street, the water-cistern was put over the closet, which was common to the whole court, consisting of several cottages. The traps were broken, and the complaints of the smell from the drains were numerous.

Draper's-place, one of those selected by Dr. Jeaffreson for his visits, is chiefly occupied by costermongers, driven from "The Brill" by the railways. It has a bad reputation, and seems to warrant as much by its looks; yet, still, in one or two things, Draper's-place can give a lesson to more pretentious-looking parts. Thus, no drains run under the houses, but they are disposed in a long row under the yards, and empty into the main drain at the end. Twelve months ago typhus was very bad here, and in one of the houses typhus and typhoid were seen in the same room; but since then the drains have been repaired, and the health of the place is now better. One nuisance, however, was there, in the shape of a gully running down the middle of the court, the trap of which at one end was stopped up, so that the slops thrown into it had accumulated, and were offensive.

At No. 20, Lancing-street were lately some bad fever cases. The drains here had, however, been examined shortly before the outbreak, which began in the first floor and extended until at last eight or nine persons were affected. In the front of the house next to this was a large heap of dust, broken pots, and dirt.

At a house in *Wellesley-street* were three cases of typhoid fever in the same room—one child 8 years old having had it first, and the two younger children having been attacked during his convalescence. It was difficult here to say how these attacks arose, for the only defect in the arrangements was a broken trap, everything else being clean and well looked to.

Isaac's-place.—Strong smell of acrolein from a tallow-chandler's; rubbish grounds in front of houses; in some no pan to closet. In one of these houses a boy died not long ago from hæmorrhagic small-pox after an illness of only three days. The house and room were very dirty.

Speedy place.—One large dust-bin common to the whole court, exposed with no lid. Three cases of typhoid fever at one of the houses. "Five-hole" drain-tiles.

Not to enter more at length into wearying details, I may add that most of that part called "The Brill" in Somers Town, has been cleared away by the Midland Railway; other courts and streets, such as *Hertford-street*, *John's-place*, *Beale's-place*, *South-place*, etc., etc., are much the same, though not quite so bad, as those described.

At 10, West-street, a man littered his horse in the yard and heaped the dung against the parlour window.

Ashby-street, King's-cross: Typhus had visited three of the houses here. Some of the people litter their horses in the back parts, and the old tale of dustheaps, exposed water-tubs, and broken privy seats might be repeated here.

In *Span's-place* I found an old harridan in a room so crowded with old garments, chairs, etc., that there was little scope for air—the place certainly was stifling, and the sense of suffocation great. A large feature here was an old arm-chair—a remnant of some owl-and-bottle club, with the motto "In nocte lætamur." I opened the window, the capability of which to be opened much astonished the occupant of the chamber.

Before taking leave of the parish, it may be as well just to notice the new model lodging-houses, which, though not very elegant externally, are still extremely healthy and commodious within. Some of the rooms can be had in sets of two for 3s. a-week, other larger ones at five shillings, and three rooms with a small scullery for 7s. a-week. The drainage is excellent, and the supply of water abundant. Those who occupy the rooms have to take turns at keeping the passages and steps clean. Typhus is a thing unknown here.

Such is a short review of the parish of St. Pancras; and it tends to confirm the conclusions drawn from reports of other parishes in this, that it is the stinginess and carelessness of the small landlords that stand in the way of sanitary improvements. So long as stubborn Vestries will not support the alterations proposed by Medical officers, so long will this system of things continue. We want decent lodging-houses built for people whose wages average 18s. a-week; houses where the drains don't run under the floors, where the water supply is good and kept in cisterns, and where cleanliness is compulsory. Only by these means can we keep away typhus, and preserve lives with less damage to our pockets.

REVIEWS.

Du Suicide et de la Folie Suicide. Par A. Brierre de Boismont, Dr. en Méd. de la Fac. de Paris, Directeur d'un Etablissement d'Aliénés, etc., etc. Second Edition. Revue et augmentée. Paris: Libraire Germain, Baillière. 1865. 8vo. Pp. 763.

On Suicide and Suicidal Madness. By A. Brierre de Boismont, M.D. Paris. 1865. Second Edition.

This is a really classical treatise. By far the most interesting question with regard to suicide is that of its causation, and on this head M. de Boismont has given us much valuable information; indeed, one-third of the volume before us is taken up by the consideration of this subject. The notes of 4595 cases of suicide, deposited in the Archives du Parquet, are the foundation upon which M. de Boismont builds his remarks upon suicide. It is but just to say that he has shown the greatest carefulness in excluding, as far as possible, the errors which are inseparable from statistical results.

Suicide is undoubtedly hereditary. It is often the only sign of madness which shows itself in a family. Fabret speaks of a family where a taciturn father had six children, five boys and one girl. The eldest, at 40 years of age, threw himself out of a window without known motive; the second strangled himself from disappointment at 35; the third jumped over a window; the fourth shot himself. A cousin threw himself into the river. We are by no means surprised to learn that men commit suicide oftener than women; the proportion is three to one. Women are exposed comparatively seldom to the exciting causes of suicide; they can lean upon another's strength, and they perhaps want the physical courage to inflict deadly injury upon themselves. When they do destroy themselves they usually select a death where there is no disfiguration. They poison themselves with charcoal or drown themselves.

In spite of the popular belief in the tenacity with which old people cling to life, statistics show that suicide becomes more common as age advances. Of all persons living between the ages of 16 and 21, 1 commits suicide in 22,417; of those living between 70 and 80, 1 commits suicide in 8717. More girls commit suicide between the ages of 15 and 20 than at any other time, showing the influence which puberty and its dangers have upon them. Young men living in large cities frequently commit suicide between the ages of 25 and 30, probably because at that period they are mentally excited, and having left the parental roof, have not yet assumed the responsibilities of a new home. But no age is entirely free from suicide. Children of 5 years of age kill themselves because they fear a scolding or because they wish to make their parents sorry, more rarely because they feel themselves a burthen to those who take charge of them. Out of the 4595 cases, 44 were of children under 16 years of age. Nor is excessive old age free. We have it on the authority of a Russian Home Minister that a serf hung himself in his stable at the age of 120.

Nothing has a better influence on suicide than married life. Out of the 4595 cases, only 1644 were married people, although in the general population there are more married than single people. 1180 suicides had children. Absolute want is not such a frequent cause of suicide as is generally supposed. Of the 4595 suicides, 697 were well off, 2000 were earning a livelihood, 1588 (or about a third of the whole number) were poor. Of these 282 appeared to have killed themselves on account of their absolute wretchedness.

The statistics on education are not very satisfactory. Out of 4595, the educational status of 3086 suicides is given. 1362 were well educated; 1656 could write without orthography; 3 could not write; and 65 could not read. M. de Boismont has attempted to trace the influence of education on suicide by comparing his own suicidal tables with those of the Minister of the Interior as to the proportionate number of children sent to school in each department. He says that, without detecting a distinct relation between education and suicide, still the latter is most prevalent in those departments where most children are sent to be instructed.

It is impossible, however, to estimate education from school returns. No doubt the high suicide rate in large towns is greatly due to the irregular education gained in theatres and ther places of amusement.

It is difficult to appreciate the effect of any profession on suicide, as we have no returns of the number of persons following each profession.

There is one class of unfortunates whose profession we have always regarded as a direct incentive to suicide. Dr. Tait tells us that in Edinburgh a fourth of the prostitutes annually attempt suicide; one-twelfth actually accomplish it. On the other hand, Parent du Châtelet agrees with de Boismont that suicide among French prostitutes is very rare. Probably this difference is due to the superior education of the Scotch women.

So much for the predisposing causes of suicide. What are its exciting causes? They are often multiple, and are consequently not easy of classification.

The wretchedness which leads to suicide is often the result of idleness, of want of forethought, of prodigality, of drunkenness, sometimes of hunger. Some men kill themselves to secure a competency for others, some because they are ruined, or because they are in debt. The depression produced by want of work, or that which follows a debauch, not infrequently impels towards self-murder.

In another class of cases suicide is committed on account of some family sorrow, the loss of a dear friend, dislike towards the inmates of one's house. Love is a frequent source of suicide. Jealousy prompts either to murder or self-slaughter. Remorse for what one has done, for some shameful action long since committed, the feeling that one is sinking in public or private estimation, often leads to suicide. Play is constantly having its victims. Pride and vanity make many follow the example of Chatterton. Every sentiment, no matter what be its nature, if it is only exaggerated enough, is sufficient to tempt certain persons to the fatal act.

In one class of cases the exciting cause of suicide is physical pain. Those of us who have watched by the bedside of a patient slowly dying from cancer will understand how ardently the peaceful grave is longed for by those whose days know no joy and whose nights know no rest.

Certain diseases, more especially those connected with the genital organs, are more apt than others to urge towards self-slaughter.

Nothing can be more difficult than to decide upon the sanity or insanity of a suicide. Some men look upon the act of self-slaughter as in itself evidence of insanity. M. de Boismont takes the opposite view. He cites typical cases of sane and insane suicide. A military man retires from military duty because a revolution has occurred and he can no longer fight with a clear conscience. The time hangs heavily on his hands. At length he finds that gaming is his only distraction. For some years he goes on gambling—now gaining, now losing, but always losing more than he gains. At a calm moment he reviews his position. He has dissipated half of his fortune; enough remains to educate his son and keep his wife comfortably. He feels that he cannot resist the passion for gambling, which has grown upon him, and that if he goes on the dear ones whom he loves will soon be reduced, by his misconduct, to beggary. He shoots himself dead to avoid such a catastrophe. Again, a melancholic patient imagines that he is persecuted. Soon he sees supposititious enemies surrounding him on every side. He believes that his friends are trying to poison him. He holds threatening conversations with invisible foes. He has not a moment of peace, and at length, unable any longer to endure such torment, he strangles himself. Surely, says our author, common sense would teach us not to class these two cases as parallel; the first was an instance of simple sane suicide, the second of suicidal madness. No doubt there is a wide difference between these two cases, but is it a difference in kind or only in degree?

There are two distinct classes of insane suicides. In the first category, self-murder is immediately due to hallucinations, to illusions, to delirium; in the second, it is perpetrated under pressure from the passions. There is an insane impulse which can always—at least, at first—be combated. But there is no sudden step from one category to another, nor is there a well-marked line between the second class and many who go about without any imputation upon the strength of their intellect.

The man who is most healthy is he whose balance of health is most perfect, whose mind is not in advance of his body, whose judgment is not overruled by his imagination, nor paralysed by his passions. It has been said that civilisation and education sometimes prove more a curse than a blessing; but this can only be because the education is partial and imperfect, so that the just balance is destroyed. That education is the

most perfect which cultivates equally the physical, intellectual, and moral attributes of our nature. But how seldom is this education to be obtained! The body is cared for, and the mind is neglected. Æsthetic enjoyment is searched for everywhere, while the reasoning faculties are allowed to decay; or we bow down and worship our intellect, and impiously deny our God.

Men of small minds still wish to shine. They select one faculty and educate it at the expense of the others. They are men of one idea; bigots, intellectual monsters, who bear the same relation to a perfect man as a blacksmith with brawny biceps and shrunken calf bears to the Apollo Belvedere. The danger in this nineteenth century of ours is, that the intellect should be over-stimulated. Realism has the advantage over idealism. There is very little danger that we shall go forth to spill our blood, fighting against windmills, to do honour to some Dulcinea whose charms and graces are entirely supposititious; but there is danger, or if no immediate danger still there is a tendency, to sit down coldly and count up the cost.

> "Whether 'tis nobler in the mind to suffer
> The stings and arrows of outrageous fortune,
> Or to take arms against a sea of troubles,
> And by opposing end them?"

The safeguard against that sane form of self-destruction, which arises because a man doubts whether it is worth his while to live, is found in the consciousness that there is a nobility in suffering, if suffering come in the way of duty, and that every one of us has his place and duty fixed here by One wiser than himself. In the words of a poet of the same school—

> "Ut melius, quicquid erit, pati!
> Seu plures hyemes, seu tribuit Jupiter ultimam,
> Quæ nunc oppositis debilitat pumicibus mare!"

Some Effects of the Climate of Italy. By Thomas King Chambers, M.D., etc., etc. London: John Churchill and Sons. 1865. Pp. 96.

Most men in good practice know the climate of Italy, not as a last and doubtful remedy for the consumptive, but as a means of warding off the commencement of degeneration and decay. The clear, dry air, the bright light, and warm sun are resorted to for the purpose, as it were, of baking, drying, colouring, and vivifying the pale, lymphatic, and flabby, who languish under the pale sky and damp air of these islands. Dr. T. K. Chambers, who writes with that knowledge derived from personal observation, will tell us where, how, and when to send our patients, what they should do and what they should avoid.

GENERAL CORRESPONDENCE.

THE SMALL-POX HYPOTHESIS OF THE CATTLE PLAGUE.

Letter from Dr. John Fairmann.

[To the Editor of the Medical Times and Gazette.]

Sir,—As the *Times* of to-day contains a letter from Dr. Murchison, in which we are informed that he no longer maintains the prophylactic influence of vaccination, there is no need for me to adduce additional instances to show that the fact of cows having had cow-pox gives no immunity from the plague. And, though it has at no time formed any part of my object to cast discredit upon the trials which have been so extensively put in practice as to the preventive power of vaccination, I cannot have been insensible to the utter want of scientific accuracy evinced in so many of these experiments. The surprise is, not that the idea of the preventive force of vaccination is now given up by its ablest advocate, but that such facility in the admission of evidence favouring this idea should have been allowed. When we found such a one-sided experiment as that of Mr. Tollemache with his vaccinated heifer advanced by himself, and not objected to, as forming "a crucial test," any one not biassed by a foregone conclusion, and aware of the real nature of an *experimentum crucis*, must have seen the utter worthlessness of all such trials as those so prominently advanced by the believers in the preventive influence of vaccination. And not only was there an unphilosophical readiness shown in admitting all manner of evidence on the one side, but a commensurate repugnance was displayed when dealing with counter proof.

The statement of fact contained in my letter which you did me the favour of inserting in your issue of the 13th inst. is an illustration of this. I made the statement there on my own personal observation, or on the evidence of competent eye witnesses. Dr. Murchison endeavoured to throw doubt upon my assertion of fact on the evidence of an informant who declined to examine these eye witnesses, and satisfied himself with the opinion of the master, who neither had personal charge of the cows nor had milked them. And we may not doubt, if Dr. Murchison had sifted the grounds upon which this "additional information" rested, he would not have allowed himself to express the doubt he seemed to entertain as to the accuracy of my statement, though it was opposed to the notion he was then so ably advocating. Very possibly, if his "cases" were examined, more doubt would arise as to their accuracy than he himself believes at all likely. Keeping to the principle of my former letter, my information places the evidence as to "Case X." of his letter to a contemporary, of January 20, in a somewhat different light from that in which we have it there given. Upon the whole, the conclusion to be drawn from this, as from too many other instances of theories having been advanced, is, with how much caution we should receive statements of fact when our own opinions are in question.

I am, &c.

John Fairmann, L.R.C.P. Edin., etc.

Staffordshire, Hanley, January 31, 1866.

BLISTERING IN ACUTE RHEUMATISM.

Letter from Dr. Herbert Davies.

[To the Editor of the Medical Times and Gazette.]

Sir,—The following brief but very satisfactory notes of the results of the blister treatment of acute rheumatism have been kindly sent to me by Mr. E. Howard Moore. The cases were under his care in the Infirmary of the Bethnal-green Workhouse. They exhibit the rapidity, efficiency, and safety of the plan.

I am, &c.

Finsbury-square, December 16. Herbert Davies.

Case 1.—W. H., admitted February 17. All joints affected, but chiefly the right hip, both knees, and right ankle. To these blisters (acetum lyttæ) were applied, which gave relief immediately the serum was evacuated. Next day the right shoulder and wrist were intensely painful and swollen, and were treated in the same way and with a similar result, which shows the necessity of blistering all joints simultaneously, whether affected much or little. Discharged cured, March 1, without any cardiac mischief.

Case 2.—W. L., admitted March 3, aged 19. Second attack. Rheumatic pains confined to the knees and ankles, but the fever in this case ran very high. Blisters applied to the affected joints as in the other case, with an equally satisfactory result. Discharged cured, March 15, without any heart affection.

Case 3.—C. N., admitted March 21. Blisters were applied to right hip, both knees, and both ankles, as in these joints only was pain felt. Much relief was afforded by the following day, but feeling some pain in right shoulder, he asked to have a blister applied to it. Discharged cured, April 3, without any heart affection.

Case 4.—J. L., admitted April 6. Blisters applied to right elbow, right wrist, and right ankle, and also over the heart's region, on account of a slight mitral regurgitant bruit. Discharged cured, May 1, without any heart affection.

Case 5.—J. B., admitted April 12. In this case the wrists only were affected. Blisters were applied, as in the other cases, above the seat of pain. Next day able to move the joints without much pain. Discharged cured, April 24.

Case 6.—S. J., aged 58, admitted April 28. Joints affected were right hip, right and left knee, and right ankle. To these blisters were applied. The fever in this case was well marked. Discharged cured, May 23, without any heart affection.

N.B.—In all these cases no medicine was given, except in Case 4, when a morphia pill was ordered at night, and in Case 6 a saline mixture as a placebo.

Bequests of one hundred guineas each, free of legacy duty, have been made to the Bristol Infirmary and Clifton Dispensary by Joseph Cookson, Esq., formerly of Clifton, Somersetshire.

REPORTS OF SOCIETIES.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

TUESDAY, JANUARY 23.

Dr. ALDERSON, F.R.S., President.

DR. C. B. RADCLIFFE related a case of

ACUTE UNCOMPLICATED MYOCARDITIS, IN WHICH THE DISEASE WAS DIAGNOSED DURING LIFE.

The case which forms the subject of this article is an example of a grave affectiou, of which there is little, if any, certain knowledge—acute uncomplicated myocarditis—or, in other words acute inflammation of the muscular structure of the heart, without any inflammation of the endocardium or pericardium. The patient was a fine, stout, strong, married man, middle aged, a varnish maker by occupation. For six weeks he had had occasional attacks of sharp pain at the pit of the stomach, and shooting thence into the left arm—attacks evidently of the nature of angina pectoris. In other respects he thought himself well in health, and he was well enough to follow his daily work, and to get about with little or no discomfort up to the day before his death. When seen for the first time (July 27, 1865), the indications of the disorder evidently pointed to a very weak heart. The pulse was extremely feeble, and somewhat slow, but not irregular. The hands were cold and clammy—remarkably so. The first sound of the heart was absent. The cardiac impulse against the walls of the chest could not be felt. The second sound of the heart could be heard; but faintly only, and several times (in an examination extending over several minutes) it was distinctly reduplicated. There were no morbid sounds of any kind whatever. In the attempt to detect the cardiac impulse the patient winced more than once, and complained of feeling sore and tender at the part. There was no arcus senilis; the arteries were to all appearance free from atheromatous deposits, and, in short, the only indications of physical disorder were those which have been mentioned. The first attack of pain happened at a time of sudden and severe mental trouble. Previous to this the health had been in all respects excellent. The patient was seen for the second time on the following day, and then he was dying. He was sitting awkwardly on the edge of a chair by the side of the bed, supported by his wife. On suggesting that his posture was a very uncomfortable one, he gasped out, "I must keep as I am—I dare not stir." He had been in this position for ten or twelve hours, literally without moving in the least. His face was pale and ghastly; large beads of sweat stood out on the forehead and went trickling down the face; his extremities, upper and lower, were clammy, and corpse-like as to paleness and coldness. The pulse at the wrist had failed altogether. His breathing was short, shallow, and gasping, and with it was a rattle of which the significance could not be mistaken. His mind was clear and collected; he complained of sickness, and said he knew that he was dying. The history given of this sudden change was this—that he got out of bed to pass urine in the middle of the night, after several hours' quiet sleep; and that while up for this purpose the pain at the pit of the stomach returned in an unusually severe form, with cold perspirations, and with a feeling of deadly faintness. For the next four hours this pain continued without intermission, even without alleviation, and then it ceased suddenly, and the condition as suddenly changed to that which has been described. The post-mortem examination was made by Dr. Willis and Dr. Bazire twenty-four hours after death. In the cavity of the pericardium were nearly two ounces of serum, reddened by blood, but having no flakes of lymph in suspension. The pericardium itself presented no traces of inflammation, old or new; its visceral layer was intensely injected with ramifying capillaries filled with dark blood, but without ecchymoses, and elsewhere it was of the natural colour and character. The heart was dilated and flabby. The muscular structure of both ventricles, and in a lesser degree of both auricles also, was soft and friable, of a mulberry-juice colour, almost black in fact, contrasting in this respect in a very marked manner with the natural redness of the muscles of the chest walls. It broke down readily under the finger like hepatised lung. As seen with the naked eye, it did not appear to be fatty, but there were considerable deposits of fat about the exterior of the heart. The endocardium and all the valves were quite healthy, and so also was the aorta. The left ventricle contained some loose very dark clots of semi-coagulated blood; and in the right ventricle were some fibrinous, but not decolorised, clots adherent to the walls. Upon lifting up the heart by a portion of the right ventricle, the muscular structure broke down and tore like wet paper by the weight of the heart itself. Unfortunately, no microscopic examination was practicable. The grounds upon which the diagnosis was made were in the main these:—The history of the disease seemed to point to acute rather than to chronic disease, to begin suddenly in a way which suggested the idea of a "broken heart." There was no sufficient reason to suspect pericarditis or endocarditis, for there were none of the morbid sounds which mark the presence of these inflammations. So far seemed plain enough. It seemed, moreover, that the main symptoms were easily explainable on the supposition that the muscular structure of the heart had been attacked by inflammation. Inflammation of the muscular structure of the heart, as a matter of course, would weaken the muscular powers of the structure, and this weakening would account for that failure in the action of the heart which was the most prominent symptom. Moreover, the same weakening would carry along with it, if sufficient in degree, absence of the first cardiac sound, and absence likewise of the usual cardiac impulse. Nay, it seemed as if the symptoms present—sudden failure in the action of the heart, with loss of its first sound and of the impulse of the apex, with some tenderness on pressure in the intercostal spaces in the cardiac region, with some pain, but without the severe pain of pericarditis, without the morbid sounds of pericarditis or endocarditis, and without arcus senilis, atheromatous vessels or other signs, good or bad, to point to common fatty heart—were all the symptoms and signs one had a right to expect in inflammation of the muscular structure of the heart. At any rate, it was on these grounds, be they sufficient or insufficient, that the diagnosis was made; and it was this diagnosis which led to the post-mortem examination, for if it had not been so, the body—such was the opposition of the friends—would have gone to the grave unexamined.

The PRESIDENT objected to the coinage of new words for cases of disease, and thought in the case just read, carditis would have been a sufficiently distinct term.

Dr. RADCLIFFE referred to Dr. Stokes as his authority for the word he had used, "myocarditis."

EPIDEMIOLOGICAL SOCIETY.

MONDAY, DECEMBER 4.

DR. HERMANN WEBER read a paper on

PROFESSOR MAX PETTENKOFER'S THEORY ON THE MODE OF PROPAGATION OF CHOLERA,

based on this author's last publication on the subject.(a) Pettenkofer believes that the disease is propagated by human intercourse, and never without it. Not, however, by simple contact with the diseased or their excretions, according to the old theory of contagion, but by means of certain local accessory causes relating to the soil. The only indispensable conditions are human intercourse yielding the germ in the excretions of cholera patients, and the soil developing this germ into activity. The qualities of the soil considered as necessary for the cholera germ are: 1. That it shall be porous—*i.e.*, permeable to air and water; 2. That subsoil water shall exist at a certain depth below the surface; and 3. That the soil shall be to some degree impregnated with the products of organic decomposition, especially those of excrementitious origin. Respecting the first condition, Pettenkofer and the members of the Bavarian Commission for the Investigation of Cholera in 1854 have found, without a single exception, that the soil in the towns and villages epidemically affected with cholera was porous, while localities built on impermeable rock were either entirely spared, or at all events exhibited only isolated cases. Several apparent exceptions were on closer examination found to confirm the law. The well-known researches of Boulbee and Fourcault are in accordance with this law. 2. With regard to the presence of subsoil water, Pettenkofer points to the fact generally acknowledged that the cholera spreads with predilection along the courses of rivers, and in

(a) "Ueber die Verbreitungsart der Cholera." *Zeitschrift für Biologie.* Jahrgang, 1865, pp. 323, ss.

hollow situations; but he regards the water of the soil underneath the habitations themselves as much more important than that of the more distant river, and maintains that, as a rule, those localities suffer more from cholera which lie nearer to the level of the subsoil water, the distance of which from the surface depends, of course, on the depth of the first impermeable strata. The level of the subsoil water in the same locality may vary considerably in the same year, and in different years; on this fluctuation the varying degree of susceptibility of the locality for the cholera epidemics seems to depend. Under equal circumstances the rise of the ground water will cause a greater susceptibility by moistening a higher stratum of the porous soil, which is generally more impregnated with organic matters the nearer it is to the surface. It is the period of receding of the ground water from its greatest elevation which is most dangerous; as this occurs usually in July, August, and September, cholera usually makes its greatest ravages at that period; but the unfavourable condition of the soil may, through unusual circumstances, occur in winter instead of in summer, and cholera epidemics may occur, as experience shows, in the midst of a Russian winter. With regard to the cholera germ itself, the author assumes it to be contained in the intestinal excreta of cholera patients, but believes that it cannot produce cholera by itself, but must first undergo some change under the influence of the susceptible soil, and thus become developed. This interchange between the cholera germ contained in the excreta and the soil may, the author suggests, either take place in the soil, and the developed germ may be thence inhaled, or otherwise introduced into the body, or it may take place within the human body itself, the product being the active germ.

[*** *Quere.*—Is not the subsoil water the direct vehicle of the poison when, and when only, used for drinking purposes, as Snow and Richardson affirm? and is not the alleged necessity of interchange between the cholera germ and the soil an unnecessary incident in the propagation of cholera?—*i.e.*, would not the *fresh* excrement of a cholera patient admitted into the mouth, or inhaled, as in the act of washing dirty clothes, be enough to propagate the disease?—Ed.]

BOOKS RECEIVED.

Clinical Notes on Uterine Surgery; with Special Reference to the Sterile Condition. By J. Marion Sims, A.B., M.D., etc., etc. London: R. Hardwicke, 192, Piccadilly. 1866. Pp. 436.

*** Dr. Marion Sims takes as the basis of his work the several conditions which are necessary, collectively, for fertility. These he enunciates in eight formal postulates; and then in as many divisions of his work treats of the physical conditions opposed to each necessary condition of fertility, and of the Surgical measures which may remove those conditions. Many things are here described on paper which have hitherto been veiled in Professional silence, even if they entered the imagination of Professional men. Still, Dr. Marion Sims has but carried out minutely, and with many a detail which he probably would be glad to have spared himself, processes of fertilisation, some of which are well known to readers of John Hunter. We shall not be surprised, by the way, if the publication of this book, and the extension of the remedial agents for sterility which it includes, shall in time supply a great want, in the shape of a new, elegant, truthful, and suggestive term of vituperation. We are already in possession of a tolerably copious vituperative vocabulary based upon the supposed paternity or maternity of the person vituperated, and varying from the mild "son of a gun" up to the more sporting phrase "son of a bitch," and to the still severer "son of a w——e." If Dr. Marion Sims's book acquire due vogue, young people in the next generation will ask in wonder the meaning of the phrase "*son of a squirt!*"

A Report upon the Epidemic Occurring at Maplewood Young Ladies' Institution. By A. B. Palmer, M.D., etc., etc. Boston: Clapp and Sons. Pp. 36.

*** A most valuable document for any one who wants to know the cause of typhoid. Here were 56 cases of typhoid and 16 deaths in a school and family of 112 persons, and all clearly proved to proceed from the effluvia of privies and cesspools.

The Westminster Review, January, 1866.

*** Good articles on Sir W. Hamilton, Coleridge, Palmerston, Livingstone; and one on Vivisection.

The Glasgow Medical Journal, January, 1866.

*** The original articles are all good;—a Successful Ovariotomy and a paper on Tracheotomy in Croup, by Dr. G. Buchanan; one on Embolism, by Dr. Gairdner; Superfœtation, by Dr. Paxton; Tetanus, by Dr. Holt; Typhus, by Dr. Perry and Dr. Currie; and Hernia of the Stomach, by Dr. Paxton.

The Quarterly Journal of Microscopical Science, etc., January, 1866.

*** A good paper by Jabez Hogg on Vegetable Parasites of the Skin.

The Half-Yearly Abstract of the Medical Sciences. Vol. 42. July to December, 1865. London: John Churchill and Sons.

Report of the Metropolitan Board of Works, 1864 and 1865.

The Use of the Hypophosphites of Soda and Lime in the Treatment of Consumption. By John C. Thorowgood, M.D. London: McGowan and Danks.

A Lecture on Sanitary Science: its Importance as a Branch of General Education. By A. B. Palmer, M.D.

Medizinische Jahrbucher. Jahrgang, 1866.

On Intra-Thoracic Cancer. Part 2. By John Cockle, M.D. London: John Churchill and Sons.

Die Febris Recurrens in St. Petersburg. Von Dr. Hermann und Dr. Kuttner.

The Introductory Address Delivered at the Opening of the Medical Department of King's College, London, Session 1865-66. By William Priestley, M.D. London: W. and R. Chambers.

A Treatise on the Principles and Practice of Ophthalmic Medicine and Surgery. By T. Wharton Jones, F.R.S. Third Edition. London: John Churchill and Sons.

The Journal of Mental Science, January. London: John Churchill and Sons.

The Journal of Social Science, January. London: Chapman and Hall.

The Harveian Oration, 1865. By Henry W. Acland, M.D. London: Macmillan and Co.

MEDICAL NEWS.

Royal College of Surgeons of England.—The following gentlemen having undergone the necessary Examinations for the Diploma were admitted Members of the College at a meeting of the Court of Examiners on the 25th ult., viz.—

Stephen Woottan Bushell, Brixton, Herbert Goldingham Budd, Worcester, and William Ifill Buhôt, M.D. Jeaff. Coll., Pennsylvania, Tobago, West Indies, Students of Guy's Hospital; Israel John La Mert, Albemarle-street, of University College; John Fraser Hussey, Salisbury, of King's College; Thomas Diver, M.D. St. Andrew's, and L.S.A. London, of St. Bartholomew's Hospital; and Henry Pelham Gordon, Queensland, of the Dublin School.

It is stated that out of the fifty-six candidates who have been undergoing their Examinations at the College during the past three days, only eight were referred back to their studies for six months.

Naval Surgeons.—At a meeting of the Court of Examiners on the 25th ult., the following Assistant-Surgeons in the Royal Navy passed their Examinations for full Surgeons in that department of the public service, viz.—

William Yarde, M.D. St. Andrew's, of Her Majesty's ship *Industry*, Woolwich Dockyard, Diploma of Membership of the College dated July 3, 1857; Robert James McMorris (half-pay)), Member May 10, 1859; Archibald Grant Colquhoun, L.S.A., of the Royal Marine Infirmary, Woolwich, Member July 30, 1861; and George Curtis, of Haslar Hospital, a Licentiate of the Royal College of Surgeons Ireland, May 26, 1861.

Apothecaries' Hall.—Name of the gentleman who passed his Examination in the Science and Practice of Medicine, and received a Certificate to Practise, on Thursday, January 25, 1866:—

Henry Pearson, Plymouth-grove, Manchester.

The following gentlemen also on the same day passed their First Examination:—

William French Thurston, Guy's Hospital; Richd. Strange Hall, Manchester, Guy's Hospital.

Of the thirty-two candidates who presented themselves for the Preliminary Examination in Arts on January 26 and 27, 1866, the following passed and received Certificates of proficiency in general education, viz.—

William Atter, Edward E. A. Batchelor, J. H. Clark, G. K. Elphinstone, William Edwd. Fulford, Henry B. Harrison, Charles Hamor Hill, Thos. Wood Hill, William Hodgson, W. H. Johnson, John C. Keighley, Henry Medd, J. W. Moss, Alfred Blake Norman, Windham Randall, B. Stewart Ringer, William Sheard, H. H. Spratt, Thomas Unicume, Samuel Walker, Francis Warner, Fredk. William Willmore.

APPOINTMENTS.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

Boxwell, Richard, L.K.Q.C.P.I., has been elected Medical officer to the Workhouse Infirmary and Fever Hospital of the Gorey Union.

Butt, W. F., M.R.C.S. Eng., has been elected Resident Surgeon to St. Pancras Workhouse and Infirmary.

Chater, Sidney, M.R.C.S. Eng., has been promoted to the rank of Surgeon in the London Rifle Brigade.

CRASTER, THOMAS L., M.R.C.S. Eng., has been appointed Medical Officer for the Bramley Union Workhouse.

FLINN, JOHN J., L.R,C.P., has been elected Surgeon to West Derby Union Workhouse.

HILLIARD, HENRY C., L.R.C.P. Lond., has been elected House-Surgeon to the Surrey County Hospital, Guildford.

SOPER, ROBERT W., M.R.C.S. Eng., has been elected Resident House-Surgeon to the South Devon and East Cornwall Hospital, Plymouth.

WEBSTER, THOMAS J., M.R.C.S. Eng., has been appointed Assistant Medical Officer to the Budge-street Workhouse, Manchester.

BIRTHS.

BATT.—On January 27, at 37, Clapham-road-place, Clapham, the wife of Edward Batt, M.D., of a son.

BELL.—On January 18, at Castle-terrace, Edinburgh, the wife of J. Bell, M.D., of a daughter.

BIGGS.—On January 25, at Springfield, Tooting, S., the wife of J. Strange Biggs, M.D., of a son.

BROWNING.—On January 30, at Stoke Damerel, Devonport, the wife of B. Browning, M.R.C.S., R.N., Surgeon H.M.'s steamer *Basilisk*, of a daughter.

DIVER.—On January 23, at South Penge-road, Penge, the wife of Ebenezer Diver, M.D., of a daughter,

FULLER.—On January 25, at Manchester-square, W., the wife of Henry W. Fuller, M.D., of a daughter.

GRAHAM.—On January 24, at Everton-road, Liverpool, the wife of Dr. A. F. Graham, of a daughter.

HARRIS.—On January 24, at Reigate, the wife of Henry Harris, M.R.C.S. Eng., of a son.

HOUGHTON.—On January 26, at 6, Mount-street, Grosvenor-square, W., the wife of Henry G. Houghton, M.D , of a daughter.

KNIGHT.—On January 5, at Sibford Ferris, Banbury, Oxon, the wife of C. F. Knight, M.R.C.S. Eng., of a daughter.

MAY.—On January 29, at 41, Sloane-square, S.W., the wife of A. S. May, M.R.C.S.E., of a son.

ORTON.—On January 27, at Clifton, the wife of Assistant-Surgeon J. S. Morton, M.D., Madras Army, of a son.

NICHOLAS.—On January 29, at Wandsworth, S.W., the wife of Dr. George E. Nicholas, of a son.

TWYFORD.—On January 24, at St. Helens, Lancashire, the wife of E. P. Twyford, M.D., of a daughter.

MARRIAGES.

FRODSHAM—D'IFFANGER.—On January 30, at St. Mark's, Hamilton-terrace, John M. Frodsham, M.D., to Therese, eldest daughter of the late Thomas D'Iffanger, Esq.

GRAY—ADAMS.—On January 18, at the Parish Church, Petersfield, Hants, Frederick J. Gray, Surgeon, of Rugeley, to the second daughter of W. Adams, Esq.

HAMMOND—HAWKINS.—On January 24, at St. Saviour's, Hampstead, Charles Hammond, L.R.C.P., to Amelia, eldest daughter of Thomas Hawkins, Esq.

JONES—SMITH.—On January 23, at Liverpool, P. W. Jones, Surgeon, of Shrewsbury, to Matilda, daughter of the late W. A. Smith, Esq.

MAUDSLEY—CONOLLY.—On January 30, at Hanwell, Henry Maudsley, M.D., to Annie Caroline, youngest daughter of John Conolly, M.D., D.C.L.

PARK—WILLIAMSON.—On January 24, at Union-street, Aberdeen, George Park, M.D., to Christian, younger daughter of the late P. Williamson, Esq.

PEACOCK—RIDGE.—On January 18, at St. Giles's, Cambridge, Albert L. Peacock, M.R.C.S.E., of Churchinford, Devon, to Fanny, eldest daughter of S. Ridge, Esq.

DEATHS.

CROSSE, THOMAS, M.R.C.S. Eng., at Thorverton, Devon, on January 22, aged 68.

DUNCAN, WILLIAM, L.R.C.S. Edin, at Amble, Northumberland, on January 21.

EVANS, WILLIAM H., M.R.C.S. Eng., at St. Albans, Herts, on January 28, aged 53.

FRAME, JOHN, M.D. St. And., at West-street, Glasgow, on January 18.

GRIFFITH, RICHARD J., M.R.C.S. Eng., formerly Surgeon R.N., at 15, Adelaide-road South, Hampstead, on January 25, aged 79.

HULME, Mr., Physician's Assistant at the Royal Infirmary, Manchester, of typhus fever, on January 20.

LAYCOCK, ROBERT, L.R.C.P. Lond., at Bramley, Leeds, on December 28.

MORTON, JOHN, late Superintending Surgeon Madras Medical Service, at 13, Brighton-park, Clifton, on January 28.

SCHUH, Professor FRANZ, the distinguished Professor of Surgery of the Vienna University, and Surgeon to the General Hospital, died at the latter end of December.

SMELLIE, JOHN, L.R.C.S. Edin., at Ruddington, Nottinghamshire, on January 18, aged 62.

STRUTT, GEORGE H., M.R.C.S. Eng., at Tutbury, near Burton, on January 21, aged 32.

WALKER, WILLIAM G., M.R.C.S. Eng., at Oxford, late of Brill, Bucks, on January 24.

POOR-LAW MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the last census.

RESIGNATIONS.

Crediton Union.—The Morchard Bishop District is vacant; area, 13,200; population, 2776; salary, £52 10s. per annum.

South Shields Union.—Mr. James Williamson has resigned the Workhouse; salary, £35 per annum.

Southwell Union.—The Eighth District is vacant; area, 16,664; population, 2091; salary, £20 per annum. Also the Ninth District; area, 19,239; population, 3361; salary, £25 per annum.

APPOINTMENTS.

Buntingford Union.—Benjamin Cocks, L.R.C.P. Edin., M.R.C.S.E., L.S.A., to the North-East District.

Clutton Union.—Alexander Waugh, M.R.C.S.E., L.R.C.P., to the Midsomer Norton District.

Croydon Union.—Peter Thomas Dean, L.R.C.P. Edin, M.R.C.S.E., to the Second District.

Dartford Union.—William Parker Hoare, M.R.C.S.E., L.S.A., to the First A District.

Derby Union.—William M. Bobart, M.R.C.S.E., L.S.A., to the First District.

Fylde Union.—William Gradwell, L.R.C.P. Edin., M.R.C.S.E., L.S.A., to the Lytham District.

St. Giles and St. George, Bloomsbury, Parishes.—Matthew Charteris, M.D. Edin., M.R.C.S. Edin., as Assistant Workhouse Medical Officer.

Isle of Wight Union.—Henry Lynch, M.D. Aber., M.R.C.S.E., L.A.H. Dub., to the Shorewell District. Frank B. Tuttiett, M.R C.S.E., L.S.A., to the Whippingham District. Ernest Powell Wilkins, L.R.C.P. Edin., M.R.C.S.E., L.S.A., to the Carisbrooke District.

THE NEW BARONETS.—The *Gazette* of Tuesday last contains the official announcement of the baronetcies conferred on Sir J. Y. Simpson, M.D., and Sir Dominick Corrigan, M.D., Physicians Extraordinary to the Queen in Scotland and Ireland.

DR. FORBES WINSLOW.—It affords us great gratification, and we feel assured the Profession will participate in the feeling, to be able to announce that this Physician, who has for these last nine months been suffering from an injury to the spine, caused by a fall from his horse, is sufficiently recovered to resume the practice of his Profession.

DEATH OF A MEDICAL OFFICER FROM FEVER.—We are sorry to announce the death of Mr. Hume, one of the Physician's Assistants at the Royal Infirmary, Manchester, who died on Monday, January 22, from malignant typhus, contracted in the discharge of his duties. He was a most zealous and earnest Medical officer, and universally beloved by those with whom he came in contact.

DEATH OF A FRENCH JUDGE FROM HYDROPHOBIA.—Two days since M. Blondel, one of the judges of the Tribunal of Arbois, France, died from hydrophobia. The unfortunate gentleman had been bitten two years since by one of his dogs while out shooting.

THE VENEREAL DISEASES COMMISSION.—The report of the members of this important Commission has just been submitted to the Lords of the Admiralty, and it is stated that some stringent measures have been proposed for the purpose of diminishing the evils which are so detrimental to the health of our sailors and soldiers.

MR. STOKES, OF NAILSWORTH.—Mr. Stokes, the highly respected Surgeon of Nailsworth, has been presented by the inhabitants of that town and its neighbourhood with a testimonial of the value of £226. It consists of a silver claret jug and stand, a microscope, and a portrait of Mr. Stokes, which is to be placed in the Subscription room.

HUNTERIAN MUSEUM.—A skeleton of the Greenland whale (*Balnœa mysticetus*) has recently been added to this collection.

MR. PEABODY has presented the poor of London with a second gift of £100,000. Considering the destruction of their houses by railways, this splendid alms is now doubly welcome. But surely English millionaires will not be outdone in benevolence by a foreigner? It will take much more than the quarter of a million Mr. Peabody has so generously given to build up the dwellings of the poor which have been destroyed by public companies. But either they must be replaced or we must be prepared to provide fever Hospitals, workhouses. and orphanages on a proportionate scale.

CAMBRIDGE.—MEDICAL OFFICERS OF UNIONS.—A great deal of discussion is now going on involving questions of the utmost importance to the Profession as to what are the duties of Medical officers of unions. At a recent meeting of the Cambridge Board of Guardians, Dr. Ransom, who had resigned the appointment of District Medical Officer and accepted that of the house, called the attention of the guardians to the fact that orders had been given indiscriminately to persons not considered paupers, and that he had attended such persons. The Board might decide that they were not paupers, whereupon Dr. Ransom writes to know to whom he is to look for payment for services rendered. It appears that

the relieving officer was to blame in granting orders to persons able to pay for medical attendance. The guardians are in a dilemma, for first they decide the persons are not paupers, and then that they are, and that the Medical officer is bound to attend anybody, and that they have nothing to do with Dr. Ransom's complaint. Up to the present time no gentleman has offered himself as a candidate for Dr. Ransom's place as Medical officer of the second district.

THE ANNUAL GENERAL MEETING OF THE ODONTOLOGICAL SOCIETY was held on the 8th instant, at 32, Soho-square; the President (Mr. Thomas Rogers) in the chair. Notice had been given by the Council of proposed alterations in the laws and bye-laws of the Society. A long discussion took place, and the matter was referred back to the Council for reconsideration. The following gentlemen were elected as council and officers of the Society for the ensuing year:—*President:* W. A. N. Cattlin, Esq. *Vice-Presidents (Resident):* W. Imrie, Esq., W. Perkins, Esq. G. A. Ibbetson, Esq. James Parkinson, Esq., H. J. Barrett, Esq.; *(Non-Resident)*, S. Tibbs, Esq. (Cheltenham), Dr. Roberts. (Edinburgh), R. H. Moore, Esq. (Dublin), C. Bromley, Esq. (Southampton). *Treasurer:* Arnold Rogers, Esq. *Librarian:* J. B. Fletcher, Esq. *Honorary Secretary (Ordinary)*: J. Drew, Esq. *(For Foreign Correspondence):* Thomas Underwood, Esq. *Councillors (Resident):* H. T. Kempton, Esq., R. T. Hulme, G. Owen, Esq., A. Hill, Esq., S. Cartwright, Esq., E. J. Winterbottom, Esq., J. Saunders, Esq., F. Weim, Esq., R. Hepburn, Esq., W. A. Harrison, Esq., J. Tomes, Esq.; *(Non-Resident)*, S. L. Rymer, Esq. (Croydon), W. Hunt, Esq. (Yeovil), J. A. Baker, Esq. (Dublin), T. R. M. English, Esq. (Birmingham), J. King, Esq. (York), N. King, Esq. (Exeter).

PORT ROYAL SENNA.—A species of senna, used largely in Jamaica by both French and English, has been very recently again re-brought to England by Dr. Bowerbank. It is the produce of the Cassia Porturegalis (Bancroft), or Port Royal senna, and passes many qualities that recommend themselves strongly to our notice. Its taste is very much—in infusion—like that of tea; it possesses very efficient purgative qualities, and never gives rise to griping or other sign of irritation; it is especially valuable for children. It may be given in infusion, or more conveniently, perhaps, in the form of a liquor. It is not at all improbable that it will very greatly supersede—when better known—the ordinary varieties, which, however prepared, always exhibit a certain nauseous quality especially disliked by children, a property which the Cassia Porturegalis seems to be entirely devoid of.

A RECIPE FOR LONGEVITY.—The *Moniteur* relates that the will of a certain Dr. Julius von Fischweilher, of Magdeburg, who died at the age of 109, has been opened with solemnity conformably to the wishes of the testator, as in it he bequeathed a communication of importance. It discloses that the whole secret of his longevity, which is also attainable by all who will follow his directions, consists in assuming the horizontal position as often as possible, and always during the night, in such a manner that the head may be kept in the direction of the north pole, and the rest of the body as nearly as possible in that of the meridian. From a persistence in this attitude, corresponding with the course of the magnetic currents which traverse the surface of the globe, there results a regular and continuous magnetisation of the mass of iron which exists in our economy, and consequently a notable increase of the vital principles upon which are dependent all the organic phenomena interested in the conservation of our existence. It is gravely asserted that a society has been formed at Magdeburg for the purpose of continuing the old Doctor's experiments, and ascertaining whether his discovery really possesses the value which he attributed to it.

ACTION OF IRON ON THE TEETH.—Dr. John Smith has contributed to the last number of the *British Journal of Dental Science* some careful observations on the Action of Medicinal Preparations on the Teeth. His experiments were made by steeping human teeth in solutions of eight preparations of iron, in solution of sulphate of quinine (gr. v., to sulph. acid gtt. i., water ʒss.), dilute phosphoric acid, and Condy's fluid. After steeping for twenty-four hours the teeth were found unaltered in solutions of the carbonate and saccharine carbonate of iron, the phosphate of iron, the iodide of iron, the citrate of quinine and iron, and in that of the sulphate of quinine. Changes had taken place in the solutions of vinum ferri, the muriate of iron, and the phosphoric acid, showing that these preparations had exerted chemical influence on the teeth. Ten days' steeping in vinum ferri, sulphate of iron, muriate of iron, phosphoric acid, and Condy's fluid, produced marked changes in the teeth. Precipitates were formed in the solutions, and the substance of the teeth was softened. From these experiments it would appear that the injurious effect of iron on the teeth depends on the mineral acid with which the metal is combined. Dr. Brown concludes that certain preparations of iron, when directly applied, do exercise a powerful effect on the substance of the teeth. And the ratio of the effects obtained would seem to prove that of all the preparations employed in these experiments that of the tincture of the muriate of iron acts most powerfully, the sulphate of iron next, and next to that again, although in comparison very immaterially, the vinum ferri—the other preparations of iron appearing to be inert.

THE following are the last week's Cattle Plague Returns. By comparison with those of the previous week, it will be seen that there have been 12,842 attacked, 8541 deaths, 740 slaughtered, and 1823 recoveries, since January 13:—

Census Divisions.	1. Attacked.			2. Result of reported Cases from the Commencement of the disease.				
	Week ending January 20.	Week ending January 13.	Week ending January 6.	Attacked.	Killed.	Died.	Recovered.	Remaining.

COUP-DE-GRACE TO THE VACCINATION THEORY.—It will be seen from the following letter of Dr. Murchison's that he has given up all hope that vaccination will be of use in staying the progress and spread of the Rinderpest; we suppose that it may also be understood that he is satisfied that Rinderpest is not bovine small-pox. The points of resemblance between small-pox and the cattle plague have been noticed by nearly every writer on the latter disease, from Lancisi downwards; but the subject has not been fully and scientifically examined until lately, and it must now be held to be fully proved that however much alike the two diseases may be, they are not identical. Dr. Bence Jones may, we suppose, be considered as now agreeing with the majority of the Cattle Plague Commissioners as to the means necessary to be adopted to stay the plague; and we will hope that the failure of the protection-by-vaccination theory will at last spur the Government into efficient action. Dr. Bence Jones and Dr. Murchison are rather hard on Mr. Tollemache and others of the "laity" who believed that the "most eminent authorities" held absolutely the doctrine of the identity of Rinderpest with small-pox. The theory was put forward so ably, and the resemblances or points of analogy between the two so insisted on, that non-Professional persons might well be excused if they fell into the not uncommon error of mistaking a very plausible theory for an accepted doctrine:—

"To the Editor of the 'Times.'

"Sir,—The points of resemblance between cattle plague and small-pox are so striking that certain observers were led to hope that vaccination might protect cattle from the prevailing disease. The experiment, I believe, has now been fairly and fully tried; and, although the first accounts appeared favourable, there is sufficient evidence that vaccination confers no permanent protection from the plague. It is well that this fact should be generally known by publication in the *Times*. Rigid isolation and the suspension of all movement of living cattle must still be the preventive measures on which we mainly rely.

"In reply to a correspondent whose letter appears in the *Times* of to-day, I may state that neither Mr. Ceely nor I

ever maintained that cattle plague and human small-pox were identical. We merely pointed out that the analogy between the two diseases was sufficiently close to call for the experimental inquiry above referred to.

"I am, your obedient servant,
"CHARLES MURCHISON, M.D.

"79, Wimpole-street, London, W., January 30."

(From the "Times" of January 29.)

"Sir,—Mr. Tollemache, in your paper to-day, says, 'The most eminent authorities seem satisfied that Rinderpest is bovine small-pox.'

"Mr. Tollemache has no authority for saying this. It would be much nearer the truth if he had said that cattle plague in many respects resembles small-pox, and belongs to the same class of diseases; but that it is not bovine small-pox, and cannot be kept off by vaccination or by inoculation, but only by insulation. "I am, your obedient servant,

"31, Brook-street, January 27. "H. BENCE JONES."

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

Dr. Falconer is thanked for his valuable table for registering the temperature of fever.

An Army Surgeon says we are wrong in stating the Committee lately sitting at the Admiralty recommended any earlier permissive retirement. Perhaps so; we only gave the rumours we have heard. If there is to be no earlier retirement for the seniors and no earlier promotion for the juniors, it is, in our opinion, tantamount to nothing being done at all. We can only trust, therefore, that our correspondent is mistaken. Time will prove.

Syphilisation.—The practice was discussed by Mr. J. S. Gamgee, Mr. H. Lee, and Mr. Victor de Meric prior to the papers of either Dr. L. Lindsay or Dr. D. Simpson. Our correspondent who furnished the memoir of the latter, was, therefore, mistaken in attributing to him priority in the matter. Dr. Simpson, however, brought the results of Christiania experience more prominently before the Profession than his predecessors.

THE GRIFFIN TESTIMONIAL FUND.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—The following subscription has been further received on behalf of the above fund:—Dr. John O'Reilly, Ware, 10s. 6d. Amount previously announced, £132 19s. 3d. Received at *Lancet* Office, £9 9s.

I am, &c.,
ROBT. FOWLER, M.D., Treasurer and Hon. Sec.

145, Bishopsgate Without, January 31, 1866.

PUERILE RESPIRATION IN PNEUMONIA.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—At a late meeting of the Medico-Chirurgical Society of London, Dr. Waters, of Liverpool, brought under notice two cases of pneumonia, in which a puerile respiration in the affected part preceded the more ordinary symptoms of the disease. On this point I beg to state that it has been long known in Dublin as occasionally occurring, and will be found specially noticed in the able work of Dr. Stokes published some twenty-five years ago. I am, &c.,

Dublin, January 31, 1866. HENRY KENNEDY.

THE LATE DISCUSSION ON LATERAL CURVATURE OF THE SPINE AT THE ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—In your impression of last week, it appears that I stated in the discussion which followed the reading of Mr. Barwell's paper on Lateral Curvature of the Spine at the Royal Medical and Chirurgical Society, that "After rotation had taken place appliances were useless." It should have been that elastic appliances were useless: but well-constructed instruments are sufficient to cure curvature of the spine even after considerable rotation has taken place.

I shall esteem it a favour if you will allow this to appear in your next number. I am, &c.,

20, Grosvenor-street, W., January 27. B. E. BRODHURST.

GOOD-SERVICE PENSIONS.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—I beg to bring under your notice and for the consideration of the Director-General of the Army Medical Department, the opportunity now afforded him for recommending for good-service pensions—vacated through the deaths of Sir John McGregor and Sir John Hall—two Medical officers from the half-pay list, who have not been so fortunate in obtaining coveted honours and lucrative emoluments as some of their brethen in the department have been.

The Director-General has ample choice from amongst half-pay Deputy-Inspectors and Staff Surgeons-Major for selecting two officers for these pensions, and I trust he will not be led away by importuning C.B's. and K.C.B's. of the substantial and substantive rank of Inspector-General, who have feathered their nests in India and elsewhere; but that he will select those who have not been so fortunate, their services being as good but their half-pay very considerably less. Colonels in the Army in the enjoyment of good service pensions forfeit therein promotion to the substantive rank of Major-General, and I do not think that Inspectors-General of Hospitals with a rate of daily half-pay of £1 17s. 6d., have any great claim for a pension, especially whilst others of equal Professional merit with a much lower rate of half-pay are eligible for the pension.

I am, &c.,

London, January 25. CRIMEA.

POOR-LAW MEDICAL REFORM.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—I shall feel obliged by your giving insertion to the annexed list of names of gentlemen who have forwarded their subscriptions towards the funds of the Association. I would willingly at once apply to the Poor-law Board and ask their consent to receive a deputation; but I fear the reply might be—"There is no proof now that any great body of the present Medical officers are dissatisfied with their position." If, however, 500 Medical men should answer the appeal which Mr. Prowse has made to them, then I should feel justified in at once taking active measures, either by a deputation to the Poor-law Board or by a bill in Parliament.

List of subscriptions sent to Mr. Prowse, of Amersham:—Blackshaw, J., Stockport, 5s.; Buée, W. A., Eton, 5s.; Brooks, W. F., Wye, 10s.; Bowes, John, Bleam, 10s. 6d.; Clark, W., Epsom, 10s. 6d.; Willon, J., Ash, 10s. 6d.; Blythman, R. O, Rotherham, 10s.; Arnison, W. C., Hexham, 7s. 6d.; Montgomery, W., Haltwhistle, 5s.; Hewitson, Hexham, 7s. 6d.; Chapman, J., Brentford, 20s.; Brodie, Bellingham, etc., 5s.; B. E., 10s. To Mr. Griffin.—Buckoll, E. C., Radford, 5s.; Turtle, F., St. George-in-the-East, 5s.; Taylor, J., Banbury, 5s.; Ashworth, G. M., Oakham, 5s.; Dicken, P., Ashby-de-la-Zouch, 5s.; Walker, T. O., Towcester, 5s.

I am, &c., RICHARD GRIFFIN.

DR. BENCE JONES'S PEROXIDATION THEORY.(a)

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—I must agree with your correspondent "Physiologist." in questioning both the correctness of Dr. Bence Jones's "Peroxidation Theory" and the logic of his arguments in its support. Now, I would ask, is it possible that in those diseases of which he has written the phenomena can be due to peroxidation when the resultant products are all more or less highly organised—*i.e.*, possessing a comparatively small percentage of oxygen? If there be, indeed, diseases characterised by processes of peroxidation, evidently peroxidated products must result; the reverse is the case. Indeed, the theories of Dr. B. Jones are contradicted by his practice, for he finds of the most signal service those agents which, as hot-air baths, injection of pure water, etc., in an eminent degree tend, not to de-oxidate, but to oxidate tissue. I should trespass far too largely on your space were I to take up Dr. B. Jones's propositions *seriatim;* one instance will suffice, and scarlatina, which has been already spoken of, will be a convenient one to test the "Theory of Peroxidation."

The chemistry of scarlet fever is evidently this: a sudden arrest of the constant conversion of superficial heat into force (necessary for the driving asunder of perspiratory water to form vapour) causes the retention of this heat in the body (blood); thus aiding in the production of that early symptom of scarlatina—rise of temperature.

This rise of temperature becomes general, owing to the universal arrest of natural decay, solid matters ceasing to be degraded into fluids (a process which would, of course, be accompanied by a corresponding conversion of heat into force). The arrest of destructive metamorphosis in the skin thus spreads to internal organs: the kidney, so manifestly compensating to the skin in its functions, has to do double duty in the elimination of effete products, which should have been removed *per cutem*. For a time this is done; but at length over-taxed, and itself ill-supplied with fibrin, etc., for renewal, and oxygen for the necessary metamorphosis of its own proper tissue, it gives way. This tale is told by the post-mortem appearances of the over-worked organ. We find fibrin, which should have passed away oxidised, retained as fibrinous deposit; lymph accumulated which healthy absorbents and an uninterrupted circulation would have removed; and epithelium both imperfectly organised and irregularly detached.

It may be asked, What, then, is the destination of that oxygen which must at first be redundant? Doubtless, it is misapplied, with the effect of reducing an unusual amount of tissue to a slight degree of oxidation.

I am, &c., EDWARD T. BLAKE.

63, Darlington-street, Wolverhampton.

LINES WRITTEN ON HEARING OF THE SUDDEN DEATH OF CHARLES G. RITCHIE, M.D., DECEMBER 22, 1865, AGED 24.

Doctor Charles Ritchie had attained high distinction in his Profession for learning, ability, and devotion to science. On the day he had signified to his family at Glasgow (he was the only son of Dr. Ritchie, of that city,) his intention of being with them at Christmas, "he was found in his consulting room in a dying state, and he died apparently from some poisonous agent with which he had been experimenting."

A victim to Science,
A martyr to Truth,
Bidding danger defiance,
He dies in his youth.
Grand was his history,
Sudden its close;
Life is a mystery,
Death a repose.

His life he devoted
To Science and truth;
His name will be noted
A lesson for youth.
In his death all consistent,
Expiring he lay,
With one purpose persistent,
The truth to essay.

Ah! life is uncertain,
What tales would be read,
Could man but lift the curtain,
That shroudeth the dead.
With his heart overflowing,
He just told a friend,
"To my home I am going,
The Christmas to spend."

To his home he has gone,
To the last place of rest,
Where we're all journeying on
And believers are blest.
The work of Salvation
He knows through Christ's Grace,
And, beholding Creation,
Sees God face to face..

ORIGINAL LECTURES.

LUMLEIAN LECTURES

ON SOME POINTS IN THE PATHOLOGY OF NERVOUS DISEASES.

By C. HANDFIELD JONES, M.B., F.R.C.P., F.R.S.,
Physician to St. Mary's Hospital and Lecturer on Medicine.

Lecture III.

(Continued from page 115.)

I will adduce now a few instances of the less severe cerebral affections, which seem to me to make it very probable that the brain tissue may suffer in a very similar way to that of the nerves. A lady, on her return from India, came under my care in a state of great prostration from frequently-recurring symptoms of distracting headache, attended with violent throbbing at the vertex, and relieved only by chloroform inhalation or large doses of morphia. Her aspect was peculiar, indicative of distress, and gave one the idea of impending insanity. After she had improved a good deal on a tonic regimen, hemicrania occurred, affecting the right side of the head, and she remarked that this extra-cranial pain was quite unlike the head attack she had had previously. A recurrence of the headache subsequently was attended with hysterical symptoms and depression, indicating that the emotional centres were involved in the morbid action. At the present time she has almost quite recovered, so that organic disease may be excluded from our view of the case. In not a few instances the headache is attended with absolute incapacity for mental exertion, or feelings of bewilderment—plain indications that the organ of the intellect is functionally enfeebled. One patient, whose case might serve as a type of neuralgic depression, complained that her head, which was cool, felt giddy and confused; such sensations came over her that she quite went out of her mind at times, while her left hand and arm got numb, and her speech failed. Iron, ammonia, and calumba benefited her much. A third has no pain, but describes her distress thus: that her head becomes numb and stupid, as if she were going out of her mind, while her hands, and feet, and her mouth also get numb; anything that startles her makes her worse. A fourth, of florid, rather sanguine aspect, which depended, however, on a morbid flushing of the face, had suffered for nineteen months with distressing feelings in her head, and was almost beside herself at times. The attacks came on her especially when she was alone; she was then obliged to get up and do something to mitigate her uneasiness. She described the attacks as consisting in a feeling of misery, wretchedness, and stupidness, while her mind was vexed with bad thoughts, which made her fear to be alone, and evidently tended in the direction of suicide. Heat flushes occurred at these times—the common signs of vaso-motor paresis. Society and moderate stimulants relieved her, and under a treatment just such as might have cured a neuralgia she amended greatly. The foregoing instances correspond most to neuralgia inasmuch as the signs of torpor and debility predominate; in the following, hyperæsthesia is more in the ascendant:—A lady subject to brow ague, and having the stamp of Indian disorder upon her, while suffering with neuralgic pain of the left side of the head, experienced such great irritability that the mere rustling of paper distressed her. Another, whose powers were failing under suckling, complained that she had a peculiar pain in the head, which she could not describe; was very irritable, and at times quite violent. She could not endure the slightest noise; her memory was very failing; sleep was bad; she felt afraid to be trusted by herself. A clergyman, aged 60, suffering from baruria, was so brain weak that a few minutes' application to reading or writing exhausted him. He was also extremely hyperæsthetic, and was intolerant of ordinary sounds.

Some cases of sleeplessness seem to be referable to no other cause than persistent cerebral hyperæsthesia. I have lately had two cases under my care—one a male, the other a female—both perfectly temperate, in which this sleeplessness was the cause of great distress; the patient sorely needed and longed for sleep, but "tired Nature's sweet restorer" would not come. The general health was very tolerable, and no cause could be detected for the insomnia, except great excitability of the nervous system. If I have thought it worth while to cite such examples as the above, it is not of course that I suppose them to be of unusual occurrence., but simply that I see no better way of picturing the state I wish to allude to. Real occurrences have, moreover, in my mind, a positive advantage over abstract descriptions, which can never be so true to nature. A further reason for my wishing to illustrate my view is this, that I think many of us are too prone to set down these common affections of worn and weary brains as "nervous" or semi-hysterical, and that we do not sufficiently consider how much of actual bodily disorder exists and gives rise to the distress. A sufferer from a sciatica or a gastralgia is apt to be regarded as more really ill than one who labours under a quite analogous affection of the organ of the intellect which expresses its troubles in a more perplexing manner. Dr. Dumont has given a highly interesting and graphic account of his sufferings from a cerebral neurosis in his recently published "Testament Medical." The whole nervous system is more or less involved; but the brain is evidently the chief focus of disorder. A heated atmosphere brings him to the verge of maniacal excitement (transport cerebral), while a highly electrical condition of the air or an eclipse produces syncope. Sensation, both special and common, memory, and ideation are more impaired than voluntary power; the mind and internal consciousness are not affected, even during his severest paroxysms. The condition seems extremely similar to hyperæsthesia of a nerve, and the retinæ appear to be actually in this state, in consequence of which visual power is seriously enfeebled. Da Costa(a) relates a very interesting case which he entitles "Cerebral Neuralgia proving Fatal by Serous Apoplexy." The patient was a female, aged 30, who had been suffering four months with neuralgia and pain in the head when she came under his care. The attacks of the disorder were of varying duration, and were separated by longer or shorter intervals. They mostly came on between 9 p.m. and 2 a.m., and were marked by violent frontal pain, great restlessness, an inclination to talk and to cry out; so that they much resembled hysterical paroxysms. Quinine and iron were beneficial, but after fifteen days a severe relapse occurred, and the attacks came on nightly as before. After some days of more tranquillity, the disorder returned in an aggravated form, the pain in the head was agonising, and death ensued in the way of coma. At the autopsy, the arachnoid and pia mater were found injected; the substance of the encephalon was everywhere healthy; but both ventricles, especially the left, were distended by clear serum. Da Costa believes that the serous effusion was the result of the cerebral hyperæmia induced by the paroxysms of pain, and compares with his case one related by Andral, in which a female, aged 35 years, suffered for some time with tic douloureux of the face. This suddenly ceased, but was succeeded by a violent pain of head, and a giddiness so intense that the patient could no longer stand up. She had at the same time very painful nausea, and vomited much bile. This lasted two hours; after which a very copious flow of serous liquid took place from the nasal fossæ, and continued some hours. When it ceased, the cerebral symptoms disappeared. If, in the former case, there may exist some doubt whether the neuralgia was not symptomatic of inflammation of the walls of the ventricles, none such can be felt with respect to the second, where the extra-cranial disorder was evidently replaced by the cerebral. In both instances, it seems to me very probable that the effusion was the result of vaso-motor nerve paresis itself occurring as a part of the neuralgia, just as it is sometimes seen to do in the outer tegument, where the part which has been the seat of pain becomes swollen, red, tender, and, in fact, is in a quasi-inflammatory condition.

I will relate here one more case which has recently occurred in my own experience, and which appears to me to have much resemblance to those cited from Torti and Andral. A gentleman, aged 47, returned in very fair health from a trip to Italy at the end of last year. He had been suffering during some years, at least the two last, with urethral stricture, the urine being pretty constantly alkaline and depositing triple phosphates. Early in February, while in the country, he had an attack of retention of urine. No catheter could be passed for some time. An eminent Surgeon who saw him with me after I had brought him to town succeeded, and after some days the stricture was split by Mr. Holt's method. For two days all appeared to go on well; the stream of urine was much more free. On the third day there was difficulty in introducing the catheter, and he felt a good deal of uneasiness in the perinæum afterwards. This, however, was subsiding, and he went out two days later for a walk, though it was

(a) De Costa, Charleston, J. XIV., 2; Schmidt's *Jahrb.*, vol. evi., p. 39.

ever maintained that cattle plague and human small-pox were identical. We merely pointed out that the analogy between the two diseases was sufficiently close to call for the experimental inquiry above referred to.

LUMLEIAN LECTURES

ON SOME POINTS IN THE PATHOLOGY OF NERVOUS DISEASES.

By C. HANDFIELD JONES, M.B., F.R.C.P., F.R.S.,
Physician to St. Mary's Hospital and Lecturer on Medicine.

Lecture III.

(Continued from page 115.)

I will adduce now a few instances of the less severe cerebral affections, which seem to me to make it very probable that the brain tissue may suffer in a very similar way to that of the nerves. A lady, on her return from India, came under my care in a state of great prostration from frequently-recurring symptoms of distracting headache, attended with violent throbbing at the vertex, and relieved only by chloroform inhalation or large doses of morphia. Her aspect was peculiar, indicative of distress, and gave one the idea of impending insanity. After she had improved a good deal on a tonic regimen, hemicrania occurred, affecting the right side of the head, and she remarked that this extra-cranial pain was quite unlike the head attack she had had previously. A recurrence of the headache subsequently was attended with hysterical symptoms and depression, indicating that the emotional centres were involved in the morbid action. At the present time she has almost quite recovered, so that organic disease may be excluded from our view of the case. In not a few instances the headache is attended with absolute incapacity for mental exertion, or feelings of bewilderment—plain indications that the organ of the intellect is functionally enfeebled. One patient, whose case might serve as a type of neuralgic depression, complained that her head, which was cool, felt giddy and confused; such sensations came over her that she quite went out of her mind at times, while her left hand and arm got numb, and her speech failed. Iron, ammonia, and calumba benefited her much. A third has no pain, but describes her distress thus: that her head becomes numb and stupid, as if she were going out of her mind, while her hands, and feet, and her mouth also get numb; anything that startles her makes her worse. A fourth, of florid, rather sanguine aspect, which depended, however, on a morbid flushing of the face, had suffered for nineteen months with distressing feelings in her head, and was almost beside herself at times. The attacks came on her especially when she was alone; she was then obliged to get up and do something to mitigate her uneasiness. She described the attacks as consisting in a feeling of misery, wretchedness, and stupidness, while her mind was vexed with bad thoughts, which made her fear to be alone, and evidently tended in the direction of suicide. Heat flushes occurred at these times—the common signs of vaso-motor paresis. Society and moderate stimulants relieved her, and under a treatment just such as might have cured a neuralgia she amended greatly. The foregoing instances correspond most to neuralgia inasmuch as the signs of torpor and debility predominate; in the following, hyperæsthesia is more in the ascendant:—A lady subject to brow ague, and having the stamp of Indian disorder upon her, while suffering with neuralgic pain of the left side of the head, experienced such great irritability that the mere rustling of paper distressed her. Another, whose powers were failing under suckling, complained that she had a peculiar pain in the head, which she could not describe; was very irritable, and at times quite violent. She could not endure the slightest noise; her memory was very failing; sleep was bad; she felt afraid to be trusted by herself. A clergyman, aged 60, suffering from baruria, was so brain weak that a few minutes' application to reading or writing exhausted him. He was also extremely hyperæsthetic, and was intolerant of ordinary sounds.

Some cases of sleeplessness seem to be referable to no other cause than persistent cerebral hyperæsthesia. I have lately had two cases under my care—one a male, the other a female—both perfectly temperate, in which this sleeplessness was the cause of great distress; the patient sorely needed and longed for sleep, but "tired Nature's sweet restorer" would not come. The general health was very tolerable, and no cause could be detected for the insomnia, except great excitability of the nervous system. If I have thought it worth while to cite such examples as the above, it is not of course that I suppose them to be of unusual occurrence., but simply that I see no better way of picturing the state I wish to allude to. Real occurrences have, moreover, in my mind, a positive advantage over abstract descriptions, which can never be so true to nature. A further reason for my wishing to illustrate my view is this, that I think many of us are too prone to set down these common affections of worn and weary brains as "nervous" or semi-hysterical, and that we do not sufficiently consider how much of actual bodily disorder exists and gives rise to the distress. A sufferer from a sciatica or a gastralgia is apt to be regarded as more really ill than one who labours under a quite analogous affection of the organ of the intellect which expresses its troubles in a more perplexing manner. Dr. Dumont has given a highly interesting and graphic account of his sufferings from a cerebral neurosis in his recently published "Testament Medical." The whole nervous system is more or less involved; but the brain is evidently the chief focus of disorder. A heated atmosphere brings him to the verge of maniacal excitement (transport cerebral), while a highly electrical condition of the air or an eclipse produces syncope. Sensation, both special and common, memory, and ideation are more impaired than voluntary power; the mind and internal consciousness are not affected, even during his severest paroxysms. The condition seems extremely similar to hyperæsthesia of a nerve, and the retinæ appear to be actually in this state, in consequence of which visual power is seriously enfeebled. Da Costa(a) relates a very interesting case which he entitles "Cerebral Neuralgia proving Fatal by Serous Apoplexy." The patient was a female, aged 30, who had been suffering four months with neuralgia and pain in the head when she came under his care. The attacks of the disorder were of varying duration, and were separated by longer or shorter intervals. They mostly came on between 9 p.m. and 2 a.m., and were marked by violent frontal pain, great restlessness, an inclination to talk and to cry out; so that they much resembled hysterical paroxysms. Quinine and iron were beneficial, but after fifteen days a severe relapse occurred, and the attacks came on nightly as before. After some days of more tranquillity, the disorder returned in an aggravated form, the pain in the head was agonising, and death ensued in the way of coma. At the autopsy, the arachnoid and pia mater were found injected; the substance of the encephalon was everywhere healthy; but both ventricles, especially the left, were distended by clear serum. Da Costa believes that the serous effusion was the result of the cerebral hyperæmia induced by the paroxysms of pain, and compares with his case one related by Andral, in which a female, aged 35 years, suffered for some time with tic douloureux of the face. This suddenly ceased, but was succeeded by a violent pain of head, and a giddiness so intense that the patient could no longer stand up. She had at the same time very painful nausea, and vomited much bile. This lasted two hours; after which a very copious flow of serous liquid took place from the nasal fossæ, and continued some hours. When it ceased, the cerebral symptoms disappeared. If, in the former case, there may exist some doubt whether the neuralgia was not symptomatic of inflammation of the walls of the ventricles, none such can be felt with respect to the second, where the extra-cranial disorder was evidently replaced by the cerebral. In both instances, it seems to me very probable that the effusion was the result of vaso-motor nerve paresis itself occurring as a part of the neuralgia, just as it is sometimes seen to do in the outer tegument, where the part which has been the seat of pain becomes swollen, red, tender, and, in fact, is in a quasi-inflammatory condition.

I will relate here one more case which has recently occurred in my own experience, and which appears to me to have much resemblance to those cited from Torti and Andral. A gentleman, aged 47, returned in very fair health from a trip to Italy at the end of last year. He had been suffering during some years, at least the two last, with urethral stricture, the urine being pretty constantly alkaline and depositing triple phosphates. Early in February, while in the country, he had an attack of retention of urine. No catheter could be passed for some time. An eminent Surgeon who saw him with me after I had brought him to town succeeded, and after some days the stricture was split by Mr. Holt's method. For two days all appeared to go on well; the stream of urine was much more free. On the third day there was difficulty in introducing the catheter, and he felt a good deal of uneasiness in the perinæum afterwards. This, however, was subsiding, and he went out two days later for a walk, though it was

(a) De Costa, Charleston, J. XIV., 2; Schmidt's *Jahrb.*, vol. cvi., p. 32.

severely cold. On returning he sat down to dinner, but could take little, and soon was attacked by sharp rigors, his face was very pallid, and he seemed for a time in a rather alarming state. Warmth and brandy and water rallied him, he was got to bed, and became more comfortable; took Dover's powder gr. xiii., and passed a good night. His pulse was notably accelerated and his skin hot after the rigor. Some urine passed this day was quite turbid, and deposited on standing a good deal of pus, and was albuminous. The microscope showed larger granulous cells mingled with pus globules. The day following this attack he had less uneasiness in the perinæum, and passed urine more freely. His appetite was, however, bad, and he was unwell. He had been taking citrate of iron and quinine some days; as his bowels were costive, this was now omitted, and calomel gr.v. was given at night. No healthy bile was passed, and the dose was repeated the following morning. About noon of this day he was taken worse; his right hand dropped and was semi-paralysed for a time; he mumbled, and could not speak intelligibly; his pulse was not affected. A stimulant was given, after which he retched a good deal and vomited some bile-tinged mucus. Subsequently he spoke plainly, and there was no marked indication of paralysis; he was dull, but conscious the rest of the day. At night, however, I began to feel seriously uneasy about him, as he seemed to be getting more stuporous. I roused him, however, about 2·30 a.m., though with some difficulty, and he took from me and drank a glass of beef-tea and brandy, using, I am almost certain, the left hand. At 5 a.m. I tried to rouse him, but in vain. Soon after his breathing became stertorous, irregular, varying much in frequency, sometimes very rapid (as much as 70 per minute), and then again ceasing for several seconds. All remedies were fruitless, and he died in profound coma at 2 p.m. The day before his death and up to the time of complete coma ensuing his scalp had been abnormally hot; after a stream of cold water had been poured on it for some time the heat disappeared, but no improvement resulted. The calomel produced several loose stools, dark and offensive, but containing scarce any trace of bile. This, as well as the evident distaste for food, flatulence, and nausea, which appeared much more like that of primary gastric disorder than that of cerebral origin, led me to regard the head symptoms at first as depending on deranged action of the liver, and to believe that they would pass off as the normal biliary flow was restored. I was the more inclined to this view because the patient had always had an hypochondriac tendency, and I thought I perceived some indications of quasi-hysterical exaggeration of his symptoms. During the last few hours of life the left arm and leg were completely paralysed, but the right hand was frequently moved to and fro in an apparently voluntary manner. The autopsy was not made until five days after death; but there was no appearance of decomposition. Rigor mortis was well marked. The head was opened first; the scalp was bloodless; the veins of the dura- and pia-mater were both full. There was no flattening of the convolutions; there was some clear fluid under the arachnoid; the brain was "wet;" there was a little fluid in the ventricles, but very little, and it appeared clear. The fornix was not softened, but it separated rather too readily from the corpus callosum; the walls of the ventricles appeared quite normal, and so did every part of the brain, cerebellum, crura cerebri, pons Varolii, and medulla oblongata. On microscopic examination, I could find nothing abnormal in the fornix; the vessels were not coated, or only one here and there very slightly; there were no glomeruli. The vessels of a piece of pia mater from a small part of the convolutions appeared healthy. The right corpus striatum presented nothing abnormal except some coating of one or two vessels with granulous matter; there were no glomeruli. The right thalamus opticus presented nothing that I could consider abnormal; there was no coating of the vessels and no glomeruli. The liver was of a dark reddish colour; appeared healthy. There was palish green bile in the gall bladder; the liver cells were normal, but contained dark pigment. Kidneys appeared quite healthy. Spleen was rather large; normal otherwise. The stomach was thin-walled, but showed no evidence of disease. The lower end of the ileum was examined; but Peyer's patches were not in the least enlarged. The bladder was large; its walls rather thickened; its mucous membrane, especially towards its lower part, presented numerous red spots, some of which at least were certainly produced by recent extravasation of blood. No pus was seen anywhere. Lungs and heart not examined.

The etiology of this remarkable case must be admitted to be very obscure. Some conditions, however, may, I think, be excluded from the list of possible causes. Among these I may mention uræmia, pyæmia, and ordinary continued fever. Uræmia cannot, I think, have existed, because the kidneys were found healthy, and because, to the best of my belief, there was no notable diminution in the secretion of urine to the last. It was, indeed, albuminous, and contained some pus one day; but how often does such a state continue for a long period without any trace of head symptoms? Moreover, uræmia would not be ushered in with rigors. The occurrence of these, indeed, made me suspicious of pyæmia, but neither the symptoms nor the autopsy warrant the view that any such state existed. The same may be said of the hypothesis which would regard the disorder as the result of any of the exanthemata miasms. To my own mind, the most probable motors of the morbid process were either a malarious taint contracted in Italy or a remote action of the operation on the nervous centres. The case already cited from Mr. Smith shows what a serious "*retentissement*" on the nervous centres urethral operations may have; but I feel much difficulty in regarding this as the real cause, on account of the long time which elapsed between the operation and the outbreak of the symptoms. Still, it is possible that the shock, unfelt at first, was really the death-blow. On the other hand, I am much inclined to view the case as one of pernicious, ill-developed ague with cerebral affection, and the state of the liver and spleen is rather corroborative. The locality of the patient's residence in the country was by no means exempt from ague, though he himself had never been attacked manifestly by it. There was a trace of periodicity in the course of the disease: its first onset was on a Thursday, about 2 p.m., and the remission was followed by a considerable aggravation on the following Saturday about noon. But whatever may have been the cause, I think the history affords considerable evidence that fatal palsy of the great nervous centres may occur without demonstrable organic lesion that can be considered adequate to produce such an effect; and that this palsy may be produced either as the result of inhibitory shock, or of a direct action of an imponderable toxic influence. In either view the case appears to me one of great interest. The history becomes the more striking if we compare it with the records of cases where extensive mischief has existed for a length of time without producing any symptoms. From this contrast one cannot but conclude that the dynamic alterations in an organ may be far more important than the structural.

It may not be out of place to introduce here an observation of Schönlein:—Rheumatism (a kindred influence, I believe, to malaria) may occasion, he says, a true nervous apoplexy, in which after death no trace of alteration in the brain is discoverable. A girl under his care, during scouring, got paralysis of the lower extremities, from which she was restored, in thirty-eight hours, by potash, hot baths, and ammon. pyro-oleosum. Returning to her work too soon, contrary to order, she was attacked in a few days with all the symptoms of apoplexy, and died. At the autopsy not the least trace of morbid change was found in the brain.

That other encephalic nervous centres suffer in a like way, as do the hemispheres, seems to me eminently probable. Schroeder van der Kolk says of epilepsy that there is sufficient reason to conclude that its first cause consists in an exalted sensibility and excitability of the medulla oblongata (v. p. 250). This state, I believe, is not a true increase of sensory power, but is the same hyperæsthesia that we have seen to exist in the nerves and hemispheres. The gentleman whose case I alluded to in Lecture I., a sufferer from the sequelæ of sunstroke, has at times some sudden and intense seizures of giddiness compared to an electric shock, which compel him to cling to the nearest object for support; these evidently have an affinity with the minor forms of epilepsy, but are not attended with unconsciousness. In hydrophobia many of the symptoms are indicative of extreme hyperæsthesia, doubtless of cerebral origin. The nerves of the skin, the mucous lining of the pharynx and of the air passages and the auditory and optic nerves are all exquisitely irritable, and continue so until the increasing asthenia—the co-product of the hyperæsthesia—brings the heart to a standstill. The ἦθος and etiology of hysteria plainly declare how largely hyperæsthesia enters as a morbid element into the disorder, and though it be difficult to determine precisely what centres are principally affected, yet we cannot doubt that the emotional and intellectual are both involved, and that the medulla oblongata is often drawn into the range of the morbid action. Romberg states that hyperæsthesia of the spinal cord occurs in two forms,—one is the

ordinary tetanus, which is independent of consciousness; the other is characterised by different varieties of pain and constitutes the state to which the name of spinal irritation has been given. He cites an illustrative case of this kind from Sir Charles Bell, where a middle-aged man suffered from an agonising pain in the whole back unattended with any motor disorder. Tetanus and chorea seem to be instances in which a morbid excitability affects the motor rather than the sensory nerve apparatus; the condition has much analogy with hyperæsthesia, but its locale is diverse.

These general remarks may be sufficient to show that the view I have propounded of the resemblance between affections of nerves and of nervous centres is not without foundation. Of course the centres, as much more complex and highly-organised structures, and endowed with higher functions, are likely to present graver, more complicated, and more diversified morbid phenomena. It seems to me, however, a real advantage, tending to give stability and precision to our conceptions of morbid action, if we can divest ourselves of the notion always too prevalent, that the groups of symptoms we term diseases are specific morbid entities, and can see how we may trace in a multitude of ever-varying conditions the prevalence of the same kind of morbid action. The *modality* (to use Trousseau's term) varies *ad infinitum* in different species of disorder; but through all this diversity there may be traced a most real affinity, and the recognition of this is most important in all endeavours after rational treatment.

To be continued.)

ORIGINAL COMMUNICATIONS.

A NOTE ON THE ZITTMANN TREATMENT.

By TILBURY FOX, M.D. Lond.

It is to be regretted that opportunity has not afforded us more acquaintance with the treatment designated the Zittmann. I first saw it fairly carried out with success in the case of a patient of Mr. Wilson suffering from old constitutional syphilis of some twelve years' standing—miscarriages, nocturnal pains, enlarged glands, deep stains of the skin, and induration of the tongue of three and a half years' duration having been the greatest troubles. All modes of cure had been tried without success, and I was surprised at the end of ten days from the commencement of treatment to see a remarkable amelioration, especially as regards the hard swelling and ulceration of the tongue. The patient's mouth had been so sore that she could only swallow with much pain and discomfort. This case placed my attention on the *qui vive*, and on my visit to Hebra's Clinique last year I observed the Zittmann plan being carried out in the cases of many patients in his wards. It is applicable in those cases of old-standing disease in which there are an obstinacy to reparative action and ulcerative tendencies. So far as skin diseases are concerned, cases of tertiary syphilis, with foul ulcers, derive most benefit. I was particularly struck with the peculiar ulcerative aspect displayed in Vienna by diseases of the skin in general, the special preponderance of what we in England should call the strumous habit, but have not seen my way clear to explain this by the mode of life of the lower orders in general. The mode of therapeute now referred to is modified in detail by different authorities, and is a compound of mild purgation, low dieting, and sweating. One has to alter the details somewhat to suit the English habit. The patient keeps his bed the whole time, in a warm room of the temperature of from 60° to 70° F., he takes a purge to begin, repeating it every second or third day. As to diet, in the morning he takes a cup of tea and some toast, at midday a chop and a potato or biscuit, and in the evening dry toast and tea again, biscuit *ad libitum*. In the way of medicine he takes before 12 noon two pints of a stronger decoction, and after 12 noon two pints of a weaker decoction of sarsaparilla. In the course of a few days the skin relaxes, perspiration is set up, the bowels generally act freely four or five times a day, and an offensive odour is perceptible about the patient and his secretions. In about fourteen days he may be allowed to get up, but still to continue some of the decoction. The *modus operandi* of this treatment is clearly "eliminative." After this tonics or other remedies may be given. I have seen sufficient to convince me that in this "Zittmann" we have oftentimes a curative process, and more frequently, perhaps, an essential help or preparation for the more necessary exhibition of tonics or such drugs as iodide of potassium. A course of alkaline waters acts most efficiently after its use. Unfortunately, we have little opportunity in England of putting it fairly to the test. As many of the decoctions contain mercury, I would just add that this should be omitted entirely; it is unnecessary. The formulæ are as follows:—

Decoction No. 1, the Stronger.—Sarsaparilla, ʒ xij.; water, O. xxiv.; boil for two hours, and then suspend in the liquor, by means of a linen bag, ʒ iss. of alum, ʒ iss. of liquorice, ʒ j. of oxysulphuret of antimony, ʒ ij. of senna leaves, and ʒ ss. of aniseed; remove it from the fire, allow it to infuse awhile, and then strain off O. xvi.

Decoction No. 2, the Weaker.—Take the residue of No. 1; sarsaparilla, ʒ vj.; water, O. xxiv.; orange-peel, cinnamon, cardamons, of each ʒ iij.; and of liquorice, ʒ vj.; infuse for several hours, and strain off O. xvi. for use. The addition of guaiacum is often desirable.

43, Sackville-street, W.

NOTES ON SYPHILIS, WITH SPECIAL REFERENCE TO ITS TREATMENT BY SYPHILISATION.

(Extracted from the *Norsk Magazin for Lægevidenskaben*, xix. Bind, 11 Hefte, Christiania, November, 1865.)

By WILLIAM DANIEL MOORE, M.D. Dub., M.R.I.A,
Honorary Fellow of the Swedish Society of Physicians, of the Norwegian Medical Society, and of the Royal Medical Society of Copenhagen; Examiner in Materia Medica and Medical Jurisprudence in the Queen's University in Ireland.

(Concluded from page 119.)

Affections of the eye occurred not so very rarely. In 21 patients, of whom 18 were not subjected to treatment, with fresh syphilis, 5 had a very short time previously been treated with mercury, and 1 had four years ago been syphilised. In 16 of the 18 fresh cases the affection of the eye occurred on an average about three months after the breaking out of the first general symptoms; in 2 it was the first distinct secondary phenomenon. The iritis was often complicated with cyclitis and chorioiditis. Both eyes were attacked in 8, the right alone in 7, the left in 6. It must be considered a chance that of these 18 fresh syphilitic patients with affection of the eyes, only 4 were found under treatment by derivation; 14, on the contrary, by syphilisation; while the proportion between those treated by derivation and syphilisation on the whole was as 53 to 97. As to the result, this was in general favourable, except in some cases where instillation with atrophia was not used. In these instances troublesome synechiæ and exudations on the pupil occurred. In 2, almost total blindness ensued—namely, in H. P. O., above mentioned, and in O. C. L., the latter of whom had, before admission, been treated with mercury, and in whom the affection of the eyes had already lasted some time. On admission the journal noted:—

"Great subconjunctival congestion; greyish obscuration of the cornea of the left eye, so that nothing of the anterior chamber can be seen; this eye can distinguish light from darkness. The right cornea is likewise obscured; the iris is prolapsed into the anterior chamber. No perception of light. Both bulbs soft."

This condition did not alter during the patient's stay in the Hospital—at all events, not for the better.

Of the syphilitic women, 14 were pregnant on admission, and were delivered in the Hospital (the 15th, who is mentioned in the following note, and who was delivered immediately before, is included, only because the child was admitted at the same time, and affords a very instructive case). Notwithstanding that the statements of such persons as to the periods of infection and conception cannot always be looked upon as perfectly accurate, I shall in a brief abstract mention the principal points connected therewith in their respective histories, as among other things these notes afford some information as to the doubtful question respecting the fate of the offspring of mothers infected during pregnancy.

1. S. F. O., admitted April 30, with tolerably recent secondary symptoms (time of infection not stated); in the fourth month of pregnancy, delivered on July 19 of an immature, putrid fœtus of the seventh month. Infection and conception in this instance perhaps coincide, unless the infection was subsequent, which is very possible, nay even probable.

2. M. G. O., admitted on May 12, with secondary symptoms of a slightly earlier date, "probably infected six months ago." Nothing is stated respecting pregnancy. Delivered on August 2 of a putrid fœtus. There is no statement of the supposed age of the latter. In this case infection took place probably either contemporaneously with conception or before it.

3. A. K. A., admitted August 14, with sores on the genitals. "Menses had not occurred for seven weeks." Secondary symptoms on September 4; delivered on December 23 of a boy in the 7th month, which lived one hour. Infection either contemporaneously with conception or subsequently to it; the latter more probable.

These three patients were admitted before my period of attendance began.

4. S. M. G., was dismissed on August 3 after a seven month's course of derivation; admitted again on the 22nd with relapse, and on the 29th gave birth to a living girl at full term—which, however, on November 12 showed indubitable signs of hereditary syphilis. The child was transferred on the 13th with her mother to the Municipal Hospital, where she died of convulsions after having been one month under treatment by syphilisation (Dr. Gjör). Infected in the first half of pregnancy.

5. P. P., admitted October 2 with secondary symptoms, observed fourteen days previously in the sixth month of pregnancy (more probably in the seventh) delivered on January 1, 1864, of a "mature healthy" boy, whose subsequent fate has already been mentioned as No. 1 of the patients dead of "angina."(a) Infection occurred in the latter half of pregnancy.

6. A. M. H., admitted on November 8, with old primary symptoms; on the 20th exhibited distinct secondaries; delivered on March 3 of a dead fœtus in the seventh month. Infection occurred in the first half of pregnancy.

7. A. H., admitted on November 20 with secondaries, of which mucous tubercles were said to have been observed for four or five weeks in the sixth month of pregnancy (must have been at least in the seventh), delivered on January 31, 1864, of a healthy boy, of whose further history see "Angina," patient No. 3. Infected in the first half of pregnancy.(b)

8. M. G., admitted on January 12 with recent secondaries, in the eighth month of pregnancy, on January 31 gave birth to a girl, already mentioned among the "angina" patients as No. 2.(c) Infection dates from the latter half of pregnancy in October.

9. A. A., admitted on February 6 with tolerably recent secondaries. "Menses seven weeks ago," which is, however, incorrect if the Journal Report of April 27 is true. It is there stated that she was delivered of a still-born child in the seventh month.(d) Infection must have occurred in the first half of pregnancy.

10. M. D., admitted February 24 with secondaries of about two months' standing in the eighth month of pregnancy, delivered on April 2 of a healthy girl, already referred to among the patients with hereditary syphilis subjected to syphilisation as No. 5. Infected in the first half of pregnancy.

11. M. O. O., admitted on March 21, with secondaries after infection three months previously; menses not present for six months; delivered on May 5 of a putrid fœtus. Infected in the first half of pregnancy.

12. B. K. O., admitted on March 22 with not very recent secondaries, infected in October or November, delivered on May 21 of a girl in the eighth month, who lived one hour. Infected at the time of, or after, conception.

13. L. J., admitted on April 1 with tolerably recent secondaries, infected rather more than three months previously in the seventh month of pregnancy, delivered on May 21 of a semi-putrid fœtus in the eighth month. Infected in the first half of pregnancy.

14. M. K. O., admitted on September 16 with primary symptoms of one month's standing in the eighth month of pregnancy, secondary symptoms became developed, the patient gave birth on October 20 to an apparently healthy boy, whose fate has already been reported under No. 5 of the "Angina" patients.(e) Infected in the latter half of pregnancy.

15. S. L. A., admitted on March 17 with secondary symptoms of one and a-half month's duration; fourteen days before admission she had given birth to an apparently sound girl, mentioned above as No. 4 among the "Angina" patients.(f) Infected in the latter half of pregnancy.

From these cases it is true that no perfectly certain result is deducible with reference to the children of women infected during pregnancy; but thus much appears at all events certain, that the offspring is infected when the mother becomes universally syphilitic during pregnancy, whether the infection take place in the first or second half of the pregnancy; the later (the nearer to birth) the infection of the mother the less is the offspring affected, but yet always with the infection in it, though this may not appear on the surface immediately at birth. The premature delivery, the immature, frequently semi-putrid fœtuses, the feeble, often atrophic condition of the children, the speedy eruption of various syphilides without preceding local symptoms, sufficiently prove this.

Von Bärensprung's observations, "that syphilis in the mother arising during pregnancy never passes over by inheritance to the children without the previous appearance of a primary affection," finds no support whatever from the above cases, which are also directly opposed to von Rosen's experience, that "the child is not born with syphilis when the mother's disease dates from the first half of pregnancy, while, on the contrary, the offspring of women infected in the latter half is always born with signs of the disease;" nor does the expression attributed to Professor W. Boeck in the number of the *Bibliothek for Læger* for October, 1864, "that it is shown by experience that when the mother becomes syphilitic first in the latter months of pregnancy the disease is not communicated to the child," derive any confirmation from them—which expression, moreover, I have not succeeded in finding in the report of the meeting of Scandinavian Naturalists in 1860.

The proposition laid down by Ferrier respecting this question, that "the mother who during pregnancy becomes infected with syphilis communicates through her vitiated juices the disease to the child," must, moreover, be certainly looked upon as correct.

(a) As I have not given the report on "Angina," I quote the following from it to complete the case:—"1. Born in Hospital on January 1, 1864, of a constitutionally syphilitic mother. The child exhibited no sign of disease until the 18th of the same month, when pemphigous vesicles appeared in the sole of each foot, and in the palm of the right hand. 25th.—Pemphigous vesicles in several parts of the body. February 2.—Frequent vomiting. 4th.—Diarrhœa. 5th.—Death. On post-mortem examination there were found catarrhal pneumonia and atelectasis; intestinal catarrh; swelling of the retro-peritoneal glands."—W. D. M.

(b) "Apparently healthy until February 20, when some erythema appeared on the nates, in the flexures of the thighs, and on the lower extremities. Died on the morning of the 24th after repeated convulsive attacks. Post-mortem: Enteritis follicularis, anæmia cerebri, and swelling of the lymphatic glands."

(c) "Healthy until February 19, on which day she was seized with convulsions, &c., lasting until morning visit next day. The child then appeared in a state of collapse and died in the afternoon. Post-mortem.—Catarrhal pneumonia in the left lower lobe with lobular atelectasis; in the right only lobular atelectasis; the anterior parts emphysematous; nodular extravasations of blood in the substance of the mitral and tricuspid valves. The intestines down to the rectum filled with a white and whitish-yellow chyme."

(d) For cases of the occurrence of menstruation during pregnancy, a fact observed so long since as by Hippocrates, see Dr. Montgomery's "Signs and Symptoms of Pregnancy." Second edition. London. 1856. Pp. 65 and 85 *et seq.*—W. D. M.

(c) "Born in the Hospital on October 20 of a constitutionally syphilitic mother. 22nd.—Blenorrhœa of the right eye. 30th.—Diarrhœa and vomiting. November 3.—Died. Post mortem: Universal atrophy, Atelectasis and hæmorrhagic foci in the lungs and kidneys."

(f) "April 1.—During the last few days an intensely red eruption with segregated, small, uneven, watery excoriations, has become developed upon the genitals and anus. 3rd.—Some spots of roseola on the face and extremities. The child is greatly emaciating. 7th.—The roseola-exanthema is more distinct on the face, and is partly desquamating. The strength is steadily declining; the body is rather convulsed and rigid. The child died in the evening. Post mortem: Interstitial hepatitis, parenchymatous nephritis, and intestinal catarrh."

CASE OF

CYSTIC DEGENERATION OF THE KIDNEYS IN AN ANENCEPHALOUS FŒTUS, CAUSING DYSTOCHIA.

By Assistant-Surgeon GEORGE F. DUFFEY, M.B. Dublin,
1st Battalion 24th Regiment.

On the morning of November 3, 1865, I was asked by the midwife of my regiment to visit the wife of a soldier then in labour. On seeing the woman I ascertained that she was twenty-two years of age, that this was her third pregnancy, and that the first child was living, but that the second was a miscarriage. The waters, which were not excessive in quantity, had come away during the night. On examination I found that the feet were presenting through the external orifice, with the toes towards the pubis, and the left leg a little in advance of its fellow. She had comparatively fre-

quent but short pains. The bowels had been opened and the bladder emptied. Little progress being made, the uterus was excited to stronger action by friction, and during the pains gentle traction was made by the feet; but although there was considerable delay in the delivery of the breech—notwithstanding that the pains got better—the expulsion of the abdomen was attended with great difficulty, and eventually was not effected—although all possible pains were taken to prevent it—without slight laceration of the perineum. The head and upper extremities came away simultaneously with the body. When the feet were touched during the time they protruded through the vagina, they retracted quickly; but when the child was born it did not respire. The placenta came away in about fifteen minutes, and was apparently healthy.

On examining the fœtus, which was very well nourished and of the full time, I observed that it was anencephalous; its face had that hideous appearance which the French term "Tête de Crapaud," (the appropriateness of which description was borne out by the midwife, who exclaimed that it was "like a toad,") its neck and chest were very short, and, as it were, fused into one piece. The bones of the vault of the cranium were undeveloped, and the integument of the face and neck was continuous with a reddish coloured structure, composed chiefly of areolar tissue, which immediately covered the rudimentary encephalic ganglia lying on the base of the skull, to which ganglia were connected a perfect medulla oblongata and spinal chord.

There were curious malformations of the hands and right foot. The fourth and fifth fingers of the right hand were united by a web up to the distal end of their second phalanges, and there was an additional or sixth finger, with a distinct nail, similarly united to the entire length of the fifth finger. The left hand and right foot had corresponding malformations, viz., an intimate union of their respective third and fourth digits, which appeared as one, but had each separate nails. The left foot was normal.

The abdomen was greatly distended, of a globular form, and dull on percussion; it measured eighteen inches in circumference. On laying open the peritoneum, two large tumours were found, one on either side, almost entirely filling the abdominal cavity; the liver was pushed upwards, and the intestines greatly displaced; the stomach could not then be seen.

On examination, these enormous tumours, to which the size of the abdomen was owing, were found to be the kidneys, and lying on and adherent to their surfaces were the ovaries and fallopian tubes, which led to a bifid uterus. A small gelatiniform polypus, attached by a long filamentous peduncle to the labium minus of the left side, hung down between the œdematous lips of the vagina. The bladder was empty. The supra-renal capsules appeared normal; there was no fluid in the abdomen. On removing the capsules from the kidneys their surfaces presented the usual lobulated appearance of the fœtal organ; but on making a section they were found to be composed of numerous small transparent cysts, visible to the naked eye, of about the size of peas, lying in a matrix of a light greyish colour, from which they could not be detached, and containing a clear serous fluid. The distinction between the cortical and medullary portion was totally obliterated, but the outline of the calyces could be indistinctly traced. The ureter was pervious.

In consequence of the wish to have a drawing of the parts taken *in situ*, the kidneys could not be weighed until after their section and exposure to air for some days; even then the weight of the right kidney—both being apparently of the same size—was six ounces. In length it measured six inches and three-quarters, in width five inches, and in thickness two inches.

The fœtus itself weighed ninety ounces; the proportion, therefore, of the weight of the kidneys to that of the entire body, would be about 1 to 7·5, instead of as in the normal fœtus 1 to 80.

This case, as well as being illustrative of the independent liability of the fœtus to disease, is, also, if one may judge from the scanty literature on the subject, interesting as an example of a remarkably rare degeneration, interesting alike to pathologists and accoucheurs.

Not laying much stress on the anencephalic condition of the fœtus, except as regards its connection with hyper-development in other parts, which I think is unique in this case, I may mention that there are but few examples on record of a similar degeneration. Rayer, in his splendid plates, delineates a case of atrophy and cystic degeneration of one kidney in a fœtus. In this case the cysts were larger but not so numerous as in mine, and the other kidney was healthy. In Vol. III., page 514 of his book, he states, that examples of this degeneration in the kidneys of newly-born infants are very rare, and he only alludes to three somewhat similar cases.

Virchow, also, in a paper on "Congenital Dropsy of the Kidneys, (Verhandl.-der Phys. Med. Gesel. in Wursburg, 1855,)" relates some instances of cystoid degeneration, with complete atresia of the pelves and papillæ, and refers to this affection as a cause of obstruction to labour.

In a case reported by M. Siebold, of Gottingen, in the *Rev. Med. Chir.*, Janvier, 1855, the head presented, but the expulsion of the child was arrested by the size of its abdomen. Repeated tractions were required. The circumference of the abdomen was seventeen inches. On inspection two enormous tumours were found in the abdomen, these were the kidneys; the two weighed two pounds, each was six inches long, four wide, three thick. On removing the capsule small cysts, containing a transparent serosity, were seen scattered about. On section, the cortical substance could not be distinguished from the pyramids; the greater portion, consisting of small cysts, visible to the naked eye.

In Virchow's and Siebold's cases, and I think in mine also, these cysts were dilations of the urinary canals.

Beggars' Bush-barracks, Dublin.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

ST. BARTHOLOMEW'S HOSPITAL.

ON THE REMOVAL OF THE ENTIRE TONGUE FOR CANCEROUS DISEASE.

Recent experience in the results of operations on the tongue has brought to light a fact as interesting and important as it was unforeseen. It is found that a person who has had the whole tongue removed retains all the functions that are usually assigned to that organ in a degree which is amply sufficient for all the purposes of ordinary life. He can talk with a distinctness which completely averts the suspicion of what his loss has been; he can swallow fluids readily, and, although with less ease, masticate and swallow solid food. Mr. Syme has lately published an account of the condition of a person in whom twelve months before he had removed the whole tongue for cancerous disease. No return of the disease had occurred, and the patient, after recovering from the operation, and while travelling in the highlands, had dined at *table d'hôtes*, and entered into conversation without betraying the deficiency under which he laboured: he could swallow fluids and finely-divided food as well as ever, and could masticate solid substances, although a difficulty was sometimes experienced from their getting into awkward parts of the mouth. In ordinary speech his words were wonderfully clear and distinct, and he could sing without difficulty. The two cases which we subjoin correspond so closely in their results with that of Mr. Syme that we think the three together may be taken as fair illustrations of the condition in which patients will be placed after suffering removal of the tongue.

The condition of persons who have lost their tongues assumes additional interest when we remember that it is connected with the question of miracles. It is well known that a favourite method of torturing heretics and others was to cut their tongues out. In some instances it was discovered that those who had been so treated could talk as plainly as before, and their being able to do so was ascribed to the fact that a miracle had been wrought in their favour. A very interesting notice of this subject is found in Dr. Newman's "History of My Religious Opinions." In a former "Essay on Ecclesiastical Miracles" that gentleman had adduced as a fact that was strictly miraculous, that the African confessors in the Vandal persecution had their tongues cut out, and yet could speak as plainly as before. Subsequently to the publication of the essay, however, additional evidence upon the point came to the knowledge of Dr. Newman, which caused him so far to modify his opinion that he says in his later work,—"Meanwhile, I fully allow the points of evidence brought in

disparagement of the miracle are, *primâ facie*, of such cogency that till they are proved to be irrelavent, Catholics are prevented from appealing to it for controversial purposes."

We regret that want of space prevents our transcribing the evidence to which the author refers in full. The following are some of the most striking details:—There is mentioned "a girl born without a tongue, who yet talked as distinctly and easily as if she had enjoyed the full benefit of that organ" (Middleton). Colonel Churchill, in his "Lebanon," speaking of the cruelties of Djezzar Pacha in extracting the tongues of some Emirs, adds,—"It is a curious fact, however, that the tongues grow again sufficiently for the purposes of speech." "In answer to your inquiries about the powers of speech retained by persons who have had their tongues cut out, I can state from personal observation that several persons whom I knew in Persia who have been subjected to that punishment spoke so intelligibly as to be able to transact important business.(a) The conviction in Persia is universal that the power of speech is destroyed by merely cutting off the tip of the tongue, and is to a useful extent restored by cutting off another portion as far back as a perpendicular section can be made of the portion that is free from attachment at the lower surface. I have never met with a person who had suffered this punishment who could not speak so as to be quite intelligible to his familiar associates." (b) The belief that the power of speech is destroyed by merely cutting off the tip of the tongue is a strange one. The results of the ordinary operations in this country afford no ground for it.

With these points before us, we are reminded of an error into which we are likely to fall in thinking loosely about the functions of the tongue. Popularly, the tongue is considered as the chief organ of speech; it is called "the unruly member," as if it were alone responsible for all speech and its results. In reality, however, it is known that the tongue holds a position in the mechanism of speech far subordinate to the larynx, and also below the lips. All the vowels can be pronounced without its help, so can many of the consonants.

Passing from these collateral considerations, however, the fact remains, as proved by results obtained in the practice of the first Surgeons of the day, that the tongue may be removed and yet the patient enjoy, unimpaired to any material degree, the power of speech and of deglutition. This is a fact upon which a Surgeon may well congratulate himself; for there is scarcely any condition of disease in which the patient's existence is one of such complete and hopeless misery as that which is present in cancer of the tongue, or one from which any humane person would be more thankful to rescue, although it were only for a time, one of his fellow-creatures.

Case 1.—*Removal of the Whole Tongue by Means of the Eeraseur for Epithelial Disease—Recovery.*(c)

(Under the care of Mr. PAGET.)

A man, aged 50, was admitted for cancerous disease of his entire tongue; his difficulty in swallowing and speaking was so extreme that he was advised to have the organ removed. This was done under chloroform, and without any great difficulty. The mouth was drawn open, and firmly fixed so, and the tongue was drawn forward. To facilitate this latter step, the mucous membrane and the soft parts on the floor of the mouth, including the attachment of the genio-hyo-glossi muscles to the inner side of the symphysis, were cut through close to the bone. The tongue was thus in great measure released from its anterior and inferior attachments, and could readily be drawn forward, so that the wire of an écraseur was, without difficulty, passed around its root, including the entire organ to its connexions with the larynx. The wire was tightened by degrees, and there was some free but not dangerous bleeding when the mass was detached.

The man's recovery was uninterrupted and very rapid; indeed, he regained his power of swallowing in so short a time that he soon ceased to require special attention in feeding, and before the end of a week he could make himself intelligible by imperfect speech, so much so that it would have been hard without actual inspection to have believed that the entire tongue had been removed. The patient continues well, with tolerable articulation, and it is now (October, 1865) twelve months since the operation was performed.

(a) From *Notes and Queries*, No. for May 22, 1858.

(b) Sir John McNeill.

(c) This case is published in *St. Bartholomew's Hospital Reports*, vol. 1, p. 55.

Case 2.—*Extensive Epithelial Disease of the Tongue—Removal of the Entire Organ by means of the Eeraseur—Recovery.*

(Under the care of Mr. PAGET.)

For the notes of this case we are indebted to the kindness of Mr. Bloxam.

S. N., aged 49, a fairly nourished woman, of dark complexion, and otherwise apparently healthy, living in the country, came to the Hospital on January 4, suffering with pain and enlargement of her tongue. On examination there was found situated on the right side, and towards the centre of the tongue, an ulcer with a hard excavated base and elevated edges; fissures extended from the margin of the ulcer in various directions; the induration passed across the middle line and backwards to the base of the tongue. The whole organ was impaired in its movements; and the patient was in great inconvenience from the constant dribbling of saliva; the neighbouring glands were not involved to any extent.

Her history was, that nine months previously she first noticed a spot on the right side of her tongue. She took little notice of this, but it steadily increased; latterly she had suffered great inconvenience and pain; she was married and had several healthy children. There was no history of cancer or of "tumours" in her family. Mr. Paget pronounced the disease to be epithelioma of the tongue, and advised entire removal of the organ by the écraseur. The operation was performed on January 6, in the following manner:—The patient being under chloroform, the mouth was widely opened, and the tongue drawn forwards. Mr. Paget divided the mucous membrane and structures connecting the sides of the tongue with the jaw, and also the attachments of the genio-hyo-glossi to the symphysis, close to the bone; the tongue being thus freed was well drawn forwards, and the steel wire of an écraseur passed so far back as to include the whole of it close to its connection with the hyoid bone. The wire was then slowly tightened, and the tongue divided, though not quite vertically, through its entire thickness. The patient lost but very little blood, the chief bleeding coming from the structures at first divided by the knife. The operation lasted only a few minutes. 3 p.m. (an hour and a-half after the operation)—The patient soon recovered from the chloroform; the mouth was kept open to expose the wound to the air. Ice ordered if necessary. 9 p.m.—No hæmorrhage; the patient was asleep.

January 22.—The woman made a most rapid recovery,(d) being able to swallow fluids after the third day, and after the sixth she could make herself intelligible. At the end of three weeks she left the Hospital able to swallow either fluids or solids, and with such good speech, that except upon examination of her mouth one could scarcely believe she had lost her entire tongue.

30th.—She came to the Hospital to-day looking extremely well; she could swallow perfectly; the divided surface of the tongue had completely healed; she was free from pain and from the annoyance arising from the constant dribbling of saliva. The floor of the mouth was considerably raised. There was no hardness in the cicatrix, nor any present indication of a return of the disease.

In remarking upon the operation, Mr. Paget said that he believed that which he had just done was suitable in the very great majority of cases in which it was necessary to remove the tongue for cancerous disease. Two points, however, must be attended to in performing it. (1.) The attachments of the tongue to the jaw, both in front, where there were the genio-hyo-glossi muscles, and at the side, where it was connected by the mucous membrane, must be thoroughly divided, so that the organ could be well drawn forward; and (2) care must be taken that the tongue was divided perpendicularly through its thickness; unless there was a definite provision to prevent it, the section would pass obliquely from behind downwards and forwards, and thus parts that had better be removed might be left. An efficient plan was to transfix the tongue perpendicularly with stout needles at the part at which the division was to be made, and to place the écraseur-wire behind these, so that it was made to cut vertically. There might doubtless occasionally be found cases in which the disease was situated so near the hyoid bone that it would be advisable to perform the larger operation recommended by Mr. Syme. Nevertheless, the écraseur operation allowed of complete removal of the sides and upper part of the tongue, and was therefore

(d) Mr. Hilton, in his lectures on "Rest and Pain," page 72, says:—"I do not know any tissue that repairs itself more rapidly [than the tongue]. It is abundantly supplied with capillaries filled with arterial blood and has enormous distribution of nerves, and these are the two elements that contribute most to rapid reparation."

appropriate in the greater number of cases. The operation besides was attended with scarcely any slight risk to life.

The following is an extract from a clinical lecture lately given, on the subject of cancer of the tongue, at the Hospital by Mr. Paget:—

The motive to operate here, as in other cases, is either to prolong life, or, without shortening, to comfort what remains. For the first there is, I believe, some advantage—not a great prolongation of life, yet enough to justify an operation which is attended with very little suffering or risk. But the chief motive is in the hope of comfort, and the comfort that may be gained is, in many cases, so great as to justify a greater risk of life than is incurred in any of the ordinary operations for the removal of cancer of the tongue. The risk is really very small. I have not had a fatal case or witnessed one—there are few of even the minor operations of which I could say so much—and the comfort given is that the patient is delivered for the time from all the misery of one of the most distressing and disabling conditions of disease, and, till the cancerous growth is renewed, may enjoy complete health, and do all his work. Doubtless the disease will return after operation, but it is as unreasonable to refuse a painless operation, and one free from risk of life, because the disease will return at some time soon after it, as it would be to refuse a course of medicine because it gives only temporary relief. When a man has only, suppose, two or three years to live, it is no small advantage if at least half the time can be spent in comfort rather than in misery, and in profitable work rather than in painful idleness. Looking back on the many cases of cancer of the tongue that I have had to do with, I should be disposed to say that there is no organ on which operations for cancer are more justly performed, or are more to be urged, even in extreme cases.

For the method of operating, the choice lies between cutting and the écraseur. Caustic is not to be thought of, unless in a case of the very smallest extent; and the cases in which the ligature should be used must be extremely rare. I have never employed it, for the only advantage which it offers, that of avoiding hæmorrhage, is just as well, and much less offensively, obtained by the écraseur. The risks and troubles of hæmorrhage are, however, much overrated, and I believe the knife may be preferred to the écraseur in all but the largest operations, such as those for the removal of the whole tongue.

SAMARITAN HOSPITAL.

CASES OF OVARIOTOMY.

(Under the care of Mr. SPENCER WELLS.)

(Continued from page 64.)

Case 74.—Large Non-adherent Cyst—Never Tapped—Ovariotomy—Recovery.

An unmarried woman, 45 years of age, was sent to Mr. Wells by Mr. Gregory, of Rusholme, near Manchester, and was admitted on November 26, 1865. The abdomen was greatly distended by an ovarian tumour. The girth at the umbilical level was forty-four inches. It was twenty-two inches from sternum to pubes, and twenty-nine inches across the front of the abdomen, from one ilium to the other. There was no evidence of adhesion; but there was crepitus, as of recent lymph, below and to the right of the umbilicus. She had complained of pain in that spot, more or less, for three months. The tumour could be felt through the posterior wall of the vagina, above and behind the uterus, pushing and flexing the uterus forwards. The cervix uteri was freely moveable. Enlargement of the abdomen was first noticed nearly two years before admission. The catamenia became less in quantity about the same time, and she had "seen nothing" for the last nine or ten months.

Ovariotomy was performed on December 13, 1865. Dr. Quincke, of Berlin, and Dr. Meryon were among the visitors. Dr. Ritchie gave chloroform. An incision six inches long was made downwards from one inch below the umbilicus. A non-adherent cyst was exposed, tapped, and withdrawn as it became empty and flaccid. A pedicle as broad as three fingers was secured in a middle-sized clamp, about four inches from the right side of the uterus, and the cyst was cut away. There was scarcely any bleeding. The left ovary was healthy. The clamp was fixed outside without any pull on the uterus, and the wound was closed as usual by deep and superficial silk sutures. The fluid removed measured twenty-nine pints, and the cyst walls weighed a pound and a-half. The progress after operation was good from the first. The only peculiar symptom was a rather copious and offensive leucorrhœal discharge on the second and third days. All the stitches were removed on the fourth day. The clamp came off on the ninth day. The bowels did not act till the fourteenth day; but no inconvenience was felt. They acted daily afterwards, and the patient returned to Manchester twenty-eight days after operation. She has been heard of since as getting quite well.

Case 75.—Adherent Multilocular Cyst—Once Tapped—Ovariotomy—Recovery.

An unmarried Jewess, 19 years of age, applied to Mr. Spencer Wells in May, 1865, with an ovarian tumour which filled the whole abdomen. It had been of very rapid growth, only having been noticed during the previous four months, although she recollected some slight fulness for about eight months. The catamenia were regular and normal. The uterus central and freely mobile. The general health good. The patient was advised to apply again if the tumour increased. In about two months she began to suffer from distension, and was admitted to Hospital on July 18. She was tapped on the 20th. Eleven pints of fluid were removed, and a multilocular cyst was felt below the umbilicus. She left on July 25, and called a month later in good health, but the cyst had filled so as to reach three or four inches above the umbilicus. For the next two months there was not much increase. The catamenia continued regular. In December increase became more rapid, and she was admitted on January 4, 1866, menstruation having ceased on the 2nd.

Ovariotomy was performed on January 10. Mr. Clover gave chloroform. Dr. Skoldberg, of Stockholm, and Dr. Stafford, of New Zealand, were present. An incision four inches long was made from the umbilicus downwards, some rather firm adhesions to the right of, and above, the umbilicus were separated, as was a piece of adhering omentum. One large and several smaller cysts were tapped, and the empty tumour was easily withdrawn. A pedicle as broad as three fingers was secured in a small clamp between two and three inches from the left side of the uterus. The clamp was fixed outside without any tension. The right ovary was healthy. There was scarcely any blood lost. The wound was closed as usual. The fluid removed measured twenty-one pints. The cyst walls and small cysts weighed twenty ounces. They consisted of two large and several smaller cysts. The inner coat was very vascular, and ecchymosed in two or three spots, but there were no signs of inflammation. On the peritoneal coat of the tumour some yellow, non-vascular patches were observed. These were beyond the ecchymosed spots, and it seemed that the vessels which had supplied the yellow patches had given way, the blood had been extravasated, and the supply to the parts beyond had been thus cut off.

A good deal of pain followed the operation, and three opiate enemas were given (twenty drops of laudanum in each) within two hours. The pain then ceased, and full reaction was established. She was sick three or four times during the night, but not afterwards. Three opiate enemas were given during the first day, and two on the second day, on account of flatulent, colicky pain. Some of the sutures were removed on the third day, and the rest on the fourth. Uterine epistaxis went on freely from the fourth to the eighth day. The clamp was removed on the sixth day. The wound was entirely healed by the thirteenth day, except the lowest stitch point, from which a little pus exuded. On the fourteenth day the face, and afterwards the whole body, became covered by a rash, which was at first suspected to be measles, as a little girl had been to see her who afterwards fell ill with measles, and the patient had never had them. But it soon appeared to be urticaria. It gradually went off after free action of the bowels, and was not attended by any unpleasant constitutional symptoms. The patient left the Hospital, looking and feeling remarkably well, twenty days after operation.

TAUNTON AND SOMERSET HOSPITAL.

REPORT OF A CASE OF CEREBRAL INJURY, WITH ANALYSES OF THE URINE.

(Communicated by F. W. GIBSON, M.D. Lond., House-Surgeon.)

CHARLES G., aged 15, admitted July 27, 1865, at 6.30 p.m, At 5.30 p.m. he fell out of a dog-cart, striking the back of his head on a stony road. He lost a good deal of blood at the time, and was stunned.

State on Admission.—Skin cold, face pale, quite unconscious. A scalp wound about an inch long at the back of the head leading down to the occipital bone, just below its tuberosity.

A linear fracture of that bone, at same site, with slight depression. 7 p.m.—Temperature 99⅗; pulse 111, feeble; respiration 24. No paralytic symptoms. Pupils equal; act to light; bladder empty. 8.45 p.m.—Temperature 99⅖; pulse 120; respiration 36. Skin cold; has been once sick; no blood in vomit. He cannot swallow. Beef-tea 6 oz., brandy 1½ oz., as an injection. 10.30 p.m.—Temperature 100⅘; pulse 110; respiration 36. Skin warm; enema retained. 11.35 p.m.—Temperature 101; pulse 120; respiration 36; skin hot and dry; still unconscious.

July 28, 9 a.m.—Temperature 100⅕; pulse 110; respiration 36. Face pale. He is very restless, cries out continually, and throws his arms about. Vomited once during the night. Cannot swallow. Ice applied in an india-rubber bag to shaven scalp. Enema repeated thrice since last report. 6.30 p.m.—Temperature 101; pulse 94, feeble; respiration 26. Skin dry. Urine retained since accident; drawn off by catheter; amount 500 cubic centimetres; specific gravity 1035; reaction acid; deposit of urates; no albumen; urea 14·0 grammes.

29th, 9 a.m.—Temperature 99⅘; pulse 85; respiration 28. Still unconscious and unable to swallow. Enema repeated thrice since last report. 6·30 p.m.—Temperature 100⅕; pulse 100, feeble; respiration 26. Skin moist. Urine drawn off; amount 560 cubic centimetres; specific gravity 1033; neutral; deposit of urates and phosphates; no sugar; no albumen; urea 21 grammes; phosphoric acid 2·8 grammes.

30th, a.m.—Temperature 99⅖; pulse 75; respiration 20. Skin dry. Paralysis of right facial nerve. Emaciation great and increasing. Can swallow and is less unconscious. Ice discontinued. Three enemata and six ounces of beef (by mouth) since last report. P.m.—Temperature 100⅕; pulse 94; respiration 22. Skin warm and dry. Urine retained; amount 650 cubic centimetres; specific gravity 1030; alkaline; no sugar; no albumen; deposit of phosphates; urea 25·4 grammes; phosphoric acid 3·77 grammes.

31st, a.m.—Temperature 99⅗; pulse 88; respiration 22; skin dry. Is still very restless and irritable. Head hot. P.m.—Temperature 99⅕; pulse 70; respiration 16. Thirty ounces of beef-tea taken since yesterday evening. Urine still retained; is drawn off twice a day. Amount 480 cubic centimetres; specific gravity 1032; deposit of urates; no sugar; no albumen; urea 18·7 grammes; phosphoric acid 2·36 grammes.

August 1, a.m.—Temperature 98; pulse 64; respiration 20. Emaciation increases. Is much more sensible. P.m.—Temperature 99; pulse 60; respiration 20. Has taken 30 oz. of beef-tea and 4 oz. of brandy since yesterday evening. Urine retained; amount 700 cubic centimetres; deposit of urates; no sugar; no albumen; specific gravity 1033; urea 28 grammes; phosphoric acid 2·32 grammes.

2nd, a.m.—Temperature 98⅗; pulse 70; respiration 20. Lies still, with legs drawn up. Puts out tongue when asked so to do. It is protruded straight. P.m.—Temperature 99⅕; pulse 84; respiration 20. Bowels, confined since admission, open once to-day. Food as on 1st. Urine drawn off twice daily; amount 660 cubic centimetres; specific gravity 1032; deposit of urates; no albumen; no sugar; urea 26·4 grammes; phosphoric acid 2·838 grammes.

3rd, a.m.—Temperature 99⅖; pulse 80; respiration 24. P.m.—Temperature 99⅖; pulse 80; respiration 20. Urine: Amount 450 cubic centimetres; urea 18·4 grammes; phosphoric acid 2·043 grammes. Food as on 2nd.

4th, a.m.—Temperature 98⅕; pulse 80; respiration 16. Passes urine involuntarily. Seems, however, much more conscious. P.m.—Temperature 99⅕; pulse 80; respiration 20. Food as on the 3rd.

5th, a.m.—Temperature 98⅕; pulse 80; respiration 16. Emaciation not increasing. Spoke for first time to-day since admission. Urine retained. P.m.—Temperature 99⅕; pulse 84; Respiration 24. Food as on 4th. Urine (from 3 p.m., August 4, to 10 a.m., August 5): Amount 660 cubic centimetres; deposit of urates; specific gravity 1031; no sugar; no albumen; urea 20 4 grammes; phosphoric acid 2·93 grammes.

6th, a.m.—Temperature 98⅕; pulse 80; respiration 16. Is much more sensible. Answers questions rationally. P.m.—Temperature 99; pulse 80; respiration 20. Food: Beef-tea 40 oz.; milk 40 oz.; brandy 4 oz.; an egg. Urine retained; amount 580 cubic centimetres; specific gravity 1030; deposit of urates; no sugar; no albumen; phosphoric acid 2·447 grammes.

10th, p.m.—Temperature 98⅗; pulse 80; respiration 20. Seems much better.

11th, a.m.—Temperature 98; pulse 80; respiration 20. Emaciation much less. Bowels open once a day since August 2. Food: Meat 2 oz.; two eggs; beef-tea 20 oz.; milk 20 oz.; brandy 4 oz. P.m.—Temperature 98⅘; pulse 68; respiration 20.

12th, a.m.—Temperature 98⅘; pulse 60; respiration 16. Complains of being very hungry; emaciation still very great, but not increasing; wound has not yet healed; bowels confined for two days. Food as on the 11th. P.m.—Temperature 98⅖; pulse 68; respiration 20. Complains of hunger. Urine no longer retained; amount 455 cubic centimetres; specific gravity 1021; deposit of urates; no sugar; no albumen; urea 15·9 grammes; phosphoric acid 1·469 grammes.

13th, p.m.—Temperature 98⅗; pulse 80. Urine: Amount 550 cubic centimetres; specific gravity 1020; no sugar; no albumen; urea 16·5 grammes.

14th, p.m.—Temperature 99⅘; pulse 80; respiration 12. Bowels open twice; urine lost.

15th, a.m.—Temperature 99⅕; pulse 80; respiration 12. P.m.—Temperature 98⅖; pulse 68. Urine: Amount 300 cubic centimetres; urea 14·8 grammes.

16th, a.m.—Temperature 99⅕; pulse 80; respiration 20. Wound healed. Is still thin, and complains of hunger. Bowels open; paralysis of facial nerve continues. P.m.—Temperature 98⅖; pulse 80; respiration 16. Urine: Amount 420 cubic centimetres; urea 14·7 grammes.

17th.—Is more sensible; lies in a semi-dozing state, save when roused. Has had since the 15th four ounces of meat, half a pound of potatoes, twenty ounces of milk, two eggs, four ounces of wine daily. Urine: Amount 550 cubic centimetres; urea 15.9 grammes. He cannot hear watch applied closely to right ear, but can hear it distinctly with left. P.m.—Temperature 98⅕; pulse 60; respiration 20.

21st.—Complains much of hunger; would eat all day long if allowed.

September 3.—Has been up to-day. He can stand, but is very weak; drags right leg slightly.

12th.—Removed from Hospital to-day. He attends as an out-patient. The nervous symptoms continue. His intellect is not materially affected.

Remarks.—This case I have considered to be worthy of record partly on account of the comparative rarity of recovery after so severe a cerebral injury, but mainly on account of its interest from a physiological point of view. The average amount of urea excretion per kilogramme during the five days, from July 30 to August 3, notwithstanding the absence of any notable fever and the relatively small quantity of food taken, was, as shown in the table, considerably above both the normal quantity and the mean amount of excretion during the five days from August 12 to August 17. Bischoff gives 0·408 grammes per kilogramme as the normal amount for boys of 16, under ordinary circumstances. The mean amount excreted by C. G. during the first period was 0.776 grms. per kilo.; the maximum 0·938 grms. per kilo. The mean amount during the second period, 0·518 grms. per kilo.; the maximum, 0·55 grms. per kilo. The mean amount of phosphoric acid excretion during the first period was 0·0875 grms. per kilo.; the maximum, 0·1256 grms. per kilo. Owing to unavoidable circumstances, the amount of phosphoric acid excretion was only once ascertained during the second period. It amounted to 0·0489 grms. per kilo.—about the normal quantity. It will be observed, therefore, that the mean amount of phosphoric acid excreted during the first period was nearly double, the maximum nearly treble, the normal quantity. May this abnormal amount of the urea and phosphoric acid be attributed to nervous lesion? The absence of any notable fever proves that the increase was not due to inflammatory action. Still, the non-existence of sugar and albumen in the urine appears to be an argument against the suggestion just thrown out.

Table.

	Date.	Urea (per kilogramme). Grammes.	Phosphoric acid (per kilogramme). Grammes.
1.	July 30	0·836	0·1256
	,, 31	0·624	0·0786
	Aug. 1	0·933	0·077
	,, 2	0·88	0·0904
	,, 3	0·613	0·0681
2.	,, 12	0·53	0·0489
	,, 13	0·55	—
	,, 14	0·493	—
	,, 15	0·49	—
	,, 16	0·53	—

The boy's weight on September 6 was 31 kilos.

My best thanks are due to Mr. Alford, the Surgeon under whose care the case was, for his permission to publish the foregoing report.

Medical Times and Gazette.

SATURDAY, FEBRUARY 10.

THE GOVERNMENT AND THE CATTLE PLAGUE.

Both Houses of Parliament have commenced their deliberations by discussing the action—or, rather, inaction—of Government under the great calamity which has befallen the country. The political aspect of the debate betokens but little inclination to condone the shortcomings of the Home Office. With but one or two exceptions, the whole of the speakers on both sides of the House united in charging the Government with having shirked their responsibility, and with having been guilty of criminal indifference and childish vacillation. The Profession of Medicine have no political bias to serve, no political party to strengthen, but the invasion and devastation of England by Steppe murrain constitutes an era in Medical history, and as many of the speakers threw considerable light on the circumstances under which it has been allowed to take place, we may be permitted to call the attention of our readers to some of the facts brought out in the debate.

In the first place, it is useless to allege that the Government were unwarned of the real nature of the disease, or of its probable importation. Full information as to the nature of Rinderpest was given before a Committee of the House of Commons in 1854 by Professor Symonds; and again in 1857 the same authority reported to the Government the existence of the plague in Galicia, and that it was then spreading in the direction of Western Europe. Government was, or ought to have been, fully acquainted with the means taken by Russia and Bavaria to extinguish the plague; and, with the increased facilities for cattle traffic afforded by steam and railways, their vigilance should have been aroused, and at least the precautions of appointing certain ports for the reception of cattle from abroad, and of a proper system of scientific inspection, should have been taken. In place of this, when the disease made its appearance in June last, the Government were in most complete ignorance as to its nature, as to the means by which it spread, and as to the best mode of combating it. But not only did they not know anything of the disease which was spreading so rapidly and fatally, but they neglected the most natural and ready means of learning. The country possesses, in the Medical Officer of the Privy Council, a functionary whose business it is to advise the Government on all matters relating to contagious diseases. But Mr. Lowe, one of the members of the Royal Commission, informed the House that the Government did not take the trouble to apply to Mr. Simon for his opinion or advice on the matter. Professor Symonds, the Veterinary Surgeon, was consulted, and then a Royal Commission was appointed to find out whether the disease was really Steppe murrain or no, and whether it was contagious. If the disease were in truth Rinderpest, there was no further need of inquiry as to its character, for the Steppe murrain was as well known to the pathologists of Europe as is any other contagious disease. The very person to whom the Commissioners turned for the solution of this question was, according to Mr. Lowe, the Medical Officer of the Privy Council, who had made Steppe murrain a particular study, and whose evidence mainly guided the Commission in the opinion they adopted, and has been entirely borne out by the course of events. But the Government might have had the benefit of that evidence at least two months before. The disease commenced in the middle of June, and it was not until the publication of the Report of the Commssioniers on the 31st of October that the country was definitely informed that the disease which was decimating its herds was the dread Russian cattle plague.

It would be waste of time to discuss the merits of the various Orders in Council with which the Government have sought to satisfy their own consciences and the exigencies of the nation. The first, according to Professor Symonds' evidence before the Royal Commission, simply had the effect of spreading the disease more quickly than it otherwise would have been. The appointment of inspectors without any real guarantee of their fitness, and arming them with power of indiscriminate slaughter, was a spasmodic effort which not only totally failed to produce any good effect, but merely multiplied the means of contagion. The Commission published their recommendations in the first week in November, and, however the public hesitated to accept the advice of the majority at the time, there was no difference of opinion on the matter by the end of that month. The Government were urged by the Royal Agricultural Society and by various deputations from different parts of the country to stop peremptorily the nsit of cattle. Instead of this, they issued orders, first to the magistrates of Petty Sessions, and then to those of Quarter Sessions, to stop traffic wherever they might think it necessary. Of course, no uniformity of action was thus obtained; in fact, in many instances the orders were simply disregarded, or an antagonism was set up between the town and county authorities, the former refusing to act in defiance of the latter. Besides, the Government were thoroughly aware that the magistrates had no power whatever to interfere with the transit of cattle on any railroad in the kingdom. Whilst, therefore, they might fine heavily a farmer who drove his bullocks across a turnpike road from one field on his farm to another, they could not interfere with the transport of infected beasts from the Metropolitan Cattle Market to Cumberland or Cornwall. It is useless to say that they had no evidence of the efficacy of the plan recommended them. They had tested it in the case of Ireland, and they had seen it tried in that of Argyllshire, and in both cases it had succeeded perfectly. When the Irish deputation waited on the Minister to beg that the import of cattle into Ireland might be stopped, they were met with the assertion that it was impossible to enforce such a measure. The deputation, however, persevered, and the Minister, doubtless with an eye to future divisions, yielded. The result is that Ireland is yet free from the Rinderpest. The defenders of Government urge that they had not the legal power to enforce such a measure as the stoppage of cattle traffic, and that the public would not have submitted to it. It seems, however, probable that they overstepped their power in the appointment of inspectors to enter any premises they chose, and to slaughter any beasts they were not bribed to spare. That the people would not have submitted to the temporary inconvenience, under the pressure of so dire a calamity, we do not believe. But at any rate, if the Government had not the power, and did not feel strong enough to assume it, they had but one course open to them. In the

face of so enormous a calamity, they might have appealed to the nation. Instead of summoning Parliament together, and laying the case before them, in November last, they actually postponed its meeting a week past the usual time, whilst in the same time we lose 10,000 beasts a week from the disease. They certainly manage these things better in France.

It is understood that the Royal Commission will shortly publish another report, but that they will abstain from offering the Government any further recommendations. Considering the way in which their former advice was received, we think this course will be the only one consistent with their dignity and position. Stoppage of traffic might have arrested the pestilence in November; but it is very doubtful whether it would avail now. We hope that the next Report of the Commission will embody the results obtained by the labours of Drs. Marcet, Beale, Sanderson, and Murchison, who have been employed in investigating the disease under their direction. We are certain that the results of their inquiry will amply vindicate the scientific and practical value of the advice which our rulers have thought proper to neglect.

PHASES OF VARIOLOUS ERUPTION.

We recently noticed, under the head of "Polymorphism in Disease," a few facts tending to the supposition that the range presented by the naked-eye appearances of the eruption of variola is considerable. Our attention has specially been recalled to the book published in 1820 by Dr. John Thomson, entitled "An Account of the Varioloid Epidemic which has lately (1817-18) prevailed in Edinboro and other parts of Scotland," containing much information, especially of a clinical kind, of interest at the present time.

Firstly. It would appear that in the epidemy referred to the eruptive fever was not unfrequently mistaken "in its commencement for typhus," a circumstance worthy of consideration in discussing the opinion of those who hold that the cattle plague is essentially a typhus of malignant aspect.

Secondly. Dr. Thomson entered largely into the question of the occurrence of secondary small-pox, a point which demands the most careful scrutiny; and it would seem that cow-pox and other forms of modified small-pox, often followed in the wake of vaccination, and even caused death.

Now, one of the arguments made use of against the identity of variola and Rinderpest is that mentioned by us in connexion with Dr. Fairmann's name—viz., that cows take Rinderpest in all its severity after suffering from cow-pox, and are therefore, in consequence, not protected by vaccination. Such in reality is the case occasionally with the human subject in the matter of vaccinal and variolous disease. The inoculation of vaccine, as at present practised, is not absolutely protective against small-pox, though it probably always modifies the severity of the latter; and therefore, upon analogical grounds—supposing, for the sake of argument, that variola and Rinderpest are allied—we might have expected that vaccination would, to a greater or less extent, fail to be protective against Rinderpest. The fact, then, that a cow may take Rinderpest and die of it after vaccination, or even cow-pox, is no ground *per se* for denying the identity of cattle plague and small-pox. A man may have typhus or scarlet fever more than once, though the first attack to some extent secures him against a recurrence.

Dr. Thomson observed that in the Edinburgh epidemic "the eruption itself has always first appeared in the form of papulæ, and many of these have decayed *without becoming either vesicular or pustular*." Here, then, is in the human subject a certain departure from the original, and apparently an approach to the appearances presented by the eruption of other diseases. A good deal of information is also given by Dr. Thomson in reference to this variability, or polymorphism, in his subsequent work published in 1822, as exemplified by the history of epidemics witnessed about the same period by different observers in France, Germany, and other countries. At page 37 of the former issue we read that in the greater number of these cases the crusts or scabs often fell off without leaving behind them any tubercles, blains, or pits. In our previous notice of this subject we mentioned the fact that Dr. Bristowe attributed very considerable importance to this, amongst other circumstances, that he "never had seen the destruction of surface of the skin which in small-pox leads to pitting." If Dr. Thomson's observations can be depended upon,—and no one will for an instant throw a doubt upon the doings and care of this most competent authority,—then even the argument of the absence of pitting is valueless. But it must be remembered that a distinct destruction of tissue has occurred, and been recognised in the tanned hides of Rinderpest beasts. At the meeting of the Epidemiological Society on Monday, evidence of the same kind was detailed in the account given by Drs. Bowerbank and Anderson of an epidemic of varicella (?) in Jamaica, preceding the outbreak of small-pox. Complete transitional forms or stages were observed linking together the papule, semi-globular and umbilicated vesicles, and the pustule of variola, whilst doubts were entertained as to the exact nature of the outbreak. Well, then, taking the above remarks as a guide, we should be justified in asserting that the eruption of small-pox has at different times so far deviated from its usual aspect as to have presented difficulty in diagnosis, and though the *structure* of the skin may to some extent have an influence in favouring or retarding vesicular and pustular changes, yet different epidemics vary as to the features of their cutaneous expressions, to some extent, independently of such an agency, and supposedly in relation to some peculiarity in the degree or kind of the poison and the general condition of the attacked. We are no supporters of the small-pox theory of Rinderpest. In some respect, errors have crept in with reference to the behaviour of variola, and we draw attention to the above facts solely from a desire to encourage the most thorough ventilation of all sides of the question, and secure impartial examination. It has occurred to us more than once that the wide prevalence of doubts and uncertainties in the matter of cattle plague eruption has only endorsed the general opinion in regard to the neglect of the study of diseases of the skin in England. Equally good observers in the general field of Medicine have differed wholly as to both the grosser and minuter characters; on the one hand affirming that the scabs, scales, and contents are only sebaceous, on the other, that true pus formation is present, or if not always this much, at least its antecedent—cell degeneration. Our shortcoming in dermatological matters is disgraceful.

THE CURE OF BARRENNESS.

So much curiosity has been excited by our comments last week on Dr. Marion Sims's new book (a) that we proceed to give our readers some notion of its contents as soon as possible. We may say at starting that the author's position and antecedents are such as to entitle him altogether to respect; for he had made himself famous by his ingenuity in devising various methods of operation for vesico-vaginal fistula; and then the fact that he had been obliged to leave his native country on account of political troubles would have procured him the warm sympathy of all liberal persons had his name ended in "owski," or had he been Pole, Hungarian, Italian, or, in fact, anything but an English-speaking native of the Southern States of the North American Republic.

The book in question does not profess to be a complete treatise on uterine Surgery, but to deal with those conditions which are opposed to conception, which all have this in common, that they prevent the free passage of living spermatozoa into the cavity of the womb. The conditions essential to conception are stated to be these eight:—"1. It occurs

(a) "Clinical Notes on Uterine Surgery; with Especial Reference to the Sterile Condition. By J. Marion Sims, A.B., M.D., etc. London: Hardwicke. 1866." See *Medical Times and Gazette*, 1866, vol. i., p. 133.

only during menstrual life. 2. Menstruation should be such as to show a healthy state of the uterine cavity. 3. The os and cervix uteri should be sufficiently free to permit the free exit of the menstrual flow, and also to admit the ingress of the spermatozoa. 4. The cervix should be of proper form, shape, size, and density. 5. The uterus should be in a normal position—*i.e.*, neither anteverted nor retroverted to any great degree. 6. The vagina should be capable of receiving and of retaining the spermatic fluid. 7. Semen with living spermatozoa should be deposited in the vagina at the proper time. 8. The secretions of the cervix and vagina should not poison or kill the spermatozoa."

These eight paragraphs indicate the order in which the writer deals with his matter; and it is but just to say that although the cure of barrenness is, as it were, the key note of the book, or the thread by which the parts are linked together, yet that the amount of information conveyed is by no means narrowly restricted, and that many a systematic treatise is less rich in details and far less graphic and comprehensible than are these "Notes."

Having laid down, then, these foregoing eight physiological postulates, Dr. Sims digresses for a moment to describe the best method of making an examination of the womb, both by touch and sight; and of this part it is difficult to speak too highly as regards its common-sense practical character and the useful rules of conduct which it lays down for the young Practitioner. The method of expanding the vagina and filling it with air, by opening the vaginal orifice at a time when the weight of the abdominal viscera tends to draw the vaginal parietes asunder, is one which we ourselves became acquainted with years ago, together with the use of a one-valve speculum, made like the bowl of a spoon; we think they only need be known to be adopted generally.

The first section, on the text that conception occurs only during menstrual life, is very short, and contains a few cases of very early and very late pregnancy (from 10 up to 52 years of age), and a few cautions on the necessity of thorough careful exploration in all cases where the doubt is between pregnancy and tumour.

The second is very much longer, and comprises about a fourth of the whole book, and is in reality a treatise on unhealthy menstruation considered as a cause or concomitant of barrenness. Scanty menstruation is very soon dismissed; not so its more important opposite, profuse menstruation. In speaking of this, and in fact throughout the book, the writer ignores, or passes over with hardly disguised contempt, all internal remedies, and for every case of confirmed menorrhagia demands an exploration of the womb, for where this condition is inveterate he says there always will be some organic cause for it. Then he enumerates the organic causes and gives the treatment of each, including granular erosion, engorgement of the cervix, fungoid granulations in the cervical canal or in the uterine cavity; polypi of os, cervix, or cavity; fibroid tumour, whether intra-uterine or intra-mural; inversion of the uterus, hæmatocele, and cancer. Hence, as we have said, the Surgical treatment of a vast variety of uterine affections is described *apropos* of the barrenness which may incidentally accompany them.

For the granular erosion, Dr. Sims prescribes a mitigated caustic application, and prefers chromic acid. Respecting the fibroid engorgement of the neck he gives one case in which he believed the ingress of spermatozoa to be impeded by the swelling, and conception followed a bilateral incision. For the fungous granulations he recommends sponge tents, and here we meet with a minute and careful account of these instruments, of their preparation and effects, which would be valuable to any young Practitioner. He tells of the effect of compressed sponge in expanding within a narrow canal; of the peculiarly fetid, dirty, irritating discharge which it sets up; of its adhesion to and interpenetration of the granular or villous surfaces in contact with it; of its power of drying or soaking up granulations and mucous polypi, and the difficulties of detaching it. The uses of glycerine, too, not only as a soothing dressing, but as a means of draining a congested mucous membrane and abating fœtor, are well told. The seatangle tent also is not omitted. Polypus comes next, with all its varieties, and with the modes of getting at the tumour in the cavity of the womb, and the use of the écraseur to amputate it. Fibroids, with the various feasible and infeasible methods of exterpation, follow next, and inversion of the womb; and, lest this last should seem a singular topic for a book on sterility, he gives Dr. Tyler Smith's case of repeated conception after reduction of an inverted womb of twelve years' standing. On the subject of painful menstruation, as may be expected, he has no half views. He says that it arises from physical obstruction to the egress of fluid, and by far most frequently that the cause of obstruction is purely anatomical and mechanical. It may be complicated with inflammation, or may not, but "there can be no dysmenorrhœa, properly speaking, if the canal of the neck of the womb be straight and large enough to permit the free passage of menstrual blood."

"The operation of enlarging the canal by incision is not always successful, but it is the only procedure from which I have derived the least benefit." He looks upon it as much safer than the bougie and tent, and immeasurably less liable to be followed by pelvic cellulitis; but in America it appears that it is far more liable to be followed by dangerous hæmorrhage than in the old country. But even incision is not a perfect simple cure. "I have often," he says, "been amazed to find the os contracted in a month to one-fourth of the size of the original incisions. I have frequently seen it cut open large enough to admit the index finger up to the os internum, and then close in a few weeks to such a degree as not to admit a No. 4 or 5 bougie, and this in spite of persevering efforts to prevent the contraction. I have been frequently compelled to repeat the operation, and I remember several patients upon whom I have operated as often as three times in the course of a few months, and even then the result was not wholly satisfactory. . . . . I would recommend the occasional passage of a bougie after the first week." He goes on to speak of occasional failures in incision, in such a way as to make it appear that "unnecessary exposure or fatigue"—or, in other words, "constitutional causes"—are not really such unimportant sources of dysmenorrhœa as Dr. Sims had previously stated. Certainly if with a patulous os and cervix cold and fatigue can cause dysmenorrhœa, the mechanical causes are put out of court. At any rate, where a No. 4 or 5 bougie can pass, spermatozoa may. But to return. If incision fail, the cause of dysmenorrhœa may be found in a small polypus obstructing the os internum; or in flexure of the womb; and these may admit of further proceedings. But considering what Dr. Sims says of his own failures, and what he says of the mischiefs of too large metrotomes in other hands, and of the incapability of a too largely incised os to withstand causes of abortion—knowing, too, as we do, and as Dr. Sims naïvely admits, that the *first* menstrual period after any operation whatever is generally comfortable, we think that if the history of cases were followed up for a few months after they have been recorded as "cured," Dr. Sims would find plenty more materials for "amazement" at the results. The whole treatise on dysmenorrhœa is that of a firm and exclusive believer in the *mechanical* school, but still of a man honest enough to speak of failures which neutralise his own doctrines.

Section III. treats of cases in which the os is large enough to allow the free *egress* of the menstrual fluid, but not the *ingress* of spermatozoa. Such narrowness may be natural or acquired. If natural, and the tube is straight, there may be no dysmenorrhœa, though there be sterility. To this category

*

belong cases in which the posterior lip overlaps the anterior in a valvular manner, so as to oppose the upward passage of liquid, and which may be relieved by splitting the posterior lip longitudinally. But the chief interest of this section lies in the testimony which Dr. Sims bears to the abuse of caustics, and especially of the potassa fusa, or the Vienna paste for the cure of so-called "ulcer of the uterine neck," and to the stricture which follows.

Section IV. treats chiefly of the elongated conical cervix, a condition liable to cause retroversion of the womb, and itself to operate unfavourably on the penetration of spermatozoa. For this, amputation of the elongated cervix is unhesitatingly recommended, and a guillotine of ingenious construction has been devised for the purpose. Dr. Sims says he has not as yet had many cases of pregnancy to follow amputation of the cervix, but he is well satisfied that if amputation had been performed in many cases in which he simply cut open the cervix, conception might have occurred where it has not. We cannot share his satisfaction.

Section V. is a treatise of nearly a hundred pages on anteversion and retroversion of the wound. It begins, by the way, as several other chapters do, with a certain amount of information on the normal place, size, and functions of the womb, which is given quite unpretendingly, but which might have been expanded in some hands into an "anatomical and physiological proem." We will not linger on this section further than to say that it treats of its subject matter fully; but the chief point of interest are the observations on the uterine sound. He regards this as a valuable means of diagnosis and exploration, but represents its use as a redresser of the retroverted womb as dangerous and painful, and objects very strongly indeed to the absurdity of replacing a displaced womb by the sound, and expecting it to remain in its place. "I have known," he says, "Physicians to replace a retroverted uterus day after day for months, but I never knew a case cured by it." Equally is he averse to the intra-uterine pessary. He has an operation for contracting the vagina in cases both of inveterate anteversion and retroversion; but in ordinary cases falls back upon pessaries, and recommends one of Hodges and Meigs' form modified by himself; at the same time, he speaks well of a plug of cotton (soaked or not in glycerine or glycerine and tannin), and has devised an instrument for introducing it effectually. For procidentia, he favours an operation on the upper part of the vagina.

Section VI. starts with the double proposition that the vagina must be capable of receiving, and not only so, but of retaining the spermatic fluid. Want of capability of reception may depend on imperforate hymen, atresia vaginæ, or absence of that canal; but chiefly on *vaginismus*, or that spasm of the vaginal orifice which corresponds with spasm of the eyelids in *photophobia*, spasm of the glottis, of the sphincter ani, etc. We gather from Dr. Marion Sims that the essence of the affection is, in his opinion, an extremely hyperæsthetic state of the outer surface of the hymen, so that the slightest touch produces intense spasm. This condition may exist, spite of the fact that the vagina is dilatable to its fullest extent under ether; and it has persisted even after repeated—though painful—connexion, conception, and labour at full term with laceration of the perineum. Dr. Sims's remedy is to clip away the hymen, which is generally thickened; and to follow this by incisions through the sphincter vaginæ muscle, and the use of a glass bougie. Yet even in one of these cases a cure was not effected till a small tubercle at the mouth of the vagina, the size of a grain of wheat (corresponding, probably, to Wood's painful sub-cutaneous tubercle) was excised. In one case we read (p. 342) "that it became the business of the Physician to repair regularly to the residence of this couple, two or three times a week to etherise the poor wife, . . . hoping that she would become pregnant, and that delivery would cure her. This etherisation was continued for a year, when conception occurred. But during the whole period of utero-gestation, etherisation was necessary to coition. After the birth of the child there were a few copulations without ether, but it was exceedingly painful, and soon the pain became so severe that they were compelled to resort to ether again. At the end of *another year of ethereal copulation*" (!!!) "there was another conception, which resulted in an abortion at the third month." This is the case above spoken of in which the perineum was lacerated during labour, and the cicatricial tissue and remains of the hymen were extirpated before a complete cure was effected.

We cannot help remarking here that cases of vaginismus in slighter degree are not by any means uncommon, and that allowing that the Surgical operation spoken of may be necessary when any thickened and unhealthy tissue or hypersensitive nodule exists; yet that English Physicians no more resort to excision in slight cases than they would cut off the eyelids in blapharo-spasm, or cut out the chordæ vocales in laryngismus stridulus. On the contrary, they apply to vaginismus rules of search for such reflex and constitutional causes as, if existing, might set up spasm. For instance, the neighbouring organ, the rectum, not seldom may be the starting-point. We should have liked to have heard Dr. Sims's experience on this topic.

We must also protest, with due deference, against the idea that it ever can become the "business of the Physician" to administer ether for the purpose and in the manner which Dr. Sims details in so matter-of-fact a way. We recollect a Biblical commentator who defended the multiplicity of wives enjoyed by one of the Patriarchs on the plea that the venerable personage desired offspring, and not pleasure. Such a plea cannot be used in the present instance to shield the "couple" nor the Physician whose *business!!* it was to etherise the wife. We should treat this matter most seriously, and check any disposition to sarcasm; still, to gratify a natural curiosity, we would ask whether the man of business was ordered to come on fixed days? or was he sent for on the spur of the moment? Did a little amiable toying in the evening between this persevering couple ever lead the husband to ask leave to send for the Physician with his bottle of ether? All this quite opens up a new world of ideas to which Monsieur Feydeau ought to turn his attention. A good deal might be made out of that adjective "ethereal." This *mot* would make the fortune of a lesser man than Dr. Sims.

Now come we to a part of the work in which Dr. Sims is (so far as we know) quite original:—"Only about three or four years since," he tells us, he "found out that some vaginas would not for a moment hold a drop of semen." He gives a case: A young woman, married for five years and barren, consulted him. Her cervix uteri was indurated, and the os small. This was cut open, but no conception followed. The uterus was all that could be wished, but the vagina rather short. Dr. Sims desired her to come to him some morning after sexual intercourse. She came; and he, on examination, found no spermatozoa in the vagina or cervix uteri. She said everything passed off instantly; whereupon Dr. Sims decided to lay aside "all false delicacy," and informed her that he must see her just after sexual intercourse. This was done by appointment, and he saw her in four or five minutes after the act. He says he discovered none of the fertilising fluid in the passage, plenty outside; the vagina short, but distensible in the cul de sac behind the neck of the womb, and contracting the moment the pressure was discontinued so as to eject any liquid. Something was done—we are not told what—to prevent forcible impingement against this posterior cul de sac, and conception followed. Dr. Sims adds that he thinks the operation of splitting the uterine neck had not been necessary.

He believes that retroflexion of the uterus also has the effect of driving out all the fertilising fluid directly after connexion, and thus of hindering conception, and describes the case of a patient whom, to verify this hypothesis, he visited fifty or

sixty seconds after the act, and on examination found no traces of the fluid in the vagina. On this point we fear that Dr. Sims will find the great body of English Practitioners at issue with him. Still more we doubt whether many a one will be found to undertake the "business" he describes. Fancy a respectable husband quitting his bed hastily, and leaving his palpitating spouse to be examined with finger or speculum in less than a minute after the nuptial mysteries! How is such a thing to be managed? Do the husband and man of business meet in the vestibule? or does the one rush out at one door whilst the man of business rushes in by another? The "arrangements" for such a visit would be strange to most of us. Where did it take place? At the patient's, or elsewhere?

Pass we on to Section VII., which states that "semen with living spermatozoa should be deposited in the vagina at the proper time." This involves three propositions. First, as to the necessity that live spermatozoa should exist, which may readily be granted. Secondly, that the semen must be deposited in the vagina, which is completely nullified by the cases quoted by Dr. Sims himself of conception without penetration; and thirdly, that there is a proper *time* for this deposition, which he infers from a purely imaginary assumption that the cervix uteri, compressed and emptied by the act of congress and by some undiscovered muscles in the vagina, expands and sucks up liquid from the vagina immediately that the male member is withdrawn, just as an india-rubber bottle does after being squeezed. This, we need scarcely say, is a mere hypothesis. No such pressure or suction is proved or probable, and experience shows it to be needless. But supposing it to be true, then it simply stultifies all the elaborate statements in Dr. Sims's book. For if the cervix uteri act in this way, it would suck up the fertilising liquid readily enough in almost any case except those in which it had been divided and made patulous. We repeat it: if the cervix uteri by compression and expansion act like a syringe, then it matters not whether it be too long or in what position it be; and certainly it will be false philosophy to split up the suction tube of a syringe.

Considering, as Dr. Sims believes, that the standing difficulty of conception lies in difficulty of entrance of semen into the neck of the womb, the question next occurs of "throwing the fructifying agent right into the cavity of the uterus." The author seems to have made fifty-five separate injections, on half-a-dozen different patients, in the course of two years, the patients being women in whom he believed a mechanical impediment existed, and who would not submit to operation. In one case, after the tenth trial, conception followed, but, unluckily, abortion cut short the existence of this squirt-begotten embryo. Dr. Sims says he has given up this branch of practice, owing to its difficulty and unsatisfactory nature; but he gives the details and precautions, and describes the necessary instruments, for the benefit of any one else who may "be able to apply the principles sought to be established by these experiments, with more exactitude than" he has. If, he says, we understood more about the proper period for conception, mechanical fertilisation might become exact enough to depend on it,—a kind of knowledge, by the way, that would be much appreciated by ladies who did not wish to conceive.

The last section treats of the various derangements of vagina and cervix uteri which pass under the name of leucorrhœa, more especially with regard to their property of killing spermatozoa. It contains directions for removing and examining seminal fluid from the vagina and cervix uteri, and, besides, some useful but fragmentary notes on the treatment of leucorrhœa.

We have thus given a full and fair summary of Dr. Sims's work, and may add that, in our judgment, it displays the highest practical Surgical ability, dexterity, and resource, conveyed in language remarkably clear. We may object, as a minor fault, that the language, though clear, is not always good; for there are such words as "utorrhœa," and a confusion of "will" and "would" for "shall" and "should" such as might have been easily corrected by some person more at home with the pen. We do not hesitate to say, however, that all mental, or moral, or hygienic, or medicinal influences are ignored. It is open to the objection that it is too purely Surgical. The author assumes at will the mechanical impossibility of the entrance of the requisite liquid into the cervix uteri, and treats woman as a mere subject for mechanical impregnation, and not as a moral agent. We are not supplied with lists of failures; we know not how many operations have not been followed by conception; whilst the fact that in such and such cases conception followed operation is assumed as cause and effect in a way which modern science does not allow. Lastly, with regard to the discovery of the total expulsion of the fertilising liquid from the vagina, and to the dabblings in that canal with speculum and syringe under the circumstances described, we can but express our unfeigned regret that Dr. Marion Sims has thought proper to found an odious style of practice on such *(im)*pure assumption. At any rate, if such practices were to be considered the "business of the Physician," there are a good many of us who would quit Physic for some other calling that would let us keep our sense of decency and self-respect. Better let ancient families become extinct than keep up the succession by such means. "Nec propter vitam, vivendi pudere causas."

THE ARREST OF CATTLE PLAGUE.

"It is one thing to stop a disease in its nascent state; it is another thing to stop it when it has acquired 14,000 centres of infection, when it has spread to every county in England, and when the air has become loaded with volumes of polluted matter." These are the words (as reported) of Mr. Lowe, himself one of the Cattle Plague Commissioners, in his speech in the lengthy debate which took place in the House of Commons on Tuesday. He was speaking of the recommendations in the Report of the Commissioners that isolation of cattle should be carried out. Had this important recommendation been acted upon at first, he showed that we might have succeeded in checking the disease, but that the prospect of staying it now, by such means, is a very gloomy one.

Every day makes it more evident that rigid isolation must now only be expected to diminish the rapidity with which the disease is spreading, and that is all. Even at the time that the Commissioners made out their Report Dr. Bence Jones felt that it was too late to rely solely on stopping the movement of cattle, and declined to join in the recommendation that it should be enforced; and we learn that the supposition made in our columns last week that this Commissioner has since changed his opinions as then expressed, is not correct. He still holds that isolation without some means of destroying the poison would be ineffectual. Had the present condition of things existed in November, it is probable that other Commissioners might not have been contented with recommending the stoppage of cattle transit alone. At least it is not fair to conclude that the recommendations which the Commissioners made in their November Report are just what they would have made under circumstances vastly differing from those which existed then.

We fear that the one great measure to be calculated on, and the only one, is the speedy destruction of every animal in which the disease manifests itself, and every healthy animal which has been in proximity to it. The immediate sacrifice of property would be great, but not so great as it appears, for the healthy animals, slaughtered as a precautionary measure, would of course serve for human consumption. Those who object to the destruction of diseased cattle on the

ground that they may recover, do not consider what is the problem for solution. It is, how to prevent the disease, not how to cure it; because even if a method of cure were established the disease would still spread, and large numbers of our cattle would always be suffering from it.

We hope soon to have before us the report of the investigations carried out by the experts employed by the Royal Commission. Some of the results they have obtained have become known, but we feel assured that much is yet forthcoming. We believe, indeed we are certain, that in their respective departments they have each done a vast amount of careful work; and we cannot but feel assured that the researches of these gentlemen, so highly qualified for the task entrusted to them, will prove to have been executed with all the skill and attention that could be bestowed on them, and with all the completeness that the limited means provided for the purpose permitted. But the study of the pathology of Rinderpest has not been left exclusively to the Commissioners. Much has been done by others; and of this we are reminded by a photograph, which lies before us, illustrating the Rinderpest eruption. It is No. X. of the second series of "Coloured Photographs of Diseases of the Skin," by Dr. Balmanno Squire. Those who have seen the admirable photographs of diseases of the human skin already published by Dr. Squire will be aware of the excellence of the representations they afford. They will find the present fall nothing short of its predecessors in life-like characters.

"The photograph presents one of the teats with part of the udder of a cow at the seventh day of the disease. The udder of this animal exhibited near the roots of the teats several well-marked crusts of about the size and thickness of a split-pea, distinct from one another, of a brown colour, of a cheesy consistence, and of a greasy character; in fact, possessed all the qualities of the berry-like crusts produced by small-pox in the human subject. In the illustration four such crusts may be seen. Portions of the erythematous skin in the neighbourhood of some of the crusts were the seat of a flaky desquamation. In other cows that I examined the eruption presented the same characters."

To this description by Dr. Squire of the photograph we may append his opinions as to the nature of the eruption.

"No human skin affection that I know of resembles the eruption of the cattle plague on the udder so closely as does the eruption of small-pox, and if a vaccine be compared with a human eruption, it is on the udder that the comparison should be made, for it is in this situation that the skin of the cow approximates most closely in consistence and suppleness to the skin of man.

"It may perhaps be thought that more would have been shown of the nature of the eruption had the pustules been represented instead of the crusts left by them, but it has been a matter of debate whether the so-called 'pustules' of this disease are really deserving of the name. This question, I think, may be decided by the scabs, since scabs presenting the characters here represented and described can, if we may argue from human pathology, originate only in pustules of corresponding size."

THE WEEK.

GOVERNMENT CHANGES.

Changes in the composition of her Majesty's Government interest us, as journalists, only according to the manner and degree in which they may affect the Medical Profession; and regarded from that point of view, we fear that but little good is to be looked for from the appointment of the Earl de Grey as Secretary for India, and the promotion of the Marquis of Hartington to the Secretaryship for War. Lord de Grey has, as Secretary for War, shown, or has at least lain under the imputation of showing, too much subserviency to the Horse Guards to allow of our hoping that he will in his new office venture on thinking and acting for himself in favour of the Medical service in India. The Marquis of Hartington has a greater reputation for talent, but it is to be feared that he may prove himself too much wedded to the traditions of the office in which he has served as subordinate, and too well trained by his late chief, to attempt to emancipate himself from Horse Guards' influence. Medical men must still trust to their own independence and spirit for obtaining any improvement in the condition of the army Medical service, and not to any hoped-for action of the new brooms.

AMENDMENT OF THE NUISANCES REMOVAL ACT.

On Wednesday, the 7th, a deputation of the Metropolitan Association of Medical Officers of Health, consisting of Drs. Aldis, Barnes, Ballard, Lankester, Liddle, Lord, Sanderson, Druitt (President), and Dr. Vinen (Secretary), introduced by Mr. Locke, M.P., had an interview with the Right Hon. Mr. Bruce, Vice-President of the Privy Council, at Whitehall, on the subject of the amendment of the Nuisances Removal Act. The Right Honourable gentleman devoted more than an hour to the various points urged for his consideration by the members of the deputation. It seemed to be the general opinion that the forms of procedure ought to be made more summary; that greater power ought to be entrusted to the Medical Officers of Health, and that the kind of remedy provided against inveterate nuisances should be one *in rem* rather than *in personam;* or that there should be some kind of hold obtained over dirty and unwholesome premises, the owners of which, if men of straw, now set the law at defiance.

THE COMMISSION AT THE ADMIRALTY.

The last rumour afloat will be not a little disheartening to our Professional brethren by sea and land. Nothing will be done. If it be true, it is another proof of that total disregard which the Government always manifests for our Profession. The Committee must be aware of the feeling of the Profession in England towards the public services, whatever may have been expressed in the evidence before it. The *Gazettes* have contained a goodly list of resignations during the past three months. It was only last week we noticed the retirement of an Assistant-Surgeon who had spent more than five years in the army. As regards the navy, there are few Assistant-Surgeons to retire. We suppose men do not quit a service for nothing, and it is clear, therefore, that these Medical officers had little or no hope of anything being done for them. How young men can be so blind to their own interests, to say nothing of the interests of their Profession, as to enter a department when those having experience are quitting it we cannot conceive. We have received many communications expressing strong opinions about the constitution, the private nature of the Committee, and the kind of witnesses examined before it. The matter is in the hands of the Profession itself. If the supply equals the demand, the Government will be perfectly satisfied for the present, of course, and it will leave the men who enter to find out, when too late, who has the best of the bargain.

THE END OF A STORY OF SICKNESS AND DEATH FROM OFFICIAL MISMANAGEMENT.

The arrival of the sailing transport *Gresham* at Spithead on the 1st inst. brings the sick soldiers, women, and children of the 9th and 11th Regiments from Hong Kong, and closes, let us hope, this tale of suffering and disease. We have heard that the 11th Regiment, or what may remain of it, has been ordered to India. The *Gresham* left Hong Kong on October 13 last. We read that 45 invalided soldiers were landed at the Cape, too ill to proceed, and the deaths during the voyage were unusually numerous—38 soldiers, 2 seamen, 3 women, and 8 children having perished. The larger number of deaths occurred at an early period of the voyage. This excessive mortality was due to the dysentery and fever which prevailed at the date of embarkation, and not to any defective sanitary arrangements on board the ship. The vessel—we gather from the *Times*—was minutely inspected by a board of officers at

Portsmouth, including the principal Medical officer there (Dr. Innes), and there can be no doubt that every attention was paid to the sick on board the ship; but at the time of their embarkation they were in too enfeebled a condition to derive any benefit from the change. Now, we are tempted to ask—How was this? Surely there were ships in China fit for the transport of troops. Then, why did not the authorities secure one for the removal of the sick while there yet remained the chance of benefiting them? The more we learn, the more assurance do we find for our opinion that the whole affair involved a series of disastrous and miserable blundering from beginning to end. We perceive the name of Surgeon Black, of the 11th Regiment, among the list of officers. There can be no difficulty now in procuring evidence for a Commission to inquire into the causes of the sickness and mortality affecting our troops at Hong Kong. The affair has become too notorious to permit of its being burked by our home authorities.

TESTIMONIAL TO DR. BURROWS.

The grand old hall of St. Bartholomew's was filled on Thursday, the 1st inst., by a number of the past and present students of the Hospital and their friends, who had assembled for the purpose of assisting at the presentation of a testimonial to the President of the Medical Council in commemoration of his high character as a Physician, and for his valuable services for thirty years on the Medical staff of the Hospital, and as a teacher in the school. The ceremony was graced by the presence of several ladies. The testimonial, consisting of a full-length portrait of Dr. Burrows, by Mr. Knight, R.A., of a silver salver, admirable as a work of art, and a very elegant time-piece with candelabra, was formally presented by Mr. Paget in a speech, the elegance and finish of which were worthy of the speaker, whilst its tone of affection and heartiness could not but add to the value of the gift. Mr. Paget said that the motives which led to the presentation were a desire to recognise the eminent position of Dr. Burrows in the Profession, and as the "elect of the elect" in the Medical Council; to acknowledge on the part of his numerous pupils their debt of gratitude to him for having taught them how to learn and how to practise their Profession; and, finally, as a sincere and lasting expression of hearty friendship for a most true friend. Dr. Burrows, in returning thanks, expressed the great gratification it had been to him that by his nomination as the first Consulting Physician ever appointed to the Hospital he still remained one of their Medical officers, and retained the right of aiding, if necessary, in the labours of its staff. It was a great source of satisfaction to him that his labours had met with the approval of those with whom he had worked. He acknowledged that if anything could have added to the pleasure he had in receiving such a testimonial from his friends, it was the selection of Mr. Paget to express their kind feelings towards him. While it might be hardly courteous in him to say that his friend in speaking of his services had transcended the limits of truth, he must say that at least he had told the truth most lovingly. In the name of himself and his wife, he begged to present the portrait to the Hospital, and ventured to hope that it might be deemed worthy of a place in the room already adorned by the portraits of Abernethy, Lawrence, and his lamented friend, William Baly. Mr. Forster White, the treasurer of the Hospital, accepted the portrait on the part of the governors, and said that it should be placed in company with the portraits of the donor's father-in-law, John Abernethy, Percival Pott, Lawrence, Vincent, and Baly.

FROM ABROAD.—DISCUSSION ON VACCINATION AND RE-VACCINATION.

Paris seems to have taken to animal vaccination and re-vaccination with a perfect *furore*, especially among the higher classes, so that the cows and heifers employed for this purpose by M. Lanois, the introducer of the practice from Naples, are in such request that they have to be bespoke several days beforehand. An application for some of the virus has been made by the English Embassy, in order that it may be transmitted here for use in the cattle plague; and M. Bouley states that he has induced the Government to purchase some of M. Lanois' heifers, who are well impregnated with cow-pox in order to transmit them to England, so that they may be inoculated with the virus of cattle plague and exposed to the immediate action of the epidemic influence. He is, indeed, at the present time over here superintending the performance of these experiments.

The Société Médicale des Hôpitaux has recently been engaged in a prolonged discussion on the subject, from which it appears that very different results have been obtained by different observers. M. Lallier observed that of between thirty and thirty-five vaccinations made at the St. Louis from the heifer only one has succeeded, and M. Hillairet has very frequently found them failing, yet other Practitioners have obtained as much success as from the ordinary mode of vaccinating. M. Empis has found in the animal vaccinations practised at the La Pitié that to prove successful they must be performed before the fifth day. If used from tubes the lymph must be very recent, for it coagulates very rapidly, forming on the lancet a little gelatinous mass which does not enter the puncture.—M. Bucquoy observed that as every one was now requesting to be re-vaccinated the question arose whether this demand should be indiscriminately acceded to. Is it demonstrated that persons in whom re-vaccination has proved successful were apt to contract variola? Should we re-vaccinate persons also who have had variola or varioloid? Are the pustules which become developed in persons who have been vaccinated other than a local production, and is the liquid they contain capable of giving rise to the same effects as the genuine vaccine virus?—M. Bergeron, in reply, observed that in his opinion re-vaccination is indicated in all the cases specified. Under the name of "flying small-pox" (*petite vérole volante*), the public often confounds varioloid and variola with varicella, this last conveying no immunity whatever. It is safer, therefore, to re-vaccinate, and severe variola has occurred sufficiently often after the 50th or even 60th year of age to justify the precaution being taken.—M. Moutard-Martin observed that, as to the absolute preventive power of re-vaccination, this cannot at present be absolutely determined, and such a power does not even belong to variola itself. Then, again, exceptional cases will offer themselves, of which he gave a remarkable example. A man, aged 19, having very distinct vaccine cicatrices, was attacked with variola, which left evident marks. Two years afterwards, on entering the army, he was re-vaccinated with success. At the age of 32 he entered the Beaujon for bronchitis, and was re-vaccinated by M. Lanois. At the very time when the pustules of this third vaccination had begun developing, he was seized in the Hospital with a confluent variola, which proved fatal. M. Moutard-Martin believes that a proposition has been laid down without sufficient proof—viz., that re-vaccination succeeds oftener in aged than in young subjects. According to his own numerous observations, the reverse of this is the truth.—M. Guéneau de Mussy stated that he had recently practised about 100 revaccinations with the heifer virus, and about one-half of the cases succeeded. An important consideration is the effect the number of pustules produced at first vaccinations may exert on the aptitude for variola or renewed vaccinia. He always now makes ten punctures. The duration of the vaccinal immunity may much depend upon individual peculiarities, the same virus producing different effects upon different persons. As an example of exceptional aptitude for variola may be mentioned the case of the woman who died in her 109th year of a ninth attack of small-pox.—M. Féréol could not but feel astonished at the statement of M. Moutard-Martin as to the greater frequency of successful

re-vaccination in the young. He thought that the contrary position was quite established, and in a great number of re-vaccinations which he has performed he has always found them rarely succeeding in the very young, and proving successful above 20 in proportion to the increasing age of the subject.—M. Bergeron called attention to the fact that besides the false vaccinia, which is, in fact, a mere local affection, and the legitimate vaccinia, we may have a variety which has been termed *vaccinella*, which differs from typical vaccinia by presenting itself (the initial papule appearing on the fourth or fifth day) as a globular pustule, which the slightest friction lacerates, giving rise to the sudden discharge of all the fluid it contains. It leaves only a smooth, narrow cicatrix, and furnishes a less durable immunity.—M. Blache entertains doubts as to the advantages in making many punctures, and referred to the practice prevalent in America of producing in women only one pustule on each arm.—M. Lailler drew attention to the fact that while in private practice the re-vaccinations succeed in about one-half the cases, the success obtained in the Hospitals is infinitely lower,—a fact, he thinks, which cannot be explained away by the state of health of the subjects.—M. Hervieux reported the results of the trials which he has made at the Maternité. Of 84 vaccinations made on new-born infants, 59 only were quite successful; but then he also found that of 95 vaccinations made at the Maternité in the ordinary mode the results were much the same, about one-fifth of the cases failing. After animal vaccination the development of the pustules is slower, and they are not so large. The animal re-vaccinations performed on lying-in women and attendants at the Maternité, subjects under 40 years of age, amounted to 156, and of these in only 26 was the normal evolution of true vaccinia produced; and, speaking without precise figures for comparison, M. Hervieux does not believe that these results differ much from those observed after ordinary re-vaccination. He also protests against the disposition which now seems prevalent to distrust the ordinary vaccination, chiefly on the ground of the possibility of the transmission of syphilis. How absurd this fear is, may be judged by comparing the millions upon millions of vaccinations with the some twenty alleged cases of transmission, several of which are not even authenticated. Let the investigation of animal vaccination be thoroughly pursued, but let not the services of ordinary vaccination be forgotten; and especially do not expect an immunity from it which is not conferred by small-pox itself.

The experience of M. Hervieux is entirely in accordance with that of M. Guéneau de Mussy and the London Small-pox Hospital that greater security is attained by multiplying the number of punctures—the practice of making only one or two having become almost inveterate in Paris. During an epidemic of variola at the Cochin, and on many occasions since, he always found that the worst cases were those which had fewest cicatrices. Another result of his experience is, that true and excellent vaccine pustules may be produced by vaccinating with the virus of what is termed "false vaccinia." There is, in fact, no such thing as true and false vaccinia, inasmuch as any vaccine pustule, whether it have the vesicular or pustular form, whether it be pointed or flattened, projecting or depressed at its centre, may furnish a perfect virus. This is no more strange than is the production of a variola from varioloid.

As to the age at which infants should be vaccinated, M. Hervieux believes that during the prevalence of epidemic small-pox not more than the delay of a week or two should take place. In the absence of an epidemic, he prefers waiting for some months. In fact, vaccination is not always an inoffensive operation in young infants. The pustules easily inflame and ulcerate, and may give rise to erysipelas and adenitis. Moreover, on the ninth or tenth day a general vaccinal eruption may appear, taking on a miliary or vesicular form, and lasting for a variable period. Then, again, very fine children become sometimes sickly and ailing for several months after vaccination; and whether this may be due to the lymph employed or to the influence of the vaccination in general, it is impossible to decide—although the parents seem to have a justification in the reproaches they never fail to give vent to. Certain it is the vaccine had injuriously affected the infants in these cases, and they would have better supported its employment had they been allowed to reach the third or fourth month before resorting to it. Moreover, variola, when not prevailing epidemically, is not so very serious an affection in new-born infants, as they frequently recover from it; while, by a remarkable peculiarity, the disease at this age leaves no appreciable cicatrices on the face or trunk.

PARLIAMENTARY.—THE DEBATE ON THE CATTLE PLAGUE.

Parliament was formally opened by her Majesty in person on Tuesday, February 6.

In the House of Lords, the Address to the Throne was moved by the Marquis of Normanby, and seconded by the Earl of Morley.

The Duke of Rutland wished strongly to call the attention of their Lordships to the last portion of her Majesty's Speech, which referred to the cattle plague. All that was yet known about that terrible disease was that they had no remedy for it, and that the only chance was trying prevention, for trying a cure seemed hopeless. He contended that the Government had full information of the approach of the Rinderpest, and also of its dreadful nature, yet they took no steps against its coming here, nor had they taken any proper precautions since it had come. Even at this late hour, however, it might not be too late to induce her Majesty's Government to wake from their slumbers, and, by utterly prohibiting the movement of cattle, either stop its spread, or at least confine and limit its ravages to places already infected.

The Duke of Richmond also condemned the supineness of the Government in the same matter, and showed by the Report of the Royal Commission that the Government were aware that the plague was steadily coming as far back as 1859. Since it broke out in the country, Professor Symonds thought that the Orders in Council had tended to spread the disease more rapidly than it would have naturally progressed had it been left alone.

Lord Faversham blamed the Government in very severe terms for not having taken a more decided course in dealing with the cattle plague. It was a grave national question, and he felt bound to move a resolution declaring that it was the duty of the Government to assume the responsibility of enforcing uniformity of action on the subject throughout the country.

Lords Essex and Winchilsea added their censure on the inactivity of Government.

Lord Granville vindicated the course taken by the Government. Did any one mean to say that it was possible as early as last July to stop both the importation and traffic of cattle? It was not until late in July that the existence of the Rinderpest was known in this country. From that date the Government and the Home Office took the most stringent precautions to prevent the spread of the disease, and every step they took was heartily approved by the late Lord Palmerston, who, up to within one week of his lamented death, employed all the energies of his active mind in considering various schemes and measures to avert the spread of the calamity with which they were threatened. The example of foreign Governments had been held up to her Majesty's Ministers, but Austria had utterly failed in stamping out the disease. Prussia, it was true, had succeeded, and so had France, but under the Constitution under which we lived no Government or body of Ministers had the power which was exercised individually by the Emperor of the French or the King of Prussia. With regard to the course which the Government intended to pursue, he might state that at the earliest period they meant to bring in a Bill which he thought would meet all the requirements of the case as to the traffic in cattle, though, of course, he did not feel at liberty to anticipate the disclosure of the enactments it was intended to propose.

Lord Carnarvon thought that the defence of the Government was worthless. If they lacked constitutional powers to enforce such rules as might have checked the course of the

disease, they should have called Parliament together to apply for them. Instead of that, however, Parliament had been called later this year than it had been assembled for many years before. The cattle plague was the greatest national calamity which had fallen on the country for years, and the Government had done absolutely nothing to check or mitigate it.

Lord Abercorn, Lord Grey, the Duke of Argyll, and Lord Derby united in blaming the Government for their laxity in not taking greater precautions against the spread of the disease.

Lord Faversham withdrew his motion.

In the House of Commons,

Sir G. Grey gave notice that on Monday next he should move for leave to bring in a Bill relating to contagious and infectious diseases in cattle.

Mr. Doulton gave notice that on the 13th inst. he should ask the Home Secretary if it were the intention of Her Majesty's Government to introduce early in the present Session a Bill having for its object the preservation of the commons and open spaces round London.

In the debate on the Address a number of speakers, amongst whom were Mr. B. Stanhope, Lord R. Montague, Mr. Lowe, Mr. Henley, and Lord Cranbourne, united in censuring the Government. All their speeches were worthy of attention, but those of Mr. Lowe and Lord Cranbourne, who are both members of the Royal Commission, carried with them perhaps most weight. We regret that we have only space to give a portion of Mr. Lowe's speech referring to an attempt made by the Under Secretary of State for the Home Department to justify the inaction of the Government on the ground of the different recommendations made by the majority and minority of the Commissioners :—

"My hon. friend states that the Report shows that there was a difference of opinion among the Commissioners, and after exaggerating that, tries to shelter the Government behind it. That, however, will be of little avail. The state of opinion was this :—The majority and the minority both agreed that the real remedy for preventing the progress of the disease was the stoppage altogether of removing cattle from one locality to another. There was no difference of opinion on that point, and I am speaking in the presence of a noble lord (Lord Cranbourne) who was a distinguished member of the minority. The second point in which we were all agreed was, that whatever was to be done—whether a larger measure or a less stringent one should be adopted—the action of the central Government was necessary, and nothing ought to be left to the local authorities. What we really differed about appears at this distance of time to be a very small matter. It could perhaps best be described as a matter of temporary expediency. The majority thought it expedient to recommend what we all agreed was the real remedy, though some of us may have felt not much confidence in its being carried out. The minority thought that it was best to modify the proposition so as to make it more acceptable to the public, not because they liked the modified proposition better than the other, but because they deemed it more calculated to please the public mind. The House, therefore, will now be able to judge how far my hon. friend is justified in sheltering himself behind the minority. The course adopted by the Government is entirely condemned both by the majority and by the minority of the Commission, and there was no one on the Commission at all who does otherwise, except Mr. Maclean, the engineer, who thought it unnecessary to do anything at all. Well, what did the Government do? We reported on October 31, and after a waste of three weeks of infinitely precious time they give jurisdiction to petty sessions, and shortly after they extend that jurisdiction to quarter sessions, and so in substance the subject stands now. I did not come here to-night to criticise the conduct of the Government, but I have been urged to say what I think on the subject. I say, then, that the Commission was right in their recommendation that a central authority ought to act in the matter, not because I have fallen in love with despotism, but because there is nothing despotic in delegating power to the only persons competent to act. The rule is simple. Matters of public interest, in which the whole community is directly interested, ought to be left to the central authority, whereas matters in which the general public is not directly concerned ought to be left to the local authorities. Now what was this cattle plague? Had it been an epizootic merely, spreading in certain districts, and influenced by climate and local circumstances not likely to go beyond those districts, I can quite understand that it would be perfectly right to leave it to be dealt with by the local authorities. But is this disease of such a nature? Why, it is exactly the contrary. Every part of England is interested in the suppression of the disease in every other part of England. One day it is at the Land's End, and the next at John o'Groat's. I believe I may say that the London market is one day infected, Edinburgh and Plymouth the next. Have Edinburgh and Plymouth, then, no interest in the conduct of the local authorities in London at that time? And if so, how can we reconcile it to ourselves that these things should be left to the discretion of local authorities?"

REVIEWS.

A Manual of Materia Medica and Therapeutics. Being an abridgement of the late Dr. Pereira's "Elements of Materia Medica," arranged in conformity with the British Pharmacopœia. By Frederick John Farre, M.D., Cantab., F.L.S., assisted by Robert Bentley, M.R.C.S., F.L.S., and Robert Warington, F.R.S., F.C.S. London: Longmans, Green, and Co., 1865.

Taylor and Rees's edition of "Pereira's Materia Medica" extended over 2543 pages, while Dr. Farre's abridgement extends only over 592 pages. The curtailment of the large work has been accomplished by omitting the parts on mental, on physical but imponderable, and on hygienic remedies ; most of the division on general pharmacology, except the author's physiological classification of medicines; the tabular view of the history and literature of the materia medica ; all notes and marginal references ; the articles on medicine not officinal in the British Pharmacopœia ; and the history of most of the medicines retained, their effects upon plants and animals, and much of the descriptive details and other matters concerning them. Of the opinions expressed by the author, Dr. Farre tells us in his preface that he has avoided as far as he could interfering with them, while he has not hesitated to alter whatever was decidedly erroneous. He further tells us that he has added much new matter, in order that the abridgement may represent more correctly the present state of our knowledge, this new matter being only occasionally indicated (viz., by the letters ED.). The author's classification of medicines has been modified and removed to the end of the work, a posological table introduced, and the matter of the British Pharmacopœia given in place of that of the others, with explanations of the processes and tests.

Having thus briefly indicated the contents of the abridgement, we proceed to a consideration of its merits, so far as our space will permit. This we may do from three points of view ; in one regarding it as an abridgement of Pereira's large work, in another as a revision of it, to bring it down to the present time, and in a third as a modification of it, to bring it in conformity with the British Pharmacopœia. As an abridgement of Pereira's "Elements of Materia Medica," the "Manual" does not seem to us a very satisfactory production. In a work the real value of which lies in the vast store of varied information it affords about remedies, little *condensation* is possible, so that abridgement of it is only practicable by omitting some of the facts. Since, however, all the facts are so arranged in it that reference to any particular set of them is made without inconvenience, there is but one advantage, so far as we can see, in cutting it down in this way, which is that its cost is diminished by so doing. Excepting this one not unimportant use, we feel that the depreciation of the value of the work is almost proportionate to the diminution of its matter. Believing this of any abridgement like the present, we feel that Dr. Farre has had an unenviable task to perform, so that we more regret that we cannot congratulate him on the manner in which he has executed it. One great objection we make to it is that, of the matter omitted, that consisting of the articles on several medicines might well have been retained. In a work on Materia Medica, however limited in extent, all substances which are stated to be medicinal ought to receive notice, unless it has been conclusively proved to the satisfaction of the Profession generally that they are really inefficacious. If the writer of such a work believes himself that a

medicine of some repute is in reality of no value, he can say so, and then leave the matter to Practitioners to try it or not, as they think best, on the authority of those who have recommended it.

Dr. Farre has omitted all medicines not in the British Pharmacopœia. Such an omission may be well in framing a text-book to enable a student to pass an examination on the officinal medicines, but it is quite otherwise in preparing a work on medicines professedly for the use of the Practitioner. The latter ought to know of every reputed means of meeting disease, in order that he may best do so; and is certainly not supposed to confine himself to the use of those medicines only, and in those forms, which he finds in a Pharmacopœia. The only legitimate object of a Pharmacopœia surely is to indicate exactly the nature of the drugs and their preparations in general use, to which certain names refer, in order that the prescriber may accurately convey by these names to the compounder of medicines the knowledge of what he wants the patient to get. In doing this the compilers, properly enough, insert just those medicines which, in their opinion, are in sufficiently general use to require defining. If we were to decide by the text of a pharmacopœia what medicines only we may employ, and what forms of them, we should be putting ourselves in Professional subjection to its compilers. We regret, therefore, to see Dr. Farre adopting such a principle in selecting the matter to be contained in his book. If his opinion of the efficacy of medicines is that all in the list of the British Pharmacopœia call for consideration, and none else, he should say so, and give that as his reason for selecting these and excluding all others. If this is not his opinion, which we believe, then he should have noticed all those medicines which in any way merited it, or else have denominated his work a manual of the materia medica contained in the British Pharmacopœia. Since, however, he surely has not "strictly adhered" to this rule when he retains articles on oxygen, nitrogen, commercial carbonate of potash, neutral carbonate of magnesia, anhydrous potassa, anhydrous nitric acid, etc., etc. —articles, too, with the exception, perhaps, of the first, about substances which have neither medicinal nor pharmaceutical use,—we have the more reason to complain that he has not broken the rule a little more, and in a more useful manner, by admitting a number of other substances of some interest as *reputed* medicines, to say the least of them. We notice, also, some undesirable irregularities in the abridgement, such as the omission of the descriptions of hepatic and Cape aloes, and other non-officinal varieties of medicines, while those of non-officinal English rhubarb, Egyptian opium, etc., are retained; the omission of the historical account of each medicine as a rule, but its retention without obvious cause in some cases, as in that of ricinus communis; the similarly exceptional retention of the commercial account of croton eleuteria; and again, the omission of the chemical account of castor oil, although that of most other medicines, important or not, is, retained.

Independently of the changes which are made in the matter retained in the present edition to bring it in accordance with our present knowledge, it has in many places been modified, evidently with a view to its improvement; but the attempt at improvement has, we think, not always been very successful. We give some instances. Pereira says of the source of hydrogen: "Hydrogen is usually procured by the action of zinc on diluted sulphuric acid." Dr. Farre has changed this accurate and comprehensive, yet simple, statement into the following, which has none of these characters:—"Hydrogen is always procured from water by means of some metal (and an acid) which combines with the oxygen of the water—*e.g.*, by means of zinc and sulphuric acid, in the preparation of *reduced iron* of sodium and sulphuric acid, in *hydrochloric acid*, and of potassium, and sulphuric acid, in *hydrocyanic acid.*" Again, in describing the action of caustic potash on *ammoniated mercury*, Dr. Farre has replaced Pereira's practically accurate statement of its nature by an incorrect one. In the account of the tinctures of iodine, we are correctly told by Pereira that the one containing iodide of potassium is miscible with water without decomposition, while that which does not contain it is not thus miscible. Dr. Farre does not mention this (the real object of adding the iodide of potassium), but says, instead, that the iodide is chiefly useful in facilitating the solution of the iodine—a very doubtful statement as regards the utility of the iodide, since the iodine will dissolve in the spirit by itself without difficulty. Pereira truly represents the action of hydro-sulphuric acid on liquor ammoniæ thus: $NH_3 + 2HS = NH_3,2HS$, or $(NH_4S + HS)$. This has been changed by Dr. Farre to $NH_4O + 2HS = NH_4S,HS, + HO$,—the substance, NH_4O, being an unknown body. In the preparation of oxide of zinc, Pereira describes the process as being the expulsion by heat of the carbonic acid and water from the basic carbonate. Dr. Farre alters this, and incorrectly represents the process as being the expulsion of carbonic acid from the normal carbonate of zinc. After describing the physiological effects which tartarated antimony has been observed to cause, Pereira, under the section headed *Modus Operandi*, tells us by what real or supposed powers it produces these effects. Dr. Farre, omitting some of the matter, has rearranged the rest in this way. Much of what Pereira said as to the mode of action has been set down as physiological effects, while the paragraph on the mode of action is formed of this remnant of its former self:—"Tartarated antimony, when swallowed, becomes absorbed, and may be detected in the blood and viscera, especially the liver. It is eliminated by the urine, in which secretion it can readily be recognised." Not one direct statement as to how the medicine acts do we find in this mutilated paragraph! Pereira, after describing the *physiological effects* of medicines, gave what he called their *uses*. Dr. Farre substitutes for "uses" the word "*therapeutics*," which, granting its admissibility, is still a substitution wholly uncalled for. But therapeutics is the "branch of medicine which has for its object the treatment of disease" (Pereira), by medicines only according to some, by any agents according to others; and the *uses* of medicines are applications of a knowledge of their curative effects—that is, applications of medicinal therapeutics, not therapeutics itself. Another of these trivial and objectionable alterations of Pereira's text is made in the definitions of the classes of medicines. Pereira defines each class as "acting on" a certain system of organs, circulatory, secreting, etc. Dr. Farre has thought fit to change this to "influencing" the particular system, an elliptical expression for *influencing the action of*. Alterations like those we have noticed are not even indicated to the reader.

Dr. Farre has modified Pereira's classification of medicines for reasons stated in the preface; but he has done so through a thorough misconception of the grounds of this classification. Dr. Farre says that Pereira's classification is rather anatomical than physiological; Pereira himself said that it was physiological, and arranged on physiological principles. Dr. Farre's reason for his assertion to the contrary is, that the classification is constructed on the organs, and not on the functions of respiration, etc. We reply that to influence respiration, or to act upon the organs of respiration, is the same thing differently expressed; that Pereira defined the class "acting on the respiratory organs" as "acting as therapeutic agents by their influence over the functions of respiration and calorification;" and that a class in which the author includes medicines acting on the nervous, muscular, and secernent systems, as well as upon any or all parts of the body, so far as they are dependent upon a duly aërated state of the blood as the cause of their actions, or so far as they are concerned in keeping up the temperature of the body, is certainly a thoroughly physiological class, and not one formed on anatomical grounds. Dr. Farre has changed Pereira's six classes into ten. He has also modified and added to the orders which they contain. Pereira classified medicines according to their physiological effects exclusively. Dr. Farre has, however, added to these several orders framed according to the therapeutic effects of medicines, and in doing so states that he is only carrying out the plan of the author. He has added, for instance, among others of this kind, the orders *antemetics*, *stomachics*, *anodynes*, and *antispasmodics*. 'Tis true we find "antispasmodics" in Pereira's classification, but only as a term, for want of a better, to denominate certain metallic salts included among medicines acting on the blood. They are *named* antispasmodics for distinction sake; but they are only *described* as a group of spanæmics, or blood-impoverishers. Dr. Farre has also removed stimulants and sedatives from the class of medicines acting on the nervous system, and made some other alterations which will hardly gain approval. We look upon these alterations and "improvements" as wholly out of place. They might be excused were they alterations called for by the progress of knowledge since the classification was framed; but they are not; and are made only in consequence of a difference of opinion between the author and his editor. Statements as to facts an editor may, and evidently should, correct when necessary; but we think it is otherwise with an author's views. These we consider an editor is bound to respect so far as to leave them unmodified; and in expressing others differing from them, to clearly dis-

tinguish them, in order that they may not be confounded by the reader with those of the author. In connexion with this, there is another matter we have to complain of. Dr. Farre has made his abridgment from Taylor and Rees' edition of Pereira; but he has usually retained the extensive additions to the work made by these gentlemen without distinguishing them from the matter written by Pereira himself. Only in some cases has the important work of these editors been indicated, which we hold to be neither fair to them nor to the readers of the present volume.

As a revision of the "Elements" bringing the work to the present time, we have little to say of it. Being an abridgement, and a work in which only officinal medicines are contained, we suppose we must not expect much in the way of notice of recent additions to our knowledge—whether or not, we have not found much. We notice that not a word is said about any use of saccharated lime, or of the use of hydrochloric acid in fevers. We also notice that the incorrect expression *bark* of the root is employed by Dr. Farre in some remarks which he has added on rhubarb, although in Pereira's text the term *cortical portion* is employed.

Lastly, we come to consider the book as a modification of the "Elements," to bring it in conformity with the British Pharmacopœia.

The processes, descriptions, tests, etc., in this Pharmacopœia have been substituted for the corresponding matter concerning the last London, Dublin, and Edinburgh Pharmacopœias. Even an erroneous statement as to a simple matter of fact, we see, has been copied—viz., that about the relative strengths of the British and Dublin tincture of the perchloride of iron—that the former is only a fourth of the strength of the latter, the fact being that it is really a third. Very seldom are the processes criticised, and when they are, not always very learnedly. Thus, of the process for Liquor Ferri Perchloridi, we are told that the hydrochloric acid is not ordered in quite sufficient quantity to prevent the formation of basic (*sic*) chloride on the addition of water. This is a mistake; in theory and in practice the quantity is sufficient, if we use hydrochloric acid of the officinal strength and dissolve the iron in it before we add the nitric acid, as we are directed to do. Again, in the process for preparing Potassæ Sulphas we are directed in the Pharmacopœia to convert the acid sulphate (nitric acid residue) into the neutral by treatment with slaked lime, and subsequent filtration; then to convert some dissolved sulphate of lime into sulphate of potash by the addition of a few grains of carbonate of potash; to filter a second time, and to neutralise with a few drops of sulphuric acid. Dr. Farre says that it would be better to use carbonate of potash in place of the lime. We ask, Why? It would certainly save one of the two filtrations; but it would make a product less pure, at a much greater cost. For a pound of the "residue of the nitric acid process" would require to convert it into sulphate the addition of about two-thirds of a pound of officinal carbonate of potash, so that the product would be contaminated with the impurities of that quantity of this admittedly impure substance, and at the same time derive a cost from this addition far beyond its marketable one, or that which the use of the almost valueless materials ordered in the officinal formula would give it.

Explanations of the processes are generally given, which, however, we feel certain, are too meagre to be readily understood by many students. Sometimes, however, explanations are wanting where most needed. For instance, we are not told why lime water is used instead of the apparently much more convenient solutions of soda, potassa, or ammonia, in preparing oxide of silver, nor why the product should not effervesce when dissolving in nitric acid. Again, we are not told that the lime ordered in the "Pure Ether" process serves to remove the acid usually present in common ether. No explanation also of the quantitative test for opium has been given.

So far as the explanations go, they seem in most cases to be correct, but certainly not so in all, whether new ones or only abridgements of Pereira's explanations of the processes of the London Pharmacopœia. As instances of their occasional incorrectness, we may mention that Pereira's explanation of the red-oxide-of-mercury process of the London Pharmacopœia is partly applied improperly to that of the British Pharmacopœia. In the former, the nitric acid, in which the mercury is ordered to be dissolved, is in quantity (compared at equal strengths) less than half that ordered in the latter, and is nearly three times more dilute than it is after the addition of the water. This difference in the formulæ, and the absence of any injunction in the British Pharmacopœia to dissolve at a *gentle heat*, makes the reaction different, and therefore Pereira's explanation inapplicable. Under the volumetric solution of iodine, we are told that, in estimating the quantity of sulphurous or of arsenious acid, it is added to the liquid until *free* iodine (known by its *brown* colour) begins to appear in the solution; whereas we add it until the *blue compound* of iodine and starch is permanently formed with starch paste previously mixed with the acid. The product of the distillation in the preparation of valerianate of soda is described as valerianate of amyl, instead of valerianic acid (with a small quantity only of other products). The quantity of sulphuric acid ordered is just sufficient to form chrome alum with all the bichromate of potash after removal of some of its oxygen by the fousel oil; and the quantity of oxygen in the bichromate capable of removal is more than sufficient to oxidise the whole of the fousel oil into valerianic acid, and this forms the principal product; but before the action is completed, a small quantity of intermediate products distils over with the valerianic acid.

The formula for morphia has been corrected, to make it accord with that given in the British Pharmacopœia; but the formula for codeia is left unchanged, because this substance is not officinal. If we ought to adopt the corrected formula for morphia, then ought we also to adopt the corrected formula for codeia. An innovation, too, is made in the spelling of the name of this substance, which is to be deprecated—the word being written "codia" instead of "codeia," by which the quantity of the second syllable will be apt to be incorrectly given, as it generally is in the similar word *conia*.

We here terminate our criticisms. The Manual does not at all please us; but in justice to Dr. Farre we must add that Pereira's large work also, valuable as it is for its comprehensiveness, and stores of information not to be easily found elsewhere, is, to our mind, not at all a satisfactory *text-book*. Dr. Farre has evidently devoted much time and attention to his troublesome undertaking, and has produced a work which contains much valuable matter from that of Pereira, together with the materia medica and pharmacy of the officinal medicines, in most parts of which, to the reader's advantage, the marks of his editorial pen are manifest. Our admiration of Pereira, and our sense of the authority which Dr. Farre's position as lecturer at one of our principal schools and London editor of the British Pharmacopœia gives him, have combined to make us more stringent in criticism than we should otherwise have cared to be.

GENERAL CORRESPONDENCE.

DR. B. W. RICHARDSON'S NEW METHOD OF PRODUCING LOCAL ANÆSTHESIA.

LETTER FROM MR. H. T. KEMPTON.

[To the Editor of the Medical Times and Gazette.]

SIR,—The report published in your journal last week of Dr. Richardson's interesting researches upon the production of local anæsthesia by means of the vapour of ether, must necessarily have excited a strong interest in the minds of your readers in respect to a method of annulling pain in Surgical operations which, if it should only prove as efficient as it is devoid of danger, must constitute one of the most valuable additions to this class of our Materia Medica that has been made during the present century.

I had the satisfaction of hearing Dr. Richardson give a full and lucid account of his method of proceeding, and of the philosophical mode of reasoning and experiment by which he was led to so happy a result, at the meeting of the Odontological Society on Monday last. Having expressed myself interested in the inquiry, Dr. Richardson kindly invited me to test the efficiency of his proposed method by operating upon a patient who was desirous of having two very sensitive and painful stumps of the upper bicuspids and a lower molar tooth removed. I gladly availed myself of his offer, and will now give a simple statement of the result, leaving it to my fellow-Practitioners to draw their own conclusions; only trusting they will thoroughly examine for themselves a remedy which I confidently believe will prove of the highest value generally, and of especial value in Dental Surgery.

A gentleman about thirty years of age had suffered for several weeks from severe pains on the right side of both the upper and lower jaws alternately. In the upper jaw the pain was caused by the irritation excited by the stumps of the

first and second bicuspids; in the lower jaw by the first molar, which was much decayed having the pulp exposed. Both of the upper stumps, as well as the lower molar, were highly sensitive to the slightest touch, showing that the disease had extended to the dental periosteum. The elevator was used in extracting the upper stumps after the diffused ether vapour had been applied for a period of not more than thirty seconds; no pain was experienced, and although the bleeding was tolerably free it became arrested at the ordinary period after similar operations. The current was then applied to the lower molar, and here I would remark that on entering the cavity of the tooth and acting on the exposed pulp it gave rise to acute pain; on observing this, the application of the ether was suspended, and the cavity plugged with cotton wool so as to prevent the spray coming in contact with the exposed pulp. The ether vapour was then re-applied for a period of forty seconds, and the tooth extracted with an equally satisfactory result as in the previous operations.

Further experience is required to determine the absolute and relative certainty of this mode of producing local anæsthesia in dental operations, and although a single instance may be of comparatively slight value in determining the reliance to be placed on Dr. Richardson's proposal, it is at least sufficient to encourage others to carry out the investigation to its ultimate results. I am, &c.

H. T. Kempton, L.D.S., F.L.S.

CASE OF TETANUS AFTER CONFINEMENT.

Letter from Mr. Henry Viant.

[To the Editor of the Medical Times and Gazette.]

Sir,—If you think the following case worthy of a place in your columns, I should feel greatly obliged by your inserting it:—

On Friday, January 5, I was called to see a woman who had been delivered on the Saturday previous of a healthy child; the midwife who attended her stated that the labour was quite natural; there was no post-partum hæmorrhage to any extent, the placenta coming away about fifteen minutes after the child.

On Wednesday, the 3rd, the patient got up and went downstairs, where she remained the whole of the afternoon and part of the evening. She went to bed quite well.

On Thursday, whilst out of bed, she was suddenly seized with trismus, of which slight notice was taken at the time, as the nurse supposed that she had taken cold and consequently had a stiff neck.

The symptoms becoming aggrevated, they applied to me on Friday, January 5, when I found the patient suffering from tetanus in a severe form, no doubt brought on whilst the nervous system was in a weakened state by exposure to the cold.

She had convulsions every two or three minutes, during which there was complete opisthotonos; the trismus always remaining persistent. There was no pain in the region of the abdomen, nor had the lochia ceased, being rather abundant than otherwise. Fortunately the patient had lost two front teeth both in the upper and lower jaws, leaving a space through which fluids might be passed, which she had great difficulty in swallowing.

The bowels having been freely opened with Ol. Ricini the day before, I ordered Tinct. Opii. ℥xv., Æth. Chloric ℥x., ex Mist. Camphoræ every three hours. Also a simple liniment combined with chloroform to be rubbed in along the spine.

On Saturday I found the patient more free from pain, but evidently becoming much weaker from the frequent convulsions and her inability to take nourishment. I administered chloroform, and found that there was a cessation of the convulsions whilst under its influence, but they again recurred when its effects had gone off. I repeated the mixture as before, but she gradually sank and died on Sunday, 5 a.m., the convulsions never having entirely left her.

If any of your readers should have met with a similar case, I should be glad to hear of it and the treatment they adopted with success. I am, &c.

Henry Viant, M.R.C.S., etc.

Southampton, January 15.

MEDICAL EDUCATION IN LONDON AS IT LOOKS TO A PROVINCIAL PROFESSOR.

[To the Editor of the Medical Times and Gazette.]

Sir,—Whilst the subject of Medical education is so much discussed, a few observations on the training afforded to London Medical students may not be altogether inappropriate, coming as they do from one who has had considerable experience of that class, and who has also seen the style of instruction adopted in most metropolitan Hospitals.

In a Medical education there are two very distinct parts,—the one is the acquisition of theoretical knowledge, mostly obtained by means of lectures or reading, the other is the application of the knowledge thus acquired at the bedside or in the out-patients' room. In both of these, as seen in London, there is a marked deficiency of the tutorial method, as already pointed out in the *Medical Times and Gazette*, nor can I say in which department the deficiency is the more marked.

Turning first to the clinical teaching seen in London, I must, however unwillingly, slightly differ from the views of Dr. Beale, stated in his letter lately published in this journal, as to the necessity of the tutorial method in clinical teaching; indeed, of the two we think it more, rather than less necessary, in this department, for by no other method can the student be properly taught to recognise and cope with disease. Unfortunately, however, this element appears to be almost equally deficient in both departments of Medical study in London, though perhaps to a less extent in the practical than in the theoretical. In all my wanderings through the London Hospitals I do not recollect seeing a student set to examine a case under the eye of his teacher, to give his diagnosis or to indicate a line of treatment. I am aware that there are exceptions to this rule, still I maintain that they are the exceptions, not the rule, and that the student is too often left to grope his way in the dark.

In most cases I have seen the teacher go round followed by his pupils, occasionally pointing out something for their observation, but never testing their knowledge by questions as to any peculiarity in the case before them, nor, in fact, by any other means. Nor can I help thinking that in most cases London teachers are too crotchety and too much of specialists to be good instructors in general Medicine. Very many of them are men who have obtained eminence in some one or other department of Medical science, and they may be pardoned if they incline to it rather than to any other. Still this is disadvantageous to the student, who thus requires to follow a multitude of teachers, and perhaps ends by not discovering how much one class of diseases is related to another. Another objectionable feature I have observed is the tendency to run after unusual cases, and to study them, while overlooking the more common maladies with which they will be compelled to contend every day of their lives.

In some of the Hospitals there may be said to be an entire absence of clinical instruction, for the only thing that represents it is the Physician's dictating certain notes, after he has examined the patient, to be entered in a case-book by the clinical clerk. Sometimes the students enter these notes in their private case-books, and attempt to verify them by examining the patients, but in too many instances no further notice is taken of them. Occasionally, even this is denied, and the student has the melancholy satisfaction of learning from his teacher that "this a case of dropsy," and "that one of fever," without any fnrther comment.

If now we turn to the more formal instruction afforded the student in the schools, we find matters in an equally unsatisfactory condition. Most of the teachers value their appointments more for the status they give and the Hospital duties which usually accompany them than from any love of teaching *per se*, and cannot therefore be expected to devote themselves to it so completely as those who love it for its own sake. Nevertheless, it might be expected that a little more pains would be taken in many instances were it only for the teacher's own satisfaction.

I do not here complain, however, so much of the teachers themselves as of the method of instruction prevalent in London. Those who are acquainted with students know well how apt they are to carry away wrong impressions of what has been said to them, and in London there are usually no means of correcting these. The lecturer comes in, talks for an hour on the subject appointed for the day, and at the end of that time leaves without knowing—we had almost said without caring—whether his pupils have been at all benefited thereby. In

some instances, and of these I believe Dr. Beale to be one of the best, the teacher remains for some time after lecture to permit any student to ask such questions as may be necessary for clearing up his notions; but in other cases, he puts an effectual check on all such troublesome practices by leaving the room as soon as he has closed his manuscript. Altogether, I say, the student is left too much to his own resources, not without happy effects in some, but usually with quite the contrary result. Nor can I help thinking that those men who have done well under such a system would have done much better under a more fostering one; their success has rather been in spite of, than in consequence of the conditions under which they laboured. Neither can it be denied that the opportunities afforded by a large metropolitan Hospital are thus wasted, when I find such a man as Professor Beale complaining of the difficulties he labours under in having to instruct students as to things they ought to have known before they entered his wards.

What, then, is the remedy for such a state of matters, and how is the difficulty to be met? To this I would reply, either let the teachers devote themselves more strenuously to their work, and let them by frequent examinations, written and *vivâ voce*, ascertain the progress of each student under their care, or as their time in most cases is too valuable to be given up to work which can as readily be done by another, let competent men be appointed for the purpose—in other words, let each school have one or more Medical tutors.

Now a few words as to the duties of a Medical tutor may not come amiss from one who has seen the system wrought in what, compared with London schools, might be called perfection. In the first place, he ought to devote himself rather to instruct the student than to enable him to pass certain examinations with *éclât*; and this really constitutes the only essential distinction between a public Medical tutor and a private grinder. To enable him to do this more effectually the class under his care should never be a very large one, or if too large to be readily manageable, should be broken up into two sections. The subjects of examination should be given out some time before the students' knowledge is to be tested, in order that time be given for the mastery of those subjects to the best of their ability. Interrogation and explanation should go hand in hand, and the grand aim in all cases should be a correct appreciation on the part of the student of the subject under discussion.

A question of some little importance is, What subjects should be thus handed over to the Medical tutor supplementary to the regular lectures delivered on them? To this we would answer, All except those that are strictly practical, such as regional anatomy and practical chemistry, which should be taught by the demonstrators of the respective subjects. All the fundamental principles of Medicine, as well as the preliminary scientific studies, would be far more efficiently taught on this plan than on any other. I have seen its good effects exemplified in men who have repeatedly taken the highest places in competitions which, had it not been for their training, they would have shrunk from altogether, or, at best, made only a mediocre appearance. Nor do I consider this method of less value when applied to clinical teaching; all the drudgery which is so distasteful to many otherwise excellent teachers might be handed over to a tutor specially relegated to this department, or to the tutor who, at the same time, superintends the higher studies of the pupils. The routine of Hospital practice might thus be learnt in a far shorter time and more satisfactory manner than is ordinarily done.

But a still more important consideration remains. Who are the men best adapted for such duties as I have enumerated or hinted at? And here I would enter my protest against the manner in which all Hospital appointments are usually made in London, for in many instances all other claims are overlooked, except the fact of having been educated at a particular school. There should be free trade in teaching as in commerce, and that school would do well for itself which instituted the practice. Nepotism, I repeat, is the bane of London schools, and some of them owe their almost effete condition to no other cause. But I am to some extent wandering from my point. I conceive, then, that the grand qualification for a Medical tutor is experience of students, and the best modes of drawing their attention. Just as it has often happened that the most famous Practitioners have been but poor teachers, so do I conceive that the very highest academical honours may not be the best surety of a successful tutor. The knowledge he requires is rather of many things than much of any one thing; by all means, let the two be combined if possible, but I repeat that the former is more essential than the latter. Facility of exposition, with a ready appreciation of the difficulties of students, are no less necessary. All these things render it somewhat difficult to obtain one exactly suitable in all points, still I have no fears of the result if any London Medical school of standing only show the example by throwing open its doors to the best man, be he who he may, wherever he comes from. His emoluments might be easily secured by adding a small sum to each student's entrance fee—small in comparison with the benefits which might thus accrue. This deficiency or absolute want of the tutorial system I consider the grand defect in the London schools, and the institution of such a system would do more to advance the interests of the students than would collecting all the best metropolitan lecturers into one great school of Medicine.

I am, &c., A Provincial Professor.

REPORTS OF SOCIETIES.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Tuesday, January 23.

Dr. Alderson, F.R.S., President.

A paper, by Mr. C. H. Moore, was read on

AN ARTERIO-VENOUS CYST IN THE POPLITEAL NERVE—AMPUTATION—RECOVERY.

A woman, aged 31, received a blow with an iron pump-handle in the middle of the ham. In a fortnight a painless, moveable swelling, of the size of a hazel nut, was found in the situation of the injury, and but for its distance from either hamstring, would have been pronounced to be an enlarged bursa. In sixteen months' time the tumour had increased, and seemed partly solid, and she first felt pain, which was referred to the foot. Three months afterwards, and twice subsequently in the following three months, the swelling was punctured, and on each occasion a yellow fluid, tinged red, first escaped, and as it flowed gradually deepened in colour, and continued to issue freely as blood from an open vein. The tension of the swelling was but temporarily reduced by these operations, and it increased in size so as completely to fill the ham, and protrude backwards in two prominent lesser swellings. The pain in them and along the leg and foot, the exquisite tenderness of the tumour, and a peculiar sudden pang shooting to the foot, while the canula was held motionless in the tumour, showed the nerve to be in some way mixed up with the swelling. After putting on a tourniquet, Mr. Moore made an incision into the tumour. Serum, black clot, loose fibrin, and some small clusters of white corpuscles were dislodged, partly with the finger and partly with a copious rush of blood from a vein at some deep part of the large cavity which had been opened. This proved to be a thin cyst, with a shining interior membrane, expanded into alternate ridges and sacculi, and traversed, like an auricle or right ventricle, by many firm cords. It being impossible to dissect it out, and improper on account of the state of the woman's health to leave the sac to suppurate, Mr. Moore at once amputated the limb. The patient recovered. Upon examining the limb the disease was found to be a vast cyst within the popliteal nerve, shaped like a double cone, one continuous with the higher, and the other with the lower end of the nerve. The expanded and hypertrophied textures of the nerve constituted the cyst, and the cords passing through it and along its walls were disparted nerve-bundles. A large vein, having no valves between it and the popliteal vein, opened obliquely like the ureter, on the front of the cyst; and in the upper cone, where alone firm lymph was collected, an artery equal in size to the superficialis volæ opened into the cyst. The disease thus proved to be an arterio-venous aneurism, but unlike those which are more commonly observed in the small size of its artery, in the possible fact of venous blood having sometimes regurgitated into it, and in the unruffled quiescence of its contents, which had even separated into their natural constituents, almost as when blood coagulates after its withdrawal from the living body.

Mr. Gascoyen eulogised Mr. Moore's treatment of his case, and thought it preferable to tying the femoral artery. He

related a case in which a patient suffered from bronchitis, and a tumour in the popliteal space, which was of an aneurismal character. He tied the femoral artery. The patient lived a year, and then died of heart-disease. The tumour in the popliteal space was found to be coated with the posterior tibial nerve, which completely encased it. The tumour was filled with coagula.

Mr. Holmes Coote was inclined to think, looking at all the circumstances of the case, that the tumour was of a malignant character. He had seen and heard of several cases in which a tumour, supposed to be a blood-cyst, turned out to be malignant.

A paper, by Mr. Septimus W. Sibley, was read on

A CASE OF MULTIPLE NEUROMATA AFFECTING THE NERVES BOTH WITHIN AND EXTERNAL TO THE SPINAL CANAL, SOME OF THE TUMOURS BEING OF A CYSTIC NATURE.

This case was submitted to the Society as being a remarkable example of the cystic form of nerve-tumour, and as an illustration of the extraordinary multiplicity which is sometimes observed in this form of disease. The subject of the disease was a coach-painter, who died at the age of forty-five in the Middlesex Hospital under the care of Mr. Henry. The patient had enjoyed good health till seven years before his death, when he became less strong, but had no definite symptoms till four years ago, when the use of his lower extremities became impaired, and by degrees he lost all power of movement. He had also suffered from sloughing of the back. When admitted into the Hospital, he had no power over the voluntary muscles of the lower half of the body, the legs being contracted and drawn up. He retained some power of motion over his upper extremities, being able to feed himself if his food were first cut up for him. Cutaneous sensibility was quite absent in the lower extremities; but he was able to feel to a certain extent with his hands. The urine and the fæces were passed involuntarily. A large tumour was observed below the elbow, and another below Poupart's ligament on the left side. He died after he had been in the Hospital a month. At the post-mortem examination there was no disease of the viscera of the chest or abdomen. The brain and the cranial nerves were healthy. On opening the spinal canal a number of tumours were observed connected with the nerves within the membranes of the cord. In the cervical region there were several tumours, and the largest of these (about the size of a large nut) had pressed upon the spinal cord, which at this point was extremely constricted and softened. There were also many neuromata in connection with the nerves in the lower part of the cord. In some places these were so numerous as to present the appearance of beads strung on a thread. The large tumour which was observed during life below Poupart's ligament was found to be connected with the anterior crural nerve. It was enclosed in a fibrous capsule, and on section presented the appearance of a fibro-cellular tumour interspersed with cysts. These cysts were of various sizes, the largest being about the size of an egg, and partly filled with imperfectly organised blood-clots. A second smaller cyst was filled with gelatinous material. The remaining small cysts were filled with clear serous fluid.

THE PATHOLOGICAL SOCIETY.

Tuesday, January 16.

Dr. Peacock, President.

Dr. Hermann Weber exhibited

SPECIMENS OF SYPHILITIC AFFECTIONS OF THE LIVER, LUNG, BRONCHIAL GLANDS, CRANIUM, AND DURA MATER.

C. F., 28, carpenter on a merchant ship, taken ill on Dec. 14, with pains, supposed rheumatic, in the right hip and both knees. Admitted into the German Hospital on December 21, with pains in both knees, which were but slightly or not at all swollen, and a moderate amount of fever. On December 29 he complained of headache, and had less pain in the knees. The headache increased, and on January 7 patient became drowsy, and had a kind of fit, after which, a semi-comatose state supervened, which was followed by a complete coma on the 9th, and death on the morning of the 11th. *Post-mortem.*—There was a thick layer of very vascular exudation on the inner surface of part of the frontal, parietal, and temporal bones of the right side, thickening of the corresponding firmly-attached dura mater, which on its arachnoid surface exhibited a similar layer of exudation abundantly supplied with new blood vessels and with small hæmorrhagic spots. The pia mater and arachnoid covering the adjacent portion of the right hemisphere were inflamed and slightly thickened in the circumference of a crown piece, but could be removed from the flattened gyri without loss of substance. A similar, but much less developed condition of the cranium and dura mater was seen on the corresponding region of the left side. The whole brain was congested, especially the pons and crura, in which were a few capillary hæmorrhages, but there was not much effusion of serum either into the ventricles or on the surface. There was a fresh node on the inner surface of the upper portion of the sternum. Both lungs were decidedly firmer than usual, all over the greater part of their surface, especially near the edges, the ramifications of the lymphatics were seen much distended and filled with creamy substance, which consisted of fat globules, very large cells, and large granular corpuscles; the sections of the lungs showed everywhere small greyish-white prominent spots, which to a superficial inspection had all the appearance of miliary tubercles, but which on closer examination proved to be caused by the exudation of creamy semi-coagulated lymph oozing from the enlarged lymphatics, of similar microscopic appearance to the contents of the lymphatics on the surface; there appeared to be also an increase of the intercellular tissue round the bronchi and lymph vessels. The glands near the bifurcation of the bronchi were much enlarged, some to the size of pigeons' eggs; from the greyish-white section of the largest, which were at the same time rather soft, a creamy fluid exuded which consisted entirely of fat globules, granular corpuscles, and an abundance of very large cells, with one, two, or three very large nuclei, more or less fatty. There were no traces of pus globules. The less enlarged glands were harder, and exhibited under the microscope a great predominance of large nuclei and nucleated cells, and a small proportion of fibres thickly studded with nuclei. The heart and great vessels were normal. The liver was of average weight and size, but had on its surface many roundish spots, from the size of a pea to that of a silver threepenny piece—greyish and depressed in the centre, yellowish red, and slightly elevated in the circumference; with rather fatty, but otherwise normal liver tissue between them. The fresh sections showed that these spots were also everywhere in the interior of the organ, and exhibited different stages of development; some of them, especially the smaller, being in the centre slightly prominent, and of deeper red than the healthy tissue, and having a yellowish circumference, paler than the normal tissue. Other spots, and especially the larger, were in the centre greyish red, and distinctly depressed, and in the circumference elevated, the inner zone of this circumference being darker and more red than the normal tissue, the outer zone of a pale yellow. The consistence of these spots differed but slightly from the surrounding substance. The depressed centre showed an increase of fresh connective tissue, and a diminution and shrinking of liver cells; the raised circumference augmented vascularity, an abundance of free fat globules, with liver cells gorged with fat globules, and some granular corpuscles. The kidneys had several cicatrices, but were otherwise normal. There was a cicatrix on the penis near the frænulum. The inguinal glands were not much enlarged, but hard. The lymphatic glands of both elbows and of the neck were enlarged and hard. There were hard cicatrices on both arches of the palate.

Dr. H. Weber said he had no doubt that the pathological alterations of the head, the liver, lungs, bronchial glands, and sternum, were due to constitutional syphilis, but that these affections were in so early a stage as had hitherto not yet been described in this country, and had altogether probably not often been seen, because patients rarely died at such a stage of constitutional syphilis. As the time of the meeting was advanced, he could not offer a more detailed description, but proposed to the President the appointment of a committee for the examination of the specimens.

A Committee was appointed to report on the specimens.

Dr. Hermann Weber next exhibited a specimen of

RUPTURE OF THE AORTA.

The patient, a man cook, aged 45, had been under Dr. Sutro's treatment at the German Hospital for Bright's disease since August 1865. According to Dr. Bauember, the resident Physician's report, he complained of violent headache on January 7. At 11 p.m. he slipped out of bed with the head foremost, the head touching the ground while the legs were still in bed, the lower part of the back resting

on the edge of the bed. Early in the morning of the 8th he had a kind of fit, when he lost his senses and turned blue in the face, without having convulsions. During the remainder of the day he was conscious, but drowsy. On January 9 he was as usual, when, while eating his dinner, he suddenly cried out, and fell back, becoming first pale, then red in the face, and died shortly afterwards. The pericardium filled with coagulated blood; the heart was hypertrophied (14 oz.), but the muscular tissue and valves were sound; the commencement of the aorta was not dilated, and but slightly atheromatous; almost immediately above the valves was a transverse rent about an inch long, part of which penetrated only the inner and a portion of the middle coat, while about half of it entirely penetrated the middle and formed a smaller opening in the external coat. There was some infiltration of blood into the tissue of the external coat around the slit. The specimen was, therefore, what Dr. Peacock in his report (*Pathol. Trans.*, vol. xiv.) called "dissecting aneurism in the earliest stage." The commencement of the rupture had most likely been caused by the fall two days before the death, the external coat, and probably some fibres of the middle, having resisted until the moment of death, which in these cases must be immediate, being effected by compression of the heart.

PATHOLOGY OF THE CATTLE PLAGUE.

Dr. Crisp exhibited some fresh preparations taken the day before to illustrate the pathology of cattle plague in its first and latter stages, in reference to the identity of this disease with small-pox. They consisted of a part of the fourth stomach, a portion of the ileum, and parts of the skin of a cow that was killed thirty hours from the first appearance of the plague, and examined by Dr. Crisp immediately after death. There was no appearance of eruption on the skin, but one irregular shaped red spot was present on the inner part of the lower lip, and the subcutaneous layer of the nose was much congested. The endocardium did not present the usual appearance of red marking and staining from extravasation of blood described by Dr. Crisp in his first communication at the Society, Oct. 17. The lining membrane of the vagina was much reddened, and under the microscope presented the mottled, spotted aspect of the skin in scarlatina. The mucous membrane of the fourth stomach was reddened, and in various parts small spots of a deep lake colour, varying in diameter from the fifteenth to the fifth of an inch, were present, the epithelum being removed. Some parts of the bases of the intestinal ridges were intensely red. On the same day, Jan. 14, another cow* that Dr. Crisp had seen when labouring under cattle plague was killed seven weeks after the first appearance of the attack. She had the disease very severely; suffered much from diarrhœa (which was checked by opium and sulphate of copper); passed bloody urine and a portion of the lining membrane of the bladder. She was much emaciated, and, although the result of the examination showed that she would probably have recovered, it was thought better to kill her. No trace of eruption was visible on any parts of the skin examined. The epithelial lining of the three first stomachs was entire. Large brick-dust-coloured patches were present in the fourth stomach; but over the greater number of these the epithelium had been restored, but in a few there was partial abrasion. The intestines were not mottled externally, and those parts of them examined had recovered their normal state. Patches of a brick-dust colour were present on the prominence of the left cardiac ventricle; but they had lost the dark appearance they usually present in the first stage of the disease.

Dr. Crisp said he wished that he could agree with Dr. Murchison as to the identity of this disease and small-pox. There might be some resemblance, but he could discover no identity either in the symptoms or morbid appearances, and he anticipated that no good would result from inoculation with small-pox or vaccine matter. He had seen several cows that he had reason to believe had had the cow-pox, and yet several of them had died of the plague, and others had had the disease very severely. His experience told him that the only way to get rid of the pestilence was to stop all movements of cattle, sheep, and pigs; kill and bury all affected, and compensate the owners. There was one important fact in connection with this disease that he had alluded to in his first communication, Oct. 17—that he had an especial bearing upon the identity of this plague and small-pox. Men employed in flaying diseased animals had often an eczematous eruption upon the arms and thighs, which sometimes continued for three or four weeks. It evidently arose from the acidity of the virus, for these men were in the habit of placing the knife between the thighs, and hence the presence of the eruptions on these parts. It first appeared as a red pimple, then slight vesication and desquamation, followed with intense itching. Dr. Crisp said he had had it on his own arm.

Mr. Spencer Watson exhibited a

CAST AND SPECIMEN OF EXOSTOSIS OF FINGER.

The patient was a woman, 40 years of age, who had lately suffered pain and inconvenience from the presence of the tumour. She wished for its removal, and would have submitted to amputation of the finger if necessary. Mr. Watson, however, decided that, if possible, he would remove the tumour without amputating. This he accomplished successfully. The tumour, which was of about the size of two filberts, presented the characters of cancellated exostosis, and had a thin layer of cartilage on its surface.

SPURIOUS ENTOZOA IN CATTLE.

Dr. Cobbold exhibited drawings and microscopic preparations illustrative of the so-called entozoa or psorospermiæ, which he finds to be more abundant in the flesh of healthy sheep and oxen than in that of diseased animals. In this connection he quoted the labours of Dujardin, Hessling, Rainey, Virchow, Gubler, Leuckart, Lindemann, and others, and showed that the bodies in question were both ecto- and endoparasitically related to man himself.

Mr. Christopher Watts showed the fragments of a

MULBERRY CALCULUS REMOVED FROM THE FEMALE BLADDER BY LITHOTRITY.

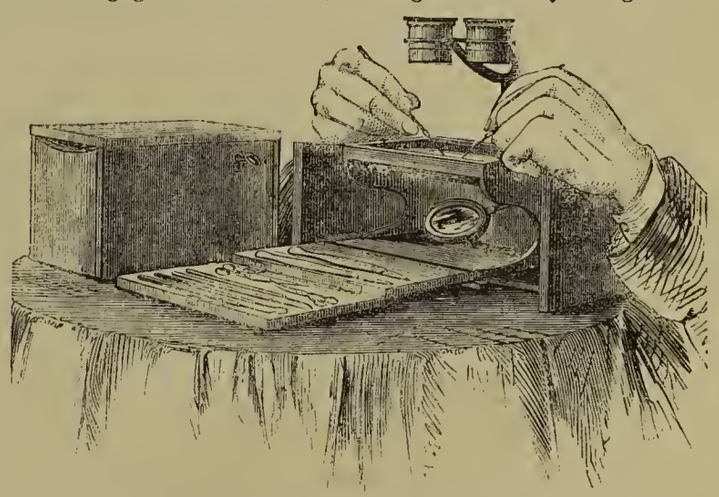
The fragments weighed 245 grains, and consisted of *débris* of triple phosphate which formed the exterior of the stone, and several large fragments of oxalate of lime calculus which formed the nucleus of a stone measuring when first grasped in the lithotrite one and a-half inches. The stone was removed, from the bladder of a lady who had suffered from symptoms of calculus for some time, in five sittings, and the patient made a perfect recovery.

(a) A fœtus exhibited, weighing about 8 oz., was found in this cow in a partially decomposed state.

NEW INVENTIONS.

DR. LAWSON'S BINOCULAR DISSECTING MICROSCOPE.

We recommend this useful microscope to the attention of our readers; it has already become a favourite instrument with those engaged in dissections, although so recently brought out.



Dr. Lawson's Binocular Dissecting Microscope.

It belongs to the class of simple microscopes, and is adapted to binocular vision. The application of the principle on which it is constructed is novel. The arrangement of it is this:—For each eye there is a disc of glass, which corresponds to one of the halves of a large bi-convex lens, cut circularly, and mounted in a short brass tube. The two eye-pieces, fixed as in the figure, are so arranged as that the discs present the thickest portions of their borders towards each other—that is, the portions which formed the centre of the original lens.

The principle of their optical action is extremely simple.

Each glass acts as an entire lens, and serves to render parallel the rays diverging from a point in an object. By its prismatic form and its position towards the other, each glass also serves to bend the direction of the axis of the rays of light passing through it from a point in the object, so as to make it less inclined than it was to that of the axis of rays from the same point passing through the other. Consequently, an object can, by means of this admirably contrived instrument, be placed very near the eyes, and thus magnified, and yet be viewed by both eyes at once without any unusual convergence of their lines of vision.

It is supplied with a gutta-percha trough, having a small piece of glass let into the bottom, so as to permit, when necessary, the transmission of light from a reflector placed beneath. This trough, containing water, forms the stage on which the dissections are made. The microscope is also provided with sliding arm-rests and the necessary dissecting instruments. It is fixed on a mahogany stand, which folds up as a box, including all parts of the instrument in a very small compass.

It is exceedingly well suited for its purpose; so that we feel confident that the Medical man will find it almost invaluable in the examination of morbid structures. It is the ingenious invention of the gentleman whose name it bears, Lecturer on Histology and Microscopic Anatomy at St. Mary's Hospital, and is manufactured and sold, at a moderate price, by Mr. Collins, the eminent microscope maker, of 77, Great Titchfield-street.

SINAPINE TISSUE, OR MUSTARD PAPER.

(Prepared by Mr. Cooper, Chemist, Abingdon-terrace, Kensington, W.)

This is a thin, glazed, innocent-looking paper, but any one who touches it with the tip of the tongue will soon become conscious that it is coated with something of a very pungent character. Wetted with cold water and applied to the skin, it produces in about ten minutes a good deal of superficial irritation. Between it and a mustard poultice there seems to us this difference, that its effects are more persistent, and not quite so circumscribed, and that the sensations it produces are not the same. In fact, if we had to give a name to it, we should rather have called it *capsicine* than sinapine tissue. Be this as it may, it is so extremely portable, convenient, and clean that persons who are in the habit of using mustard poultices or other ready forms of counter-irritation—as for coughs, sore throat, deafness, etc.—may easily carry a supply in their card case. Probably a hot poultice *over* a bit of this paper would answer well in cases of pleurodynia, etc.

LEATHER-FELT SPLINTS.

These very simple and admirable splints are the invention of Mr. J. G. Hides, of Mortimer-street. They consist of stout felt, lined on one side with wash leather. All that is necessary for their application is to place a splint (with the leather side downwards) upon a table, then paint the felt side with a liquid which is supplied with them, apply the splints to the injured limb, and bandage with an ordinary roller, leaving a little interval between each turn of the bandage. If properly used, the splint will harden almost like a piece of wood in about thirty-five minutes, taking the temperature of the limb at 100° F. The advantages over other appliances seem to be their lightness, perfect adaptability to parts, and, as no padding whatever is required, they are more quickly and easily applied, and the bandage uniting with the splint as the liquid dries more support is given.

They can be used again and again by merely painting the felt side afresh with a weaker solution of the liquid. They are cheap, the price for a set of eight arm and hand splints being about the same as that of wooden splints. If additional support be required, the felt has only to be made of thicker quality.

We believe that they have been much approved of by Mr. Partridge, of King's College, and Mr. De Morgan, of Middlesex Hospitals. We have ourselves tried them for a fractured arm, and had every reason to be satisfied with them. The fracture was rapidly put up, and had the appearance of lightness and neatness so delightful to a Surgeon's eye. We fancy they would be capital splints for field practice in the army.

Proportions of Rejections in the French Medical Examinations in 1865.—These were between 11 and 12 per cent. at the Strasburg Faculty, between 12 and 13 per cent. at that of Paris, and between 14 and 15 per cent. at Montpellier.

MEDICAL NEWS.

Apothecaries' Hall.—Names of gentlemen who passed their Examination in the Science and Practice of Medicine, and received Certificates to Practise, on Thursday, February 1, 1866:—

Edwards Mills Grace, Downend, Bristol; Henry Charles Bury, Whetstone, N.; Henry Rundle, Plymouth; Josiah Oake Adams, Plymouth.

APPOINTMENTS.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

Bowstead, R. M., M.D., has been appointed Medical officer for the Saunderton Workhouse, Wycombe.

Cook, Dr. Francis, has been elected President of the Gloucestershire Medical Association for the year 1866.

Dickson, John T., M.R.C.S. Eng., has been appointed Assistant Medical Officer to the City of London Lunatic Asylum, at Stone, near Dartford.

Flinn, J. J., L.R.C.P., has been appointed Surgeon to the West Derby Union Workhouse.

Norrish, John S., M.R.C.S. Eng., has been elected Assistant Medical Officer to the Cheshire Lunatic Asylum.

Turner, John S., M.R.C.S. Eng., has been appointed Surgeon to the Penge General Dispensary.

BIRTHS.

Evison.—On January 18, at Milnthorpe, Westmoreland, the wife of Hanson Evison, M.R.C.S. Eng., of a son.

Grosvenor.—On February 2, at 1, Buckingham-terrace, Kensington-park, the wife of G. Fox Grosvenor, M.D., prematurely of a son.

Harmer.—On February 5, at Pix-hill, Hawkhurst, the wife of Dr. W. M. Harmer, of a daughter.

Hastings.—On February 3, at 56, Curzon-street, W., the wife of Dr. Cecil Hastings, of a daughter.

Hovell.—On January 27, at Clapton, the wife of D. de Berdt Hovell, M.R.C.S. Eng., of a son.

Jones.—On January 28, at the Priory, Wrexham, the wife of T. Eyton Jones, M.R.C.S. Eng., of a daughter.

Langston.—On February 6, at Broadway, Westminster, the wife of Thomas Langston, M.R.C.S. Eng., of a daughter.

May.—On February 5, at Reading, the wife of George May, jun., F.R.C.S. Eng., of a son.

Murchison.—On February 5, at 79, Wimpole-street, W., the wife of Charles Murchison, M.D., of a daughter.

Picard.—On January 30, at 24, Abbey-road, St. John's-wood, the wife of P. Kirkpatrick Picard, M.D., of a son.

Savage.—On February 2, at Bordesley, Birmingham, the wife of Thomas Savage, M.D., of a daughter.

Stuart.—On January 21, at Chirnside, Berwickshire, the wife of Charles Stuart, M.D., of a son.

Taylor.—On January 23, at Woodstock, Oxon, the wife of Frederic Taylor, M.D., of a son.

Traquair.—On February 3, at Pau, France, the wife of T. G. Traquair, M.D., of 1, Eccleston-square, of a son, stillborn.

Watkins.—On January 31, at 85, Guildford-street, W.C., the wife of Edwin T. Watkins, M.D., of a son.

MARRIAGES.

Brigstocke—Tomkins.—On February 1, at St. Luke's, Cork, Richard W. Brigstocke, Surgeon, R.N., to Lizzie, youngest daughter of W. J. Tompkins, Esq.

Cheadle—Murgatroyd.—On January 31, at the Parish Church, Bingley, Walter B. Cheadle, M.D., to Anne, youngest daughter of the late William Murgatroyd, Esq.

Elliot—Bradley.—On January 20, at St. Stephen's, Coleman-street, George S. Elliot, M.D., to Elizabeth Dorothy, widow of the late William O. Bradley, Esq.

Gale—Driver.—On February 1, at St. Thomas's, Heaton Norris, A. Stanley Gale, M.B., to Miriam Driver, the adopted daughter of the late Samuel Benison, Esq.

Gilbert—Tacon.—On February 1, at Rodborough, Stroud, Edward G. Gilbert, M.R.C.S. Eng. to Selina Anne, eldest daughter of Robert Tacon, Esq.

Henry—Delany.—On February 1, at St. John's Church, Islington, James Henry, M.D., Surgeon R.N., to Nannie, eldest daughter of John Delany, Esq.

Hills—Parker.—On January 25, at Edlington, Roland Hills, M.R.C.S. Eng., to Harriet, daughter of Edward Parker, Esq.

Maurice—Kindersley.—On February 1, at St. Paul's, Knightsbridge, James B. Maurice, M.D., to Mary Agnes, only daughter of the late N. W. Kindersley, Esq.

Peet—Giraud.—On February 6, at St. Mary's Church, Dover, John Peet, M.D., Surgeon-Major Bombay Army, to Nind Laura, daughter of Herbert Giraud, M.D.

Watson—Watson.—On February 3, at St. Bartholomew's, Sydenham, George H. Watson, M.R.C.S. Eng., to Caroline Amelia, eldest daughter of the late Robert Watson, Esq.

DEATHS.

ALLANSON, HENRY G. M., M.D. St. And., at St. George's-terrace, Sheffield, on January 28, aged 37.

BARTON, Dr. J. J., at Brighton, on January 29, aged 62, formerly of Bexley.

BIRKETT, GEORGE, M.D. Lond., at Northumberland House, Stoke Newington, N., on February 1, aged 47.

COLMAN, THOMAS E. T., M.R.C.S. Eng., at Wymondham, Norfolk, on January 24, aged 58.

FOTHERGILL, GEORGE, L.S.A., at Morcland, Westmoreland, on January 16, aged 60.

LEITCH, JAMES, L.R.C.S. Edin., Surgeon, R.N., at Crieff, Perthshire, on January 16, aged 84.

MACKIE, RICHARD G., M.R.C.S. Eng., at Hushwaite, Yorks, on January 25, aged 29.

MCSORLEY, EDWARD, Surgeon, R.N., Surgeon H.M.S. *Rattler*, at Nagasaki, Japan, on November 26.

MONRO, ANDREW, Surgeon, at Monkwearmouth, on January 18, aged 77, formerly of Ovingham.

POOR-LAW MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the last census.

APPOINTMENTS.

Atcham Union.—Henry John Buck, M.R.C.S.E., L.R.C.P. Edin., to the Kenley District.

Basford Union.—John Hall, M.D., C.M. Glasg., L.S.A., to the Wilford District.

Bramley Union.—Francis Hudson, L.R.C.P., L.F.P. and S. Glasg., to the Bramley District; Thomas L. Craister, M.R.C.S.E., L.S.A., to the Workhouse.

Dewsbury Union.—Thomas Wade, M.R.C.S.E., L.S.A., to the Mirfield District.

Watford Union.—Roderick W. Henderson, M.R.C.S.E., L.S.A., to the Rickmansworth District.

West Ward Union.—Thomas Blades, L.F.P. and S. Glasg., L.R.C.P. Edin., L.M., to the Moreland District.

ROYAL COLLEGE OF SURGEONS.—The annual course of lectures on Comparative Anatomy were commenced on Friday last by Professor Huxley, who will deliver twenty-four lectures on the Structure and Classification of the Mammalia, in continuation of his course of last year. The following is an abstract of his syllabus on the subject:—General remarks upon those mammalia which are wholly or largely inhabitants of the sea—viz.:—The *Sirenia*, or dugongs, manatees, and sea-cows; the *Cetaeea Balænoidea*, or whalebone whales; the *Cetaeea Delphinoidea*, or toothed whales; the pinnipede *Carnivora*, or seals and walruses. The anatomy and physiology of these mammals. The structure and affinities of the extinct genera *Zeuglodon* and *Toxodon*. The structure of the ordinary, or cursorial, *Carnivora*. The anatomy of the *Proboscidea*. The anatomy and affinities of the genus *Hyrax*. Remarks upon the relations of those mammals which are provided with zonary, deciduate placentæ to the rest. The anatomy of the Mammalia Didelphia, as exemplified by the order *Marsupialia*. The anatomy of the Mammalia Ornithodelphia, represented by the order *Monotremata*. A summary of the results arrived at in the three courses of lectures on the *Mammalia*.

THE LATE JOHN GIBSON, R.A.—We learn in a private letter from Rome that this distinguished sculptor was nearly meeting with the fate of Cavour and Sir Charles Eastlake, as his Italian Surgeon persisted in bleeding him, against the strongly-expressed wishes of an English Surgeon practising in Rome, Dr. Topham. This gentleman at once communicated his feelings on the subject to a lady in attendance on the distinguished patient, who immediately telegraphed all the symptoms to Mr. Samuel Solly, of St. Thomas's Hospital, who confirmed the opinion of our countryman, and urged the lady to be guided by him alone in the endeavour to prolong a life so valuable.

DEATH OF DR. REYNOLDS, OF BOOTERSTOWN.—Our obituary notice records the death of Dr. Reynolds, of Booterstown, an old and skilful Practitioner, thoroughly respected and venerated in his neighbourhood, and regretted by a large circle of admiring friends. Not only was he an able Medical man, but he contributed extensively to our periodical literature even to within a few days of his death, and had written several novels, which were pure in style and excellent in their moral tendency. He had also produced some dramas, which were highly successful. He was a charming companion, a genial and generous friend, and a most benevolent man. The gifted and skilful young gentleman, Dr. Emerson Reynolds, who has distinguished himself in the scientific branches of his profession, especially chemistry and chemical analysis, is the son of the amiable gentleman whose death we now record with unfeigned sorrow and the utmost respect for his memory.—*Saunders's News Letter*, Feb. 3.

ROYAL INSTITUTION OF GREAT BRITAIN.—At the general monthly meeting, on Monday, February 5, the Earl Percy in the chair, the Earl Spencer, K.G.; Joseph Brandeis, Esq.; Charles Lucas, Esq.; Frederick Mouat, M.D.; and Abraham Walter Paulton, Esq., were elected members of the Institution.

THE CHOLERA CONFERENCE.—Since our last the following further appointments to the approaching Cholera Conference have been announced:—Dr. Goodeve, to be the English Medical colleague of the Hon. W. Stuart; Salih Effendi, director of the Medical school at Koombarhané; and Dr. Bartoletti, member of the Board of Heath, to represent the Porte; Drs. Pelikan and Bykow and Mr. Lintz to represent Prussia; Drs. Grissinger and Herch to be the Prussian representatives; and Dr. Salvatore, with the Chev. Vernoni, first dragoman of the Italian legation, to represent Italy. Dr. Goodeve, our own Medical representative, has had great experience in India, and was strongly recommended to Lord Clarendon by the India Office as of exceptionally high qualification for this mission. He is expected to reach Constantinople by the Trieste steamer of Friday. Count Lallemand, the French representative, arrived by the Marseilles packet of Sunday. The precise time for the opening of the Conference has not yet been fixed.—*Levant Herald*, Jan. 24.

CHOLERA IN PORTUGAL.—The last advices from Portugal are wholly silent on the head of cholera in that country, except as regards its existence in Freixo de Espada à Cinta, a small town neighbouring upon Spain, and lying in a straight line between Salamanca and Oporto, just within the Portuguese frontier. At the last report, January 11, the infection, which had been present in the town some three or four weeks, seemed rather on the decline. The number of persons attacked were sixty-three, of whom twenty-two died. Of the fatal cases five were men, ten women, and seven children. Relatively to the population, it may be considered to have been extensive in its incidence, if not extraordinarily fatal; but it would seem that at present little anxiety is felt in Portugal.

ANDERSON'S UNIVERSITY.—A *pro re nata* meeting of the Trustees of Anderson's University was held on Tuesday in the Philosophical Society's Hall, when, out of the eighty-one, the whole number of the trustees, sixty-two were present. The object of the meeting was to appoint a Professor of the Practice of Medicine, in the room of Dr. J. B. Cowan, now Professor in the Glasgow University. The candidates for the chair were Dr. Thomas M'Call Anderson, a relative of the founder of the University, and P. A. Simpson, M.D.—Mr. William Euing, President of the Managers of the University, on taking the chair, announced the object of the meeting, and read a letter from Dr. Simpson, who, in deference to the high Professional talent of the other candidate, and the fact of his being a relative to the founder, requested that his name should be withdrawn from the list of candidates. The announcement was received with applause. Mr. Smith, of Jordanhill, then in warm terms proposed the appointment of Dr. Anderson, which was seconded by the Rev. Dr. Craik in a highly eulogistic speech. On a ballot being taken, Dr. Anderson was unanimously elected.

A DOCTRESS IN THE RIGHT PLACE.—The French Government, finding that the indigenous Doctors educated at the Medical School of Algiers were not allowed access to the interior of the Arab families any more than Europeans, has authorised a Mademoiselle Rengguer, who had already obtained with great distinction her diplomas of Bachelor (or rather spinster) of Letters and Sciences, to take out regular inscriptions in order to become a Doctoress. She is represented to be a lady of great acquirements, and aptitude, and there is little doubt that her example will be followed by others of her sex.

THE SOUTHAMPTON MEDICAL OFFICERS OF HEALTH.—The local Board of Health for the borough of Southampton notify, by advertisement, that they "are prepared to receive applications from Medical gentlemen (not desirous of entering into or continuing in practice) willing to take the post of Officer of Health. He will be charged with the health of the town, and must possess competent Medical, chemical, and microscopical knowledge. Inspectors of nuisances will be appointed. Salary, £150 per annum." Is not this worse than childish? What can be more important, especially in a seaport town, than that the officers of health should be thoroughly efficient? Yet the Officer of Health for Southampton is to be a gentleman who has tried and cannot

make £150 per annum out of the Medical Profession, or who feels assured that if he went into practice he could not make £150 per annum!—*Evening Standard*, February 1.

CAMBRIDGE.—MEDICAL OFFICERS.—At the weekly meeting of the Board of Guardians held on Wednesday last, the question of electing a Medical officer for the second district, in the room of Dr. Ransom, resigned, came on for decision. The Clerk announced that there were but three candidates—Mr. Arthur Taylor, of Camberwell; Mr. J. C. Pritchard, of Putney; and Mr. J. S. Smith, of Harston, Cambs. Mr. Taylor and Mr. Smith were in attendance at the time named, but when Mr. Taylor was called for—the favourite candidate—he was absent, it being stated that he had left to make inquiries as to the duties. The Board were kept in suspense for some considerable time, without any prospect of Mr. Taylor forthcoming; and the Board deeming that Mr. Smith's qualifications were not sufficient, it was eventually determined not to appoint a Medical officer that day, but to refer the question to the Finance Committee for them to consider the expediency of raising the salaries of the Medical officers, it being the opinion of several Guardians that they were not sufficiently paid.

THE following are the last week's Cattle Plague Returns. By comparison with those of the previous week, it will be seen that there have been 23,642 attacked, 9845 deaths, 607 slaughtered, and 2331 recoveries, since January 20:—

Census Divisions.	1. Attacked.			2. Result of reported Cases from the Commencement of the disease.				
	Week ending January 27.	Week ending January 20.	Week ending January 13.	Attacked.	Killed.	Died.	Recovered.	Unaccounted for.

CATSUP!—The following appears in the police report of the *Times* of Friday, Feb. 2:—Southwark.—Dr. Parker, the Medical officer of Bermondsey Vestry, accompanied by Mr. Rushton, the sanitary inspector, attended before Mr. Woolrych to apply for summonses against a tradesman carrying on business in Bermondsey for having on his premises a large quantity of salted bullocks' liver which was putrid, yet intended for human consumption.—Dr. Parker said that in consequence of information he received he went to a field in Upper Grange-road, where he found a large shed in the occupation of Mr. Hope. It was used as a manufactory of catsup and jams. On entering the place he found a large cask containing about 2 cwt. of bullocks' liver and very thick brine. He examined it and found some of it putrid, but it was so strongly impregnated with brine that he could hardly detect its condition. The foreman told him it was to be used in the manufacture of catsup, and he saw some in the course of manufacture.—Mr. Woolrych: I never heard of such a thing before. I always thought that catsup was made from mushrooms and walnuts. Was any portion of it fit for human consumption?—Witness: I don't think it was.—Mr. Woolrych: Where is this catsup sold?—Witness: I cannot tell; but I received a large placard, on which was printed "Hope and Co., manufacturers of genuine Leicestershire catsup and jams, Upper Grange-road, Bermondsey." I don't know where it is sold, but I saw large quantities in bottles and casks ready for removal.—Mr. Giles Rushton, the Inspector of Nuisances for Bermondsey, confirmed this evidence. Mr. Hope, the proprietor, came into the manufactory while he was inspecting it, and told him he was going to use the liver in the manufacture of catsup. Witness saw some under preparation and in the course of manufacture.—Mr. Woolrych asked if Mr. Hope told him what other ingredients were used in the manufacture of catsup?—Witness replied that he showed him some burnt malt under preparation, which he said was used to colour the catsup. Witness said he had some of the salted liver outside the court if his worship would like to inspect it.—Mr. Woolrych left the court for that purpose, and on his return said that he could not grant a summons under the circumstances. The Act of Parliament set forth that the party must be before him on a specific charge before he could deal with such a case.—Dr. Parker said that he should mention the circumstances to the Vestry, and ulterior proceedings would no doubt be taken.

CHLORINE IN STINKING BREATH.—Dr. Clemens states that during the last thirty years he has constantly found the administration of numerous small doses of weak chlorine water a certain remedy for this distressing inconvenience.—*Wurzburg Med. Zeit.*, *Bd.* 6.

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

Medicus.—We have no doubt that the practice of the Hospital named would be open to any duly-qualified Practitioner who applied to the Medical officers.

A Competitor.—The award for the Jacksonian Prize Essays sent in at Christmas last has not been made; neither have the new subjects been yet published. They will both appear at the same time, probably in the course of a month or two.

Erratum.—In our last "From Abroad" the name of Professor Bruns was printed in mistake for that of Dr. Brück, a dentist, of Breslau.

THE GRIFFIN TESTIMONIAL FUND.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—The following subscription has been further received on behalf of the above fund:—Dr. J. Birkbeck Nevins, Liverpool, 10s. 6d. Amount previously announced, £133 9s. 9d. Received at *Lancet* Office, £9 9s.

I am, &c.,

ROBT. FOWLER, M.D., Treasurer and Hon. Sec.

145, Bishopsgate Without, February 6, 1866.

CATTLE VACCINATION.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—I think it my duty to call the attention of the public to the utter worthlessness of the vaccine lymph supplied to the Profession by Mr. W. Faulkner, whose advertisement appears weekly in your paper. A friend of mine, by my direction, about three weeks since, called on Mr. Faulkner, and was induced by him to purchase lymph from the cow instead of human lymph as I had directed. Thirty-six points were purchased at one shilling per point—six to be used for each cow—and these were most carefully inserted near the vulva in six cows in three separate herds in this neighbourhood, no result following in either case. That vaccination is now proved to be no protection against Rinderpest does not make this result the less annoying; and the fact that I was for years public vaccinator for this district will probably be some proof of the careful way in which the operation was performed.

You will oblige me by inserting this letter in your next issue.

I am, &c., FREDERIC DUKE, M.R.C.S. and L.S.A.

Buckingham, February 5, 1866.

*** We have often known the most expert operators fail with points even when they have been well and carefully charged. It is only by using fluid lymph from a capillary tube, or, better still, fresh lymph from the arm, that you can ensure success.

THE CATTLE PLAGUE AND SMALL-POX.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—Resident for some time in this country, into which the cattle plague, so fatal to English herds, has made only the most feeble struggle to effect its entrance, I have been much struck with the fact that, although a virulent and malignant epidemic of confluent small-pox is raging amongst us to an extent equal, if not greater, than the one which prevailed two years ago in England, yet the oxen thus surrounded by disease have almost wholly escaped. Such a fact causes me to doubt excessively the identity of the two disorders so much and so laboriously insisted upon by Dr. Murchison, and so boldly and philosophically put to the test by him.

It is well known that great precautions have been taken on all the frontiers and sea coasts of France against the intrusion from infected countries of all bovine animals—precautions which must have failed long ere this over such a great extent of barrier, and which are clearly useless if the poison be (assuming Dr. Murchison's view to be correct) within our gates, and ready for transmission from man to the animals about him. I am aware that, in opposition to this, it will be urged that, perhaps, the small-pox poison cannot be transmitted by infection to lower animals; but inoculation goes a long way to prove the contrary; for variola has been given in this way from man to both cow and horse, and they have had it—most mildly, it is true, but decidedly. Moreover, the small-pox has been seen in the horse; but I am not aware that any fatal case has been discovered. It is exceedingly doubtful whether these animals ever have small-pox except in its mildest form, and it is believed that they are frequently the subjects of it.

There is one disease which, although seen in isolated cases, is not known as being either endemic or epidemic in France, and that is typhus—a disorder believed to be greatly the child and companion of starvation, and of low and unnatural forms of diet, conditions not wanting in the summers of 1865 and 1864, when all green food was dried up—a disease, moreover, believed by Government commissioners to have been present in Russia last spring under the name of the Russian plague. We may

then ask, Cannot the present Rinderpest, known to have come to us from the Continent, be a typhus of a most malignant form? and cannot its absence from France be explained?

The post-mortem appearances described by Dr. Murchison are not altother at variance with my supposition; and as for the pustules, the presence of which in all cases is very far from being established, may they not be a product of the disease to which such cattle are believed to be very often subject, and to which so many of us owe our unseamed faces, and perhaps our lives?

False pathology leads to false treatment, both to waste of time and life—facts which must be an apology for a very long letter.

I am, &c., FREDERICK SIMMS, M.B. Lond.

75, Rue-de-la-Pouche, Passy, Paris, January 30, 1866.

ARMY MEDICAL DEPARTMENT.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—That clause of the Warrant which substitutes selection for seniority, and empowers the Director-General to promote any one he pleases out of the entire number of Surgeons and Surgeons-Major, was undoubtedly a great mistake, and has proved a heavy blow and discouragement to the Medical Department of the Army. It was a violent innovation, introduced without any proved necessity or justifying reason. Medical officers did not desire it, and there was no imputation of failure or incompetency against such as had been advanced to administrative position in the strict order of seniority.

The general opinion is, that an equal amount of talent would have been exhibited by Surgeons-Major in the order of seniority as has been displayed by the seventeen individuals who were selected by the late Director-General out of the entire number of Surgeons and Surgeons-Major, and promoted (some of them much to their own astonishment) to be deputy-inspectors in a single memorable *Gazette*.

If this is the case, there can be no reason for continuing a practice which makes promotion a matter of accident, and which no amount of meritorious service can with certainty secure. If promotion to the administrative grade by selection is so beneficial to the public service, it may be confidently asked why the principle is not extended to the scientific corps of Artillery and Engineers; and it would be interesting to learn what are the distinguishing peculiarities of the Army Medical Department which render promotion by selection desirable or necessary. Sir Andrew Smith desired to "wash his hands of it" (see Blue-book), and Sir James Gibson's former evidence was of similar tendency.

I am, &c. A RETIRED DEPUTY-INSPECTOR.

SWELLING OF THE NOSE.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—Recent notes in the *Medical Times and Gazette* on "Recurrent Swelling of the Tongue," put me in mind of a very curious case that occurred in my practice a few years ago. A gentleman, in the middle rank of life, sent for me and asked if I could do anything for that, touching at the same time a large swollen nose. I inquired after the cause. "Guess," said he. "Well, have you been stung with bees or with a wasp?" "No, with neither." "What then?" "Well, I suppose I may as well tell you, for I daresay you will never guess. I have a peculiarity to the effect that whenever I eat raw beans or pease, my nose swells up as you see it. I was amusing myself in my garden this morning by sowing some beans, and I incautiously ate some of them, and you see the result." I replied, "If this is the cause, send to my Surgery immediately, and you shall get the cure;" he did so, and the raw beans were sent tumbling from his stomach by a drachm dose of sulphate of zinc. This was in the forepart of the day, and I met my friend in the bowling-green in the evening, cheerful, and freed of his large proboscis.

I would ask, Does this case throw any light on "recurrent swelling of the tongue?" If gastric irritation can cause sudden swelling of the nose, it is much more likely to cause sudden or recurrent swelling of the tongue, seeing that that organ is more intimately connected with the pneumo-gastric nerve. If so, then we have the key to the treatment—viz., remove the gastric irritation. This may be done, as in my case, by an emetic, or by sedatives, purgatives, and counter-irritation. I am, &c.,

Blantyre, February 2. T. DOWNIE, M.D.

MEDICAL WITNESSES IN CORONERS' COURTS.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—I wish to lay before you a few facts as to the treatment of Medical witnesses in coroners' courts, and to ask you if you think it is such as the Profession has a right to expect.

On December 12, 1865, I was Medical witness in an inquest held by Dr. Lankester on the body of Agnes Cowie. I had previously made a post-mortem examination in the case. I signed a receipt for my fee of two guineas, but did not receive the fee at the time, for I left, after having given my evidence, before the technical details of the inquest had concluded. It is usual for the coroner's officer to call at the Medical witness's residence with the fee, and custom is so strong that the officer deducts the two shillings from the fee as a usual thing. As up to last week I had not received the fee, I wrote to the coroner's officer for it; and moreover, as an inquest had since occurred in which a Medical man had, as I consider unjustly, been subject to a vote of censure—a circumstance that would not have occurred if the coroner's officer had communicated with the Medical man in question—I stated that I should allow no abatement from the usual fee. The coroner's officer called upon me on January 29, during my time for seeing my morning patients, and with the utmost effrontery accused me of endeavouring to obtain the fee twice over. I could never have believed that beadledom could have reached such a standard of audacity as this. The interview will be best explained by a letter which I wrote immediately afterwards to Dr. Lankester:—

"Sir,—I have just had an interview with your officer for Islington, named Stanwell. You will remember an inquest which you held on the body of Agnes Cowie at the "Ram and Teasel." I never received my fee for attendance and post-mortem upon the case. I wrote to the man for the fee, and at the same time told him that I should not allow any reduction, as seems to be the custom here, to be made from it.

"I have now to complain of this man's insolence, and to request that the fee be sent from your office. The man told me that it was his conviction that the fee had been paid in the room, 'and his conviction would be so to his dying day.'

"Under these circumstances, I determined to refuse the fee which he proffered and to write to you on the matter; and I begged my servants to usher the man from my presence.

"I leave, Sir, the whole matter to you, and remain yours truly,

"29, Duncan-terrace, Jan. 29." "A. ERNEST SANSOM.

To this I received the following reply:—

"8, Savile-row, W., January 30th, 1866.

"Dear Sir,—I am sorry to find you have had any difference with my excellent and highly-respectable constable at Islington. I have never known him otherwise than punctual in his payments and truthful in his statements. I will speak to him on the matter; but as you have refused to take the fee which you think you have not had, I do not know what further I can do. "I remain, dear Sir, very faithfully yours,

"A. Sansom, M.B." "EDWIN LANKESTER.

I again wrote to Dr. Lankester, stating that I considered that of the consummate insolence of the man's manner there could be no doubt whatever; that it would have been impossible for me to have accepted a fee so proffered; and to dissipate the effect of the man's "conviction" I enclosed a letter from one of the principal witnesses in the case. This was the enclosure:—

"Dear Sir,—Having been present as a witness at the inquest on Mrs. Agnes Cowie, at the 'Ram and Teasel,' on the 12th ult., and having spoken to you immediately before you left the room, I hereby declare that you held no conversation with, nor received any fee from, the coroner's officer on that occasion. It would have been impossible for you to have received your fee unobserved by me. "Yours faithfully,

"Dr. Sansom, 29, Duncan-terrace. "G. M. COWIE.

"26, St. Thomas-street, 30th January, 1866."

I scarcely need explain that my reason in making these facts public is not personal gratification, nor the obtaining of the withholden fee; but it is to add to the evidence which already exists of the anomalous position of Medical witnesses in coroners' courts. I am, &c.

A. ERNEST SANSOM, M.B., etc.

29, Duncan-terrace, N., February 1, 1866.

POOR LAW MEDICAL REFORM.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—I shall feel obliged by your giving insertion to the annexed letter, that the Poor-law Medical officers may be made acquainted with the steps taken towards an improvement in the Medical relief of the poor. Since the last list of subscriptions was published, I have received the following:—Bucknill, S. B., Rugby, 10s. 6d.; Fox, L. O. Stockbridge, 10s.; Turner, N. B., Sutton, etc., 5s.; Roe, R. Barton-on-Irwell, 20s.; Dorning, D., Barton-on-Irwell, 20s.; O'Reilly, T., Ware, 10s.; Sedgewick, C., Hollingbourne, 10s.; Giles, W. F., New Forest, 21s.; Bencraft, H., Southampton, 10s. 6d.; Cheeseman, G., Southampton, 10s. 6d.; Griffin, R. W. W., Southampton, 10s. 6d.; Lawrence, L. A., Southampton, 10s. 6d.; Wiblin, T., Southampton (not union), 10s. 6d.; Tweddle, J., Cockermouth, 10s 6d.; Mason, T. J., Stratford-on-Avon, 10s. 6d.; Nevin, J. B., Liverpool (not union), 10s. 6d.; G. W. F., 10s.; Taylor, H., Guildford, 10s.; Foster, O., Hitchin, 10s.; Colbourn, W. W., Chippenham, 27s.; Crisp, J., Chippenham, 5s.; Ludlow, A., Castle Combe, 10s. Mr. Prowse, of Amersham, has received the following:—Barker, Mr., Aldershot, 10s.; Bywater, F. E. G., Pontefract, 10s. 6d.; Meynott, H., Ludlow, 5s.; Pink, G., Petersfield, 5s.; Knaggs, S., Huddersfield, 5s.; Davies, F., Pershore, 21s.; Reddrop, J., Tiverton, 5s.; Norris, H. E., Bridport, etc., 5s.; Weston, R. P., Wellington, 10s.; Thomas, J. L., Carmarthen, 5s.; Holton, C., Stoke-on-Trent, 5s.; Pearson, J., Cockermouth, 5s.; Morgan, W. W., Newport, 10s. 6d.; Jennings, O. C., Newport, 5s.; Harday, G., Rugby, 10s.; Raymond, L. R., Bromsgrove, 5s.; Rhodes, G. W., Huddersfield, 10s. 6d.; McLachlan, R., Halifax, 10s.; Savory, J. T., Wycomb, 5s.; Spurgeon, C., Samford, 5s.; Few, W., St. Ives, 5s.; Muriel, J. S., Cosford, 5s.; Leech, H. P., Stow, 5s.; King, E. P., Chepstow, 5s.; Dean, P. T., Upper Norwood, 5s.; Kingdon, A., Bideford, 5s.; Kendall, J. M., King's Lynn, 5s.; Newington, J. D., Cranbrook, 10s. 6d.; Royle, O. N., Kendal, 10s. 6d.; Elliott, J. R., South Molton, 10s.; Whitehead, W., Mansfield, 10s. 6d.; Lipscombe, R. M., Berkhampstead, 5s.; Pilkington, W., Blackburn, 21s.; Marley, H, Columb St. Major, 6s.; Hall, C. S., Carlisle, 5s.; Pritchard, W., East Retford, 10s. 6d.; Organ, R., Barwick, 5s.; Davison, R. S., Castle Ward, 21s.; Breach, J., Bradfield, 10s.; Raynes, H., East Retford, 10s.; Cook, M., Barnstaple, 10s. I am, &c.,

12, Royal-terrace, Weymouth, February 5. RICHARD GRIFFIN.

"12, Royal-terrace, Weymouth, 3rd February, 1866.

"Sir,—Since the commencement of this year a large number of Poor-law Medical Officers have sent their subscriptions to enable me to defray the necessary expenses consequent upon an application to be made to Parliament and the printing of a pamphlet, demonstrating the necessity of a thorough revision of the present wretched system of Medical relief to the poor. But prior to this procedure, I feel I should best consult the interest of all parties concerned by laying before you, as the head of this great Department, which has annually under its management over a million and a quarter of sick poor, the draft of a Bill which appears to me would, if passed, be of national advantage; and if you would take charge of it, or of one of similar import, and introduce it into the House of Commons, or make it a part of your new Poor-law Continuance Bill, I feel sure you will immensely benefit the public. That you may have knowledge of the sentiments of the Poor-law Medical Officers on the subject, I request you will permit such of them as can spare the time to wait upon you as a deputation; and if you will fix a time, giving me a clear fourteen days' notice, I will call them together for the purpose; and should you in the interval desire a private interview with me, relative to any arrangements, I will gladly wait upon you any day you may fix.

"I have the honour to be, Sir, your obedient servant.

"The Right Hon. C. P. Villiers, M.P., President of the Poor-law Board."

MEDICAL CHARGES IN SCOTLAND.

At the Small Debt Court, yesterday, before Sheriff Cowan, Dr. W. J. P. Kidd, Surgeon, Renfrew, sued Archd. Campbell, Esq., of Blythswood, for payment of an account amounting to £16 2s. 3d., restricted to £12; being charges made by the pursuer for Professional visits and medicine to a poor woman named Mrs. M'Clay, residing about three miles from the burgh of Renfrew. Mr. Thomas Campbell, writer, Paisley, appeared for the defender, and stated that the pursuer had been asked by Mrs. Campbell, of Blythswood, to visit a poor woman residing in her neighbourhood, in whom she takes a great interest. Dr. Kidd made seven visits, and handed in his account to Mr. Campbell, charging in all £6 3s. 3d. Mr. Campbell returned the account to Dr. Kidd, saying there must surely be some mistake, and requesting him to revise the account, as the woman was not a member of his family, nor one of his attendants. The pursuer did amend the account, but in place of charging at the rate of 15s. a visit, as he had done in the first account, he increased the charge to two guineas per visit, making the account £16 2s. 3d. Mr. Campbell had desired him (his agent) to mention that if he could he would have been present at the Court himself. He was not resisting payment of a fair charge, but he

considered it was due to the public that so exorbitant an exaction should be refused, as it would tend to check the exercise of charity altogether. Another Medical gentleman in the burgh was in the practice of charging only 2s. a visit to the same place during the day, and 2s. 6d. at night. Defender's agent said he would prove that 3s. a visit was ample payment for the pursuer. Dr. Kidd produced a printed table of fees, to be charged by Medical Practitioners, issued by the Faculty of Glasgow, and stated that he had charged in the present case in accordance with that scale. The patient resided two and a half miles beyond the boundary of the burgh, and he had charged at the rate of 10s. 6d. a mile. He considered he had nothing to do with the woman he attended in making his charges, but with the party who had employed him, and he charged according to the rank and circumstances of his employer, and not of the patient. In the first account he rendered he charged only 15s. a visit, simply to give Mr. Campbell the benefit of the reduction from two guineas, to which he (the pursuer) held he was entitled. Witnesses were called to prove the usual fees charged in similar cases by other Medical men. Dr. Stobo, Renfrew, said his charge for attending a labourer's wife, residing two and a half miles from Renfrew, would be 3s. a visit, and he certainly would charge no more though he was employed to visit a poor patient by Mr. Campbell, of Blythswood. He had sometimes visited Mr. Campbell's servants for that charge. Dr. Patison, Renfrew, said 3s. was the most he ever got for visiting similar cases two and a-half miles from the burgh, and he considered he was well paid. The Medical Profession in this district had a table of fees, but it had not been acted upon strictly for a good many years. In Dr. Kidd's account 5s. was charged for each of two operations on the patient. Dr. Patison said he would expect 4s. 6d. for each operation, in addition to the fee for visiting. Dr. Donald, Paisley, said he usually charged 4s. for the first visit and 3s. for the subsequent visits for attendance on patients of the class, and at the distance referred to. He charged according to the position of the patient, and not of the person who employed him. Mr. Campbell submitted that 3s. a visit would be sufficient payment to the pursuer, with 9s. for the two operations. He made no objection to the charge for medicines. The Sheriff said when the account was brought under his notice it certainly did occur to him that there was a considerable overcharge. The position of the patient in this case appeared to be a very humble one. The pursuer appeared to have been employed to visit her as a matter of charity by Mr. Campbell, of Blythswood. It was perfectly clear from the statement of the witnesses that the practice of the Medical Profession—and it recommended itself to his mind as a very reasonable one—was to charge the fees, not according to the circumstances of their employer, but of the person whom they visited. Now, the pursuer has rendered an account charging at the rate of 15s. a visit, which he afterwards increased to two guineas. That was very extraordinary, seeing that 3s. was the usual charge made by other Medical men in Renfrew for visiting poor persons at the same distance. He therefore thought the pursuer was not entitled to more than that, notwithstanding the circumstances of Mr. Campbell, who had employed him. He thought 4s. 6d. was a reasonable sum for each of the operations. The medicines furnished were charged 18s. 3d.; and seven visits, at 3s. each, amounted to 21s.—in all, £2 8s. 3d.; for which sum his Lordship decerned, subject to a deduction of £1 for the expense of the witnesses.—From *Glasgow Herald*, January 19.

At the Royal Observatory, Greenwich, the mean height of the barometer in the week was 29·553 in. The atmospheric pressure was 30·05 in. on the morning of Sunday; it fell to 29·13 in. on Friday, and rose to 29·82 in. on Saturday.

The general directions of the wind was S.W. and W.

* The average weekly numbers of births and deaths in each of the above towns have been corrected for increase of population from the middle of the ten years 1851-60 to the present time.

† Registration did not commence in Ireland till January 1, 1864; the average weekly number of births and deaths in Dublin are calculated therefore on the assumption that the birth-rate and death-rate in that city were the same as the averages of the rates in the other towns.

‡ The deaths in Manchester and Bristol include those of paupers belonging to these cities who died in Workhouses situated outside the municipal boundaries.

§ The mean temperature at Greenwich during the same week was 45·1°.

‖ The usual return from Liverpool not having been received, averages of the births and deaths in the previous six weeks have been substituted for the correct numbers.

APPOINTMENTS FOR THE WEEK.

February 10. *Saturday (this day).*

Operations at St. Bartholomew's, 1½ p.m.; St. Thomas's, 9½ a.m.; King's, 2 p.m.; Charing-cross, 1 p.m.; Royal Free Hospital, 1½ p.m.

Royal Institution, 3 p.m. Prof. Westmacott, "On Art Education."

12. *Monday.*

Operations at the Metropolitan Free Hospital, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 9 a.m. and 1.30 p.m.

13. *Tuesday.*

Operations at Guy's, 1 p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; St. Peter's Hospital for Stone, 3 p.m.

Ethnological Society of London, 8 p.m. Mr. Crawfurd, "On the Physical and Mental Characteristics of the European and Asiatic Races of Man." Mr. T. Valentine Robins, "Notes and Sketches on the Niger."

Royal Medical and Chirurgical Society (Ballot, 8 p.m.), 8½ p.m. Mr. Henry Thompson, "Case of Phosphatic Calculus, with Nucleus of Bone." Mr. Joseph Allen, "Case of Lithotomy; Mulberry Calculus."

Royal Institution, 3 p.m. Prof. Tyndall, "On Heat."

14. *Wednesday.*

Operations at University College Hospital, 2 p.m.; St. Mary's, 1½ p.m.; Middlesex, 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; St. Thomas's, 1½ p.m.

Microscopical Society, 8 p.m. Anniversary. Annual Meeting for the Election of Officers.

15. *Thursday.*

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Surgical Home, 2 p.m.; Royal Orthopædic Hospital, 2 p.m.; West London Hospital, 2 p.m.

Harveian Society of London, 8 p.m. Dr. Camps, "On Railway and other Accidents attended with Violence: their Effects on the Nervous System."

Royal Institution, 3 p.m. Prof. Tyndall, "On Heat."

16. *Friday.*

Operations, Westminster Ophthalmic, 1½ p.m.

Royal Institution, 8 p.m. Sir Henry James, F.R.S., "On the Ordnance Survey of Jerusalem."

ORIGINAL LECTURES.

LUMLEIAN LECTURES
ON SOME POINTS IN THE PATHOLOGY OF NERVOUS DISEASES.

By C. HANDFIELD JONES, M.B., F.R.C.P., F.R.S.,
Physician to St. Mary's Hospital and Lecturer on Medicine.

Lecture III.

(Concluded from page 141.)

From this discussion relative to neuralgia I will now ask you to pass with me to the consideration of spasm, intending thereby, of course, that kind of muscular contraction which we observe in tetanus and in some similar affections. The almost invariable occurrence of intense pain along with the contractions is a very noteworthy circumstance. It is a constant and often very distressing part of common cramp, which is plainly allied to tetanus. That the pain is not simply the result of intense muscular contraction must, I think, be admitted, because no amount of voluntary muscular effort that we can make produces any similar sensation, and because in some very painful cramps the muscles are by no means powerfully contracted. Brown-Séquard explains the pain of cramp in the following way:—He believes that every muscular contraction generates a galvanic excitation of the sensitive nerves in the neighbourhood of the muscular fibres, and that the degree of excitation, and consequently of pain, is in proportion to the energy of the contraction. This view seems to me to be contradicted by the fact above mentioned of the painless character of the most energetic voluntary contractions. These may produce a sense of fatigue, but nothing like the pain of cramp. It is also opposed by the results of Faradising the muscles of a limb. Experimenting in *propriâ personâ*, I find that, with a current strong enough to excite vigorous contractions of the muscles of the calf, no cramp-like pain is felt in the part traversed by the current, but a forcible, quivering, or tremor-like sensation in the outer part of the foot, where the external saphenous nerve is distributed, which passes higher up through the range of the electric stimulation. Here, then, is certainly galvanic excitation of sensitive nerves; yet no cramp. To me it appears that the occurrence of severe pain in states of spasm sets a broad distinction between this kind of contraction and that which is healthy and natural. The attendant pain is of the nature of neuralgia, and the action of the motor nervous apparatus must be, I think, essentially morbid, as far removed from the healthy mode of contraction as neuralgia is from healthy sensation.

A point which seems to me very worthy of notice is, the affinity which is not obscurely marked between spasmodic contraction and paralysis, however widely at first sight the two states appear to contrast with each other. I will adduce some instances. Exposure to cold is a recognised cause of tetanus, and we have seen that it is also of facial and some other forms of paralysis. Dental irritation will sometimes cause trismus (a spasm), sometimes ptosis (a paralysis). Mr. Moodeen Sherriff has recorded some instances of paralysis not depending on organic lesion, in which there was rigidity of one limb, and simple immobility of the other on the same side, the same cause having given rise to both conditions, and the same treatment removing them. Dr. Little, many years ago, expressed the opinion, as the result of extensive observation, that with regard to spasm and paralysis the nature of the primary lesion in the central organ is the same in either case. He regards, however, paralysis as the result of a higher degree of lesion than spasm. A patient of mine who suffered from brachial neuralgia, which yielded to quinine and iron, stated that if she worked hard in the day she had not only severe pain at night, but also complete stiffness of the hand, induced, of course, by spasm of the muscles of the forearm. If she worked but little, the spasm did not occur. In this instance the influence of exhaustion in inducing muscular spasm is very apparent, as also the relation of the latter to the paralytic sensory disorder. A case of cataleptic affection is related by Mr. Buchanan, in which the muscles were rigid as iron during the attacks, which lasted twenty-four hours. They were induced by excitement, want of food, and fatigue, and subsided with the aid of rest, warmth, and an opiate. In most persons languor and weariness would have been the result of the above-named exciting causes rather than spasm. The inference, however, seems just that these states, dissimilar as their outward show is, are not in their origin essentially opposites. Mr. Bryant relates the case of a female, aged 17, who was suddenly attacked with contraction of the flexor muscles of the left hand and forearm a week before she came under his care. Her health was good, catamenia regular; the sensation of the part affected, perfect. Iron was given, and in three weeks the natural movements of the part were restored. The nerves of sensation, however, now became involved, and complete anæsthesia of the whole hand and forearm made its appearance. This condition also disappeared in two months under the same treatment, sensation and movement being at last perfect. Here it can hardly be questioned that the spasm was the equivalent of the sensory paralysis.(b) In a boy who was undergoing the operation of resection of the knee-joint, and had been rendered completely anæsthetic by chloroform, I observed the limbs in a state of marked rigidity, the arms more so than the legs. Here sensory paralysis coincided actually with spasm. A case is recorded by Plagge(c) where a strong healthy soldier, aged 25, after eight hours' march, when the temperature was 63°, fell down suddenly, and lay pulseless, pale and without consciouness, with half-flexed limbs and closed jaws. Stimulants were given, and consciousness soon returned, and the rigidity ceased; but the patient could not move, and complained of severe pain in the back. Examination of the spinal column brought on immediately the most violent tonic contractions, without trismus or loss of consciousness, accompanied by the most frightful pains. An attempt to put the patient into a conveyance brought on the paroxysm afresh. Twenty ounces of blood were taken and morphia administered, whereupon the spine ceased to be painful. After a short journey the spasmodic contractions returned, but yielded to cold applications to the loins and stimulation of the extremities. The next morning the patient was quite well. Plagge entitles this a case of hyperæmia of the cord, but it seems to me to have much more claim to be regarded as one of exhaustion with consecutive nervous disorder. Had active hyperæmia of the cord really existed, recovery could not have ensued so rapidly. The primary sudden syncope, the severe pains, and spasms are much more consonant with the view of a tetanoid than of an inflammatory affection. It is most probable that the above was an instance of the malady termed by Trousseau tetanilla, which is induced by diarrhœa, fevers, lactation, and cold, and is treated advantageously by venesection and sedatives or quinine. In the description given of this disorder, it is stated that the intermittent contractures are usually preceded and accompanied by loss of muscular power; the hands, though half flexed, cannot be completely closed, and the tactile sensibility is also much impaired,—in fact, both in the causes and phenomena of this neurosis there is an evident affinity indicated between spasm and paralysis. I remember when taking my first lesson in aquatics with youthful enthusiasm, that my fingers for some time afterwards were contracted and retained the position they had taken while grasping the oar—a contrary result to what one would have expected from the prolonged fatigue of the flexor muscles. A friend tells me he experienced the same, and so I suppose did the Israelitish worthy who arose and smote the Philistines until his hand was weary and *clave* unto his sword. In a case recorded by Mitchell severe spasms of the facial muscles, cervical and lingual, were found to depend on the presence of carious teeth. This cause would most commonly have given rise to neuralgia, which, as we have just seen, has decided affinities with paralysis. If Earle records a case in which trismus was cured immediately by the discharge of a tape-worm, a case I have cited in Lecture II. proves that the same cause may give rise to facial paralysis. If we pass from tonic spasm to clonic, we find still more frequent indications of its affinity to paralysis. It may be sufficient merely to allude to choreic affections, which often contain quite as much of one morbid element as of the other. The same is exemplified in disorders of the internal organs depending on debility. I met a Medical friend some years ago in the street, who was looking pale. Said he to me, "My solar plexus is worn out; I want a new one. I am not ill otherwise; but I can't keep anything on my stomach. I have not been out of London more than a day consecutively for six years." Here was surely a state essentially depending on nervous paresis, but presenting phenomena of irregular muscular action. Such cases are sometimes cured by strychnia—a fact which further illustrates their true nature.

(b) *Vide Medical Times and Gazette*, June 14, 1862.
(c) *Vide Schmidt's Jahrb.*, vol. 107, p. 29.

The preceding observations appear to me to afford considerable evidence that spasmodic contraction is a very different thing *quoad* innervation from voluntary, and is a morbid mode of action related to paralysis, much in the same way as neuralgia is to anæsthesia. It is, of course, impossible to state in what respect the molecular condition of a nerve-cell which gives rise to a spasm differs from that which gives rise to paralysis. The constituents of the living tissues are not accessible to our microscopes; and, if they were, it is by no means certain that we should be able to distinguish any visible deviation from their healthy appearances in conditions of mere functional derangement. It is conceivable that some such changes in the nervous currents as occur during polarisation in luminous undulations may be the cause of neuralgia and spasm in the sensory and motor nerves respectively. I am utterly disinclined to enter into barren speculation, but it seems to me by no means such to endeavour to form a just estimate of the *nature* of the morbid actions which come before us, and to ascertain in what direction they differ from the healthy. We may be quite unable to acquire a full and complete knowledge of a disease, but we may, nevertheless, obtain very practical and useful knowledge respecting it. Thus we may never find out precisely what malaria is, or be able to demonstrate exactly in what way it acts upon the frame; but it is a highly practical and important point to know that it enfeebles and lowers nervous energy, and that most of its morbid effects can be explained on this view of its operation.

It seems to me an established point that the *quality* of nervous action differs greatly in different instances of disease, and that we cannot regard it as either simply increased or diminished in energy. This does not seem to me to have been always kept in view. In the motor nervous apparatus we have the state of healthy vigorous action replaced by tonic or clonic spasm, by tremors, choreic jerkings, and finally by paralysis, all without organic lesion. Muscular contractions, which our common persuasion holds, and I think correctly, to be an evidence of existing nervous power called into play, are most evidently not in all cases produced by the same *kind* of nerve action. Many actions might indeed be classed as *actions of weakness*, in apposition to actions of *strength*. The depression of the jaw in yawning when we are weary and languid is surely *quoad* nervous power, not the same kind of action as that which occurs when a hungry man is eating, and the jactitations of chorea are not prompted by the same kind of nervous impulses which direct the strong, steady strokes of an oarsman rowing a wager. The movements of chorea are usually readily controlled by a steady grasp of the agitated limb, but I had recently under my care a girl whose arm I was quite unable to keep still by all the force I could exert with both my hands. At the same time the legs were weak and tottery. Here the morbid condition of the lower part of the cord must evidently have been different to that of the upper. In some epileptic attacks there is much more tetanic rigidity than in others, yet we cannot think that different nervous centres are affected in the one case and in the other. In the sensory apparatus we have gradations from healthy sensation by hyperæsthesia, endless varieties of dysæsthesia and neuralgia, down to complete anæsthesia.

Without recognising the different quality of nervous action in different instances, it would be impossible to explain the great varieties we find in the action of certain medicines. This remark leads us again to consider whether, while we view spasm as the result of a particular kind of action in nerve cells, there may not be varieties of this special mode of action itself, some being of a more sthenic, others of a more asthenic character. Certain cases of tetanus are beneficially affected by aconite, and show a very remarkable power of resistance to this potent agent; others are not at all relieved by it. The same may be said of nicotine. Conway records two cases of traumatic tetanus cured by the exhibition of tartar emetic in large doses, while in other instances free stimulation and tonics appear to have been successful. The spasm of asthma is sometimes markedly relieved by depressants, as emetics and tobacco, sometimes by free doses of alcohol and ether. Some cases of chorea are much benefited by antimony, some by sedatives, some by tonics. The above-mentioned facts seem to me to indicate plainly that all spasmodic actions are not of the same quality, and that the same sort of difference prevails among them as there does between instances of hyperæsthesia and neuralgia. To recognise this is, I think, important, because it does away at once with any idea that the disorders of which spasm is the characteristic element are to be treated in any unvarying manner, even when we have arranged them in their classic groups. Nothing impresses me more as I grow older in practice than the manifoldness of disease, and how insatiable is the variety which Nature exhibits in her deranged as well as in her healthy aspects. We are too prone to imagine that where we see an outward show of resemblance there exists an internal and real identity; and this idea is hard to displace, though it be negatived again and again by the testing action of remedies. I will now attempt to apply the above views respecting neuralgia and spasm to a disease respecting the true nature of which authorities are by no means agreed—I mean angina pectoris. Dr. Stokes says, "If we inquire into the nature of a paroxysm of angina, two completely opposite views present themselves. Is it to be explained by spasm of the heart or referred to diminished action?" Now, the position I would take is that these views are not completely opposite; that spasm of the heart is much more akin to paralysis of the organ than to healthy contraction. The latter is unattended by pain, or indeed by any feeling except it be a certain indefinite sense of "wohlsein," and what we may term whole-heartedness. The former is essentially and distressingly painful, and attended with that sensation of imminent peril of life which is characteristic of all, even of minor, cardiac dysæsthesia. The pain I regard as the more constant and essential phenomenon, and the muscular spasm as a secondary and varying. It is of course possible that death might result during an attack from closure of the cavities in tetanic contraction; but though Lussana is inclined to adopt this view, the evidence in favour of it seems to me but scanty. There are only three observations in which the heart is stated to have been decidedly contracted after death, and it is reasonable to conclude that in many of the cases where the muscular tissue has been found more or less diseased the condition of the cavities was very different. But even could it be shown that the fact was otherwise it would be of no great weight, for it seems most probable that the post-mortem condition of the heart is determined in this disease, as we saw that it was in peritonitis and in similar states, by the amount of contractile energy possessed by the cardiac muscle. If this is great, the cavities close in a kind of rigor mortis, the contractility of the fibre outliving the inhibitory influence of the neuralgic pain; if it is the reverse, as one may conclude where the organ is found thinned, softened, or fattily degenerated, the cavities will remain more or less open. The treatment found most beneficial in angina is evidently such as contemplates a stimulating and invigorating rather than a sedative effect. Opium is, indeed, to be given in tolerably full doses, but this is for the purpose of counteracting and quelling the pain, and not of producing any narcosis of the nervous system. Stokes seems to be averse from employing this remedy when the heart's action is very weak. Stimulants are by general consent accounted our chief remedies in angina, and I am free to confess that I hold with those who look on opium as primarily and essentially (at least, in moderate doses) a powerful though peculiar nervine stimulant. The most practical point for consideration in all cases of angina is whether the breast-pang which threatens to, and sometimes actually does, arrest the heart's action is of organic or non-organic origin. If we are obliged to consider that the former is the case—that the neuralgia has its starting point in a nervous filament pressed upon by a patch of calcareous deposit in the coats of the aorta or coronary arteries—the prospect is, of course, very unfavourable. If, on the other hand, we can hope that some existing rheumatic, gouty, or malarious disorder has produced the neuralgia, we may be more hopeful, though I have known a patient die in whom an autopsy demonstrated the absence of any organic lesion.

Time warns me to close, and I will now only enumerate the principal conceptions which I have endeavoured to lay before you in these lectures.

(1) That of the direct paresis of a nerve or nervous centre as the result of the action of some imponderable influence.

(2) That of inhibitory paresis where the result is produced by some morbid irritation, the vasomotor nerve centres seem to be more liable than others to suffer in both these ways.

(3) That of the influence of nerve-prostration in altering the texture of capillary vessels at the same time that it dilates arteries, thus giving rise to extravasation of blood in greater or less quantity.

(4) That of the paralytic character of neuralgia and hyperæsthesia.

(5) That of the morbid affections of the nervous centres being very analogous to those of the nerves.

(6) That of the affinity between spasm and paralysis.

I am well aware that the grounds which I have assigned for the views above enunciated are insufficient to demonstrate their truth, and when I compare my own work in these matters with the long laborious researches of others, I feel very conscious of short-coming. Still, it is to be remembered that when we come to stand at the bedside, we often feel the want of more than the bare facts which we can ascertain by observation; we need to have also ideas appropriate to the facts, and which may enable us to interpret their meaning aright. I am not without hope that these lectures may have done something to supply such conceptions, or to make them more familiar, and if this be the case I shall be well content.

THE SUBSTANCE OF A

LECTURE

ON NIGHT-BLINDNESS.

SYMPTOMS — CAUSE — PATHOLOGY — RESULTS — TREATMENT.

By HAYNES WALTON,

Surgeon to St. Mary's Hospital, and to the Central London Ophthalmic Hospital.

BEFORE anything else, I shall speak of the names of this defective state of sight. Night-blindness, as used to signify the symptoms, certainly gives a correct idea of the complaint. Short definitions have much to recommend them. It is impossible to include in one or two words both symptoms and pathology, and usually when giving a name it is more convenient to express the former. The high-sounding terms "Nyctalopia" and "Hemeralopia" are, however, those most used; sometimes the one and sometimes the other, and the first has also been applied to another condition of the eye. This is bad every way: it causes confusion and discouragement to learners. Eye subjects in particular are clogged with such impediments, and they are multiplying fast. A new language has lately sprung up. Of course there must be a nomenclature, as also scientific terms, in all sciences; but we should be ever jealous to make as few as possible. It certainly answers every purpose better to use the vernacular whenever an idea can be expressed in it as clearly and concisely. I have always adopted this rule myself, and have always endeavoured to induce others to follow it.

Night-blindness, then, is usually considered a tropical complaint, because for the most part it attacks persons, generally young ones, in tropical climates. But it has been witnessed in a slight degree during the summer time in northern Europe, and among so many persons at a time as to be called epidemic.

A short description of a case in a young man, who was brought to me a few days ago by Mr. Giles, of Hackney, will show the characteristics. This sailor youth had been at home more than a week. He was in robust health. When he was coming from Calcutta, the return voyage of his first trip to sea, he discovered about mid-passage one night after sundown, that he could not see. He groped about with difficulty, a lamp-light gave him scarcely any help, for however much objects were illuminated, he could not see them. When within a week's sail of England his sight returned.

His eyes remained well when at home and during a second outward voyage, but when at the Bombay Harbour, where he had been with his ship for five months, on came the night-blindness, and in a worse degree than formerly. It lasted for four months, and disappeared as before when near home.

That his day sight was not very bad may be inferred from the fact that up to the latest period of the last voyage, he was often sent aloft to keep a "look out." But on this passage there was some evidence of eye irritation, for when the sun was shining, the reflection from the water always produced discomfort.

I could not see from an external examination of the eye that anything was wrong. I found, however, that a very slight degree of near-sightedness had come on, but there was not any impaired vision as regards the definition of minute things, nor in the accommodating power of the eye.

Thus, from the attack coming on after the eye having been used in tropical glare, from being sudden, from the day sight being perfect in the earlier part of the attack, and from the addition of complications when the affection may be said to be chronic, such as the intolerance of light, is the history of these cases told. I do not know if near-sightedness is usual here. Possibly it has nothing to do with the night defect. It is only to add that in very chronic cases the eye may become so diseased that blindness may ensue.

This is the first instance of the kind of all that I have seen, that I have examined with the ophthalmoscope, and the only apparent departure from a perfectly healthy state was a want of the full tint of the arterial and venous colours. My colleague, Mr. Taylor, who has examined several, tells me that there has been in all an anæmic condition of the interior of the eye. I suppose, when the affection runs on to blindness, there are more decided changes to be seen. Possibly some observers have knowledge on this point.

The pathology does not appear to me to be clear. The disease is met with almost entirely in one part of the world, and has, as we may well suppose, for its exciting cause the intense light of that region; but it is a rare affection, while impairment of sight arising out of this very tropical influence is very common, and is always associated with congestion of the eyeball; the surface is highly injected, and so is the interior. There is most marked intolerance to light, and any minute use of the eye causes pain. Sight is best then at night.

When the eye occasionally suffers in a temperate climate after having been subjected to the heat, glare, and dust of furnaces and fires, the symptoms are, according to what I have seen, congestion, or inflammation, and impaired sight. But I have never met with, nor heard of, night-blindness from such a cause. Perhaps it is, that there is naturally or acquired some peculiarity of the eye that predisposes it to this loss of sensibility to feeble light and to artificial light, and afterwards to worse symptoms.

So far as history serves me, the prognosis of these cases is very favourable. Remove the eye from the heat and glare, and complete visual function is restored. Such restoration is not, of course, to be expected, if the change is delayed till the complications have arrived. I was consulted by Mr. Giles to determine whether his patient might go again to sea. I advised most strongly that he should never go again to the tropics, and that it would be better to give up the naval life altogether. The captain had refused to take him again.

ORIGINAL COMMUNICATIONS.

NOTE ON THE

NEW METHOD OF PRODUCING LOCAL ANÆSTHESIA BY NARCOTIC SPRAY.

By BENJ. W. RICHARDSON, M.A., M.D., F.R.C.P.

SINCE the publication of my original paper on the "New Method of Producing Anæsthesia" (see *Medical Times and Gazette* of February 3) I have made one or two observations of importance to which I would direct immediate attention.

I. I find that all the ordinary ethers of the shops contain alcohol, the presence of which substance materially interferes with the success of the process; it prevents perfect anæsthesia, and it causes tingling and burning sensation at the beginning of the process and during the brief period of reaction. I would, therefore, point out that before Practitioners resort to the process they test the purity of the ether they are about to use, by the following simple experiments:—

TESTS FOR ETHER.

(A) Take the specific gravity. The specific gravity should not exceed 0·723.

(B) Try the boiling point. Warm the hands by gently blowing into them the warm breath. When the hands feel as warm as the breath, make the palm of one hand into a cup and pour in one or two drachms of ether. The ether ought immediately to boil briskly without giving any pain.

(C) Test the effect on mucous membrane. Put one or two drachms of the ether in the palm of the hand and quickly take up the ether into the mouth with the tongue. The ether should at once pass off, leaving neither smarting nor burning, nor any sensation except a slight coldness.

(D) Pour a little of the ether on a piece of clean white blotting-paper and lay the blotting-paper on the warm hand. The paper should dry within a minute, leaving no moisture and no smell whatever. If the paper, while drying, yield an odour like eau-de-cologne, there is some alcohol present. If it give a smell slightly pungent, and which hangs about for a

time, there is some methylated compound present. Perfectly pure ether, in a word, leaves no persistent odour.

(E) Try the degree of cold producible by the ether. Charge the bottle connected with the spray producer, and direct the spray on the bulb of a thermometer. The mercury ought to fall rapidly to six degrees below zero Fahr., and the falling of the mercury should continue until there is a deposit of snow on the bulb of the thermometer from condensation of water in the air.

(F) Test the effect on the skin. Direct the spray, at a distance varying from half an inch to an inch and a-half from the jet, on the back of the hand. In a space of time, extending from thirty seconds to two minutes, a slight hoar-frost deposit should form on the skin, followed immediately by a diffuse blanching. The skin is at this moment altogether insensible.

(G) Test the reaction of the ether by litmus. The reaction should be neutral.

These are the ready and necessary tests. A pure ether answers to all of them, and no other ether ought to be used.

For a little time the Profession may experience a difficulty in obtaining pure ether, because it is not commonly vended. At the same time, as there is nothing more required than repeated rectification to render ether quite pure, it will be produced so soon as there is a demand; and, although the prime cost will be increased, it will be saved in the end, because the quantity of ether required for each operation is reduced in proportion to the purity of the fluid. Already, indeed, Mr. Robbins, of the firm of Garden and Robbins, of Oxford-street, has, with his usual promptitude, produced for me an ether which bears all the tests I have described above.

II. I have observed in producing local anæsthesia by this new process that the peculiar hardness of the skin which occurs when the freezing mixture of ice and salt is applied, does not occur. The tissues, on the contrary, are comparatively lax, so that difficult dissections may be carried on with ease and nicety.

III. I have found during the last few days that the application of the narcotic spray to parts of the body subject to neuralgic pain gives immediate relief.

I have only to add, in conclusion, the gratifying intelligence that I have now applied the local anæsthetic in forty-three minor operations with a result of complete success in thirty-six cases, and with more than partial success in the remainder. In those cases where the success has not been absolute, the result has been due to imperfection either in the ether or apparatus, or to deficient experience (unavoidable in all preliminary inquiries) in the mode of application. The reaction has been rapid, painless, and satisfactory.

ON THE

TREATMENT OF FRACTURE OF THE RADIUS AT THE STYLOID PROCESS BY MEANS OF GORDON'S SPLINT.

By Mr. LAWSON TAIT.

Few fractures have had so many painfully ingenious splints devised for their treatment as that common injury to the radius, which generally goes by the name of Colles's fracture, if we except fracture of the patella with the awe-inspiring hooks of the late M. Malgaigne. The French pistol splint for twisting the hand to one side, Dr. Bethune's ingenious pivot splint for twisting the hand to either side, the American splint for twisting the hand down, and some other kind of splint for twisting it up, have all been used, and nearly all given up as insufficient, besides being, for the most part, perfectly intolerable to the patient. Thus it is that we find Sir William Fergusson recommending the ordinary palmar and dorsal straight splints for the treatment of this fracture, and these, I believe, are used by most British Practitioners with the addition of various supplementary pads as required by the exigencies of each case.

In spite of the utmost care most cases of this fracture turn out unsatisfactorily, and many are the actions of damages that have been raised on its account. The reason of this non-success is, I think, very plain; and let any one examine his own wrist, and the following explanation will be clear. Holding the hand straight out in a plane with the forearm, it will be seen that, while the dorsal aspect is almost a straight line, there is a considerable concavity at the wrist on the palmar aspect; indeed, that a line drawn from the elbow to the ball of the thumb would be, so to speak, the chord of a segment of a circle. Thus it is that when an arm, with the radius broken as it is in Colles's fracture, is pressed by two straight splints, one on either aspect, extending from the elbow to the fingers, the upper fragment must necessarily be pressed towards the palmar aspect of the limb; while the lower fragment, which is practically the same in this condition as the ball of the thumb, is pressed in the opposite direction—in fact, that the distortion is only increased by the splints as they press the fragments in the very direction in which they are already displaced. If this be correct, then it is easy to understand the success which has attended the use of Dr. Gordon's splint in the treatment of this fracture, and to believe that it is devised on sound anatomical and mechanical principles—that it really is what all splints ought to be, viz., a dermal skeleton.

This instrument was originally invented and described by Dr. Gordon, of Belfast, the only notice, however, which I am aware that it has subsequently received is in a paper by Mr. Stokes in the *Dublin Medical Journal*. It is composed of two pieces of wood, the one for the palmar aspect of the forearm being about nine inches long, two and a quarter inches wide at the wrist, and three and a half wide at the elbow; the surface to be in contact with the skin is slightly hollowed out to fit the arm, and along its radial border it has screwed to it a wooden bar or pad, which is rounded off at the distal extremity to fit the concavity of the radius; this latter, of course, necessitates that, to fulfil this condition, separate splints are required for the right and left arms.

The pad, in addition to its being rounded off at the extremity, is rounded all along its inner surface so as to press accurately against the radius throughout nearly its whole length, and it is of sufficient height to embrace rather more than half the thickness of the forearm. The other portion of the apparatus consists of a plain piece of three-eighth inch board, two inches and a quarter broad, and two inches longer than its fellow; it is for application to the dorsal aspect of the forearm, and has the surface to be in contact with the skin slightly hollowed, and it likewise has its distal extremity transversely rounded. Its application is effected as follows:—The fracture having been reduced, the limb is retained in position by an assistant, the lower part of the apparatus is then applied, padded with spongio piline or lint, to the radial portion of the forearm alone, and not to the hand. Then the upper splint is to be applied, likewise padded, in such a manner that the proximal ends of the two parts of the apparatus are maintained at the same level, while the distal end of the upper one projects about two inches beyond the end of the radius. For a more particular description and a drawing, see *Dublin Medical Journal*, for February, 1865. The whole apparatus is firmly secured by two small straps with buckles. In this manner no pressure is exerted on either of the fragments but what is calculated to keep them in their correct position. The arm, during the after progress of the case, is recommended to be kept in the position most agreeable to the patient, which will be found to be that of almost complete pronation. In the employment of this apparatus the wrist will be found to be confined only to a limited extent, while the movements of the fingers and carpo-metacarpal articulations are quite unimpeded; thus entirely doing away with the most objectionable condition of stiff joints, which is such an annoyance both to Surgeon and patient for weeks after the common splints have been removed from the forearm.

Shortly before I became acquainted with this splint, I met with two cases of Colles's fracture, in which, in spite of the greatest care I could possibly bestow on them, there still resulted a considerable degree of the deformity peculiar to this particular injury. The first case occurred in an old lady, and the other in a young collier lad; in both the injury resulted from a fall on the palm of the hand. The unsatisfactory results of the ordinary methods of treatment of this fracture having been thus prominently brought under my notice, I was induced to pay special attention to what had been suggested by Surgical authors as to the cause of the displacement and as to the best means of overcoming the resulting deformity. Much has been written on the action of those muscles which some have supposed to be the cause of this peculiar deformity; but I think that this is one of the many instances where muscular action is blamed for ill effects of which it is blameless. The deformity seems to me to be caused solely by the direction of the violence which is the cause of the injury, this being almost invariably a fall on the palm of the hand. The mechanism of the fracture seems to be that when the patient

falls on the hand, and that by its being forced outwards it drags with it the apophysis of the radius, the ligaments breaking the bone rather than yielding themselves. Much the same, indeed, as in the very analogous fracture of the fibula at its lower fourth, where the internal lateral ligaments of the tarsus much more frequently drag away with them the tip of the malleolus externus than are ruptured themselves. Again, the idea that the displacement depends merely on the violence is borne out by the occasional occurrence of a case where the patient falls on the back of the hand, and when the ball of the thumb and lower fragment of the radius are driven upwards and towards the palmar aspect of the forearm. Bearing these things in mind, and looking at the great improbability of fragments so displaced returning spontaneously to their normal position, it seems to me that, in this instance at least, the theories which would attribute to particular muscles the power of drawing particular fragments this or that way, thus producing and maintaining the displacement, are quite needless. What is required in the treatment of this fracture, if we wish to obtain a perfect result, is not mere repose of the parts, which alone is secured by the ordinary straight splints, but such special adjustment of the normal curve of the shaft of the broken radius with its apophysis as will restore their normal relation to each other, and to the corresponding extremity of the ulna. This result theory satisfied me was obtainable by the use of Dr. Gordon's apparatus, and the result in the following cases will, I think, satisfy any one of its utility and success.

Since reading Mr. Stokes's paper on this splint, I have met with two cases of the fracture, both of which were treated by means of it with remarkably pleasing results. The first occurred in the left arm of a boy, about eight years old, who fell from a height and lighted on the palms of his hands. In this case, the deformity was excessive, putting me in mind at the moment of that mysterious symbol connected with our early faith, known to antiquarians as the zig-zag sceptre ornament. He had his arm in the Gordon splints scarcely three weeks; and now, from careful examination of both wrists, it could not be told in which arm the fracture had occurred. The other case occurred in a gentleman, aged 63, whose carriage was upset, and who likewise lighted on his palms. In this instance the deformity was well marked, but not nearly to so great a degree as in the former example. After their original adjustment, the splints were not touched for six weeks, and there now exists not the least deformity. In fact, I had an opportunity of examining this gentleman's wrist within the last few days, and am quite as well satisfied with it as with the other.

Recently Dr. Heron Watson mentioned to me a case of this fracture which he had treated by Dr. Gordon's apparatus with the most satisfactory results. The patient was an adult male, and had met with the accident in the usual way. "The injured limb," writes Dr. Watson, "had been put up in the first instance in Gooch's splints by my House-Surgeon; but when I saw him next day, as he was uneasy, I took them off and applied Dr. Gordon's. They were adjusted two or three times while they were required, which was only four weeks. The original displacement was well marked, and the result was eminently satisfactory, the position of the ulna with reference to the carpus being natural, and the movements of the wrist quite unimpaired; while the rotation backwards and outwards of the styloid process and articular surface of the radius was, if present, imperceptible."

In none of the cases did the patients complain of the slightest pain or inconvenience arising from the apparatus.

CASE OF OVARIOTOMY—DEATH ON THE THIRD DAY.

By W. M. TURNBULL, M.D.,
Physician to the Melbourne Lying-in Hospital.

The following case was sent to me by my friend Dr. Robertson. For the history and details of the after-treatment, I am indebted to the Resident Surgeon of the Hospital, Dr. Mackenzie:—

C. S., aged 33, a native of Ireland, domestic servant, admitted into the Hospital September 12, 1865. She states that she has been troubled for the last eighteen months with irregular menstruation, during which time she began to lose flesh, and her appetite became bad. About four months ago she perceived a swelling in the region of the right ovary, which has gradually increased in size. On admission she complained of a great swelling of the abdomen, loss of appetite and flesh, and great dyspnœa when she attempted to lie down, and that the menstrual discharge was irregular and scanty.

On examination it was ascertained that there existed a large fluctuating tumour in the abdomen. It was felt to the right of the median line, extending above the umbilicus.

September 13.—Appetite bad; tongue slightly coated; bowels naturally costive. Ordered liberal diet; compound rhubarb pills, two to be taken when required.

14th.—A medium-sized trocar and canula, with drainage tube attached, was inserted about one and a-half inches below and to the right of the umbilicus, and about two gallons of dark brown gelatinous-looking fluid drawn off, after which the wound was closed, and a flannel bandage applied in the usual way. The fluid was highly albuminous; its specific gravity 1·020. The urine was not albuminous; specific gravity, 1·015.

16th.—Pulse regular; complains of burning pain through abdomen; takes her food; one grain of opium to be taken at bedtime every night.

18th.—The opium pill makes her feel sick; ordered half a grain of morphia instead.

25th.—Pulse regular; sleeps well; increasing in size; urine scanty, and bowels regular.

October 9.—A consultation, due notice of which had been given, was held with Drs. Robertson, Barker, and Livingston (Dr. Tracy being unable to attend); it was then deemed advisable that ovariotomy should be performed. I may state that the very morning after being tapped, and almost every time when going my rounds, the patient inquired when I was going to operate; she had previously been made aware of the dangers attending the operation.

On the 12th I proceeded to operate. Before doing so, due precautions were taken, as recommended by Baker Brown. I may as well state, at this time I had made up my mind to follow the plan recommended by him. The bowels had been freely moved in the morning by castor oil and enema; the temperature of the room was duly kept at about 70°. Dr. Robertson administered the chloroform. Drs. Barker, Livingston, Thomas, Tracy, and Mackenzie were also present and assisted me. I first made an exporatory incision of about three inches in length in the linea alba, and whilst cutting cautiously down upon the peritoneum, the director was unfortunately passed through it into the sac; this allowed a large quantity of the contents of the cyst to escape, and embarrassed the future steps of the operation very much. After several ineffectual attempts to seize the ruptured portion of the sac the incision was enlarged, and the trocar (Spencer Wells's) passed through the opening in the sac, and attempts were again made to seize it with the hooked apparatus attached to that instrument. With some difficulty this was effected; the hand was then passed round the sac, and several extensive and chiefly abdominal adhesions were found, but being recent were easily broken through. In removing the sac considerable adhesions of the omentum were discovered, which being also comparatively recent were easily destroyed by the fingers; no bleeding followed. The tumour was now drawn outwards: the pedicle was very short; a clamp was applied, which in tightening broke, and two pieces fell into the abdomen; these I at once removed, and applied another. A ligature was then passed close to the clamp, and the tumour removed. The stump was brought to the lower end of the wound, which was united by needles and twisted sutures, one needle being passed close under the clamp. Thick cotton wool was applied over the abdomen, and confined *in situ* by a many-tailed flannel bandage. The patient was then removed to bed, and 40 drops of the solution of muriate of morphia administered, and a hot water-bottle applied to her feet.

12th, 11 p.m.—Pulse 100; tongue and skin moist; no pain.

13th. 9 am.—Pulse 110; tongue moist; slept through the night; has had strong beef tea, barley-water, ice, and brandy through the night; temperature of the room kept between 65° and 70°; urine was drawn off by Dr. Mackenzie every four hours.

14th, 2 a.m.—Pulse 120, feeble; complains of great thirst; is greatly troubled with belching; ordered nothing but ice to suck for some hours. 8 a.m—Belching not so troublesome; ordered champagne and ice. 11 a.m.—Belching relieved; clamp removed from pedicle; wound looking healthy;

light linseed-meal poultices to be kept applied to abdomen. 4 p.m.—Pulse 110; skin moist; tongue dry and irritable; ordered strong mutton soup, brandy, and ice. 8 p.m.—Pulse 120, feeble; abdomen tympanitic; countenance anxious; tongue dry and rough; is inclined to be restless; great thirst. There is a sero-sanguineous looking discharge oozing from pedicle; still takes the brandy and ice and beef tea.

15th, 2 a.m.—Pulse 130, thready; is very restless; complains of no pain; abdomen tympanitic and swollen in right iliac region; thirst very great. 8 a.m.—Pulse 140, very feeble; features becoming pinched; is very restless, wanting to get out of bed; the hot poultices were still kept applied to abdomen; there is considerable discharge from the pedicle. Died at 11·30 a.m. Throughout the treatment occasional doses of morphia were given.

Post-mortem Appearances. — Present: Drs. Robertson, Livingston, and Thompson. On removing the needles and opening the wound, very little attempt at union by the first intention was found. The pedicle of the tumour was very short, and situated on the left side of the fundus of the uterus, which was rather enlarged; the omentum was thickened and collected into a mass. There were adhesions of the ascending colon with the small intestines by bands of lymph. There were no signs of active inflammation about the peritoneum, but there was a small quantity of sero-sanguineous fluid in the abdominal cavity. The kidneys were normal; there was slight cirrhosis of the liver. The uterus was removed, and was sent to Professor Halford for examination. The result of that gentleman's examination, given below, of this body, as well as of the cyst, would evidently point to exhaustion consequent on the malignancy of the disease as being the cause of death.

Remarks.—I consider that it was fortunate the rupture of the cyst took place whilst making the exploratory incision, and not later, as thereby a larger quantity of the contents of the cyst was prevented from escaping into the abdominal cavity. I cannot say that I found the facilities afforded by Spencer Well's trocar and canula to be such as I was led to believe, but perhaps this was owing to the imperfect manner in which the instrument was manufactured here.

This is not the first occasion on which I have considered it my duty to report unsuccessful cases to the Medical journals, and if the statistics of ovariotomy and other capital operations in Victoria are to be of any service, it would be well if my example were more generally followed.

I now come to a very disagreeable subject. I allude to that most ungenerous, to say the least of it, report which has been put into general circulation—viz., that I had thrust the pin through the uterus. I requested Professor Halford to make a minute examination with a view to ascertain if such were the fact. His reply is given below:—

"University of Melbourne, Oct. 25, 1865.

"My Dear Sir,—The ovarian cyst sent me for examination was malignant, partly colloid and partly medullary cancer, the latter in greatest quantity.

"The appearances were such as are described by Paget, Rokitansky, and others.

"The body of the uterus contained also two distinct patches, as large as beans, and its cavity was full of creamy matter of cancer, verified by microscopic examination.

"No pin or any other sharp instrument had passed through the uterus Of this I am certain.

"I am, my dear sir, yours truly,

"George B. Halford."

An Epizootic.—The silkworm disease which has been prevalent in France and other parts of Europe has reached the Caucasus, and is producing great distress amongst the population who get their living by trading in silk.

Charlotte Winsor.—The case involving the life of the convict Charlotte Winsor is still undecided. She has been further respited, the Attorney-General having seen cause for issuing his *fiat* to have argued before the Court of Error the question as to the legality of discharging the first jury without a verdict. In the meantime the wretched woman has made a "confession," admitting that she was present at the murder of Harris's child, but asserting that the deed was done by Harris. This is the substance of a long letter written for publication in the newspapers, but stopped by the governor of the gaol. When informed of her further reprieve she professed total indifference to her fate, and advised her husband to marry again.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

GUY'S HOSPITAL.

HYSTERICAL SPEECHLESSNESS — SPEECH RESTORED BY THE INTIMIDATING EFFECT OF GALVANISM.

(Under the care of Dr. PAVY.)

The following particulars are from the report of Mr. Vaudrey:—

S. C., aged 17, having been occupied as a domestic servant at Tottenham, was admitted into Mary Ward, under the care of Dr. Pavy. Her history, which she gave in writing, is as follows:—About seven months ago, whilst out on an errand in the evening, a man laid hold of her arm and demanded money of her. He tore her jacket, but inflicted no personal injury upon her. She was so frightened that she could neither speak nor move for some time. She, however, at length reached home, although she does not remember how. On her arrival home she had a hysterical fit, which lasted for two hours and a-half, and from that time up to her admission—a period of nearly seven months—she has been perfectly speechless and partially deprived of the use of her lower extremities.

She is healthy in appearance. When spoken to she does not attempt to answer, but shakes or nods her head. The movements of her tongue and lips are free enough for other purposes besides speaking. She can move her legs, but requires support in walking; neither leg, however, is dragged, as in paralysis. Apart from the speechlessness, her other faculties are right. She usually has a fit of a hysterical nature every night, about nine. Catamenia regular, and bodily functions in general healthy.

Dr. Pavy remarked that he believed this to be one of those strange vagaries brought about by hysteria. Here was a girl of healthy and lively appearance, and of good bodily condition, who had not uttered a single word for seven months. Doubtless she had excited the commiseration and sympathy of her friends, but one would have thought it must have been a great hardship to endure to forego speaking altogether for such a length of time. There was evidently nothing physically to interfere with her speaking. She was never to be caught unawares. When spoken to she made no attempt to answer by speech, but was ready to write down her reply. It was difficult to suppose that the girl was a voluntary agent in the part she was performing, or that she was practising a wilful deception. It was more rational to suppose that she was herself deceived—that she was so impressed with the conviction, so deluded with the belief that she could not speak, that she did not make the attempt. Some powerful impression would have to be made to dissipate the delusion. The galvanic shock had succeeded before in such cases, and Dr. Pavy would have it tried in this. An instrument in use by a paralytic patient in the ward was set to work, and the girl made to grasp the handles. The battery was not strong enough to yield a very powerful shock, and she did not utter any sound, although she cried and moved her mouth as though attempting to speak. She was told that a more powerful battery would be used another time if she did not find her voice, and that she was meanwhile to try all she could herself to speak. The next day she had a fit of hysteria, and afterwards uttered some sounds. She now began to speak, and in the course of a few days talked as freely as any patient in the ward. The use of her legs also became restored, and her hysterical attacks disappeared. The medicine administered was sp. ammon. fœt., ℿxx.; inf. valerianæ, ℨj., ter die.

THE LONDON HOSPITAL.

RESUMÉ OF A WEEK'S ADMISSIONS.

BEING THE SUBSTANCE OF A CLINICAL LECTURE DELIVERED WEDNESDAY, JANUARY 10.

(Cases under the care of Mr. HUTCHINSON.)

[Reported by Mr. Waren Tay.]

(Continued from page 120.)

CASE OF FRACTURE OF LONG BONES.

Amongst our cases of fracture we have five of fracture of tibia and fibula. None of these present any exceptions to he

general statement that the lower end of the upper fragment is displaced forwards and inwards, and in three of them this displacement is considerable. Two cases of fracture of the femur have been admitted. Two of fracture of the tibia only, and two of fracture of the fibula only. In one of the latter there was very considerable displacement of the foot outwards and backwards, so that the inner malleolus and lower end of tibia projected forwards and inwards. No doubt the deltoid ligament was completely ruptured. This kind of displacement is often very difficult to deal with, and constitutes a not infrequent complication of Potts' fracture. Two cases of fracture of the humerus have been admitted, one because the patient was very old, and the fracture was of the Surgical neck.

COMPOUND DISLOCATION OF THE ANKLE-JOINT.

Our case of compound dislocation at the ankle joint is of great interest. The patient is a young man, who, whilst resting on one foot, had a heavy weight fall on his back. The result was that his ankle gave way, the inner malleolus being broken off at its base, the external ligaments torn through, and the end of the fibula and tibia driven through a laceration in the skin on the outer side. Mr. Dove sawed off the ends of the projecting bones—about an inch and a-half of the fibula and half an inch of the tibia, and then easily effected reduction. There was some trouble from hæmorrhage from a small vessel afterwards. Ice has subsequently been applied to prevent inflammation. There was no laceration of important arteries or nerves; as the violence was indirect, there was no contusion of the soft parts. You will therefore watch with much interest the result of a compound dislocation at the ankle treated by free excision, and occurring in a young and healthy subject.(a) I have often taken occasion to point out that these cases, however treated, and whatever may be the state of the patient's health, are of very serious nature, and that we very rarely succeed in saving the limb.

DISLOCATION OF THE ASTRAGALUS.

There was another curious case of dislocation of the astragalus. A man fell from some steps, between two of which his foot was caught and most violently twisted. Mr. Dove informs me that when admitted there was great deformity. The foot was twisted inwards and backwards, so that the inner malleolus projected forwards, but there was in addition a rounded bony mass on the instep, which could be no other than a displaced astragalus. It was reduced without much difficulty, and there has been no undue inflammation about the parts since. We conjecture that the astragalus remaining in connection with the tibia had been displaced from the scaphoid and os calcis.

MISCELLANEOUS CASES.

Amongst the cases of contusion, ten in number, we have one in which we believe the kidney is lacerated. At any rate, the patient, after a severe blow on the back, chiefly in the right loin, continued for three days to pass considerable quantities of blood in his urine.

Amongst the cases admitted by governors' letters—*i.e.*, not "accidents"—we have three of unusual interest. A case of syphilitic disease of the larynx with urgent dyspnœa, in which we expected that tracheotomy would have been necessary, but which has been relieved by large doses of iodide of potassium and black wash gargle.(b) A case of soft tumour on the inner side of the knee in a young man, into which, in the belief that it was an abscess, an incision was made, and which has since proved to be one of soft cancer growing from the bone. This patient has refused our recommendation of immediate removal of the limb, and has left the Hospital, and will probably seek admission elsewhere.(c) The pseudo-fluctuation of soft cancer is a fact which often comes under our notice. In the last three cases of soft cancer of bone which I have seen in all an incision had been made in the belief that matter existed. You will well recollect a very interesting case of malignant tumour on the buttock of a young girl, which Mr. Curling removed a month or two ago, in which the sense of fluctuation was so definite that, excepting for the knowledge that grooved needles had been several times thrust into it without result, one might have felt certain that there was fluid. Another case, which I will reserve for future mention, is that of the woman with suspected abscess in one tibia, who has twice previously been in the Hospital, and in whom we have incised the periosteum to-day.

STRANGULATED INGUINAL HERNIA—REDUCTIO EN MASSE—OPERATION—RECOVERY.

I have reserved to the last the most important case of the week. Yesterday morning, on going into the Hospital after lecture, I was informed that a man had been admitted who had had a strangulated hernia reduced by the taxis the day before, and who had been sent in because some doubtful symptoms of strangulation still persisted. I found our patient a healthy man, aged 45. I learnt that he had been the subject of inguinal hernia, and had worn a truss for some years; that his hernia had become strangulated during the night of Sunday. He had sent for a Surgeon as soon as he found that he could not return it; and this gentleman succeeded, after a forcible attempt, in getting rid of the tumour. On the following morning, however (Monday), the tumour was again partly down, and another reduction was effected. Since this last attempt, there had been no protrusion externally, but as the pain and sickness had continued, the man was sent to the Hospital. When I saw him on Tuesday morning, about thirty-six hours had elapsed from the first strangulation. The man's countenance had a somewhat anxious and distressed expression, but his tongue was only a little furred, his abdomen was neither distended nor tender, and his pulse was but little quickened. He had been in the Hospital twelve hours, and although he had felt sick, he had not actually vomited. His bowels had acted on the previous day, but the motion was only a very scanty one.

You will observe that this man had no hernial tumour whatever externally. I could make out the tail of a hernial sac extending about an inch below the external ring, but it was quite empty, and it did not fill when the man coughed. The problem before us was to determine whether an internal strangulation existed. Against such an hypothesis was the very slight character of the symptoms of the obstruction, the freedom with which the man allowed his abdomen to be examined, the absence of urgent sickness, etc.; whilst in the opposite scale we had the fact that, although the symptoms were but slight, they had been sufficient to make the man apply for relief, and that his own conviction seemed very decided that the rupture was not put right. He stated that the hernial tumour had in the first instance almost filled his scrotum; whereas the portion of empty sac which remained was not more than an inch below the external ring. This favoured the idea that the greater part of the sac had passed up with the intestine. I carefully examined the inguinal regions, both in the erect and the recumbent posture, and I made myself certain that a slight degree of fulness and resistance to pressure might be felt on the right side which was not present on the left. I passed my finger up into the inguinal canal, and in the right side I could feel something driven against the finger when he coughed the like of which I could not feel on the left. The fact that the hernia could not be made to come down again by any amount of coughing seemed to favour the supposition that the sac had been reduced, since the inguinal canal was large and the hernia had often been down before, and under ordinary circumstances it ought easily to have come down again. Putting together all these consideration, I ventured to express an opinion that we had to do with a *reductio en masse*. You will easily see, however, that the decision to operate involved great responsibility. On the one hand I was most unwilling to leave a strangulated hernia unrelieved, and on the other I had before me the risk of opening the peritoneal cavity, only to find that that measure was not necessary. We determined, therefore, to wait a few hours; and meanwhile we abstained from doing anything which would complicate the symptoms. Three hours later I saw the man again; he was sitting up in bed with the utensil before him, and, although he had not vomited, he still persisted that he felt very sick. His countenance was decidedly more anxious; his other symptoms as before. When I proposed an operation he willingly assented, and we had him at once removed to the theatre. I made a free incision obliquely over the external ring, took up the little pouch of sac below it and laid it open. Drawing down the sac a little, the distended convex end of a coil of intestine became visible. The nature of the case was now clear. I passed my finger up into the sac, and as high as it could reach I detected a stricture. Having drawn down the sac as much as we easily could, I got my finger under this stricture, and then notched it with the bistoury. Still reduction could not be effected;

(a) The result has been death on the eleventh day, from acute inflammation of the cellular tissue of the limb, sloughing of the skin about the wound, and traumatic delirium.

(b) Tracheotomy has since been required, and the patient is now doing well.

(c) The poor fellow has since returned in a much worse condition, and I fear it is too late to think of amputation.

and on renewed examination I found another and much tighter stricture an inch and a-half higher up. The hernial sac was thus almost wholly within the cavity of the abdomen, being, however, of course, behind the parietal layer of peritoneum between that membrane and the rest of the abdominal wall. My finger passed up so far that one of my colleagues who was assisting me remarked that it must be free in the abdominal cavity. I had some difficulty in bringing this upper stricture within reach, but at length succeeded in dividing it and in returning the contents of the sac. These contents were coils of small intestine much congested. The sac itself would, I think, easily have held a fist.

Having completed the operation, the wound was closed with metal sutures, and we directed that a large bladder of ice should be kept on the abdomen just above it, and that the man should take two grains of calomel and half a grain of opium every three hours. I explained to you that I commenced the calomel treatment thus early in order to get the start of any traumatic peritonitis which might result from the operation. Up to the present time the man has done uninterruptedly well. His abdominal pain and tendency to sickness were wholly removed by the operation, and have not returned.(d)

This case is full of instruction, first, as an instance of complete "reductio en masse," complete, at any rate, so far as the contents of the sac were concerned. This occurrence is, I believe, more common than writers would have us to suppose; at any rate, this is the third case which has come under my own care during the last five years. Secondly, the case shows how slight may often be the symptoms by which strangulation of the intestine is denoted, and very fully bears out the practical rule, "When in doubt, operate." Probably the symptoms were less severe owing to the fact that the strangulation was caused only by the neck of the sac itself, and not by any tense ligamentous structures. Lastly, as to the results of treatment,—I scarcely ever recollect to have seen so good an instance of healing by the first intention after an operation for inguinal hernia, and the incision had been a very free one, and the manipulation considerable. The efficient use of ice had probably a good deal to do with the non-occurrence of inflammation of the wound. As regards the use of mercury, I will not at present ask you to believe that a state of ptyalism is conducive to the rapid healing of wounds; but I will ask you to note this as a clinical fact, that it does not prevent it.

ST. GEORGE'S HOSPITAL.

SUBCUTANEOUS INJECTION OF NARCOTICS FOR NEURALGIA.

(Cases under the care of Dr. JOHN W. OGLE.)

Subcutaneous Injection of Aconitine and Morphia for Neuralgia. Mary K., aged 22, became an out-patient September 11, 1865, suffering from neuralgic pain, which she had had for some weeks, down the back of the left thigh and in the muscles forming the left buttock. This was at times excruciating, and could not be connected with disease of any organ. She was, however, not a very robust person.

Dr. Ogle at once ordered the subcutaneous injection of $\frac{1}{40}$th of a grain of aconitine, and enjoined that she should come again to the Hospital in three days' time, and have $\frac{1}{30}$th of a grain of aconitine injected. Valerian, steel, and quinine were also prescribed.

She experienced a certain amount of relief from the subcutaneous injection, but not so much as was expected; so that on the 18th half a grain of acetate of morphia was injected. After this she complained of feeling "very queer" for three hours, and subsequently passed a restless night, "sleeping and waking," as she said. The next day she felt "weak;" but for two or three days decidedly less pain was experienced. On the 25th the pain had returned very acutely, and therefore $\frac{1}{25}$th of a grain of aconitine was injected. At the end of a week she returned, saying she had received very great good from the last injection, and had been quite free from pain ever since. She was accordingly discharged, as being no longer in want of treatment.

Subcutaneous Injection of Atropia and Morphia in Neuralgia of the Thigh.

Emma G., a rather delicate and pale young woman, was admitted under Dr. Ogle's care on September 6, 1865, with acute pain down the back of the left thigh of a persistent character. There seemed to be no actual disease of any organ. It appeared that she had been previously in the Hospital with a similar attack, which was benefited by subcutaneous injection of some sedative. Accordingly Dr. Ogle at once ordered $\frac{1}{30}$th of a grain of atropia to be injected beneath the skin of the thigh and a senna draught to be given. This produced no good result whatever, and then a draught with half a grain of morphia every night was prescribed, and in a day or two quinine in 7-grain doses twice a day and occasional pills with colocynth and hyoscyamus.

On the 18th Dr. Ogle ordered half a grain of morphia to be injected subcutaneously. This gave a considerable degree of relief, lasting a whole day, and on the 25th it was repeated. She quickly improved after the latter injection, and on Oct. 2 was discharged free from pain. It is right to state that she also had gone on with her quinine daily, and had been taking ordinary meat diet.

Neuralgia of the Face (Infra-Orbital Branch of the Fifth Cranial Nerve)—Relief from Steel, Quinine, and Subcutaneous Injection of Morphia, etc.

Anne V., aged 58, a widow, thin, and delicate looking, had for four months been subject to acute pain extending from below the right orbit to the middle of the upper lip, which was rather swollen. She became an out-patient January 9, 1865. This was wont to come on suddenly, lasting a minute and a-half, as well during the night as day. The pain was described as being like scalding with hot water or violent pricking, and was brought on by lifting up the lip with the finger, sucking, swallowing spittle, eating and drinking, etc. Very rarely the pain was also felt *above* the orbit. Moreover, all along the course of the pain the surface of the skin was *exquisitely hyperæsthetic*. There was a slight degree of drooping of the right upper eyelid, but there was no paralysis of the facial muscles, or of those of the arms or legs, etc. The pupils were natural. There were no teeth in the upper jaw, as they had been extracted or had fallen out from being decayed when young.

The patient thought that her pains began with "cold and great discharge from the nose." The mental powers seemed intact. For several weeks she was treated with steel and five-grain doses of quinine. Belladonna ointment was applied to the painful part, but the patient thought this made her worse at the time: perhaps it was from the friction. On the whole she much improved, the pain still being described as "jarring," "pricking," "throbbing," but in the intervals of pain she was much stronger and more comfortable. As this appeared to be especially so after the use of night pills containing half a grain of acetate of morphia, the same quantity of morphia was injected (February 27) beneath the skin of the right cheek. This gave great temporary relief. She afterwards took quinine with four minims of the tincture of aconite. On March 20 one grain of morphia was injected subcutaneously. Since that time the patient has not presented herself at the Hospital.

Fever is rife in Friars-mount, Bethnal-green. The Divisional Surgeon states that he has attended eighteen cases of typhus and typhoid in two of the houses. The *Times* states—"The place was utterly filthy; there was a want of water, the closets were full, and the drainage inoperative. There was an accumulation of vegetable and other refuse. The result was to be expected."

University of Dublin.—At the spring commencement held in the Examination Hall of Trinity College on Shrove Tuesday, the 18th inst., the following degrees and licenses in Medicine and Surgery were conferred:—*Baccalaurei in Medicinâ.* — Gulielmus Morton Harman, Jacobus Thompson, Gulielmus Robertus Mac Dermott, Thomas E. Little, Alexander Loney, Michael Shanley, Christophorus Armstrong, Ricardus Edgeworth, Samuel B. Gamble. *Magistri in Chirurgiâ.*—Samuel B. Gamble, Jacobus M'Cutchan, Edvardus Kough. *Licentiati in Chirurgiâ.*—Wellington Gray, Ricardus Murray Vesey. The answering of Mr. Little, who obtained the first place at the examination in Medicine, amounting to 87 per cent., may be taken as an illustration of the fact often observed in Dublin University, that those students who distinguish themselves most in the Arts course are also the most distinguished in their Medical studies. Mr. Little, during his Collegiate career, held both a Science and a Medical Scholarship in Trinity College.

(d) This patient has, since the lecture was given, made a perfect recovery. Slight ptyalism was apparent on the third day, and the mouth remained sore for nearly a week. The man had no peritonitis, and the wound united by first intention without the formation of a drop of pus. On the ninth day we were able to order a truss.

TERMS OF SUBSCRIPTION.

Twelve Months (Prepaid) stamped for post £1 10 0
Six Months (do.) 0 15 0

SATURDAY, FEBRUARY 17.

THE GOVERNMENT AND THE CATTLE PLAGUE.

In introducing a bill on the cattle plague on Monday night, Sir George Grey stated that the desire that the most stringent measures might be taken in order to check, if possible, the progress of the disorder and to prevent the consequences which would ensue from its unchecked advances, had been evinced within a short period. Opinion had been greatly changed on the subject, and he felt that this had occurred within a very limited period—not within the last few weeks, but since the week which preceded the meeting of Parliament.

Now, it is certainly very natural that opinion should change during the spread of an evil like the cattle plague. Every week it is more felt by us and is extended to greater numbers of us. Our neighbours' misfortunes naturally concern us much more deeply when experience has opened our eyes to the unpleasant conviction that they are what our own misfortunes are only too likely to be in a short time unless help and protection be vouchsafed to us. Besides, the state of an epidemic visitation materially affects the nature of the means to be adopted. It is, therefore, only as might be expected that those who proposed a set of measures suitable to the occasion when the cattle plague first entered the country advocate different measures, or at least a modification of them, now that it rages through the land. The public demand that active measures be taken has certainly become stronger—so strong, indeed, that no government would be safe that ventured to disregard it; and the conviction has become firmer and more general that certain means only out of the many proposed afford any promise of proving successful in subduing the disease; and no wonder, when the country has been left to learn by sad experience the utter futility of the many recommendations that have been offered upon grounds that a very little of the wisdom in the country, if appealed to and heeded, would have shown to be baseless. Having been left for months by the Government to try means of cure in a thoroughly haphazard way, the country, more awake to its helplessness, now cries out to the Government to save it from itself.

These reasons, however, why a change in public opinion should have taken place, and why a louder voice than before should have been raised by the country in asking that something be done, are not sufficient to account for the feeling that has been excited in Sir George Grey's mind that a great change in opinion had occurred since the week which preceded the meeting of Parliament. But has there been any such sudden change? Is it evidence of such a change that when at last Parliament comes to assemble, the country makes a stir, in hopes of now getting done what the Government has hitherto shown itself so apathetic in undertaking to do? Is it strange that, with fresh hopes, societies should meet, and conferences be held, and resolutions be made, and recommendations be passed, and deputations sent to wait upon Sir George Grey? We think not. The meeting of Parliament, after a period of inaction by the Government, naturally called forth strong expressions of opinion in different quarters. And months of bitter experience, having made many wiser, have made the opinions expressed more unanimous and different from those at first uttered.

But there is nothing new in these opinions. Personal experience has only taught the farmer the truth of what the Royal Commissioners and other competent authorities told the Government months ago. Here is where we feel the Government have contracted the heavy responsibility of having allowed the diffusion of the cattle disease to be as great as it is. Of course, enlightened measures, proposed with foresighted knowledge, are sure to be attacked by the interests which they have to interfere with; but this is no reason why they should not be brought forward. The wisdom of adopting them would be made patent by the discussion they would receive. The Government should not have so long disregarded the statements of its official advisers. It cannot for a moment attribute, with any show of reason, its inactivity to the differences of opinion held by skilled men on the subject.

The Government was cautioned in 1857 in the reports of the Consul-General in Poland, copies of which were laid before the House on Monday, about the means by which the Steppe murrain might enter our country, and informed of the uselessness of treatment hitherto, and of the only means at all successful in arresting its progress. When the cattle plague appeared in the land, overwhelming evidence of its identity with the Russian distemper was received by the Government. Hence it could know the terrible mischief of inactivity in repelling the inroads of the disease; and it could know, also, how surely certain means of meeting the enemy would fail, and certain others as surely succeed. This was not all; it was told that the disease was without doubt closely allied to human diseases, such as scarlatina, typhus, variola, and others, for all of which no curative treatment has ever been made out. It therefore learned that no *cure* for cattle plague could be looked for with any degree of hope, but, at the most, only an improved system of nursing. It could thus see the force of the recommendation to slaughter at once; for the disease was very fatal, and where recovery was to be hoped for there would be a long retention of a return of infection, which could hardly be prevented from spreading the disease. On the other hand, it could see the shallowness of the objections raised by some popular organs against the adoption of slaughtering instead of attempts at curing. We were not to kill merely because we knew of no successful line of treatment for a very virulent distemper, but because, while trying to save one very doubtful life we were risking hundreds of others. These were points upon which it was informed, and by those who, as members of our Profession and from their eminence among us, deserved the full confidence of the Government on such a subject. As to the means for carrying out the ends to be aimed at, the Government must surely have seen how impossible it was for them to be effectually put in force without its active interference and assistance, and this being so, it seems deservedly to fall under the censure of having been so far heedless of the public welfare.

However, it is now at last in action. Let it show the country that it is going to make up, so far as is possible, for the past by adopting means which must certainly go far to quell the advance of the disease, if not fully successful in doing so. By the provisions of the Ministerial Bill, all diseased animals are to be imperatively slaughtered; but other animals which have been exposed to infection from these are only obliged to be slaughtered by the orders of local authorities. This arrangement, if put in force, will surely prove imperfect in its purpose of exterminating the sources of disease. The slaughtered animals are to be buried at least six feet deep. Disinfection of

the places contaminated by diseased animals is to be practised, and fresh animals are not to be removed into them.

As regards the movements of cattle, the restrictions it is proposed to enforce are assuredly insufficient. Cattle can be removed by license during the day, and it can hardly be supposed that, in every case, the license will be granted with sufficient circumspection to ensure that the sources of contagion may not still be diffused through the land. We were glad, therefore, to see that Mr. Hunt introduced a bill on Monday, of which one provision is, that cattle traffic shall be totally suspended by road and rail. A strong support was given to this proposition; and a most influential meeting held the same night in the tea-room of the House of Commons passed resolutions denouncing the movement of cattle along common roads and railways. Railway cattle traffic at least ought to be totally suspended, since it seems impracticable to carry out any regulation of it with sufficient care. There was one point of great interest mentioned by Mr. Hunt in the debate on Monday respecting railway transmission of cattle. He stated that there was a moral certainty that in Northamptonshire animals were infected by trains of diseased cattle passing through it, for in every case in the county they had been able to trace the origin of the disease, except in most of those cases occurring adjacent to the railway, unless they were attributable to this cause.

In the new Report of the Commissioners which was presented to the House on Monday night, some evidence is afforded of the spreading of the disease by contagion. Whether the disease has had or continues to have spontaneous origin in this country, we learn from the Report that the great breeding districts of the kingdom into which cattle are seldom imported have remained comparatively free from the disease; and that from the centres of contagion on the eastern coast the disease has travelled west or south-west, traversing alike low and elevated lands, having been apparently uninfluenced by varieties of soil.

The successful mode of arrest of the disease in France and Belgium by means, it is to be hoped, we are now at last about to adopt, and the operation of the Orders in Council issued from time to time by our Government, are fully gone into in the Report. The system of investigation of the disease with the view to establish a sound basis for curative or preventive treatment is explained. It also contains a statement of "some of the points of more or less practical moment at which the Commissioners have arrived." These are:—1. That no thoroughly efficacious treatment of the disease has been discovered. 2. That vaccination is no protection against the plague. 3. That the only means of combating it consist in the stoppage of the movement of stock, and of things likely to be vehicles of infection, in the isolation and slaughter of infected cattle, and in the use of disinfectants.

FENIAN STATISTICS IN THE "LANCET."

Our contemporary, the *Lancet*, in its first leader in last week's issue, has stumbled upon the most extraordinary statistical mare's-nest which ever rewarded the search of "a professed grievancemonger," and has proceeded to build upon this frail basis a sensational superstructure of most portentous dimensions. It appears that certain Fenian prisoners, who are described in one part of the article as "men of active mind and impatient temperament," and in another as not having "much cerebral matter to experiment upon," have been sent to Pentonville, where, in common with other prisoners who have earned sentences of three years and upwards, they are to spend six months or so in separation, with all its horrors, added to the cruel obligation of keeping their cells clean. These men may also, if they please, bring upon themselves floggings and the "black hole," by not conforming "minutely to a strict system of rules." But the worst remains to be told. Madness looms in the distance; and statistics which scaree madness itself could imagine, or imbecility believe, vindicate to the full the scandalous dictum that "anything may be proved by figures." But, strangely enough, the awful figures are not the figures of Pentonville, but of Chatham. It is not the separate system of the first that is accountable for the results, but the associated labour of the last prison. But, as Chatham is partly fed with convicts by Pentonville, it is probably intended to assert that the results reported are really due to the six months' confinement which the fraction from Pentonville had to undergo before they left it. Be this as it may, the writer in the *Lancet* contrives to find in "the 'Convict Prison Report' for 1863, that out of 852 convicts received at Chatham during that year, 85 had to be sent to the Asylum at Broadmoor." This beats Mr. Reade's fictions hollow. It would, indeed, be time to mend, if not too late to do so, if these awful statistics, or anything like them, were true. But, fortunately for us, Blue Books are cheap and easy of access, and the "Prison Report" for 1863 explains itself without much questioning. The figures are absurd and incredible on the face of them, but the explanation is at hand. The convicts sent from Chatham to Broadmoor were destined, not to be shut up as madmen in the Asylum, but to work, under proper superintendence, on the still unfinished grounds of the establishment. In turning over the leaves of the report we think we see statistics which, if carefully studied, would comfort Mr. Pope Hennessy, Mr. Reade, and our benevolent contemporary himself. To each and all we commend the proverb of the novel and play, "It is Never Too Late to Mend,"—even in the matter of statistics.

HOSPITAL DOCTORS AND WORKHOUSE PATIENTS.

One good always leads to another, and we are quite sure of being uncontradicted when we say that whatever would give pay, status, and dignity to the Medical attendants of the poor would secure also greater skill and kindness for the poor patients.

Here is an astonishing contrast. England is dotted here and there with Hospitals supported by voluntary contribution or by charitable endowment, varying in size from Mr. Napper's Village Hospital with its half-a-dozen beds to the stately St. Bartholomew's or Guy's with as many hundreds. The Medical offices attached to these Hospitals are regarded as the prizes of the Profession, and the holders are looked up to and respected as the best and highest in the Profession.

Again, in every union there is what is virtually a Hospital, though it pass under the name of sick wards of the Workhouse or Workhouse Infirmary. This Hospital is supported out of the public rates. If the parish be a rich one, the sick poor may have nothing to complain of; but if it be poor, the space for the sick is small, the Medical staff scanty, the nursing and diet inadequate, and the Medical officer a man who works hard for a small pittance, and with no honour, status, or prestige to act as compensation.

The buildings which we are accustomed to call the Hospitals—that is, those supported by voluntary contributions—so far as London is concerned, provide barely 4000 beds. But in the Workhouse Infirmaries the number is at least four times as many. Yet the former are considered the *public* institutions; they are the places to which Practitioners attach themselves for distinction's sake, and pupils for the sake of study; and they have each a large staff of officers to attend on the sick, and not only so, but to take note of facts worthy of record; so that they are, as it were, the head quarters of scientific Medicine.

As for the Workhouse Infirmaries in London, there are men such as Godrich, Bloxam, Randall, Rogers, and others who hold office in them, quite capable of practising or teaching, but where are the pupils? There is no staff, no registrar, clinical clerk, nor pathologist; there is plenty of material, but no scientific result.

We are glad to know that there is at last a "Society for Improving the Condition of the Sick Poor in the London Workhouses." It is not a "benevolent" society in the ordinary sense of the word, as it will give nothing away directly in charity. Neither is it a perpetual association, with collectors and annual guineas. It is designed, now, at the opening of the new Parliament, to put a pressure on the Government and the Poor-law Board to effect a reform and consolidation of the Infirmaries of Workhouses, and to procure for them the status and organisation of other Hospitals properly so called, and when its work is done to vanish. We wish the Association every success, and may refer such of our readers as take interest in the subject to Dr. Anstie, Mr. Ernest Hart, and Dr. Rogers, the hon. secretaries.

If we may venture on one word of criticism, we would urge the promoters of this scheme carefully to define their objects, so that they may not be met with the accusation of attempting impossibilities. Workhouse Infirmaries at present serve first, for that proportion of the regular inmates of the Workhouse who are sick—and as the regular inmates include the old, disabled, broken-down, lame, halt, blind, and drunkard, that proportion is a large one—probably one-half. Secondly, they serve as places of refuge for persons who have received sudden hurts or illnesses not usually received into general Hospitals, by which they may become chargeable to the parish. Thus, maid-servants discovered to be with child, domestic servants who become lunatic, or affected with small-pox, and the like, are sent off *instanter* to the Workhouse Infirmary. Thirdly, in low neighbourhoods, certain cases of acute disease are sent in from crowded rooms, kitchens, and other poor dwellings, in which the sick can have neither quiet, care, cleanliness, food, nor nursing in any shape. But alas! it must be obvious that in large parts of many parishes there is not a single room inhabited by a family that is fit for a sick person to be treated in—more especially if the disease be infectious. But it would be clearly injudicious to propose Hospital accommodation for too large a mass of the out-pauper population. Let the improvements be confined at first to the Infirmaries for the regular inmates of Workhouses.

Then, in the next place, one word for the ratepayer. There seems to be an inexhaustible fund of philanthropic Billingsgate applicable to that much-suffering Briton, the ratepayer. The epithets, greedy, pinching, mercenary, skinflint, inhuman, jobbing, low, uneducated, heartless, and grasping, are applied without mercy to ratepayers, and to such of their members as are elected to serve on representative vestries. Does it ever occur to those philanthropic vituperators that ratepayers may be poor—struggling, half-starved, denying themselves, to pay their way; frugal; pinching themselves to be able to pay their workmen on Saturday night, whilst said workmen, being true rate-eaters, squander their money in gin and prate Liberal politics at public houses? There is no reason why the provision for the destitute should be laid solely on the man who hires a house. Rates are heavy enough already on the industrious tradesman. Take rather the money from the Consolidated Fund, so that the consumers of beer and tobacco, the lodgers, the idlers, and the hoarders may contribute their just share.

Anyhow, Medicine will be benefited by the establishment of institutions in which comfort to the sick and the promotion of science go hand in hand.

THE THERMOMETER IN DISEASE.

Much attention has of late years been paid to the temperature of the body in disease, and much practical information has been gained from this study. We therefore propose to lay before our readers an account of the help which we may get from the temperature of the body in the diagnosis, prognosis, and treatment of disease.

To Traube, Baerensprung, and Wunderlich on the Continent, and to Parkes and Sidney Ringer in England, we are chiefly indebted for the information we possess on this subject. By the use of the thermometer we are enabled to distinguish between diseases the symptoms of which are so similar that the most practised must wait for the disease to declare its true nature by its further development. Such cases constantly present themselves to the Practitioner. They baffle his skill, compel him to postpone his treatment, and they may injure his reputation. In such cases the thermometer, by the evidence it gives of the temperature of the body, often affords us a certain means of diagnosis.

A patient is suddenly seized with a severe pain in the side. This is increased by breathing, coughing, or pressure on the chest. The expression is anxious, and the breathing is hurried and superficial. There may be slight cough. The pulse beats quickly and feebly. Sleep is prevented and the appetite becomes impaired. By a physical examination of the chest we find that the painful side expands imperfectly. The percussion note may be slightly dull and the respiratory murmur is weak and jerking.

This group of symptoms is unfortunately too common. Have we here a case of pleurisy or pleurodynia? How are we to decide? The pain is of itself sufficient to explain all the symptoms and physical signs. This prevents the free play of the chest, and consequently the movements are hurried, jerking, and abrupt. It quickens and enfeebles the pulse; it prevents sleep. The pain and want of sleep impair the appetite. On account of the impairment of the movement of the chest walls, the respiratory murmur is weak on the affected side.

In such a case the presence or absence of cough and the state of the pulse may afford much information. But this evidence cannot be implicitly relied on. With pleurisy there is always some cough, and, owing to the fever which accompanies the disease, the pulse is quickened. Neither of these symptoms usually occur in pleurodynia; but cough due to some bronchitis may be present in pleurodynia, and pain, or fear, or the excitement caused by the visit of the Medical attendant may cause the pulse to beat quickly. Pleural friction often cannot be detected by auscultation. But pain is common to both pleurisy and pleurodynia. This pain, as we have seen, may produce all the symptoms and physical signs that are often present in either disease. The diagnosis, therefore, at the onset of the attack becomes in some instances impossible, and must be postponed till well-marked physical signs are developed.

Fortunately, by means of the information that we gain by the thermometer in very many cases we can at once decide the true nature of the disease in question. Pleurisy is an inflammatory disease; pleurodynia is not so. *In all acute inflammatory diseases the temperature of the body is raised.* Hence in all cases of pleurisy the temperature is considerably raised at the very commencement of the attack. In pleurodynia the temperature remains normal. The temperature of the body in health varies from 97° to 99·6° Fah. In pleurisy it rises to 101°, or even to 105° Fah.

On the other hand, with such an elevation of the temperature as that just mentioned, occurring with the symptoms detailed above, we are justified in diagnosing pleurisy. It is true that this elevation may be caused by some co-existing disease. This, however, is a rare coincidence, and such co-existing disease can be mostly detected; therefore, in the absence of such co-existing disease, our diagnosis must be pleurisy, and the event will justify such a conclusion. Should it be urged that the hand can detect this elevation, and that thus the use of the thermometer is uncalled for, it may be answered that, firstly, if the hand alone be employed, much error is liable to be incurred; for a dry skin of natural temperature may feel preternaturally hot, while, on the other

hand, a hot but moist skin may feel to be considerably cooler than the temperature indicated by the thermometer.

As a means of estimating the amount of preternatural heat, the hand is all but useless. But it is important to obtain an exact estimate of the elevation of the temperature; for by careful observations it has been shown that *the degree of elevation is proportionate to the severity of the disease that causes it.* Hence the amount of preternatural elevation of the temperature forms one of the most important factors on which the prognosis is made. This exact information the thermometer alone can give us. Nor are the other symptoms, individually or collectively, at all to be compared to the temperature in this respect; *for in every case of fever, no matter from what it originates, the temperature is elevated, and this elevation of the temperature is the only constant symptom of fever.* It alone is pathognomonic of fever. Thus fever and preternatural heat of the body are used as synonymous terms; for the pulse may beat with the frequency of health, the tongue may be clean, and even the appetite good, and thirst may be absent; but there is always preternatural heat of the body if fever exists. Thus cases are recorded (and such frequently occur to those who use the thermometer) where from the presence of various symptoms grave disease was apprehended, while an appeal to the thermometer negatived this assumption; or from the apparent mildness of the symptoms an unimportant complaint has been suspected, when the thermometer has indicated some grave affection. In all these cases the predictions made by the assistance of the thermometer have proved correct. The following cases illustrate these remarks:—

A girl, aged 18, was admitted into Hospital. She was extremely weak, so that she had to be assisted into the ward. She had been ill eight days. During this time she had suffered from severe frontal headache and some diarrhœa. The motions were liquid. The tongue was thickly coated. The attack had commenced insidiously. There were no typhoid spots, and her abdomen was not distended. Her sister was at that time in the Hospital under treatment for typhoid fever. These circumstances were sufficient to render it highly probable that she suffered from typhoid fever. Her temperature, however, was normal, and thus our diagnosis was corrected. In two days she had so far recovered as to be able to dress and walk about the ward, and in a few days more she left the Hospital.

A girl, 22 years of age, was admitted into Hospital a month after her confinement. She felt slightly indisposed. Her appetite was good and her tongue clean. She assisted in the work of the ward. On careful examination very slight tenderness of one breast was discovered. Of this, however, she had not previously complained. Her temperature varied between 101° and 102° Fah. In a few days the breast became much enlarged, hard, red, and tender, and subsequently an abscess of considerable size formed.

While advocating, however, the use of the thermometer, we by no means wish to lead our readers to the conclusion that the information it gives us enables us to disregard the remaining symptoms; for it is from these latter that the diagnosis must be mostly made. It is from these that the greatest information in respect of the treatment is obtained. Much care is necessary in the use of the thermometer. It is, therefore, advisable that we should make a few remarks respecting the method of its application.

The temperature of the body should be taken by a thermometer placed in the axilla. The patient should be in bed and undressed; otherwise the temperature of the surface of the body may be considerably below that of the internal parts. A difference of 2°, or even 3°, Fah. can easily result from the non-observance of this precaution. The patient should be in bed an hour before the temperature is taken, as this time is often regulated before the surface of the body recovers from the effects of the previous exposure. The patients should be placed diagonally on the right or left side; for if placed on their back patients are apt in their anxiety to retain the thermometer in the axilla to press the arm too firmly against the side. The axilla is thus converted into a cavity in which the bulb of the thermometer moves about loosely without coming thoroughly in contact with the tissues. This is specially apt to occur in emaciated people. On the other hand, if placed quite on the right or left side, the distal end of the thermometer becomes depressed, thus rendering the reading of it difficult—nay, sometimes the column of mercury divides when part gravitates down the tube, giving a fictitious result. If, on the other hand, the patient be placed neither completely on the back nor side, but in a medium position, these objections are obviated; for the parts then fall naturally together, no muscular effort being required to retain the thermometer. Care should be taken that the patient has been previously covered up, and that the axilla has not been exposed; otherwise a difference of 2° or 3° Fah. may result. It is, therefore, better, if the patient has been lying on one side, to turn him diagonally on the other, and to use the axilla which was previously most dependent. Care should be taken that the thermometer be in complete contact with the skin, and that no clothes are in the way to separate it from the surface of the body. All these precautions being observed, it is better to allow the thermometer to remain in the axilla at least five minutes. The temperature should be taken twice in the day—at 8 a.m. and 8 p.m. If only one observation can be made in the day, the evening must be chosen, for often the temperature is normal in the morning, but very considerably elevated at night.

It is better to use a thermometer constructed for the purpose. Those of the ordinary make are often untrue, and are always difficult of application. Trustworthy and suitable thermometers can be obtained of Mr. Casella, of Hatton-garden.

THE WEEK.

DEATH OF PROFESSOR BRANDE, D.C.L., F.R.S.

We have this week to record the death of a veteran in science. William Thomas Brande, Assayer to the Mint and Honorary Professor of Chemistry in the Royal Institution of Great Britain, after a life spent in the advancement of science, died at his residence at Tunbridge Wells on February 11, aged 80. Although his life was a long one, the announcement of his death will be read with surprise by many who knew him, for his green old age and remarkable retention of mental powers still promised years of activity. Professor Brande was educated at Westminster School. He loved chemistry from his boyhood, and has recorded in the Introduction to his Manual that on a half holiday it was his greatest pleasure to steal away and gratify his taste at the Royal Institution. His first chemical instructor was Mr. Charles Hatchett, who introduced him "as a boy fond of chemistry" to Sir Humphry Davy. Brande afterwards went abroad, but on his return renewed his acquaintance with Davy, which grew into an intimacy that lasted until Sir Humphry's death. When Sir Humphry resigned the Professorship of Chemistry at the Royal Institution, he recommended Brande as his successor. After delivering a probationary course of lectures, the latter was unanimously elected to the chair on June 7, 1813. Several letters published in the memoir of Davy, in the Introduction to which we have referred, testify to the affectionate regard which he bore to his successor. Brande's works on chemistry have been in the hands of generation after generation of Medical students, and his last volume, written conjointly with Professor Taylor, showed that the advance of life had not left him behind in the advance of science. At the time of his death he was engaged in editing a Dictionary of Science, Literature, and Art, of which, we believe, the first three parts only have appeared. He was a Member of the Society of Apothecaries and Professor of Chemistry and Materia Medica

at the Hall. He had, however, for some years discontinued lecturing, but he still superintended the examinations for the prizes offered by the Society. He was one of the last links between the times of Sir Humphry Davy and the present, and he leaves a name as a chemist which will endure for long years yet to come.

OVARIOTOMY AND JOURNALISM IN VICTORIA.

We print this week four documents from the other side of the globe. The first is a case of unsuccessful ovariotomy by Dr. Turnbull, quoted from the *Medical and Surgical Review* of Nov. 1, 1865; the second is a letter from the same periodical, signed NO_5, a signature which is the formula for nitric acid, and aptly symbolises the sour, uncharitable tone which the writer permits himself to adopt; the third is a letter from Dr. Turnbull to ourselves, conceived in a manly, frank spirit, and showing a not unnatural indignation against NO_5; the last is an announcement from the publisher that he has resolved to discontinue the *Medical and Surgical Review* from the difficulty of finding an impartial editor. How is it that members of a Profession whose scope and aim is to do good are so uncharitable to each other?

SIR CHARLES BELL'S WATERLOO SKETCHES.

It was known to members of his own Profession that Sir Charles Bell united to his eminent character as a Surgeon and Physiologist the accomplishment of being a rapid and effective draughtsman. The class drawings by which he illustrated his lectures, executed by his own hand in water colour, were distinguished for breadth, form, and truthfulness, without appearance of undue labour bestowed upon them. It is told that it was his custom to work upon these drawings on the easel with large, fully-charged brush, while dictating at the same time the subjects of his various publications. Among them his former pupils will remember a series representing soldiers wounded at Waterloo. They were seventeen in number, and were made from sketches which he took shortly after the battle in the Hospitals at Brussels. Inspired with a strong interest in the subject of gun-shot wounds, as soon as intelligence of the great victory reached England, Sir Charles Bell hastened, with others bent on the same good object, to lend his assistance to the wounded. On a former occasion, when the men wounded in Sir John Moore's campaign, closed by the battle of Corunna, were being brought to our shores, he took up his abode at Haslar Hospital, that he might the better study their condition and be of service; and during the subsequent Peninsular War he paid frequent visits to the sufferers in the York Military Hospital at Chelsea. In that respect he followed the example of his senior brother, John Bell, who, prompted by a zealous desire to impart the best instruction he could give to the youths then about to be sent out as military or naval Surgeons, left Edinburgh, on the occasion of the victory of Camperdown, and lived among the wounded, for a time, in Yarmouth, making sketches or drawing up cases, which afterwards enriched his works on Surgery. Thus, when Sir Charles Bell found himself surrounded at Brussels by crowds of severely-wounded soldiers, French as well as Allied, in the churches or extemporised Hospitals, he was not inexperienced in the kind of their injuries. Most of the days, from the eleventh to the sixteenth after the battle, were occupied, early and late, in consultations and operations; yet he had time for the exercise of his ready pencil. His sketch-book contains above forty figures of soldiers seriously maimed; and, regarding them as sketches, what one chiefly remarks concerning them is the large significance of the few, well-directed, decisive lines of which they consist. On the margins of the drawings he has written brief, expressive notes as memoranda. Besides that, he had carried with him an interleaved copy of a dissertation on gunshot wounds, published by him some years previously; and he jotted down numerous remarks in it for future use. Moreover, for some time after he left, he was furnished with reports of the progress or termination of the cases in which he was principally interested, by the Army Surgeons who succeeded to the care of the patients, and many of these letters have been preserved. The seventeen class-drawings, the original sketch-book, and the note-book referred to, the widow of Sir Charles Bell has just presented to the country, through the Minister of War, to be placed in the School of Military Surgery at Netley. Before they are sent away from London, the Council of the Royal College of Surgeons have allowed them to be seen in their Museum during the ensuing fortnight.

Mr. Wormald, the President of the College, has just presented another series of seventeen drawings by Sir C. Bell to the library of the College, and Sir William Fergusson, at the same meeting of the Council, presented an original drawing, by John Bell, of the fatally-wounded admiral at the battle of Camperdown.

GORE V. WALPOLE.

This case, which occupied the Court of Queen's Bench for nearly two days, was an action brought against the Right Hon. Spencer Walpole for an alleged wrong to the plaintiff in 1858, when Mr. Walpole was Secretary of State for the Home Department. According to the *Times'* report, the case in substance came to this:—

That in 1856 the plaintiff was a prisoner in the Queen's Bench Prison for debt, and upon proper medical certificates that he had become of insane mind, he was removed, under a warrant of Sir George Grey (then Secretary of State for the Home Department), to Bethlehem Hospital. In 1858, upon the medical certificates given by Dr. Wood and Mr. Helps, that he had became again of sound mind, Mr. Walpole, then Secretary of State, issued his warrant to remove him back to the Queen's Prison, there to remain until liberated in due course of law. In 1861 he was released under the Insolvent Debtors' Act, and he then brought his action against Sir George Grey for issuing his warrant to remove him to Bethlehem. The case was tried before Lord Chief Justice Erle, and, as the plaintiff raised the issue of his sanity at the time of his removal, there was evidence on that point, and the trial occupied two days. The jury determined against him, and the question of the legality of the warrant was carried to a Court of Error, and there decided against him. The plaintiff then brought the present action against Mr. Walpole for issuing his warrant in April, 1858, to remove him back to the Queen's Bench Prison, his case being that, as he had been illegally removed to Bethlehem, the Secretary of State had no power to remand him back to the Queen's Bench, but was bound to release him absolutely; and as he had not done so, but had remitted him back to his former custody, he was answerable for its continuance, though he admitted that his original custody in the Queen's Bench Prison was lawful. So that the action was in effect for taking him out of Bethlehem, and as the first action was against Sir George Grey for putting him into Bethlehem, so the present, against Mr. Walpole, was for taking him out. The defendant—Mr. Walpole—who, it will be borne in mind, ceased to be Secretary of State in 1859, pleaded, first, a denial that he had caused or was liable for the plaintiff's confinement in the Queen's Prison; and also pleaded the Statute of Limitation, which, in actions of trespass, is four years. He further pleaded a justification, in which, without stating that the plaintiff was insane when removed to Bethlehem, he stated that certificates of Medical men were duly issued under the statute that he was so, and then stated that afterwards, in April, 1858, upon certificates of Dr. Hood and Mr. Helps, 'duly' given under the statute, he duly issued his warrant under the statute for his removal to the Queen's Prison. The plaintiff took issue upon the plea, and in opening the case to the jury insisted that this plea raised the question of his sanity when he was removed to Bethlehem; and stated nothing against Mr. Walpole, except that he had issued the warrant for his removal from Bethlehem, which, however, he did not prove.

The plaintiff conducted his own case, and certainly did not thereby increase his chance of obtaining a verdict, the Lord

Chief Justice having great difficulty in keeping him "in order." Dr. Hood gave evidence as to his mental condition when in Bethlehem, and the jury found that the plaintiff was of unsound mind at the time of the original confinement in Bethlehem. We do not quote the case as one of direct Medial interest, but as a rather interesting psychological study, in so far as it illustrates the mode in which "a gentleman of exceedingly subtle and ingenious mind," as the plaintiff was termed —somewhat emphatically, we think — by the Lord Chief Justice, may harrass those who have had the misfortune to be obliged to meddle with him; and it is very noteworthy also as showing that others besides Medical men may, by the license and liberty of the law, be legally attacked for humanely following their duty by men of the plaintiff's temperament and mental characteristics. The Solicitor-General remarked that the plaintiff had earnestly desired what had been done, and sued Mr. Walpole for acceding to his own request. But for Mr. Walpole, he would have remained in Bethlehem to this hour. Mr. Walpole had taken him out, and for that he was sued in this action—one of the most absurd, groundless, and vexatious actions ever brought. And the Lord Chief Justice, in his summing-up, told the jury that "a more cruel, groundless, and ungrateful action never was brought." Very few will dispute this; but we think we could quite match it with not a few cases of actions brought against Medical men, though we fear we should find some difficulty in showing such warmth of sympathy with a Medical defendant by the presiding judge. Some points as to the legality of the warrants were left still to be tried, and, "lest the objections to these should prove well founded," the jury, having given the verdict we have mentioned, also gave the plaintiff "one farthing damages, conditionally only." Truly wonderful are the mysteries and the subtleties of law!

FROM ABROAD.—TREATING WOUNDS BY PNEUMATIC OCCLUSION—A NEW GALVANO-CAUSTIC KNIFE—CONGENITAL DISLOCATION OF THE CRYSTALLINE.

M. Jules Guérin, who during the last thirty years has been developing the principles and practice of subcutaneous Surgery, read at the last meeting of the Academy of Medicine a memoir on the "Treatment of Exposed Wounds by Pneumatic Occlusion," intending by this not very well expressed title to indicate the action of an apparatus which he has contrived, by the aid of which open wounds involving the skin and subjacent parts may be assured of a protection from the action of the air analogous to that afforded by the skin in the case of subcutaneous wounds, and therefore, freed from suppurative inflammation, enabled to heal by immediate union. After trying a long series of experiments by covering the wounded surfaces with various substances capable of isolating them from the atmospheric air, and finding these one after another fail, either by reason of the penetration of the air or the accumulation and putrefaction of the products of secretion and exhalation—he believes that he has now devised an apparatus capable of successful application. Envelopes of various forms and dimensions formed of vulcanised caoutchouc are adapted to any part of the body, and when applied to the injured part they are introduced into a metallic receiver, which is kept constantly exhausted. Between the wounded surface and the caoutchouc envelope is placed a very thin, permeable tissue, in order to facilitate exhalation from the surface. Capable, as M. Guérin believes, of a very wide application, this apparatus has at present been tried in the following cases—viz., (1) An excoriated wound left after the removal of a fibrous tumour from behind the malleolus, was covered with some waxed silk and placed in the air-tight apparatus, rapid cicatrisation without suppurative inflammation following. (2) In a fracture of the forearm, with a fragment of the radius penetrating the skin, the same mode of dressing was applied, and at the end of the fourth day, the wound of the skin having become closed, the case was treated as a simple fracture. (3) After an amputation of the thigh the flaps were brought together by seven points of suture, and the stump having been placed in the apparatus, cicatrisation was found to have become completed by the seventh day. As it was not sufficiently solid, however, the apparatus was re-applied until the eighteenth day; neither fever, suppurative inflammation, nor notable pain occurring during the treatment. (4) The palm of the hand having been much shattered by the explosion of a cartouche exposing the metacarpo-pharyngeal articulations, fifteen sutures had to be applied to bring the fragments of skin together before the part could be placed in the apparatus. Once there, however, all suffering ceased, elimination of mortified parts taking place with ease, and excellent cicatrisation following.

At the Société de Chirurgie, M. Broca exhibited a new galvano-caustic knife, invented by M. Séré, of the Military Hospital at Vincennes. The blade of this knife, formed of platinum, can be heated as high as 1500° C. by the passage of a galvanic current from a Grenet pile. Platinum being a soft metal, this blade has no cutting edge, but it acquires an excellent one under the influence of the electrical heat, which instantly communicates to it a special temper, the blade again becoming blunt upon the abatement of the heat. At 1500°, a white-red heat, the vessels cleanly divided remain open, and the blood issues freely out. The instrument is, in fact, graduated from 1500° to 600°, the heat being increased or diminished by a very simple procedure, which consists in elongating or shortening the portion of platinum comprised in the circuit. The blade can thus be made to pass through all the intermediate degrees from a white-heat at 1500° to a dull red at 600°; and by means of these graduations the instrument can be made to fulfil three different Surgical indications,—(1) at 1500° it divides the tissues, producing hæmorrhage; (2) at 600° hæmostasis is produced at the same time as the incision; (3) and between these two limits it divides and cauterises simultaneously. It is, moreover, in its mechanism an ingenious improvement upon the galvano-caustic knife already in use.—M. Demarquay observed that he has once had occasion to employ the instrument, and he became alarmed at the extreme facility with which this knife, without a cutting edge, cuts through the tissues; and if care be not taken much more of these may become divided than is intended. He thinks Surgeons should have their attention drawn to the excessive and truly fearful cutting powers of this knife.—M. Broca could really see nothing alarming in the powers of the knife; but that may be from his temperament being different to that of M. Demarquay.

At the same Society, M. Follin presented a patient, 20 years of age, the subject of a very rare lesion, judging from the silence of authors upon the subject—viz., a double congenital dislocation of the crystalline. From early childhood the patient's friends observed abnormalities in his visual powers, the child not being able to distinguish his toys, and at a later period even large letters of the alphabet. It was not until he employed a small Galileo telescope that he became able to read; but by its aid he can distinguish the smallest print. He is the subject, also, of a double convergent strabismus, and of a binocular diplopia, resulting from a double image—the one produced by the passage of the rays through the lens, and the other through the vitreous humour. The lens on the left side continues quite transparent; that of the right side has a slightly whitish colouring; so that the patient cannot see so well on one side as on the other. The lens is placed behind the iris, being situated upwards and inwards. The patient possesses no power of accommodating the eye to distances, not being able to see objects placed within or beyond from twenty-five to thirty centimetres distance, this being for him the limit of visual power. M. Follin endeavoured to substitute convex glasses for the Galileo telescope, which is troublesome to employ and adjust; but, after some trials, the patient preferred the means he had been so long accustomed to.

PARLIAMENTARY.—THE CATTLE PLAGUE—MORTALITY AT HONG-KONG—OPEN SPACES AROUND LONDON — IRISH COUNTY INFIRMARIES.

In the House of Commons on Monday, February 12,

Sir George Grey explained the provisions of the Cattle Plague Bill which he asked leave to introduce. After referring to the great change of opinion which had taken place within a very recent period in favour of more stringent measures, he laid down four main points to which the attention of the Government had been chiefly directed by the numerous representations which had reached them from various quarters. These were, the compulsory slaughter of all infected cattle with compensation, the absolute or qualified prohibition of the removal of cattle, the isolation of suspected animals and the disinfection of suspected premises, and regulations as to cattle brought into the country by sea. Having quoted the resolutions agreed to on these points by the Royal Agricultural Society, the Conference of Local Agricultural Societies, the Highland Societies, and other bodies, which, he observed, were almost unanimous in principle, Sir George said that the principle of the Bill would be to lay down certain general rules applicable to the whole country, from which no local authority should be able to depart, to make use of the local authorities in carrying out the rules, and to give them a discretion in certain matters on which they must be best able to form a judgment. With regard to the slaughter of cattle, the Bill proposed to make it imperative on the local authorities to order the slaughter of all infected animals, and gave them a discretion to order the slaughter of animals which had been exposed to contagion, and they were allowed to grant compensation in the first class to the amount of two-thirds, and in the second class to the amount of three-fourths of the value of the animals, the maximum not to exceed £20 and £25 in each case respectively. On the subject of the removal of cattle, the bill laid down statutory restrictions applicable to the whole of the country, leaving it open to the local authorities to apply them. For a limited period the removal of cattle by night would be entirely prohibited, and there would be a general prohibition to move cattle at other times except by licences given by the local authorities under certain conditions. Instead of a penalty of £20, the driver would be liable to arrest, and the magistrates would be empowered to direct the slaughter of the cattle without compensation. The local authorities would be empowered to declare a district infected, and upon their notice being issued to that effect no further removals in that district would be permitted under any circumstances. The public sale of lean and store cattle would be prohibited for a limited period, and no market for fat cattle would be allowed to be held except with the licence of the local authorities. No beast once brought to market should be removed before being slaughtered, and in small boroughs the concurrent licence of the county magistrates would be necessary to holding a fair or market. The bill further provided that foreign cattle should not be removed from the port of entry before slaughter—with the exception of cattle from Ireland, if they were immediately sent forward from the port without passing into a market where they might meet with infected cattle. On the difficult question of compensation, which was to be retrospective, Sir George proposed that two-thirds of it should be provided from the county rate, the remaining third by a cattle rate not exceeding five shillings per head, power being given to borrow money from the Public Works Commissioners on security of the rates, and a discretion being also vested in the magistrates to remit the whole or part of the rates in cases where farmers had suffered severe losses. After explaining several minor provisions of the Bill relating to disinfection, penalties, combinations of districts, and similar matters, he fixed the second reading for Wednesday.

Mr. Hunt was of opinion that the perpetuation of removals under licenses or permits would afford no security against the spread of the disease, and urged the Government particularly to prohibit all removals by railway. He explained the provisions of a bill which he himself had prepared, based on the resolutions of the conference held at St. James's Hall last Thursday, the chief features of which were the entire suspension of all traffic for March 1 to 31, the provision of additional slaughterhouses, and the disinfection of railway trucks and platforms. Of the scheme of compensation he expressed a general approval.

The Chancellor of the Exchequer offered no objection to the introduction of Mr. Hunt's Bill, which, he remarked, really differed from Sir G. Grey's only on one point; but doubted whether a complete suspension of the movement of cattle was possible, or would be tolerated by the country. He impressed on the House the necessity of promptitude.

After several speakers had expressed their regret at the complication of the measure advocated by the Government, leave was given to introduce the Bill, and it was read a first time.

In the House of Commons on Tuesday,

Colonel North moved for a return showing the accommodation for the troops of all arms at Hongkong and Kowloon at the time of the arrival of the 2nd battalion 9th Regiment and 2nd battalion 11th Regiment, specifying the nature of the accommodation and number of cubic feet allowed per man; also for returns of the mean annual strength, total annual sickness, mortality, and invaliding of the troops of each arm, officers and men, at Hongkong, up to the year 1855; and of the number of deaths annually on the voyage to England of the troops invalided, in a tabular form, giving the date, corps, mean annual strength, number of sick, deaths, invalided, and died on the passage to England.—Agreed to.

Mr. Doulton asked the First Commissioner of the Board of Works whether it was the intention of Her Majesty's Government to introduce early this session a bill having for its object the preservations of commons and open spaces in and around the metropolis?

Mr. Cowper replied that it was his intention to propose a bill which he had in preparation, and he hoped that he should be able to introduce it very shortly.

Lord Naas, in moving for a copy of the report of the committee convened by the Lord-Lieutenant of Ireland to consider the measures that might be adopted for arresting the progress of the cattle plague, asked when the bill which was to be carry out the recommendations of this committee would be ready?

Sir G. Grey replied that the bill had been drafted, and would be introduced at an early day.

Mr. P. Urquhart obtained leave to bring in a bill for the better regulation of county infirmaries in Ireland.

In the House of Commons on Wednesday, February 15,

Sir G. Grey moved the second reading of the Cattle Plague Bill.

Mr. Hunt passed in review the provisions of the bill, condemning the system of licences, and expressing his preference for a compulsory and uniform set of regulations applicable to the whole country. He approved many of the regulations of the bill, pointing out that some of them, however, were already in force under the Orders in Council. He regretted that the Government had not proposed to stop the movement of cattle altogether for a limited period, both by road and rail, and announced his intention of taking the sense of the House upon this point.

Mr. Bright was of opinion that a strict system of isolation would diminish the necessity for compulsory slaughter, which, coupled with compensation, he feared would lead the farmers to slacken their preventive and curative efforts. He inveighed strongly against the compensation clauses, which, he said, were contrary to all the principles on which Parliament had ever acted in reference to other interests, the effect of which, he said, would be to tax towns and villages to indemnify rich landowners and others for losses which were the result of the visitation of Providence.

Colonel Lloyd-Lindsay supported Sir G. Grey's Bill, approving particularly its permissive character. He believed that the stringent compulsory measures proposed by Mr. Hunt would not be tolerated by the country.

Mr. Lowe reminded the House that the compensation provided by the Bill was not for losses sustained by the death of cattle from the disease, but for cattle which had been slaughtered by the direct orders of the Government to effect a public benefit. He pointed out that the great argument for compensation was that it gave the farmers a motive for revealing the existence of the disease the moment it appeared among their cattle, and showed how necessary this was to prevent its spreading. As to retrospective compensation, he argued that it should be borne not out of the county rate, but the general funds of the country. He approved the provisions of the Bill relating to slaughter, but hoped that the Government would take power to suspend compulsory slaughter, in case any of the experiments now being made should result in the discovery of an efficient cure. He objected to the second rate on cattle, thinking it unfair that the stock-holder should thus be made to bear a double share of the burden, and urged the Government to reconsider their decision as to the prohibition of the

total removal of cattle, suggesting that the prohibition and the exceptions should be embodied in the Bill, with the view of making the law uniform and intelligible.

Mr. J. S. Mill, while admitting the justice of the principle of compensation, asserted that as carried out by the bill it was excessive in amount, and that the burden of it was not fairly distributed. He entered into a long and elaborate argument as to the proportion which the compensation should bear to the loss, and contended that as the ultimate loss, by reason of the rise in prices, would fall on the consumer, it was not just that the class which suffered the first loss should be compensated by the whole community. He argued that the chief hardship of the calamity to the farmer was the inequality of its incidence, and drew from that the conclusion that those who had been unfortunate should be compensated by their fellows in the same class who had suffered no loss.

Lord Cranbourne protested against the narrow view which regarded this question as one affecting merely the agricultural interests, and warned the House that foreign Governments, for their own interests, might find it expedient to stop the exportation of cattle, when the calamity would be brought home with much greater force to the consumer. In criticising the Government Bill, he objected to the ill-timed compliment which it paid to local authorities, and asserted that the effect of this portion of the Bill would be to prevent the cattle reaching the consumer, while it would give every facility to the plague passing to the cattle.

Mr. Ayrton asked some questions as to the operations of the bill in the city of London, to which no answer was returned.

The discussion was continued by Mr. Acland and Mr. Grenville, who supported the bill, and after a few words in reply from Sir G. Grey the bill was read a second time, the committee being fixed for Thursday.

Mr. Hunt's bill on the same subject was also read a second time, and the House adjourned at half-past five o'clock.

ON BRASS PLATES.

(*From a Correspondent.*)

Is there a Practitioner living who can recall without emotion the sensations he experienced when he ordered, for the first time in his life, his name to be written in bold, legible characters upon some part of the front of the house in which he was about to commence his Professional labours? To the uninitiated it may seem a matter of the most trifling importance *how* the name is written, but the young Doctor considers for a long time, and then perhaps finds great difficulty in deciding as to the form and size of the letters, whether they shall be cut in brass or zinc, or painted in black, or gold, or colour.

How various the ways chosen by different Practitioners to inform the public of their readiness to take charge of their health and relieve their sufferings! One legally-qualified Practitioner writes his name in letters a foot long, blazing with gold, on an enormous board over a grand window, in which gigantic globes filled with bright blue, and red, and yellow coloured fluids, excite the wonder of the pedestrian by day, and strike him with awe by night. Another orders a little brass plate no bigger than a card-plate, with his name engraved in characters so tiny and so elegant, that it must excite the admiration of the most fastidious; or, so averse is he to obtrude himself upon public notice, that the name is written on the margin of his letter-box.

These extremes are connected with one another by the most delicate and almost insensible gradations, and a careful scrutiny of the Medical names he passes, will afford the observer who travels from Mile-end to Park-lane not only amusement but matter for serious reflection.

If a Practitioner desires to let the inhabitants of certain parts of Eastern London know that he is qualified to doctor them, he must make his name six feet long, suspend evidence in the front of his house that he is duly qualified, exhibit the actual bandages, splints, and instruments he uses in his calling, and draw attention to the excellent qualities of the rhubarb and magnesia he has provided for public consumption. Nay, in some cases, it seems necessary to show that the very leeches he would apply are the true and proper species, and allow the intending patient an opportunity of examining their zoological characters at his leisure, and assuring himself they are not their equine representatives before he risks his fee.

By the time our traveller reaches the City, he will find the fashion has sobered down. The names have been gradually reduced till even a long one is compressed into the length of eighteen inches, and they are now strictly confined to the door or doors; but still there is room for the display of individual taste. Sometimes two doors enable the Practitioner to exhibit his name in two different characters. The inner one, covered with bright red cloth, exhibits the name on a handsome brass plate, with an elegantly wrought border; while on the outer door, exposed to the inclemency of City weather, and to the dirt and chalk of City boys, the name is painted usually in sober colours, but the letters are bold and easily legible, even by old ladies passing on the other side of the street. In order that the numerous persons taken with aches and pains after dark may find relief without trouble, attention is directed to the man who cures by a bright red or blue light; but this ridiculous, vulgar, and useless practice is seen in all parts of London and the environs, and sometimes a transparency with the name in full, titles and all, is added.

In Bloomsbury and Russell-square, though brass plates largely predominate, the custom of painting the name on the street door still remains, and it is scarcely before Savile-row is reached that the letters become reduced to ordinary dimensions, and painted names entirely give place to brass plates. Westward of Savile-row, however, woe to the fortunate Doctor who, migrating from the E.C. or W.C. to the classic W. district, omits to follow the different fashion that prevails. Custom that must not be departed from has ordained that no Practitioner living within that charmed ground bounded by Bond-street, Oxford-street, Park-lane, and Piccadilly, shall write his name in letters longer than one inch. Many have attempted to introduce a new custom, but a very short residence has invariably been sufficient to bring them to a sense of their grievous bad taste, and the plate has been reduced. In some instances the sudden transition from the large letters to the small ones was too much, and the necessary reduction has been gradually accomplished.

Some might be inclined to conclude that Professional men living in different parts of the town differed as much in skill, character, in taste, and refinement as their door-plates; but those acquainted with the peculiarities of Medical life know that this is not invariably the case, and that in this, as in many other things, a man *may* have to give way to a vulgar fashion without necessarily being in any way vulgar himself. The surroundings make all the difference in the manner in which a man must come before the public, although they may have little or no influence upon the individual man. The most refined Practitioner in the West-end, whose name is engraved in letters too small to be read, meets, and on a perfectly equal footing, his apparently more obtrusive friend who practises in the most unpleasant parts of E.

And this is as it should be. What could be more monstrous than to exclude men from a society merely because their names were written in very large letters, "Surgeon" printed on their cards, or blue bottles and leeches exhibited in their windows, or pretty coloured lamps over their doors? Is it not obvious that these things *may* be mere accidents or necessities of the situation, and that in spite of them the Practitioner may be a well informed and high-minded gentleman? They may, however, be fairly held to exclude men from private clubs, for the members of a club have a perfect right to exclude any one who does or does not wear bright red kid gloves if they choose; but a club differs entirely from a learned society, established for the furtherance of a special department of human knowledge. Would it not be utterly inconsistent with the liberty of science if a scientific man could not be admitted a Fellow of the Royal or other scientific or learned society simply because he put up his name in very large letters, or kept a shop, or advertised, or sold rhubarb, or extracted teeth?

That which scientific and Medical societies have never attempted, however, may perhaps yet be carried out by a section of the Medical Profession—the Dental Surgeons. A certain party of the dentists appear desirous that as far as regards a certain dental society their department of the Profession shall be subdivided into at least two classes—1, those who extract and insert teeth without advertising, and, 2, those who advertise painless extractions and faultless insertions. The extreme sensitiveness of the successful dentists in these days is not a little amusing; and all the delicate refinements by which the exact status of a man is fixed, according as he has "dentist" on his card, or more detailed information conveyed in many kinds of letters with beautiful flourishes, or exhibits artificial

teeth at his door, are most curious, but very difficult to master. It would require a volume to describe briefly the various transitional forms by which we pass from the highest and most refined professors of the art, grade below grade, until we come to the grim wretch, whose death's head invites you to have your tooth out for a shilling, or one in for five, or prints his name in veritable human molars. But horrid as this last appears, it may be after all but the accident of circumstances, and these molars and advertisements may possibly be but illustrations of exceeding bad taste upon the part of most ingenious and not otherwise unpleasant persons, who may, in spite of all this, be seriously advancing the mechanical and other departments of their Profession. Nor can it be too frequently mentioned that some of the brightest ornaments and the most vigorous intellects in all professions have sprung from very low in the scale. Let us, therefore, rather exclude a man from our societies for his conduct as an individual than for the mere accident of his position, or the size of the letters in which he makes his name known to the public. S. P. E.

REVIEWS.

On Hip-Joint Disease, with Reference Especially to Treatment by Mechanical Means, for the Relief of Contraction and Deformity of the Affected Limb. By W. Curtis Hugman, F.R.C.S., late Surgeon to the Hospital for Deformities, Great Portland-road, London. Second Edition. London: John Churchill and Sons.

Absolute quietude in the *prone* position during the earlier stages, and the use of extension and other mechanical appliances to prevent and remove deformity, seem the leading features of Mr. Hugman's book. It is well got up, and shows a great deal of patient observation on hip-joint disease.

A Latin-English Dictionary for the Use of Junior Students. By the Rev. J. T. White, M.A. London: Longmans and Co. Pp. 650.

This Dictionary is of handy size, and adapted to help the student who wishes to know something of the etymology of Latin and the derivation of English and French words. It does not contain all the technical terms in Celsus, which would be needless in a junior scholar's dictionary. By the way, a big schoolboy at our elbow wonders what would be said to him if he shortened the *i* in the noun suspicio?

The Treasury of Botany. Edited by John Lindley, Ph.D., etc., and Thomas Moore, F.L.S. In two vols. London: Longmans and Co.

This is a short botanical dictionary, containing an account of such plants as are likely to be of interest to the general reader. It is a popular book, contains much interesting matter, and is profusely illustrated by woodcuts and steel engravings. We have tested it by looking out for names of plants useful in cookery—as winter cherry, oyster plant, tea, etc., and have not been disappointed.

Contributions to Surgery. By W. H. Van Buren, M.D., Professor of Anatomy, University of New York, etc. Pp. 203.

This is a collection of important cases published by Professor Van Buren in various periodicals during the last few years. The most remarkable are three cases of amputation at the hip-joint. His method of operating somewhat resembles that recommended by Professor Spence as regards the flaps; the disarticulation is effected with a straight scalpel. Two of the three were primary and fatal. He treats painful ulcers and fissures of the lower part of the rectum by forcible dilatation of the sphincter ani, so "as to paralyse the sphincter for at least a week." There are some interesting cases of stone, dislocation of the femur, and strangulated hernia of the tunica vaginalis. An elaborate paper on Ligature of the Subclavian Artery, and a case of salivary fistula complete a list of cases which reflect the highest credit on their narrator and American Surgery generally.

We regret to state that Dr. Lewis Brittain, House-Surgeon of the Chester Infirmary, has died of typhus fever, caught in the discharge of his duties.

GENERAL CORRESPONDENCE.

MEDICAL EDUCATION IN LONDON AS IT LOOKS TO A LONDON TEACHER.

Letter from Professor Lionel S. Beale.

[To the Editor of the Medical Times and Gazette.]

Sir,—I do not think the "Provincial Professor" is quite right in attributing the defects in London Medical teaching to the London teachers. He argues as if the thirst for information on the part of the student was not satisfied by the teacher and our existing arrangements, while the real difficulty on the part of the teacher is to *excite the thirst*. I can show that the very same information, communicated in the very same way, will be gladly paid for as an extra by students who have passed their examinations, while of existing students only a very small minority can be interested or persuaded to pay the slightest attention to it. Were it not for the small minority of thoroughly earnest students who really like work and support earnest teachers with all their heart, the task of a teacher would in these days be dismal and useless enough. Some of us are quite ready to teach tutorially, or in any other way, in our wards and lecture-rooms, and to instruct men in the very elements, and to appoint tutors to help us in the work;—but does the Provincial Professor suppose that the general run of Medical students will come to the bedside to be drilled in the elements of diagnosis when the College of Surgeons does not examine candidates for its licence in Clinical Medicine? Is it wonderful that, under existing circumstances, a young student should consider his chemistry and his physiology and microscope work as mere useless grind, all very well for scientific people, but unnecessary for those who are going to be thoroughly practical men!

I believe that there would be more inclination on the part of many to learn if there were no examinations to pass at all than under the present system. An inefficient examination actually discourages work, and encourages idleness. It leads students to laugh at all save that small modicum of Medical learning required from them by the examiners, and thus it happens that an earnest teacher soon finds that he has to contend against not only the apathy of the less energetic of his class, but a far more powerful influence behind, which is tacitly but most powerfully fostering and encouraging this.

It is very well to talk of instructing students in what will be of great value to them in after life without reference to examinations; but the fact is, many of the students do not wish for such instruction. All they want is to pass the College of Surgeons; and now and then a man will tell you that when he is a Member of the College he intends to begin to work a little at Medicine and the microscope!

If there was a general feeling on the part of the students that it was necessary and desirable to work at Medicine, you may depend upon it clinical work would soon be well taught in all our schools. If the teacher asks many questions at the bedside there is danger of driving the very few away who enter the Medical wards, and this will almost certainly be the result if the Surgeons during their visit ask no questions. If, however, no man could pass his examination without answering questions of a practical clinical character, both in Medicine and Surgery, the very same men would flock to the teacher who asked the most questions and took the greatest trouble to teach at the bedside. I am quite certain I could convince the "Provincial Professor" that at any rate the vast majority of the London teachers are quite ready to perform their part. That the fault does not rest with them is very easily proved, and most conclusively.

I quite think that the time has come when something ought to be done; but is it not simply absurd to suppose that any amount of energy displayed by the most earnest and enthusiastic teacher, or all the arguments he could advance, would convince the majority of Medical students of the real importance of certain branches of Medical education, while examiners of far higher Professional standing than the teacher, necessarily with ten times his influence, and of perhaps twice or three times his age, simply ignore them? What is the use of making zealous hardworking men teachers if their pupils are to be examined by those who think nothing of the subjects you call upon them to teach? A lazy man may pity, or respect, or even love his teacher, but he fears his examiner, and is it not probable that the fear of being plucked exerts a more powerful influence upon him—at any rate, during his first

year—than pity, or respect, or love for his teacher? The loss of a year, if he failed to pass an examination at the end of his first winter session, would be a penalty which no one would pay even for the pleasure of idling away the first and most important period of study—that which probably exerts a greater influence upon his future than any other part of his student's life. The first year is the time when a man's character is made, and yet our examining boards allow the first year to pass without any examination, and a man may spend it in idleness.

Either the training in our schools ought to be adapted to the examination for the Membership of the College, or that examination ought to be modified to suit the requirements of Medical education in the present day. Either men ought to be examined in what they are taught, or they should not be bored with that which examiners regard as worse than useless. As far as I can see, improvements in education and advance in Medical knowledge emanate from teachers; and I am quite sure that, as a body, the London Medical teachers perform their work honestly and well. If they were not practically discouraged in their efforts by those who have real power in their hands, I am quite sure that no one would long have reason to find fault with the progress of the London School of Medicine. I am, &c.

Lionel S. Beale.

SUPPOSED COMMUNICATION OF RINDERPEST TO MAN.

Letter from Dr. Wm. Cholmeley.

[To the Editor of the Medical Times and Gazette.]

Sir,—In answer to some inquiries about a reported case of human inoculation with Rinderpest virus, I received from the Surgeon I had written to a communication of so much interest that I send it to you for public use. Local skin affections, such as eczematous eruptions on the arms, are, I believe, not very uncommon in those who have much personal contact with cattle suffering from Rinderpest; but I have not heard of any cases similar to these reported by my friend, Mr. Harbord. I give his letter without any further comment, except to point out as of special interest, the vaginal affection which he describes. I am, &c., Wm. Cholmeley, M.D.

In his first letter answering my inquiry, Mr. Harbord states—"The case of Mr. J. Heanley's foreman's wife was this:—She incautiously rubbed her right cheek with the coarse flannel which her husband used to cleanse his hands with after coming from the sick beasts. In a few hours she had tingling pain in the cheek, and the following day some redness and commencement of eruption. This eruption lasted for fourteen days, and then died away in the form of desquamation, has left no mark beyond slight discolouration and roughness. There was no abrasion on the cheek, but as the woman has a most thin delicate skin, I consider that she inoculated herself with Rinderpest virus by means of the rough flannel. The eruption was the most beautiful cluster of herpes I have ever seen, and corresponds with that seen in the mouth of the ox during the very earliest stage of its malady. I have myself suffered from herpes on the hands most painfully after performing a post-mortem examination; in my case the spots had very much the appearance of vaccinia. I have several cases of fever corresponding in symptoms with Rinderpest; in all there is herpetic eruption on the lips, and in one case, that of a child, diphtheritic deposit as well. I have no doubt that Rinderpest is herpetic fever, which, if left to itself, runs into one of two states, typhoid or diphtheritic; in the former it torments its victim for several days, in the latter form death is earlier. On this account it ought to rank as an exanthem. It certainly is not variolous, and vaccination is a positive evil, and often leads to the result it was intended to avert."

The second letter gives fuller information about the cases of fever mentioned in the first:—

"The enclosed illustrations will, I hope, give you some idea of the nature of a malady of which I have several cases, all presenting the same pathological features as Rinderpest, as a rule. In some the more purely diphtheritic condition exists, in others a typhoid state without exudation, but with ragged ulcerations of the mouth and fauces. Of these cases, by far the greater number are females, and the vagina exhibits a condition similar to the mouth. In every case a near residence to infected yards happens; in two cases there had been actual contact with the cattle; and in one inoculation—viz., the case of the foreman's wife. Figs. 2, 3, and 4 are from a case I have seen to-day, in which the symptoms, especially laryngeal and intestinal, were marked. In this case the woman, about 40 years old, has not felt in good health for three weeks, being anxious and depressed. Yesterday she complained of soreness of the mouth and enlargement of the tongue, stiffness of the neck, pains in the belly, and a sense of constriction of the chest; swelling of the genitals, and great pain on voiding urine, which is scanty and high coloured and offensive; Bowels somewhat costive; stools blackish-green in colour. Fig. 2 shows the highly vascular gum which, with the lip, is studded with vesicles, singly or in patches; there are two or three bullæ, and some dark streaks. Fig. 3, the palate, on which are two large bullæ, several patches of diphtheritic deposit, some deep sloughing ulcers, and here and there a few vesicles. Fig. 4, mucous membrane; vagina swollen, much injected, studded with vesicles, diphtheritic patches, and sloughing ulcers. The patient complains of loss of power in the legs, and of a sensation along the spine of which she says she can give no adequate description; eyes suffused; lips and tongue swollen and brown, with reddish margin; pulse 180, feeble; respiration frequent; chest sounds unaltered; great tenderness over right hypochondriac region, and also about the umbilicus; has no desire for food or drink; lacteal secretion nearly suspended (been going on six months) since last night. This is truly an interesting case. The diagrams I have not done justice to, being hurried; but they convey a good idea of the nature of the case. What I have observed in cows having Rinderpest is analogous, but on a more extensive scale—herpetic eruption of the mucous surface, with or without diphtheritic deposit, and sloughing ulcers, attended with fever of a low type, and intense congestion of the liver and intestines. Two of my cases have taken on a remittent form after running a course of three weeks, and one has passed rapidly into active dysentery. In this case (a child), the sloughing of the mouth is fearful. If you think my observations of any use, pray do with them as you think best. "Yours, &c.,

"Wm. Harbord, M.R.C.S.E., &c., &c."

"Wainfleet, Lincolnshire, February 12, 1866.

P.S.—The illustrations sent me are water-colour drawings, so that they cannot be re-produced; but Mr. Harbord describes sufficiently clearly the conditions they represent.

AN UNSUCCESSFUL OPERATION FOR OVARIAN DISEASE.

Letter from Dr. W. M. Turnbull.

[To the Editor of the Medical Times and Gazette.]

Sir,—I beg to enclose a copy of the *Medical and Surgical Review* of November 1, containing my account of an unsuccessful operation for ovarian disease, also an account of the same operation by an individual writing under the signature of NO_5 (and who was not present at the operation). You will observe that Mr. Baillière, the publisher of the *Medical and Surgical Review*, for reasons given, has discontinued the publication of the journal, and when I inform you that NO_5 is the editor of the *Australian Journal*, you will easily understand that I have no means of replying to the scurrilous and mendacious letter alluded to. I trust, therefore, to your sense of justice to allow me, through the medium of your columns, an opportunity of justifying myself to the Profession here and my few Medical friends who may recollect me in the mother country, your journal being widely circulated in this colony. I am the more induced to send the accompanying remarks to you as Spencer Wells, in your journal of Sept. 30, manfully lashes those crawlers, such as NO_5. I can assure you when I read his remarks I slept sound that night. Those remarks do him alike credit as a man and a member of the Profession. I feel pleased that my own sentiments should be endorsed by him. Would that we had many such in the Profession!

Spencer Wells talks of the men of large experience who conceal their blunders. One of my greatest decriers is a man who cut down upon a phantom tumour. Professor Halford's letter will show you the falsehood of NO_5's statement as regards the puncture of the uterus. I am grieved to say that the rumour was set in motion by men who punctured the sac. I have his admission to the facts. The allusion to the ligature is an unmitigated lie. Every

requisite had been provided for by my resident Surgeon, Mr. Mackenzie. In justice to Spencer Wells, allow me to state that the manufacture of the instruments was bungled, but when discovered it was too "late to mend," and I had to work with the tools at hand.—I am, &c.,

W. M. Turnbull,
Honorary Physician to the Melbourne Lying-in Hospital.
101, Spring-street, Melbourne, Dec. 12, 1865.

IMPROVEMENTS IN OVARIOTOMY.

[To the Editor of the Medical and Surgical Review (Australian).]

Sir,—Mr. Spencer Wells, Mr. Baker Brown, and others are wrong. Their elaborate directions of the conditions to be observed in the performance of ovariotomy are demonstrated absurdities. It remained for an Australian Hospital obstetrician to show to the Profession that it is not necessary to prevent any of the fluid in the cyst entering the peritoneum, and that the complicated trocar is a needless embarrassment. The proper method is to cut boldly into the cyst, and let the fluid flow freely among the abdominal viscera. A certain amount of dramatic effect can be communicated to the business by using clamps that break, and in eventually securing the pedicle with a bit of old ligature silk accidentally found in the pocket of a bystander. Finally, the operation is appropriately concluded by passing the sutures through the body of the uterus, and in the course of the following day regaling the patient with sparkling Moselle, freely exhibited. It is totally unaccountable that the patient should die on the fourth day, but patients do sometimes die most perversely. The brilliancy of the operation, however, remains unquestioned; and it is to be hoped that European Practitioners will promptly modify their manner of operating, now that it is shown how differently ovariotomy may be managed.—I am, Sir, your obedient servant. NO_5.

REPORTS OF SOCIETIES.

OBSTETRICAL SOCIETY OF LONDON.

Wednesday, January 3, 1866.

Dr. Barnes, President.

The following gentlemen were elected Fellows:—Messrs. R. J. Cave, Birmingham; John Deans, Cranbrook; F. H. Gervis, Adelaide-road; W. K. Giddings, Calverley, Yorkshire; T. Langston, Broadway, Westminster; W. T. Mollay, Balmoral, Victoria; Jabez Thomas, Swansea; Drs. W. C. Lucey, Bermondsey; J. E. Neild, Melbourne, Victoria; Mark Tanner, St. George's-square, Pimlico; H. J. Yeld, Sunderland.

Dr. Swayne, of Clifton, read a case of Double Monstrosity.

Mr. W. Owen read a case of Mechanical Obstruction to the Growth of a Fœtus.

Dr. Cory exhibited an Ovum Forceps.

Dr. Murray showed two large Kidneys, weighing seven ounces four drachms, and six ounces three drachms and a half, which had been removed from a still-born fœtus otherwise normally made.

Dr. Eastlake read

BRIEF NOTES ON SOME UTERINE THERAPEUTICS.

The author first drew attention to the action of the resin of podophyllum on the uterus. He found an emmenagogue effect produced in several cases where it had been prescribed for constipation. He referred secondly to the beneficial use of the spiritus pyroxylicus rectificatus in cases of obstinate vomiting; and lastly spoke of "iodoform; as a sedative in cases of cancer especially attacking the uterus. The drug was discovered by Scrullus in 1824, and is produced by the action of iodine and alkalies or alkaline carbonates on wood spirit, alcohol, or ether. Dr. Eastlake has used it with much success locally, by means of medicated pessaries, the effect produced being a marked diminution of pain and discomfort.

Dr. Greenhalgh stated that eighteen months ago Dr. Eastlake called his attention to iodoform, suggesting its use as an anæsthetic and alterative, especially in cases of cancer. He (Dr. Greenhalgh) first gave it in quarter-grain doses, but soon found that it might be administered in pills of three to five grains thrice daily. He had prescribed the drug in carcinoma, epithelioma of the uterus, rheumatic gout, neuralgia, and other painful diseases, in most of which it had been followed by good results. In some cases, but slight effects appeared to result from its use, whereas, in a limited number, when given at once in full doses, sickness was occasioned. He considered it had the advantage of never producing that malaise so frequently attendant upon the use of opium, and regarded the drug as a valuable addition to our present stock of medicaments.

Mr. Gaskoin remarked that for many years he had been aware of the employment of iodoform as a disinfectant in many parts of the Continent; but that he had been unsuccessful in obtaining much information concerning it. The objection to its general use was its expense as compared with other disinfectants.

Dr. Woodman said that a small quantity of iodoform is produced when the compound tincture of iodine is prescribed with liquor potassa—a favourate combination with many country Practitioners, and considered by many to be more efficacious in the treatment of bronchoceles than iodine alone.

Dr. Hall Davis communicated the report of a case of

FIBROID TUMOUR OF THE UTERUS WITH EARLY PREGNANCY.

At first there had been retroversion of the womb and retention of urine. The latter was relieved by the catheter, the patient being placed in the kneeling posture; the former by the caoutchouc ball air-pessary. Nine days later (Sept. 29) the patient came into Hospital, presenting a considerable-sized solid enlargement of the abdomen, extending as high as the last rib. She was feverish, reduced in flesh, frequently vomiting; subsequently dysuria and renal pain appeared; later scanty urine and drowsiness, and also sloughing of the cornea, etc. She died on October 18, after on the day previous discharging a putrid fœtus of about four months' growth. The morbid specimen, which was exhibited to the Society, showed a large fibroid tumour, of kidney shape, attached to the fundus of the uterus; also others much smaller growing from the cervix, in the substance, others bulging on the surface of the body of the uterus. The kidneys contained purulent deposits; the ureters were dilated. Dr. Davis concluded that this patient died from pyæmia, and that had an early discharge of the decomposed fœtus been brought about, the patient's life might have been saved. It first became apparent at the autopsy that the largest fibroid might have been easily removed; others, however, would have remained for subsequent development had the patient survived extirpation of the tumour.

Dr. Routh said the case was important, viewed in the aspect of what should be done in such cases—*i.e.*, when we had abdominal tumours and pregnancy coexistent. The post-mortem examination revealed a large fibroid extra-uterine, with small pedicle; precisely the case most favourable for gastrotomy. Should this patient have been operated upon before labour had taken place, or should labour have been prematurely induced first? He thought the latter: First, because it commonly happened that when abdominal tumours, whether ovarian, but especially if fibroid, were operated upon before labour, a miscarriage or premature delivery occurred; occasionally death. Secondly, if premature labour was induced, then not only was diagnosis made more easy as to the exact nature and bearings of such a tumour, but the impetus given to its rapid growth by pregnancy was removed.

ANNUAL MEETING.

The report of the auditors of the accounts of the treasurer for the year ending Dec. 31, 1865, was read, from which it appeared that the balance in the hands of the treasurer is £234 18s. 8d., and the amount invested in Consols is £831 10s., representing in Three per Cent. Annuities £955 12s. 1d.

Dr. Tyler Smith moved the adoption of the report, and warmly congratulated the Society on its present very flourishing condition.

Mr. Mitchell seconded the resolution, which was carried unanimously.

The report of the hon. librarian (Dr. Meadows) was then read. After detailing the general condition of the library, the report recommended that attempts should be made to establish in connection with the library a museum of pathological anatomy, by preserving such specimens as, having been exhibited to the Society, were afterwards presented for that purpose. The entire cost of the library for the year was £61 3s. 5d. The number of works presented was upwards of sixty, making a total of nearly 900 volumes, a classified catalogue of which is about to be published in the forthcoming volume of *Transactions*.

Dr. Greenhalgh moved that the report be received and adopted. He warmly commended the suggestion of the estab-

lishment of a museum, and offered a donation of five guineas towards a separate Museum Fund, and a similar sum towards a Library Fund.

Dr. Wynn Williams seconded the resolution, which was unanimously carried.

Dr. Martyn proposed, and Dr. Cory seconded, "That the best thanks of the Society be and are hereby given to the President and officers of the Society for their services during the past year, and that the special thanks be given to Dr. Braxton Hicks, the retiring hon. secretary, for the very efficient way in which he has discharged his duties."

The President (Dr. Barnes) and Dr. Braxton Hicks respectively returned thanks.

The report of the Scrutineers was read, and the following gentlemen were elected officers of the Society for the year 1866:—Hon. President: Sir Charles Locock, Bart, M.D. President: Robert Barnes, M.D. Vice-Presidents: Dr. Gream, Dr. Greenhalgh, Mr. Haden, Dr. Hicks, Dr. Hall (Brighton), Dr. Wilson (Glasgow). Treasurer: Dr. Graily Hewitt. Hon. Secretaries: Dr. Meadows, Dr. Murray. Hon. Librarian: Mr. James Reeves Traer. Other Members of Council: Dr. Aveling (Sheffield), Mr. Thomas Bryant, Dr. Earle (Birmingham), Dr. Eastlake, Dr. Gervis, Dr. Leishman (Glasgow), Mr. Mitchell, Mr. Newton, Dr. Oldham, Mr. Oldham (Brighton), Dr. Timothy Pollock, Dr. Priestley, Mr. Ray, Dr. Richards, Dr. Skinner (Liverpool), Dr. Tyler Smith. Mr. Wm. Squire, Mr. Symonds (Oxford).

The President then delivered the

ANNUAL ADDRESS.

After adverting to the continued prosperity of the Society, and the place which its *Transactions* occupied in obstetric literature, he observed that hitherto the annual surplus had been invested in the Funds; but now, the position of the Society being secure, it was thought better to put out what money could be spared at scientific interest. There was nothing so fruitful as knowledge spread abroad. It gathered increase at an infinitely quicker rate than did capital in the Three per Cents. He hoped, therefore, that more money might in future be spent upon the library and in forming a museum. The sale of *Transactions*, indeed, during the past year had more than covered the rent and cost of maintenance of the library. The President then passed on to recount the losses the Society had sustained amongst its Fellows. It had never before fallen to the lot of its President to record so long a series of losses by death. He gave sketches of the lives of the late Dr. F. W. Mackenzie, Dr. Edwin E. Day, Mr. Decimus Nelson Frampton, Mr. Arthur Octavius Arden, Dr. Thomas Herbert Barker, Mr. Henry Merton Gould, Mr. Charles Saunders, Dr. William Bloxam, and Dr. Charles G. Ritchie. He dwelt more especially upon the personal and Professional merits of Dr. Barker and Dr. Bloxam. Turning from the task of commemorating the lives of lost companions in labour, the President directed attention to the work before the Society. He hoped the proposed conversazione and exhibition of instruments would prove interesting and instructive. By bringing together the instruments that had been used in different ages and in different countries for the purpose of overcoming those obstetric difficulties which are met with in all ages and in all countries, we should be able to read by those tangible symbols the most important chapter in the history of obstetrics; we should be able to enter into the thoughts of our predecessors and contemporaries by studying the visible expressions of their minds labouring in the cause of our common science; and do something towards identifying and preserving the original forms of instruments as they were designed and used by their inventors. An instrument was not less the offspring of a man's mind than was a book. Libraries preserved books in their original form. But the security for preserving an instrument so that it should, even for a brief time, tell truly the working of the mind that produced it, and continue to answer in the hands of others the purpose for which it was designed, was very small. Instruments were made under instructions that were more or less faithfully observed; and there was a constant tendency to depart from the original forms under the hands of mechanicians and the ideas of subsequent Practitioners. Considerations such as these suggested to the President the project of instituting this exhibition. It had met with the cordial approval of the Council; and the College of Physicians had, in the most liberal spirit, given him permission to hold the exhibition in their building. The Council would endeavour to preserve a scientific record of the specimens sent; a *catalogue raisonné* would be drawn up; and drawings would be procured of such ancient and modern instruments as could not be presented for actual exhibition. It was anticipated that we might thus lay the foundation of a museum of instruments that should render a service to science similar to that which libraries rendered to literature.

A vote of thanks to the President for his valuable address was proposed, seconded, and carried by acclamation. The Society then adjourned.

BOOKS RECEIVED.

The Journal of Social Science. February. Chapman and Hall.

*** A good paper by Mr. Begg, on the only true and effective mode of providing homes for the lower orders—that is, encouraging them to provide them for themselves. The Peabody donations can be but a drop; they may benefit a certain number here and there. What we want is some scheme for enabling the whole working population to benefit themselves.

Essai de Pneumatologie Medicale. Par J. N. Demarquay. Pp. 860. Paris: J. B. Baillière et Fils.

*** An elaborate systematic treatise on gases—whether existing in the body in health or in disease, or whether applied or used for therapeutical purposes.

Short Sermons for Hospitals and Sick Seamen. By the Rev. J. B. Harbord, M.A., Chaplain R.N. Pp. 246. W. Blackwood and Sons. 1863.

*** It would be out of place to say more than that these sermons are very short, very easy to be understood, and of a comforting rather than of a scolding tone. They are intermixed with hymns, and would, doubtless, be useful to all sick people, whether landsmen or seamen.

The Popular Journal of Anthropology. No. 1, January. London: Trubner and Co.

*** A new shilling monthly magazine. The Anthropological Society is said to be "a refuge for destitute truths;" and this magazine may serve as a repertory for discussions on the nature, habits, and peculiarities of the human race, which would not be admitted into the popular religioso-politico-humanitarian periodicals of the day.

MEDICAL NEWS.

Royal College of Physicians and Surgeons, Edinburgh.—Double Qualification.—The following gentlemen passed their First Professional Examinations during the recent sittings of the Examiners:—

John Kerr Davidson, Wick; Edward E. Purcell, Limerick; Henry Bath, Glastonbury; Rd. Young, New Lanark; John Riddell, Ballybay.

And the following gentlemen passed their Final Examinations, and were admitted L.R.C.P. Edinburgh and L.R.C.S. Edinburgh:—

Cornelius John M'Kenna, Tipperary; Lewis Miller, Dublin; Colles Litchford Anderson, Madras; Alexander Ramsay Ritchie, Edinburgh; Wm. Hugh Holmes, Cork; Arthur Luke Hackett, Cork; Thomas Alexander Thompson, Carrickfergus; Wm. Wylie, Poyntzpass; James Loos, Ceylon; Samuel Parke, Gilford; David Joshua Jones, Carmarthenshire; William John Grier, County Longford; Robert Pattie, Dumfriesshire; Howison James Johnstone, County Longford.

Royal College of Surgeons, Edinburgh.—Mr. Rolt Ayre Smith, Monkwearmouth, passed his First Professional Examinations during the recent sittings of the Examiners; and the following gentlemen passed their Final Examinations and were admitted Licentiates of the College:—

John Aloysius Walsh, Carrick-on-Suir; John Charles Douglas, Wigtownshire; William Thomas Greene, Dublin; George Wardlaw Turnbull, Linlithgowshire; John Wright, Derbyshire.

Apothecaries' Hall.—Names of gentlemen who passed their Examination in the Science and Practice of Medicine, and received Certificates to Practise, on Thursday, February 8, 1866:—

George Thomas Hankins, Guy's Hospital; Frederic William Lloyd Hodder, Toronto, Canada West.

The following gentlemen also on the same day passed their First Examination:—

William James Todd, King's College Hospital; William George Kemp, St. Bartholomew's Hospital.

APPOINTMENTS.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

Anderson, T. McCall, M.D. Glasg., has been elected Lecturer on the Practice of Medicine in Anderson's University, Glasgow.

Bland, Mr. W. C., has been appointed Assistant to the House-Surgeon at the Huddersfield and Upper Agbrigg Infirmary.

Brennan, R., M.R.C.S. Eng., has been appointed Resident Surgeon to the Birmingham and Midland Counties Lying-in Hospital and Dispensary for the Diseases of Women and Children.

HAMMOND, EDWARD C., M.R.C.S. Eng., has been appointed Honorary Surgeon to the Wallasey Dispensary, Egremont, Birkenhead.

NEWETT, ROBERT H., L.R.C.S. Edin., has been elected House-Surgeon and Superintendent of the Belfast General Hospital.

OLIPHANT, JOHN, M.D. Edin., has been appointed Junior House Surgeon to the Northern Hospital, Liverpool.

POCOCK, GAVIN E., M.R.C.S. Eng., has been appointed Consulting Surgeon to the Brighton and Hove Dispensary.

SANKEY, W. H. OCTAVIUS, M.D. Lond., has been appointed Lecturer on Mental Diseases in University College, London.

SYKES, Mr. E. J., has been appointed Dispenser to the Devonshire Hospital and Buxton Bath Charity, Buxton.

TUXFORD, ARTHUR, M.D. Edin., has been appointed Medical Officer to the Boston Local Government Board.

BIRTHS.

ASHFORTH.—On February 11, at Market Overton, Rutland, the wife of G. M. Ashforth, M.D., of a daughter.

DAVIS.—On February 8, at 2, Marine-villas, Croydon, the wife of Theodore Davis, jun., M.D., of a daughter.

EAMES.—On February 3, the wife of Dr. Eames, of H.M.S. *Gladiator*, of a daughter.

FLEMING.—On February 9, at 17, Princes-street, Stranraer, Wigtownshire, N.B., the wife of Ebenezer Fleming, M.D., L.R.C.S.E., of a son.

HAMILTON.—On February 7, at 1, Princes-road, Liverpool, the wife of Robert Hamilton, F.R.C.S. Eng., of a daughter.

LIVEING.—On February 9, at 52, Queen Anne-street, the wife of Edward Liveing, M.B., of a son.

MOFFAT.—On February 3, at Thornhall, Polmont, N.B., the wife of Robert Moffat, M.D., of a daughter.

SIBLEY.—On February 13, at 12, New Burlington-street, W., the wife of Septimus W. Sibley, F.R.C.S. Eng., of a daughter.

TAYLOR.—On February 6, at Ebury-street, S.W., the wife of Theophilus Taylor, M.R.C.S. Eng., of a daughter, still-born.

THOMPSON.—On February 3, at Westerham, Kent, the wife of Charles R. Thompson, M.R.C.S. Eng., of a son.

WILLIAMSON.—On January 24, at Maryport, the wife of J. N. Williamson, M.D., of a daughter.

MARRIAGES.

BROWN—GATES.—On February 7, at St. Margaret's, Plumstead, Alfred G. Brown, M.R.C.S. Eng., to Emma Hodgson, only daughter of Charles Gates, Esq.

DAVIDSON—CAMPBELL.—On February 6, at Edinburgh, Robert H. Davidson, M.D., Deputy-Inspector-General of Hospitals, to Eurella Elizabeth, second daughter of Arthur Campbell, Esq.

GORNALL-GUEST.—On January 25, at the Parish Church, Warrington, John H. Gornall, M.R.C.S. Eng., to Mary, youngest daughter of the late John Guest, Esq.

HAWKINS—HICK.—On February 8, at Christ Church, Harpurhey, Manchester, Thomas Henry Hawkins, M.R.C.S. Eng., to Mary, daughter of the late Benjamin Hick, Esq.

MILES—BEDDOE.—On February 7, in the Lady Chapel, Hereford Cathedral, Edwin J. Miles, M.D., to Frances Anne, youngest daughter of John Beddoe, Esq.

SHEPHEARD-WYMER.—On January 31, at Lowestoft, John Shepheard, M.R.C.S. Eng., to Fanny Olivia, youngest daughter of the Rev. E. Wymer.

DEATHS.

BRITTAIN, THOMAS L., M.D. Edin., House-Surgeon, General Infirmary, Chester, on February 1.

BROWN, FREDERICK, M.D., at Benham Lodge, Newbury, on February 2, aged 79, late 4th Dragoon Guards.

GEISOW, Dr. F. L., at Frankfort-on-the-Maine, on February 5, aged 62.

GIRAUD, FREDERICK F., M.R.C.S. Eng., at Faversham, on February 11, aged 62.

HAWTHORNE, ARTHUR N., F.R.C.S. Eng., at Eccleshall, Staffs., on January 28, aged 46.

JONES, WILLIAM, M.D. St. And., at Torquay, on February 6, aged 59, formerly of the Strand, London.

RIDDELL, ROBERT F., at The Grove, Clapham-common, S., formerly H.H. the Nizam's service, and late Superintending Surgeon Hyderabad Contingent, on February 7, aged 68.

TAGGART, JOHN, M.D., at Antrim, Ireland, on January 30.

WARD, NATHANIEL, F.R.C.S. Eng., at The Ferns, Clapham-rise, on February 10.

WILLIAMS, HENRY D., M.R.C.S. Eng., at Brow Llan, Llanstffraid, Conway, North Wales, on February 6, aged 71.

POOR-LAW MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the last census.

RESIGNATIONS.

Atcham Union.—Mr. James Weaver has resigned the Alberbury District; area, 16,430; population, 2098; salary, £30 per annum.

Forehoe Incorporation.—The Fourth District is vacant; area, 8445; population, 3426; salary, £50 per annum. The workhouse is vacant; salary, £25 per annum.

Sheffield Union.—The North District is vacant; population, 25,125; salary, £40 per annum.

Thorne Union.—Mr. Pullan has resigned the Belton District; area, 8530; population, 1871; salary, £17 per annum.

Totnes Union.—Mr. R. F. Burrough has resigned the Dartmouth District; area, 200; population, 3176; salary, £17 per annum.

Walsingham Union.—Mr. Damant has resigned the Fakenham District; area, 12,539; population, 4655; salary, £52 per annum.

APPOINTMENTS.

Chesterfield Union.—Walter Simpson, M.R.C.S.E., to the Bolsover District.

Glanford Brigg Union.—Charles Frederick George, M.R.C.S.E., L.S.A., L.M., to the Kirton District.

Martley Union.—Frederick A. Cramer, M.R.C.S.E., L.S.A., L.R.C.P. Edin., to the Fourth District.

Nottingham Union.—John Wheatcroft, M.R.C.S.E., L.S.A., to the First District.

Penistone Union.—John Ward, M.R.C.S.E., L.S.A., to the Workhouse.

Redruth Union.—Thomas Michell, M.B. Lond., M.R.C.S.E., L.S.A., to the Redruth District. Thomas S. Reed, M.R.C.S.E., L.S.A., to the Hlogan District.

Richmond (Surrey) Union.—James Adams, M.D. St. And., M.R.C.S.E., to the Barnes District. Charles W. Browne, M.R.C.S.E., L.S.A., to the Kew District.

Southwell Union.—Edward Wright, M.R.C.S. Edin., L.R.C.P. Edin., to the Eighth and Ninth Districts.

Stroud Union.—Samuel Rowe, M.B. and C.M. Aber., M.R.C.S.E., L.M., and L.S.A., to the Fourth District.

THE CHOLERA CONFERENCE.—The following telegram appeared in the *Times* of Thursday:—"Constantinople, Feb. 13. The Cholera Conference was opened to-day *pro forma* with an address from Aali Pasha. The regular sittings will begin on the Monday after the Bairam."

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—The following Members of the College having been elected Fellows at previous meetings of the Council were admitted as such on the 8th inst.—viz., Messrs. Charles Reynolds Rowe, Wimborne Minster, diploma of membership dated June 1, 1835; Clement Mears Harris, Wootton-under-Edge, December 21, 1138; and Thomas Guy, Doncaster, July 2, 1841.

RECOGNITION OF MEDICAL SERVICES IN FRANCE.—The French Government has decided that seven Medical students who particularly distinguished themselves by their services during the prevalence of the cholera at Toulon, Sollies-Pont, Var, and Raon l'Etape, Vosges, shall be exempt from all further charges in the completion of their studies.

SPHYGMOGRAPHY.—At a meeting of the Midland Medical Society of Birmingham, held on the 6th inst., a paper was read by Dr. Foster on the investigation of the pulse in disease by the sphygmograph. The paper was illustrated by a large number of pulse tracings which the author had taken from various cases of heart disease and other affections. Dr. Foster pointed out the manner in which the use of the instrument afforded not only valuable aid in diagnosis, but also in prognosis. We believe that this is the first systematic paper on the subject read at an English society.

ODONTOLOGICAL SOCIETY.—At the ordinary monthly meeting, on Monday evening, February 5, the newly-elected President, W. A. Cattlin, Esq., gave an address on taking the chair. The set of false teeth found with the body in excavating for the Thames embankment were submitted to examination, and the subject discussed. Dr. Richardson read a description of his new process for producing local anæsthesia by narcotic spray, which elicited considerable interest.

WE are informed that at the monthly evening meeting of Metropolitan Medical Officers of Health on Saturday evening, the 17th, Mr. Begg will open a discussion on the dwellings of the labouring classes, and the best mode of improving them.

DR. HENRY TRIMEN and Mr. W. Thiselton Dyer are collecting materials for a Flora of Middlesex, on the plan of the Essex and Cambridge Floras; and they would feel obliged for notes of localities or any other matter (even the slightest) relating to the subject. In the case of doubtful or critical species, scraps sufficient for identification would be most acceptable. Address, "Dr. Trimen, 71, Guilford-street, Russell-street, London, W.C."

MR. WINDHAM'S BRAIN.—This young man, whose mental state was the subject of the long and expensive Commission in Lunacy, has lately died suddenly. The cause of death was plugging of the pulmonary artery by fibrinous clots. His brain has been carefully weighed and measured, and the result completely confirms the accuracy of the opinions of the experts, who declared that he must be deficient in intellect.

ST. PANCRAS WORKHOUSE.—On Wednesday Mr. Butt, the Resident Surgeon of St. Pancras Workhouse, reported to the Board of Guardians that a fresh outbreak of fever had occurred in the Workhouse, and that four patients had been sent to the Fever Hospital. A letter was received by the Board from Mr. Finn, the Secretary to the Fever Hospital, stating that a new wing, capable of accommodating forty patients, had been opened, so that an increased number of patients could be received, and also that the foundation of another wing, capable

of accommodating sixty patients, had been laid. The wards of the Workhouse lately occupied by the fever patients, it was reported, had been cleansed and disinfected.

BROTHERLY LOVE.—The following notice to subscribers appended to the number of the Australasian *Medical and Surgical Review* of November 1, 1865, does not give a very satisfactory impression as to the state of the Profession at Melbourne:—"Notice to Subscribers.—In consequence of the impossibility of obtaining an editor capable and willing to conduct the *Medical and Surgical Review*, as an impartial scientific journal, the publisher begs to announce his intention to discontinue the publication of the same at end of current year; and, at the same time, begs to thank his numerous subscribers for their past support.—104, Collins-street East, Melbourne."

CAMBRIDGE.—In Congregation on Thursday, the Vice-Chancellor presiding, graces were submitted having for their object the adoption of the report of the syndicate appointed to consider of the best mode of providing for the teaching of anatomy and zoology in the University. There were three graces. That proposing the adoption of the Professor of Anatomy of the Department of Human Anatomy and Physiology, separate from the other departments, and that the sum of £300 per annum be continued to him from the University chest, on certain conditions, was non-placeted, but carried by 152 placets to 15 non-placets. The grace proposing the appointment of a Demonstrator in Anatomy, at a stipend of £100 per annum, was not opposed. The grace proposing the appointment of a Professor of Zoology and Comparative Anatomy, who may so arrange his course in conjunction with the Professor of Anatomy, that the lectures of both be mutually dependent, and supply the needs of the Medical as well as the natural science students, the salary of this Professor to be £300 per annum, was also non-placeted, but carried by 163 placets to 17 non-placets.

CAMBRIDGE.—At the meeting of the Cambridge Philosophical Society on Monday evening last, Dr. Drosier read a paper "On the Functions of the Air-cells and the Mechanism of Respiration in Birds," in which he disproved the commonly received theories of the use of the air-cells—1. That they are intended to assist in supporting the bird in flight, by rendering it lighter in consequence of the rarefaction of the air contained in them, and their continuations into the hollow bones; 2. That they assist directly in the oxidation of the blood. The lecturer calculated that the floating power from the rarefaction of the air in the air-cells and hollow bones of a pigeon weighing ten ounces, or 4375 grains, would be less than one grain. He also showed in a hen injected and dissected that the air-cells are bounded by a delicate membrane in which the blood-vessels are exceedingly minute and sparsely scattered, and offer, therefore, very little blood for oxidation. The view he took of their uses was that they act as double bellows, causing a constant circulation of fresh air through the minute air spaces of the lungs, whereby the oxidation of the blood in the capillaries was promoted. He also brought forward new explanations of several details in the mechanism of respiration in birds.

HUNTERIAN SOCIETY.—The forty-seventh anniversary meetings of this Society were held last week. On Wednesday evening the annual oration was delivered at the Society's rooms, No. 4, Blomfield-street, by Mr. D. De Berdt Hovell, who in his address gave a comprehensive sketch of the modern practice of Medicine as influenced by recent discoveries in science, and in reference to the life and period of John Hunter. The dinner took place on Friday, at the London Tavern, Alfred Smee, Esq., F.R.S., the retiring President, in the chair. Seventy gentlemen sat down to table, a larger number than usual, the President having specially invited several prominent members of the various learned, scientific, and art societies to meet the members of the Hunterian Society on this occasion. Amongst others present were the President and Vice-Presidents of the Royal College of Surgeons; the President of the Medical Society; Professor Owen; Rev. Dr. Kynaston, head master of St. Paul's School; Sir James Tyler; Dr. Miller, Treasurer of the Royal Society; Mr. White, Treasurer of St. Bartholomew's Hospital; Professor Abell and Colonel Boxer, of Woolwich Arsenal; the Rev. Mr. Rogers, Rector of Bishopsgate; Professor Owen Jones; Mr. H. Weigall; Mr. Brook, President of the Meteorological Society; Mr. Hawes, Chairman of the Society of Arts; Professors Frankland, Odling, &c. Besides the usual loyal and patriotic toasts and that of "The Hunterian Society," which was responded to by the venerable Treasurer, Dr. Cooke, who in return gave "The President," the various other institutions represented were proposed and replied to. The interest and pleasure of the evening were enhanced by the excellence of a glee party under the direction of Mr. Montem Smith.

DR. EDWARD CRISP, in a letter to the Lords of the Council, headed "Dogs and Disinfectants," treats minutely on the subtlety of animal and other effluvia, and their easy transportation. "The scent from the foot of the deer," he says, "is so potent that this animal may be tracked by almost any dog; but this, it will be said, is a natural secretion, and has no analogy to the poison of cattle plague. Let us take an artificial scent. In some parts of India the jackal is hunted early in the morning, before the dew is off the ground, the oil of aniseed, or some strong perfume, being placed upon the feet. In this country, by the same practice, any digitigrade animal may be hunted; and I question whether the scent would be lost after many hours' running. There is no reason why the odour of cattle plague, which is very potent and characteristic, should not likewise be retained. So peculiar is the smell, that I know of an instance in Norfolk where the presence of the plague was detected in this manner:—A gentleman, who had seen much of the disease, was driving along a public road in his own parish, and, in passing a shed, he at once recognised the smell of cattle plague, and told the inspector, who found a cow in the last stage of the disease. The owner, not approving of the Government plan of killing without compensation, and adopting the motto of a late duke, "that a man might do what he liked with his own," had concealed the fact from the inspector. In another instance, diseased animals, when the wind was favourable, could be smelt at a distance of more than three hundred yards; and it is not to be wondered at that cows at this distance were soon infected. If, then, my Lords, the smell of aniseed and other odoriferous substances remain on the feet of jackals and dogs for a long period, it may naturally be asked, why the scent of cattle-plague poison should be more evanescent, or why the virus should be removed from the hair and pad of the dog's foot by friction or dirt? A dog may, I believe, in this way, contaminate every blade of grass he passes over. If restrictions as regards dogs are necessary for single dogs in Ireland, why, it may emphatically be asked, are packs of dogs allowed free liberty in England? Surely, my Lords, to quote a vulgar proverb, 'this is straining at a gnat and swallowing a camel.'"

A PLAN for the protection of cattle from the plague has been suggested by Mr. White, M.R.C.S. Eng., Finchley, N. "Let the cattle breathe air only," says Mr. J. White, "which is disinfected; and assuming that the disease is communicated chiefly by the atmosphere, they will be for the most part free from the disease. Let the cattle shed be air-tight; let the only entrance to the shed be by a porch with a door at each end, having a space between them sufficient for a man with a barrow to be in (say about six feet high by six feet long by three feet broad, inside measure). Let the doors and sides of the porch be of canvas (that used by paper-hangers will do) tacked on the frame. Through this canvas all the air admitted to the building is to be made to pass. This canvas is to be kept constantly wet with a disinfecting fluid (diluted or undiluted), for the purpose of disinfecting the air which passes through it, in the following manner, viz.:—Fix a water-tight vessel, *e.g.*, of wood lined with zinc, over the top of the porch, of such a size as covers it. Let a band of woven fabric, as wool, or flannel, or calico (the more bibulous the material is, the better), be secured by one of its long edges to the bottom of each side of the interior of the vessel, and let this fabric lie over the top edge of the vessel, and descend with its other long edge to the bottom of the exterior of the vessel, so as to impinge against the canvas which is bent over the upper edge of the sides and doors of the porch. Thoroughly soak all parts of the canvas and the band, and fill the vessel with the fluid. The band will, by the process of capillary attraction, empty the vessel, and the fluid, descending by force of gravity by the canvas of the doors and sides of the porch, will keep them wet, and flow off by the floor. When the vessel is emptied, re-fill it. The result will be that the air which enters the building has to pass through the canvas of the doors and sides of the porch, and will, through sufficient contact with the disinfecting fluid, be made pure." Cattle kept in such a building cannot receive the plague through the atmosphere, if the plan is carefully carried out; and there is not much probability of their receiving the infection through any other

medium if ordinary care be used to prevent the entrance of infected matter. The apparatus may be made complete, and fixed to a shed by any carpenter, at the cost of from £4 to £5. A model of the apparatus may be seen at Mr. Weir's, agricultural engineer, 142, High Holborn.

MILDEW IN COTTON GOODS.—There is more than an analogy between the action of minute fungi on dead organised matter and that on the living. As fever germs act on the living animal or plant, so do mildew germs on calico. The preventive and hygienic measures in each case are alike. Let your calico be well made, well sized, and kept from damp. Let your living body be well fed, washed, and aired. If defective food predisposes schoolboys to ringworm, so does defective size predispose calico to mildew. "The Report of the Committee of the Manchester Chamber of Commerce, appointed to consider the subject of Mildew in Cotton Goods" might be read as an appendix to the chapter on parasitic disease in any treatise on pathology. "The researches of your Committee tend to the conviction that mildew plants colonise certain decaying matters, each species living and propagating on its appropriate pabulum; and your Committee are not without hope that ere long such knowledge will be gained by a continued search amongst the mildewed pieces returned to this country, that special 'mildew growths' will be traced to distinct defects of size, and that parasites which affect cloth will be no less marked out than the parasites which affect animal life. Your Committee would observe that the dust from mildewed pieces is a spawn which can be sown amongst sound pieces, if damp, to the future destruction of the same, and would advise that mildewed goods should never be left about in the sample room, as the sporules float for hours in the air. Attempts have been made to prevent the growth of mildew by various antiseptics, but with very partial success. Your Committee have examined several of the proposed remedies, and the difficulties which beset the question are so many (the health of the operatives being studied), that they consider no immediate solution is at hand. With the return to a *well-compounded flour or starch size*, the occasion for an antiseptic would pass away. Your Committee believe that it would be a loss of time to distract attention by experiments directed to a search for anti-mildew specifics." Just so, a well-washed man needs little perfume, and a well-aired house little, if any, disinfectant.

THE following are the last week's Cattle Plague Returns. By comparison with those of the previous week, it will be seen that there have been 11,443 attacked, 7636 deaths, 626 slaughtered, and 1893 recoveries, since January 27 :—

Census Divisions.	1. Attacked.			2. Result of reported Cases from the Commencement of the disease.				
	Week ending February 3.	Week ending January 27.	Week ending January 20.	Attacked.	Killed.	Died.	Recovered.	Unaccounted for.

NOTE.—209 Inspectors have not reported this week in time for this return. Among these, and belonging to the county of York, are Messrs. Hoskinson, Stone, Harrison, Pennock, and Holt; to Shropshire, Mr. Benjamin Duff; to Staffordshire, Messrs. B. Duff and Llewellyn; to Cheshire, Messrs. Storrer and Lewis, the latter of whom has, however, forwarded a partial report. The inspectors returned 2304 cases last week, and the apparent decrease of disease is probably more due to their neglect than to any real diminution of attacks.

"THE SPORTING TIMES."—In the annual retrospect of this well-conducted paper the editor states that "it is with no little pleasure, and no small amount of pride, that we are able to point to the fact that the *Sporting Times* is the only newspaper in which quack medicines are not advertised." This is an example which might be followed with great advantage to the community by other journals.

REMOVAL OF A CATARACT OF EIGHTY-THREE YEARS' STANDING IN A MAN 93 YEARS OF AGE.—Mr. W., now 93 years old, when 10 years of age was struck on the right eye by a stone, and cataract resulted. When seen, in 1865, the field of the pupil was occupied by the capsule, most of the lenticular substance having become absorbed. His left eye began to fail in vision five years since, and an operation was therefore proposed for the cataract in the right. The cornea having been punctured with a broad needle, the canula forceps was introduced, and most of the cataract withdrawn, leaving the pupil clear. The patient was enabled to count the operator's fingers immediately afterwards. A few weeks afterwards he was able to see large objects and tell the time by a watch with a glass of four and a-half inches radius, an attack of conjunctivitis from cold preventing him as yet trying reading-glasses.—*Boston Journal*, August 31.

SECOND REPORT OF THE CATTLE PLAGUE COMMISSIONERS.

THIS Report, laid before the House on Monday night, is divided into five sections.

Section I. treats of the spread of the disease in the United Kingdom, the circumstances affecting it, and of statistical matters with which our readers must be sufficiently familiar.

Section II. refers to the spread of the disease in Continental countries.

Section III. is devoted to a notice of the several orders in Council which have been issued.

In Section IV. there is the following statement of the opinion of the Commissioners as to the nature of the disease. The Report says :—

In our first report we humbly submitted to your Majesty the conclusions at which we had arrived respecting the general character of the disease and the measures which should be adopted with a view to arrest its progress. We agreed (Mr. M'Clean dissenting) in the opinion that the only reasonable hope of effecting this object lay in imposing for a limited period restrictions of a very stringent kind on the movement of cattle, and that these restrictions should be uniform, and should be carried into effect at a time when the disease had not spread to an unmanageable extent, and when they would be attended with fewer difficulties and with far less of loss and inconvenience than must necessarily surround them towards the approach of spring. We differed in some degree as to the amount of stringency which we might reasonably venture to recommend. We think it right to say (Mr. M'Clean still dissenting) that the opinions in which we then concurred not only remain unshaken, but have been materially strengthened and confirmed by the deplorable experience of the last three months.

After laying before your Majesty our recommendations on this head, it remained for us to pursue the investigation which we had already begun into the nature of the disease, with a view to ascertain how far it could be combated by curative or preventive treatment. This investigation included a thorough and minute observation of the symptoms and progress of the disorder, and careful inquiries into its general and chemical pathology and morbid anatomy, a microscopical examination of the tissues and fluids of the bodies of diseased animals, a trial of various methods of treatment, experiments on disinfection and ventilation. It was further desirable to ascertain by actual experiments to what other animals it was communicable.

These inquiries were committed, under the general superintendence of the Medical and scientific members of the Commission, to the following gentlemen :—

1. Nature, Propagation, Progress, and Symptoms of the Disease—J. B. Sanderson, Esq., M.D.
2. General Pathology of the Disease and its Relation to Human Diseases—C. Murchison, Esq., M.D.
3. Chemical Pathology of the Disease—W. Marcet, Esq., M.D.
4. Morbid Anatomy of the Disease—J. S. Bristowe, Esq., M.D.
5. Microscopical Researches on the Disease—Lionel S. Beale, Esq., M.D.
6. Treatment of the Disease—George Varnell, Esq., M.R.C.V.S., and William Pritchard, Esq., M.R.C.V.S.
7. Disinfection and Ventilation—R. Angus Smith, Esq., Ph.D.

On several of these heads no definite conclusions could be formed without long and laborious inquiry. On most of them we have already received reports, and all the reports will very soon be completed. We shall then lose no time in laying them before your Majesty, together with a brief general account of the results reached by the different lines of investigation. This will form our third and last report.

An experimental investigation of the nature and treatment of the disease was commenced at an early period by several gentlemen of high Professional and scientific eminence at Edinburgh, and a valuable report by them has been already published. These gentlemen are continuing their researches, and have undertaken to place in our hands a further report upon the subject.

A large mass of statistical information respecting the progress of the disease has been collected by the Veterinary Department of the Privy Council Office; and the department has also obtained, by printed forms very extensively circulated, information respecting the various modes of treatment which have been practised in different parts of the country, and their respective results. A comprehensive digest of the information so procured under both heads is being prepared under the direction of the secretary of the department, and we hope to be enabled to append this digest, with some illustrative maps, to our third report.

The last Section states some points of practical moment, to which it is thought right to advert. We extract from it the following important remarks :—

"All endeavours to discover a method of treatment on which some re-

liance could be placed have entirely failed. Innumerable suggestions of this kind have been made or communicated to us, to none of which any substantial value could be assigned, and the knowledge and ingenuity of Practitioners in every part of the United Kingdom have been exerted for this object in vain. The experience of the Dutch Physicians and Veterinary Surgeons, during the present outbreak, appears unhappily to coincide on this point with our own.

Vaccination is not a protection against cattle plague. Careful experiments, conducted at our desire by the most experienced operators, have shown that an animal successfully vaccinated, and in which cow-pox has been fully developed, may, within a few days after exposure to the infection of cattle plague, contract that disease and die of it. We have at present no evidence that vaccination fortifies the system against this new assailant in any degree.

The possibility of mitigating the virulence of the disease by inoculation with the matter of the disease is a subject of much interest, and has engaged our attention. Such inoculation has been tried repeatedly, and on a considerable scale, by the Russian Government, and the effect of a long series of transmissions has been carefully noted and recorded; but the experiment has not been very successful, and it has for the present been abandoned. The Dutch Government, though much pressed to introduce it in South Holland, has refrained from doing so for fear of the consequences. Whether modes of inoculation may not yet be found which will effect the desired object is a question which can only be solved by various and repeated trials. Further information on the subject will be given in our third Report. It is obviously unadvisable that any experiments of this kind should be tried, unless by persons of competent scientific knowledge, and under the strictest precautions to prevent the spread of infection.

The only means of combating the disease which remain consist in the stoppage of the movement of stock and of things likely to be vehicles of infection, in the isolation and slaughter of infected cattle, and in the use of disinfectants.

The careful and thorough use of disinfectants, which attack and neutralise the poison either when floating in the air or when adhering to solid or liquid substances, cannot be urged too strongly. In every locality measures should be taken to circulate information as to the best disinfectants, and to insure their being used.

For the purposes of disinfection carbolic acid and chloride of lime are recommended in a note appended to the Report.

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

A Third Year's Student.—Permission to attend Professor Huxley's lectures will be given on your making application.

Mr. H. R. Myers, of 30, Melton-street, Euston-square, writes to inform us that he supplies the Profession with perfectly pure vaccine lymph, collected by himself from healthy infants.

F.R.C.S.—It is stated on good authority that the gentleman named will retain his seat a year longer, owing to the contemplated resignation of a colleague.

W. M., B.A. Cantab.—Dr. Shebbeare was condemned to stand in the pillory at Charing-cross for publishing "An Eighth Letter to the People of England."

An Old Subscriber.—Mr. F. K. Hunt was the author of "The Fourth Estate." He was a qualified Surgeon, and at the time of his death a few years ago was editor of the *Daily News*.

A Provincial Surgeon.—On inquiry, we learn that no more catalogues of the Museum can be given away. The money value of those lately presented to recognised Hospitals by the Council of the College is represented by £690. The price per set to members is £18; but we think a reduction has lately been made.

H. S.—To the late Dr. Valentine Mott, of New York, is due the merit of having been the first to suggest, and the first to effect, the ligature of the common iliac artery.

E. R., Kennington.—In the little vestry beneath the organ gallery of the Temple Chapel is, or was, a marble tablet to Oliver Goldsmith, who was buried in the ground east of the choir April 9, 1774.

Dr. James C. L. Carson, of Coleraine, is author of a work on "The Form of the Horse."

Mr. Henry Clark, one of the Committee of the Liverpool Northern Hospital, who appears to be a teetotaller, has published the following return of various Hospitals in various parts of the country, with cost of intoxicating drinks consumed in one year, as follows:—

	In-patients.	Cost of Beer, Wine, Spirits in One Year.
Newcastle-on-Tyne	1720	£312 0 0
North Staffordshire	922	109 7 0
Salisbury	904	162 0 0
Lincoln	748	112 14 0
Bedford	669	266 15 0
South Hants	642	60 12 0
Adenbrook	638	118 18 0
Kent and Canterbury	625	193 2 6
Suffolk	474	124 9 6
Cumberland	457	72 4 6
	7819	1532 2 6
Liv'pool Northern Hospital (1864)	1735	540 4 2

A comparison of the above returns shows that the expenditure of the Liverpool Northern Hospital is largely in excess of other Hospitals, being 6s. 2d. per patient, against 3s. 11d. elsewhere, or about £200 per annum greater on the average than that of many other institutions.

We should conceive that Mr. Clark's wisest course would be to leave the matter in the hands of the Medical Committee.

An Ingenious Perversion of Popular Physiology.—Sir Walter Trevelyan evidently "a close observer of nature," has published in the *Gardeners' Chronicle* the following theory in support of the beneficial effects of plants in bed-rooms:—

"Some time ago, thinking that carbonic acid gas might be an active agent in the promotion of sleep, I looked into various authors on the subject, but could not find any allusion to what may perhaps prove an important fact.

"The sedative nature of this gas, as shown in producing drowsiness, has been more or less felt or observed by most persons, when it has been generated by the human lungs in crowded or ill-ventilated rooms.

"With a majority of animals in a state of Nature, sleep comes on about the time when the development of carbonic acid gas from growing vegetation commences, at or soon after sunset; and it relaxes its hold about sunrise, when it ceases, and that of the stimulant, oxygen, succeeds, and rouses into action their nervous and muscular system.

"This applies principally to herbivorous quadrupeds and birds. Those carnivora which are constituted to roam at night in search of prey, resort during the day to deep and narrow caverns, in the recesses of which the air must soon be vitiated by their respiration, and thus be adapted to promote their sleep.

"So that, instead of being a gas which should always be avoided, carbonic acid, however deleterious in large quantities, may serve an important and beneficial purpose in the life of man, as of terrestrial animals in general.

"The presence of vegetation in or near our sleeping apartments, which has generally been deprecated, may be favourable to the promotion of healthy sleep, and only require to be avoided as deleterious, when connected with imperfect ventilation, a damp atmosphere, or with exhalations arising from organic decay and the consequent evolution of sulphuretted or phosphuretted hydrogen.

"That a mixture of the air with carbonic acid gas may be essential for healthy sleep, might indeed almost be inferred from the fact that most animals, including man, when instinctively composing themselves for sleep, do so, not only in a position that gives the greatest ease and relaxation to the muscles, but at the same time they place the head so as to favour the accumulation of that gas about it, and consequently its inhalation.

"The head of man, when at rest generally lies low, on a soft and depressed pillow, those of most quadrupeds couched between their paws, and those of birds nestled among the feathers of their backs or wings, so that, in all these cases, besides the normal nocturnal dilution of the air with carbonic acid gas, that part of it which is breathed becomes necessarily, at every inspiration, still further mixed with a portion of what has been already discharged from the lungs, much of which, from the low and confined position of the mouth and nostrils, must be inhaled again; whereas from the generally erect or more elevated position of the head during waking hours, and from the great specific gravity of the carbonic acid gas expired, very little of it can mix with the fresh air that is then inspired."

Mr. Worms' System of Treatment of the Rinderpest.

The Rinderpest.

In order to discover the disease, the animal's mouth should be opened, and the breath smelt. If the breath be at all offensive, the Medicine should be given without a moment's delay. It is also advisable to examine the dung, which, when the animal is affected, becomes peculiarly offensive. After the Medicine has been administered, the animal should be kept warm, and the stable or shed well ventilated and disinfected with chloride of lime. All infected animals should at once be separated from those in good health.

Medicine.

Take a pound of small red pickling onions, and a pound of garlic, peel them, put them together into a mortar, and reduce them to a fine pulp; to this pulp add a pound of ground ginger, and mix thoroughly.

Take three-quarters of a pound of assafœtida, pour sufficient water over it, then allow it to boil till no sediment remains, carefully removing all hard portions. Pour this decoction of assafœtida over the pulp of onions, garlic, and ginger, and stir the whole mass thoroughly. Add to this eight quarts of rice-water, and allow it to cool. This is sufficient for fourteen full-grown animals.

Dose.

To a full-grown animal	1½ pint.
To a heifer	½ ,,
To a calf	⅜ ,,

Treatment.

Two or three hours after the dose has been administered, give the animal (if full grown) four or five pints of rice gruel, to a heifer or calf two or three pints; add a little salt to make it palatable and drench with it if the animal refuses to drink. The animal is to be fed, during two days, three times a day with thick rice gruel, and, at each meal, may have a handful of sweet hay. Should the animals be accustomed to roots, they may, on the third day, have a quarter of their allowance in two meals without rice; on the fourth day, half their portion, and so on.

Should the animal's mouth be sore, wash it with a pulp made of the rind of Seville oranges boiled. Should the animal's bowels be confined after twelve hours, and the stomach swollen, administer to a full-grown animal, half-a-pound; to a heifer or a calf, a quarter of a pound, of fresh unsalted lard, made into boluses.

Sufficient stress cannot be laid on the necessity of administering the Medicine the moment the breath is tainted.

27, Park-crescent, London, February 12, 1866.

On Sterility.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—Your review of Dr. Marion Sims's book has brought back to my mind an idea which has frequently occurred to me. It seems to be universally taken for granted that the condition of the os uteri is constant and unchangeable, or, in other words, is the same during the time of sexual intercourse as at other periods. Now, it appears to me extremely probable that, in a healthy state, the neck of the womb has the power during sexual intercourse of dilating in such a manner as to permit the injection of the fertilising fluid directly into the cavity of the uterus. I merely throw out this idea at present, reserving my reasons for holding the opinion to another time. If from rigidity of fibre or any other cause the dilatation is prevented, sterility will be the consequence.

I am, &c.

Coleraine, February 12. James C. L. Carson, M.D.

Swelling of the Lips and Nose.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—Some time ago a patient came to me with his lips and cheeks swelled, hard and brawny, and of a tallowy paleness. The disfigurement of his features was extreme, but there was neither pain, itching, nor any other special symptom. I learned from him that these symptoms were liable to come on quite suddenly and to disappear with almost equal rapidity, after lasting sometimes a few hours, sometimes many days. The exciting cause was always a bout of drinking. I put the case down as belonging to the category of urticaria; but then if I were to try and explain what urticaria is I should soon be out of my depth.

I am, &c. Delta.

Poor Law Medical Reform.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—I shall feel obliged by your giving insertion to the following letter from the Poor-law Board. I strongly advise the Poor-law Medical officers to forward their subscriptions, as it is quite possible we may yet have to fight the battle in the House of Commons, and therefore shall have need of funds. I am preparing a pamphlet explanatory of the various clauses in the Bill, otherwise the members of the House of Commons may be deceived, as the Select Committee were on a recent occasion.

I am, &c. Richard Griffin.

12, Royal-terrace, Weymouth, February 10, 1866.

List of subscriptions received by Mr. Prowse:—Hemsted, H., Whitchurch, 10s.; Jeffery, B., Worcester, 10s.; Day, R. W., Epping, 5s.; Robertson, W., Alnwick, 2s. 6d.; Foster, W. F., Isle of Wight, 10s.; Moore, A. J., Henley, 5s.; Cooper, W., Bristol, 5s.; Frankland, T., Ripon, 20s.; Fitch, F., Kidderminster, 5s.; Jeston, A. F. Letter from the President of the Poor-law Board:—

"Poor-law Board, Whitehall, February 5, 1866.

"Sir,—I am directed by Mr. Villiers to acknowledge the receipt of your letter of the 3rd inst., together with the draft of a proposed Bill 'for the better regulation of Medical relief to the poorer classes in England and Wales,' and I am to inform you that the provisions contained in the Bill shall receive the consideration of this Board.

"I am, Sir, your very obedient servant,

"Richard Griffin, Esq." "John Thornely.

Inoculation Modified as a Preventive in the Rinderpest.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—Never, perhaps, has any new theory been received, a few cases excepted, with such universal approbation by the Profession and the public than the vaccination of cattle as a protection in the Rinderpest; and although it has unfortunately failed to stand the test of experiment, it may yet, if properly worked out, lead to a satisfactory issue, and should therefore not altogether be rejected as futile. Had the Rinderpest actually been bovine variola, as was believed by many, the inoculation with vaccinia would assuredly have led to a happy result. The want of success, therefore, only proves that it is not small-pox, but a specific malady, an infection *sui generis*.

If I rightly recollect, it has already been proposed to inoculate cattle with the Rinderpest virus; but as such a process could only produce the same disease, with all its direful consequences, the adoption of such a plan could not be recommended; yet the suggestion, like the vaccination theory, has not been without its use, as it has indicated the proper direction to be pursued in seeking for a preservative.

It is a well-established fact that human small-pox, if inoculated in a cow, will not produce the small-pox, but the cow-pox; and if the latter is inoculated back to man it will produce the ordinary vaccine pustule. This clearly proves that the cow-pox is only a modification of the small-pox, and that the prophylactic virtue of the former consists in so modifying the organism that the varioloid poison, when it reaches the system, has but little or no influence upon the same; according to the principle that no two closely-related forces can exist side by side without the weaker being attracted by the stronger, or where they are of equal strength both being weakened in their intensity. Now, if in the case of the Rinderpest we were to do as in variola—start from the same disease—we might (I am merely speaking theoretically) possibly arrive at an infection that would act as a protection against the cattle plague, the same as vaccinia does in variola.

What I propose is simply this, to inoculate the Rinderpest in a different species—say a dog or a horse, or any other animal that would take it in a modified form—and then re-inoculate the virus thus obtained back to the bovine species. The poison thus altered might in the ox take on a milder form, which, similar to vaccinia in small-pox, would act as a preservative in Rinderpest. I merely offer this to the public as an hypothesis, and only regret having no opportunity of putting the theory in practice and testing it by experiment, which is the only way in such matters of arriving at a just and unbiassed conclusion.

I am, &c.

F. E. Jencken, M.D.

Vaccination of Cattle.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—In looking over the *Medical Times and Gazette* of the 10th inst. I was very much surprised to see that a charge was made against Mr. Wm. Faulkner for supplying lymph that was utterly worthless. I myself have been supplied with lymph upon several occasions by Mr. Faulkner, and the last occasion was in the beginning of January, having been urgently requested by several friends to vaccinate their cows, and having used all my own lymph, I telegraphed to Mr. Faulkner for all he could send me by return of post and regardless of expense. He sent me thirty-six points and one tube, stating that that was all he should be able to send me for three or four days. I used that lymph, and was equally as successful with it as with any I had collected myself.

I and my brother have vaccinated upwards of 2000 cattle, and with carefully-armed points we found in one instance the whole herd except two were unsuccessful, and in many herds we found several were unsuccessfully vaccinated; so that with carefully-armed points and careful vaccination you cannot always ensure success.

I have been tempted to send this for insertion in the *Medical Times and Gazette* as I have generally had success with Mr. Faulkner's lymph, and consider it a great convenience to have some one to send to for lymph that we can depend upon, and at his usually moderate charge. Apologising for the length of my letter,

I am, &c.

Wm. Mathews, M.R.C.S.E.

Advertising Quacks.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—A few days ago I was asked to see a young man who was said to be very ill. On visiting him I found him in a very nervous state, but could detect nothing calculated in the slightest degree to account for it, there being no real cause of illness about him. I soon learned, however, that about ten days before I saw him he complained of "an uneasiness" in his chest, and was advised to consult "Dr. Watson or his confidential secretary, Mr. William Hill," who advertises extensively in the "Manly Vigour" style. He did so, and in reply to his letter received another, of which the enclosed is an exact copy. Of course, Dr. Watson's letter was the key to my patient's nervousness. It had made him "daily apprehend the appearance" of the evils—or better still, the "serious evils"—mentioned in this remarkable production of "Dr. Watson or his confidential secretary, Mr. William Hill."

Could nothing be done to prevent the publication of those disgusting and mischievous paragraphs which lead to such correspondence and consequences? Could not a newspaper censorship be instituted for the purpose of granting licence to respectable and necessary advertisements and suppressing those of a filthy and insinuating character which are frequently seen in the columns of apparently respectable newspapers? The really respectable require no censor, and would not fear one; but such proprietors and editors as have not decency enough to avoid offence require restraint.

This is not the first case of the kind that has come to my notice, though I must say "Dr. Watson or his confidential secretary, Mr. William Hill," is about the mildest in requesting a preliminary fee. In one case I know the amount of £5 was asked and forwarded before any medicine (?) was supplied; but "Dr. Watson or his confidential secretary, Mr. William Hill," only asks £1 1s.

I am, &c.

W. Watson Campbell, M.D.

Dunse, Berwickshire, N.B., February 7.

*** This is the old story. A nervous boy receives a filthy and insidious letter, threatening him with loss of health and virility, and his nervous system receives a shock, which is apt to induce confirmed hypochondriasis, whilst his pocket is a prey to the extortionate quack. As for such a censorship as is proposed, it would be impossible to obtain it in this country, for if public opinion or private sense of decency do not suffice to deter the editors and publishers of respectable and religious newspapers from inserting obscene advertisements there is little chance that a law could be obtained. Our own notion is that the only possible safeguard is such a degree of physiological knowledge and moral firmness as shall enable young people to withstand the lures of the tempter. We cannot publish the quack's letter, which is a *fac-simile* of others with which our readers are only too familiar.—Ed.

Genuineness of Mr. Faulkner's Lymph.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—As Mr. F. Duke has called the attention of the public to the worthlessness of vaccine lymph supplied by me, I trust you will allow my version also to appear.

A gentleman called on me for fluid human lymph. I had none, and recommended the cow lymph on points as being more suitable for cattle vaccination, showed him the remarks of the collector, a gentleman of the highest respectability and a most successful operator on cattle, whose letter I enclose for your perusal, together with that of others, who were perfectly successful with the same points, and quite satisfied with all I had sent them. In a few days I received a letter from Mr. Duke, saying he did not like the points; on which I immediately wrote and said if he would return them that fluid human lymph should be sent per return; instead of which he used the points—how he does not tell us, although being a public vaccinator he expected all to succeed—a thing which occurs with but few of the best operators, even from a child's arm; but that is known to the Profession perfectly well, and requires no comment from me. In a few days again he writes demanding back his money, or he would expose me in the *Medical Times and Gazette;* to which I answered that had he put the case differently most willingly would I have sent a further supply gratis; but as he had threatened to expose me he had better do so. Like the little boy who had eaten his bun and wanted his penny back again, so did Mr. F. Duke want his cash; and if I had foolishly sent it, you, Sir, and the public would not have heard anything of my worthless lymph. Out of the hundreds I have supplied last month for cattle vaccination, Mr. Duke stands proudly pre-eminent as the only gentleman who has used my lymph and, failing, demanded back his money. I am quite aware there must have been as many failures as successes with lymph I collected and sold; but the same result occurs to all, and at page 153 of last week's *Medical Times and Gazette* it is stated that M. Lallier observed that of between 30 and 35 vaccinations made at St. Louis from the heifer, only one has succeeded! Also at page 154, of 84 vaccinations made on new-born infants, 59 only were successful. I could multiply such remarks; but any Medical man will know how to value

Mr. Duke's remarks, that because he failed to vaccinate six cows with thirty-six points that therefore the said points were worthless. In conclusion, I beg to state that the points referred to in the letters I send you are precisely the same as those furnished to Mr. Duke, and collected at the same time and taken indiscriminately from the same parcel. Apologising for trespassing on your valuable space, I am, &c.

WM. FAULKNER, M.R.C.S.

*** Mr. Faulkner's letter is accompanied by numerous well-authenticated testimonials as to the efficacy of the lymph supplied by him.—ED.

THE LUNG SICKNESS—A MOST FATAL CATTLE DISEASE AT THE CAPE—PREVENTED BY INOCULATION, AND MODE OF PERFORMING IT.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—I am indebted to a member of our Profession (Thos. Fotheringham, Esq., who has resided eight years at the Cape) for informing me that a disease, well known in that country as the "lung sickness," is prevented by inoculating an ox or a cow by means of a piece of the lung taken from an animal having died of the disease. The operation is performed by making a deep incision about two inches in length in the tail of the animal, and then introducing a piece of the lung, about the size of a walnut, into the wound, and allowing it to remain. In the space of about fourteen days the disease is developed, and the end of the tail drops off.

Mr. Fotheringham informed me that no individual would purchase an animal which had not been inoculated, owing to the disease being so fatal; but instances did sometimes occur when the inoculation failed to protect the animals. Mr. Fotheringham having seen a great deal of the disease, and having inoculated several animals himself, I venture to give, by his permission, publicity to a mode of inoculating which might be worth a trial in the prevention of the Rinderpest, provided, however, it has not been already tried. The lung which is used for inoculating is kept in a jar, and when required for use a portion is cut off and inserted, as I have already mentioned.

It would be interesting to know whether the muscular tissue of an animal affected with lung sickness is infested with entozoa; and it would be also interesting to know whether entozoa are found in the lungs of animals affected with the cattle plague.

To vaccinate an animal for the prevention of the Rinderpest, even if the disease should prove to be small-pox, does not appear so rational as inoculating with human variola. But to inoculate with a portion of the lung, saturated, as it probably is, with the morbid poison, appears more rational, especially if the disease does not owe its origin to entozoa. Should, however, entozoa be the cause or the result of a morbid process in the animal, we may, perhaps, expect to find a remedy in benzine, which is said to kill trichinæ in the human body. I am, &c,

Southampton, July 8, 1866. HENRY OSBORN, M.R.C.P. Lond.

*** Inoculation in the tail has been performed in London dairies for some years for the prevention of pleuro-pneumonia.

"GREASE" AND VARIOLA.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—At the present time the following statements may be interesting, and lead to the settlement of the long-disputed question as to the analogy between the true grease in the horse and the vaccine in the cow, and its transmission to the human subject. About a month ago I was applied to by the tenant of a large dairy farm in Shropshire for some vaccine lymph. I forwarded a full supply, but at the same time suggested that if he could find a horse suffering from grease he would have an unfailing supply of matter from which all his stock and that of his neighbours might be inoculated. The results are contained in the following extracts from letters received since January 31:—"Until last Friday Mr. H. was not able to try your suggestion respecting the grease from the horse, but having found a horse suffering with it, the farrier inoculated some cows from it on Friday last, and on Monday it was apparent how well they had taken, so much so that the farrier has done the remainder of the cows to-day." "The vaccination from the human body makes but little show." In consequence of my suggestion, another large stockholder has had all his cows inoculated with this matter, and in every instance it has fully taken, the pock being well developed, and in some animals producing constitutional disturbance. Of its particular power I of course at present say nothing. I am in the receipt of some of the matter taken from the cows, and am testing it on the human subject. If it produces a true vaccine pustule, the question in dispute is at rest, but at any rate it has proved that this matter of grease will develope a genuine cow-pock in the bovine race. A gentleman, in taking some of this virus from a cow, pricked his finger four or five days ago, and I am given to understand that a pustule is forming. Either next week or the week following I will forward you the results of my own experiments.

I am, &c. THOMAS WHATELY.

Egerton-house, Great Berkhamstead, Feb. 7.

At the Royal Observatory, Greenwich, the mean height of the barometer in the week was 29·624 in. The atmospheric pressure rose to 29·91 in. on Sunday, and fell to 29·33 in. on Saturday.

The general direction of the wind was W.S.W., W., and S.W.

* The average weekly numbers of births and deaths in each of the above towns have been corrected for increase of population from the middle of the ten years 1851-60 to the present time.

† Registration did not commence in Ireland till January 1, 1864; the average weekly number of births and deaths in Dublin are calculated therefore on the assumption that the birth-rate and death-rate in that city were the same as the averages of the rates in the other towns.

‡ The deaths in Manchester and Bristol include those of paupers belonging to these cities who died in Workhouses situated outside the municipal boundaries.

§ The mean temperature at Greenwich during the same week was 45·1°.

APPOINTMENTS FOR THE WEEK.

February 17. *Saturday (this day).*

Operations at St. Bartholomew's, 1½ p.m.; St. Thomas's, 9½ a.m.; King's, 2 p.m.; Charing-cross, 1 p.m.; Royal Free Hospital, 1½ p.m.

ROYAL INSTITUTION, 3 p.m. Prof. Westmacott, "On Art Education and How Works of Art should be Viewed."

19. *Monday.*

Operations at the Metropolitan Free Hospital, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 9 a.m. and 1.30 p.m.

MEDICAL SOCIETY OF LONDON, 8 p.m. Clinical Discussion. Mr. Victor De Méric, "On the Use of Mercury in Syphilis." Mr. R. Wm. Dunn, "On the Mercurial and Non-Mercurial Treatment of Syphilis."

20. *Tuesday.*

Operations at Guy's, 1 p.m.; Westminster, 2 p.m.; National Orthopædic, Great Portland-street, 2 p.m.; St. Peter's Hospital for Stone, 3 p.m.

PATHOLOGICAL SOCIETY, 8 p.m. Meeting.

21. *Wednesday.*

Operations at University College Hospital, 2 p.m.; St. Mary's, 1½ p.m.; Middlesex, 1 p.m.; London, 2 p.m.; St. Bartholomew's, 1½ p.m.; Great Northern, 2 p.m.; St. Thomas's, 1½ p.m.

HUNTERIAN SOCIETY (Council, 7½ p.m.), 8 p.m. Mr. Hutchinson, "On Compression of the Brain."

22. *Thursday.*

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 1 p.m.; Surgical Home, 2 p.m.; Royal Orthopædic Hospital, 2 p.m.; West London Hospital, 2 p.m.

23. *Friday.*

Operations, Westminster Ophthalmic, 1½ p.m.

ORIGINAL LECTURES.

NOTES ON

SOME OF THE MORE RARE FORMS OF FRACTURES AND DISLOCATIONS,

BEING EXTRACTS FROM LECTURES (CLINICAL AND OTHERWISE) DELIVERED AT

The London Hospital.

By JONATHAN HUTCHINSON, F.R.C.S.,
Surgeon to the Hospital and Lecturer on Surgery.

Dislocations of the Os Innominatum.—The case which I shall mention first is that of a young man who was brought to the Hospital having been knocked down by a bale of goods which fell from a crane above him. He was admitted with his right thigh much everted and abducted, and fixed in that position. There was also a laceration of the skin between the scrotum and the left thigh. I was sent for on the supposition that it might probably be a compound dislocation at the hip-joint. As the poor fellow was in great pain and resisted all attempts at examination, we gave him chloroform before proceeding. The strange position of the limb and its comparative immobility certainly favoured the conjecture that a dislocation forwards had occurred. On examination of the wound, however, I found that it led obliquely inwards to the symphisis, and that there was a wide separation at the latter. Two fingers might easily have been placed between the pubic bones. The whole right os innominatum was detached and displaced backwards and outwards. It was very firmly fixed in its new position. On introducing a catheter, we found that the urethra was, as might be supposed, extensively lacerated. I made sure that the head of the femur was not dislocated forwards, it was not to be felt either in the thyroid foramen or on the pubes; and although the fixity of the limb in its new position still remained much as at first, I could only attribute it to the displacement of the os innominatum. On the next day the lad had traumatic delirium, and on the third he died. His relatives refused permission for an autopsy, but by examination of the wound after death and by movements of the limb I confirmed my diagnosis as to there being no dislocation.

During the same week another curious case of fracture of the pelvis was admitted under my care. The man had most extensive injuries, and died a few hours after his admission. I did not see him until he was on the post-mortem table. His left lower extremity was much shortened and everted. We found the head of the left femur projecting into the pelvic cavity through a starred fracture of the acetabulum. I show you the bone; you will observe that it is most extensively fractured. In all probability, the violence which caused such a fracture was received directly on the great trochanter, driving it inwards and upwards.

We have during the last year (1864) had under care several cases of dislocation of the whole of one os innominatum. This accident is always caused by very great violence, and is usually attended by laceration of the urethra or bladder. If the displacement is sufficient to enable us to give a positive diagnosis the case will almost necessarily end fatally. It is possible that now and then a case may recover in which the diagnosis was never established and only contusion suspected. It is an accident which is often overlooked during the patient's life and only discovered on the post-mortem table. Careful examination, first about the pubic symphisis and secondly by the side of the sacrum, in order to detect irregularity or gaping, is the plan by which we seek to establish a conclusion.

Abnormal mobility of the whole haunch is usually a marked symptom, but it is one which, owing to the pain caused and the risk of further damage, we must be very cautious in using. Sometimes I have seen displacement upwards, so that there was positive shortening and so that the crest of one ilium could be distinctly seen to be higher than its fellow. The most useful symptom in practice is the irregularity behind. The posterior borders of the ilium are so immediately subcutaneous that any displacement here is easily appreciated. The patient is usually quite unable to move the limb, and complains of much pain if it is moved by others.

Case of Recovery after Dislocation of the Os Innominatum.—Since the lecture from which the above is extracted was given, I have had under care a case of separation of the os innominatum at the sacro-iliac synchondrosis, in which recovery took place. A German, aged about 30, was admitted in November, 1865, having been run over. He had the appearance of having sustained severe injuries, and during the first few days was in a critical state. He complained of much pain about the pelvis, and his motions passed unconsciously into the bed. We could not, however, make out any actual paralysis. The incontinence ceased on the third day. On the fourth or fifth day it was discovered that there was movement of the left iliac bone at its junction with the sacrum, and that its posterior border was displaced backwards more than half an inch. This led us to make more careful examination of the bone in front, but neither at the symphisis nor in any part of the rami of the pubic bone could we find any irregularity.

Our patient went on very well, being simply kept in bed without any appliance. The displacement of the bone backwards was permanent, but at the end of a month he could bear pressure on the lower extremity, and was very desirous to get up. He left the Hospital soon after, able to walk.

Cases of Fracture of the Pelvis, if not involving injury to the bladder or urethra, very frequently do well. We have recently discharged two patients in whom the ilium was fractured deeply through its body without any ill symptoms following, and other similar cases have been under the care of my colleagues during the last few months (June, 1864). Uncomplicated fractures of the pelvic bones, and especially those involving only the body of ilium, are, in fact, often attended by very slight symptoms indeed. During the year 1865 I have had three or four such in the Hospital, and in two of them the patients could hardly be induced to remain in bed after the first fortnight. The fragments usually continue to be moveable for a week or ten days, and then rapidly consolidate. I have no doubt that simple fractures of the pelvis often get well without having been diagnosed.

There is now (October, 1864) a man in Talbot Ward, on account of cataracts, who has clearly had a fracture of his left iliac bone. He is a sailor, and his injuries were received in a fall from the mast. The anterior and upper third of his left ilium has been displaced outwards. The irregularity is considerable, but the union is firm, and it causes him no inconvenience.

About two years ago we had under care a man whose pelvis had been crushed by a hogshead of sugar rolling down upon him. At first we recognised only severe contusions, and it was not until three weeks later when the swelling had subsided that I discovered a fracture through the ischio-pubic ramus at about the position of the junction of those bones. There was very considerable irregularity, the ramus of the pubis being half an inch in front of that of the ischium. They were now united together, and quite firm. The man recovered perfectly. With such displacement at that part, it is almost certain that there must have been a counter-fracture at some other part in order to permit of movement. Very possibly the second fracture passed downwards through the horizontal ramus into the thyroid foramen; but of this I could obtain no proof. No doubt that had we carefully examined the ramus at the time, we might have detected the fracture, and I mention the case chiefly to show the importance of a systematic manipulation of such parts of the pelvis as can be felt externally in all cases of so-called contusion of the hips, more especially if the violence received have been severe. It is true that if the fracture be discovered there is little to be done in the way of treatment. Still, it is very possible that a timely recognition of the exact nature of the case may save the Surgeon from subsequent criticism.

A curious case was brought to the Hospital a few years ago, and one which at first sight perplexed us much. A young man had been crushed by a fall of earth, and was carried into the receiving room on a stretcher. The House-Surgeon asked me to see him, and pointed out a remarkable irregularity on his pelvis. On the right side just below the crest of the ilium, and not far behind the anterior spinous process, was a large projecting bony mass. It was quite firmly fixed, and we could not produce crepitus. The movements of his hip-joint were free. When I examined him he was in a state of collapse, and could give us no information. On being got to bed, he rallied, and then told us that the lump which had excited our anxieties had been there as long as he could remember. The case was one of contusions only, and the bony lump an exostosis.

Dislocation at the Hip-joint.—We have had several cases of dislocation at the hip-joint recently, and one of them a very

peculiar one. The first fact to which I will advert is that in all we have succeeded in effecting reduction by manipulation only. My own experience comprises five cases, all dislocations *backwards*, and in all success was easily secured. Two of the patients were boys and three were adults. In all five chloroform was given. In four out of the five the reduction occupied only a minute or two, in the fourth it took a quarter of an hour, as the bone slipped upwards from the ischiatic notch to the dorsum ilii. The cases of which I speak were of course all dislocations from violence, and they were all recent. In several instances of dislocation from disease of the joint I have also succeeded by manipulation in getting the head of the bone into the acetabulum again, but in these the difficulty is not usually in reduction, but in retention afterwards. I have never once resorted to pulleys in the management of a dislocated hip, nor have I ever seen a case in the hands of my colleagues or friends, in which they became necessary after a fair trial of manipulation. The principle upon which manipulation succeeds is, I think, very simple; it is that of leverage, instead of traction. Some Surgeons prefer that the muscles should be active, believing that they assist importantly in dragging the bone into position, but my own impression is strong that it is better to give chloroform to its full extent; at any rate, to this fact I can speak positively, that reduction is usually very easy when the muscles are fully relaxed. Having drawn the patient to the edge of the bed, you bend his leg at the knee, and then carry the knee upwards to the abdomen. Having the foot in one hand, and your other hand placed on the inside of the knee, you now sway the knee rather forcibly outwards, carrying the foot across the opposite thigh. If the bone do not at once slip into place, you next bring the limb down again, still forcibly pressing the knee outwards. You will see that this is in some respects exactly the reverse of what is attempted by the old traction method. Instead of dragging the bone downwards, we use the shaft of the femur as a lever, and endeavour by its aid to push the head of the bone forwards into place. If the bone were dislocated forwards (either pubic or obturator) we should have to employ our leverage in a different direction, but of its efficiency or otherwise in these forms I have no experience of my own to give you. In our last two cases we were able to appreciate accurately at what part of the process the reduction took place, and in each it occurred when the knee was pressed outwards to the utmost, and the limb was being at the same moment brought down to the side of the other.

In one case in which I succeeded very easily by this method very powerful efforts by extension had been made on the previous day, and without result. I also once saw Mr. Cock, at Guy's Hospital, reduce a dislocation at the hip in like manner very easily, when most persevering traction attempts in the hands of the House-Surgeon and dressers had failed. One caution I must enforce in reference to this plan, and that is, that you must keep in mind that you are employing a very powerful lever, and not use too much force. The reduction is to be by manipulation rather than by force, and if you chance to turn the limb in the right direction it will slip in very readily.

I will next mention the particulars of a very rare case, which most of you will remember, since the man was under care not long ago in Gloucester Ward. The case is important, not as an instance of success by manipulation, but because we had reason to believe that the trunk of the sciatic nerve had been injured in the accident. I am not acquainted with any parallel case on record, though very probably there may be some.

Dislocation Backwards at the Hip-joint—Easy Reduction by Manipulation—Permanent Paralysis owing to Injury to the Sciatic Nerve.—In the early part of the present year a middle-aged labourer was admitted, into Gloucester Ward, with a dislocation at the right hip and a fracture of the left leg. The symptoms present, as regards the dislocation, were, very conspicuous deformity about the upper part of the thigh, a slight degree of inversion, and slight shortening. The shortening looked more to the eye than we could prove it to be by measurement. From half to three-quarters of an inch was all that it measured. The great toe pointed to the ball of the same toe of the opposite foot, and the patella looked inwards towards the opposite knee. The great trochanter did not seem to be much out of its normal position, a little higher and a little further back. The whole thigh looked short and twisted, and the muscles were thrown into irregular bulging masses; more especially, the tensor vaginæ femoris was very conspicuous, and its whole mass might easily be isolated and grasped in the fingers. The head of the bone could be felt in the ischiatic region, but only with difficulty, The vessels and other structures in the femoral region had lost their due support, and on pressing backwards in this position a decided hollowness might be appreciated.

As the man was in great pain, and as reduction had been previously attempted by Mr. Weller, I decided to give chloroform before proceeding to any manipulations. In his struggles whilst inhaling the man repeatedly drew up the injured thigh, until the femur was at right angles with the trunk. This I pointed out to those present, and remarked also that the range of motion was much greater in most directions than we usually found it in such cases. When he was fully under chloroform I had him down to the bottom of the bed, and having flexed his leg at the knee, carried the thigh upwards towards the abdomen. Then taking his foot in my right hand and placing my left on his knee, I rotated the thigh outwards, and abducted, and at the same time lifted the limb somewhat. On the first trial it did not move in the least. On the second, Mr. Rossignol placed his hand on the knee, and assisted me in making forcible abduction of the thigh when the femur was elevated, and whilst I was in the act of bringing it down again the bone slipped into its place with a very audible snap. It was quite clear to us both that the vigorous abduction of the thigh whilst it was elevated and moving was the cause of the reduction. Perfect symmetry was restored.

On the third day after the reduction I examined the limb, and asked the man if he could move it. He said he was in no pain, but that he could not move his foot, and on examination I found that his foot and leg were almost completely paralysed, both as regards sensation and voluntary motion. A pin thrust into the palmar aspect of his great toe for a quarter of an inch was not felt in the least. He could not move any of the toes. On the inner aspect of leg and of the instep and foot, almost as far as the nail of the great toe, he could feel well. On all other parts below the knee, sensation, although not wholly lost, was almost so. On the dorsum of the foot he could only just tell when we pricked him with pins.

I think it probable that in this case the dislocation, when I saw the man, was in the spine of the ischium. The slight degree of inversion and of shortening would well fit with this diagnosis. At any rate, it was quite clear that it was low down in the ischiatic notch. The lower down in this position the greater would be danger of injury to the sciatic nerve. Unfortunately, it did not occur to us to test the condition of this nerve before the reduction, nor, indeed, until some days afterwards.

The man had been in great pain from the time of the accident until the reduction; he was, indeed, at the time I saw him, pale and collapsed from the shock and suffering caused. I feel certain that the damage must have been done before our reduction, and not during the latter. My manipulations did not altogether occupy more than two or three minutes, and no material amount of force was applied, excepting just at the last moment, when it had the effect of at once slipping the bone back into its socket. Until it thus slipped back it had never moved.

In ordinary dislocations into the sciatic notch the head of the bone lies above the pyroformis, and, of course, above the trunk of the sciatic nerve. Any pressure upon the latter would only be downwards against the somewhat yielding ligaments. If, however, the laceration of the capsule and escape of the bone were beneath the tendon of the internal obturator muscle, as is the case in dislocation upon the ischiatic spine itself, then the nerve trunk would be above the bone, and might easily be stretched or even lacerated if the latter moved upwards.

One of Maclise's drawings shows the head of the femur in this position, with the sciatic nerve crossing the neck of the bone like a strap. I do not find, however, any reference to injuries to this nerve in the works which I have consulted.

With regard to the permanence of the paralysis, I may state that I examined this man six months after his accident, and that he was still without sensation or motion in the structures supplied by the sciatic nerve.

General Remarks on the Diagnosis of Injuries at or near the Hip-joint.—I do not propose to enter here upon any systematic description of the different forms of disclocation or fracture, but to make a few general remarks applicable to cases in which doubt is felt. In the *first place*, let me urge, as I have often done before, that in difficult cases of injuries near joints the Surgeon should always allow himself the advantage of chloroform. Examination is so much facilitated by this agent

that unless a clear judgment can be come to without its use it ought never to be neglected. Many an unfortunate mistake would be avoided were this rule of practice adopted. Not only does it aid in diagnosis, but it often gives most material assistance in the treatment also. *Secondly*, let me caution you not to be misled by the patient's statement as to what he can accomplish with the injured limb into the belief that he has sustained no serious injury. Patients with dislocation at the hip are often able to lift the limb from the bed (in two of our recent cases this could be done), and now and then they are even able to walk.(a) Especially we may often note that under the partial influence of chloroform, when sensation is diminished, but the muscles not paralysed, a patient will often use a dislocated limb very freely. *Thirdly*. As a rule, in dislocations the range of motion is diminished, and in fractures it is increased. If in the case of an injury near to the hip you find the range of motion decidedly increased so that you can bend the limb into abnormal positions, you may be almost certain that it is a fracture with which you have to deal. In many cases, however, the converse of this is not true, and you may have much diminished motion although the bone is broken. This may occur either from the patient's muscular resistance, or more frequently from impaction of the fragments. *Fourthly*. Do not expect your cases to conform with exactness to the descriptions given in books. The majority will do so, but a large minority are cases which deviate in one or other direction from the orthodox types of injury. In order to avoid risk of error, you must therefore let each case have its own peculiarities, and very carefully investigate them all. Have the patient stripped, and examine both hips at once. Make your examination systematic, and point by point compare the relations of the bones on the two sides. Always use a measuring tape, but do not trust it too far; unless its results are definite it may easily mislead, for accurate measurements are very difficult to make, especially in reference to the lower extremity, and the eye is often more trustworthy than the tape. *Fifthly*. Take into due consideration the age of your patient and the conditions of the accident. Dislocations may occur at the hip from the earliest periods of childhood, they are tolerably common in adult life, and very rare in old persons. Separations of the epiphysis can only occur under the age of 21. Fractures of the neck of the femur are very common in old age, but may happen at any period. Dislocations are caused by indirect violence, severe twists of the limb, etc., never by direct blows. Fractures of the neck are common both from direct and indirect violence. Impacted fractures can only result from direct violence, *i.e.*, blows or falls on the trochanter. *Sixthly*. Remember that many cases of fracture through the cervix are attended by impaction, and that the unkindest thing you can do for your patient under such circumstances is to make a correct diagnosis at the expense of separation of the fragments. Whenever impaction is suspected examine very cautiously. *Seventh*. Remember that although eversion is the rule in fracture of the cervix, inversion is sometimes met with. With inversion the case might be thought to resemble a dislocation upon the dorsum.

Separations of the Upper Epiphysis of the Femur.—The diagnosis of this accident has only been attempted within recent years. Sir Astley Cooper's work does not even mention it. I am not aware that any specimen of traumatic detachment of this epiphysis exists in any of our London museums. It is, I think, a very rare occurrence. Ossification begins in this epiphysis during the first year, and is not complete until the twenty-first or twenty-second. The epiphysis comprises only the articular head, and if the separation were complete it would be left in the acetabulum, attached only by the ligamentum teres, and obtaining its nourishment only through that structure. The epiphysis would about fill the acetabular cavity.

The symptoms which we should expect in this accident would be those of fracture of the neck of the femur within the capsule — *i.e.*, slight shortening, eversion, and abnormal mobility. The facts which would aid us in the differential diagnosis would be, the age of the patient and the absence of rough bony crepitus. At best a plausible guess is all that is possible.

Dupuytren does not record any instances of this accident, but he writes in general terms. "In children and young persons who have been saved by the anatomical peculiarities from fracture of the neck we sometimes find separation of the epiphysis."

In Dr. Hamilton's excellent work on "Fractures and Dislocations" I find three cases of supposed separation of the upper epiphysis of the femur, but none of them from his own practice. In none of them can the diagnosis be considered as conclusive. The first is recorded by Mr. South in his edition of Chelius. A boy, aged ten, fell from a first floor window and hurt his left hip. There was scarcely any difference in the length of the limbs, but the left foot was slightly turned outwards. "The thigh could be moved eadily in any direction, and without much pain; but on bending the knee and rotating the limb outwards a very distinct dummy sensation, as it seemed, within the hip joint, as rif one articular surface had slipped off another." The boy suffered so little inconvenience that he two or three times got out of bed and walked about for a short distance. In this instance it seems probable that the separation was, at any rate, incomplete, or possibly the symptoms as much resemble a fracture of the pelvis. The second case is recorded by Dr. Parker, of New York, but was only seen by him seven years after the accident. A girl of eleven fell on her hip, abscess followed, and she eventually recovered, with an inch and half of shortening, an everted foot, but perfect motion at the joint. This latter circumstance led to the diagnosis of separation of the epiphysis. In the third case, Dr. Post, of New York, saw the patient, a girl of sixteen, the day after the accident, and found the limb everted, and an inch shortened. Crepitus was detected. The age of the patient renders the diagnosis of separated epiphysis very probable. The patient recovered, with slight shortening of the limb.

I have myself seen two cases under the care of other Surgeons in which this accident was diagnosed. In each the patient was between seventeen and twenty. In one union was delayed for several months; but in both it was eventually completed. The following are the particulars of the only instance of it which has been under my own care. I was sent for one night to the London Hospital to see a patient with a supposed dislocation of the femur. The House-Surgeon believed that he had reduced it more than once, but it had slipped again. I found that my patient was a lad of eighteen, who had been violently knocked backwards by an explosion of gunpowder. His limb (the left) was slightly everted, and shortened to the extent of about an inch. The great trochanter moved with the shaft. We could draw the limb down, but it slipped up again as soon as the traction was remitted. I did not succeed in eliciting distinct bony crepitus, but a somewhat rough grating could be easily produced. In order to facilitate accurate coaptation, we gave chloroform. When the muscles were fully relaxed, we had the limb very forcibly extended, and then carefully secured it at full length on a straight splint with perineal band. No readjustment of the splint was required for a fortnight, and I then had the limb carefully held by dressers whilst it was effected. We did not remove the splint until six weeks had elapsed, and then found that union was tolerably firm. As a precaution, the splint was reapplied, and retained three weeks longer. The result was perfect, the limb being of the same length as the other, and the union quite firm. As regards the diagnosis in this case, I may remark that the only question is as to whether it was a fracture through the cervix or a detachment at the epiphysal line. That there was a complete solution of continuity at some part of the cervix there could be not the slightest doubt. Whichever view we adopt, therefore, the case is an instance of a very rare occurrence, and of great value on account of the good union which resulted. The mere fact that union resulted will, I know, incline many to regard the case as an extra-capular fracture; thus, Dr. Hamilton writes of bony union after epiphyseal separation, "a supposition which, as far as I can learn, no Surgeon has yet ventured to make."

In close relation with separations of the upper epiphysis we have *fractures of the neck of the femur in young adults*. These are very rare, and differ but little in their symptoms from the same accident in elderly persons. The age of the patient and the detection of bony crepitus distinguish them from detachments of the epiphysis. The chief point of practical interest in regard to them is the question as to whether union may be expected. I believe I have seen at least half-a-dozen cases of fracture of the neck of the femur in patients between the ages of 20 and 35, and I do not remember one in which union did

(a) Sedillot, of Strasbourg, has recorded two cases proving that patients suffering from dislocation into the thyroid foramen can occasionally walk well. One man did duty for years as a soldier with an unreduced dislocation of this kind, and an autopsy at length verified the diagnosis. In another instance a man walked about (lame slightly) for three days before it was diagnosed. Reduction was then effected.

not result; nor do I recollect ever to have met with an instance of ununited fracture through the cervix in a young adult. You will see, then, that we have every inducement to be painstaking in our use of the long splint, and that we must by no means allow the rarity of union in similar cases in old patients to influence our practice in these. We have at present (January, 1866) in Richmond Ward a good instance of satisfactory union of a fracture of the neck of the femur in a young man:—E. C., aged 24, was admitted with a compound fracture of the left femur on the right side; all the symptoms of fracture of the neck of the bone were clearly marked. The limb was shortened and everted, but we could draw it down to full length, and produce crepitus by pressing the trochanter. For a week after his admission he was so ill in connexion with the compound fracture of the opposite femur and other injuries that we did not venture to cause him pain by extending the limb, and it was merely kept steady by sand-bags. At the end of that time the symptoms were as at first, and we now applied a long splint with perineal band, and brought the limb to its full length. The splint was kept on for two months, and union is now complete. He can lift the limb well. Its exact comparative length we cannot ascertain, as both limbs were injured, and probably the other is somewhat shortened. Whether in this instance the fracture was intra- or extra-capsular, I can give you no certain opinion. That there was a fracture through the cervix at some part there can be not the slightest doubt. Some of the facts favour the opinion that it was external to the capsule. As regards the infrequency of fracture of the cervix at this age, I may give you the following facts. Dr. F. Hamilton records twenty-four cases of fracture of the cervix, the average age of the patients being 60, and the youngest patient being 39. Dupuytren writes—"I have never seen a fracture of the neck of the femur in a child, and they are extremely rare in young people generally. . . . With few exceptions, the individuals under treatment in the Hôtel-Dieu are above fifty years of age." Sir Astley Cooper states that the accident rarely occurs before the age of 50.

Why detachments of the epiphysis in children and fractures of the cervix in young adults should be so rare, whilst fractures of the cervix are so common in the old, it is not very easy to say. The clinical fact is, however, undoubted, that in children and young adults dislocations at the hip are much more easily produced than fractures through the cervix. Mr. Canton denies that the neck of the femur in old persons is in any material degree altered in its direction as regards the shaft; and Mr. Bransby Cooper has shown that the relative proportion of earthy to animal matter is not increased in the bones of the aged; and we thus seem to lose two of the chief conditions which it is customary to allege in explanation of the fact alluded to. There can, however, be no doubt that if the earthy constituents of the bone are not altered in quantity, they are in quality, and that the bones of the aged are more brittle. In this fact of atrophic brittleness we must seek the main reason for the frequency of these fractures in old persons.

Fever in Newcastle-on-Tyne.—Typhus fever, which has been fatal in some of the more neglected parts of the east end of Newcastle-on-Tyne during the winter, seems to be travelling into the more wealthy quarters of that town. Last week Dr. Watson, a highly respectable Medical Practitioner, was carried off by it, and on Monday Dr. Hawthorn, a gentleman in large practice, fell a victim to the same disease. On Monday also Mr. John Benson, a Town Councillor, and a gentleman taking a very prominent part in the public movements of the town, died of typhus fever, after a very few days' illness.

Fever in Cheshire.—A correspondent of the *Guardian* newspaper, signing himself H. R. B., reports an outbreak of fever at Buglawton, Cheshire. He writes:—"A month ago we had four or five cases, the next week perhaps twenty, last week above eighty, and now above one hundred. Our silk mills appear to be poisoned with the infection. One after another whole rows of young workmen and workwomen are carried out of the mills in a fainting and prostrate condition. I shall be very much obliged if any reader will kindly inform me of the best way of disinfecting mills and dwellings." The fever is said to be typhus. He states that the employment of wine, brandy, and stimulants has not been attended with favourable results.

ORIGINAL COMMUNICATIONS.

ON THE FORMATION OF ANEURISM IN CONNEXION WITH EMBOLISM OR WITH THROMBOSIS OF AN ARTERY.

By JOHN W. OGLE, M.D., F.R.C.P.,
Assistant-Physician, and Lecturer on Medical Pathology, St. George's Hospital.

In the summer of 1855, whilst considering some cases of acute rheumatic fever in our Hospital, in which the loud cardiac valvular bruit that unmistakeably came on during the course of the disease entirely vanished, the *rationale* of this event engaged the attention of myself and others working in the wards. In the cases alluded to it appeared to me to be most probable that the bruit had been produced by the deposition of fibrine from the blood on the valvular apparatus of the heart,(a) and that its disappearance resulted from the final removal of the precipitate by the force of the blood-stream, which, after undergoing the necessary changes (or, in the language of histologists, the necessary involution), had decayed, become diffluent, and again been re-absorbed or incorporated with the blood, inducing no ultimate evil effect.(b) Such an interpretation was quite in accordance with what we know of the molecular transformations or retrogressive metamorphoses which often occur in coagula of blood formed under some conditions in arteries and veins, in the conical obturating clot or thrombus consequent upon the ligation or continued pressure of blood-vessels, and in fibrinous effusions in various parts of the body. Wishing to try how far the possibility of the disintegration and removal of fibrinous masses which have been liberated into the general blood-current could be determined by experimental research, I resolved to seek the opportunity of artificially injecting portions of fibrine into the arteries of some animal, and of killing it after a certain time for the purpose of discovering what had become of the injected material. Accordingly, having prepared a sufficient quantity of fibrine (partially drying and comminuting it) removed from the interior of an aneurism, by the kind assistance of Prof. Gamgee, I performed the experiment of introducing it low down into the ascending aorta of an ass, so that, if possible, it should reach the left ventricle of the heart. The following are the notes which I possess of this procedure, recorded at the time of observation, and bearing date December 14, 1855:—

"The operation was performed at 11.30 a.m., the fibrine, by means of a long flexible tube arranged for the purpose, being passed down one carotid artery as far as the heart. A quarter of an hour afterwards there was much quivering of the muscles of the neck, body, and limbs. Both pupils were rather contracted, but equal in size. The heart's sounds were natural, its action rapid, and the respiratory movements quickened. The pulse at the jaw was indistinct and uncertain. At a quarter past 4 p.m. the animal looked dull, but the appetite was good, and it had eaten a quarter of a peck of bran. The respiration was normal, but the pulse was rapid and very indistinct; the valvular sounds of the heart were somewhat confused. After this the animal progressed satisfactorily, and eventually became in all respects well; the wound healed, and in twenty-one days it was killed for the purpose of examining the various organs. The wound of the artery was found to have quite closed and healed, and the heart, lungs, and every part of the animal was found healthy, *excepting one branch of a mesenteric artery, which was found to be the seat of an aneurism*, in which one or two strongyli were coiled up."

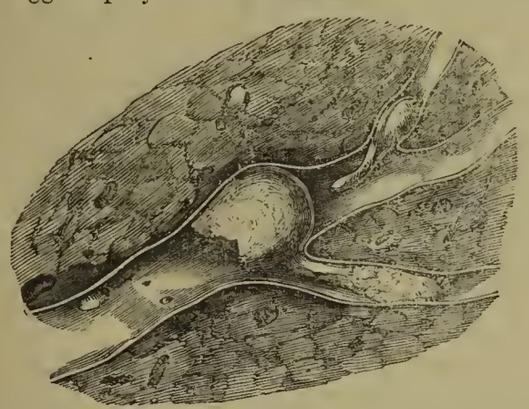
Whatever the relation may have been between the setting free of the fibrinous masses into the blood-current and the disease of the mesenteric artery of the ass, the result of this experiment led forthwith to the suggestion in my mind that in man a not uncommon cause of so-called spontaneous aneurism in the smaller arteries might be the impaction of coagulated fibrine in the canal of the artery, whether, on the

(a) I am aware that in some cases other explanation of the subsidence and removal of endo-cardiac murmurs which supervene during the progress of rheumatic fever has been offered.

(b) Admitting the possibility of the complete removal, without subsequent detriment, of such fibrinous masses from the valvular apparatus as give rise to endo-cardiac murmurs, it is very clear that in certain instances at least the gravity of prognosis which attends cases of rheumatic fever complicated by cardiac murmurs must be modified.

one hand, such mass of fibrine may have been carried thither, having previously been dislodged from the surface of the valves or lining membrane of one of the cavities of the heart, or, on the other hand, may have been originally deposited from the blood (owing, it may be, to its stagnation, determined by some local cause, or to disease of the vessel, etc.), and formed at the portion of the artery affected. (e) Reflection has since strengthened this suggestion.

Let me suppose, for instance, that a mass of solidified fibrine becomes migratory, dislocated from its connection with the inner surface of the heart (or other part of the arterial system,—it may even be from the interior of an aneurism), and driven centrifugally to a part of some vessel where it becomes arrested and fixed, the constant pressure of the blood *a tergo* cannot fail (whilst wedging the mass more firmly in the blood-vessel) to have a tendency to dilate the yielding walls of the vessel, as well at the part exactly corresponding to the plug as on the proximal side of the plug; and this will be in proportion to the completeness with which the canal is occluded, and resistance offered to the impulsion of the blood, until, of course, collateral circulation is established. Such a dilatation of an artery in connection with embolism I have occasionally observed in post-mortem examinations. It is incidentally mentioned by Mr. Shaw in a case of obstruction of the right middle cerebral artery, related at page 34 of the sixth volume of the London Pathological Society's *Transactions*. Mr. Shaw there describes the artery as being obstructed "by a firm white substance," "*causing it to be stretched to about a third above its usual size.*" This condition is also well figured in the same *Transactions*, volume ix., page 93, in connection with a case described by Mr. Callender of clots in the pulmonary artery; and by that gentleman's kindness I am enabled here to reproduce the woodcut showing the dilatation of the bloodvessel at two parts where plugged up by fibrinous masses.



Now, assuming that the entire calibre of the artery is not quite occluded by the fibrinous mass, but that the passage of a certain amount of blood is permitted; or should the calibre of the tube have been completely filled up, supposing that the blood has subsequently forced its way *through* the plug (I here allude to the well-known process of tunnelling, so-called) or *alongside* of it, still the onward current of the blood, tending to widen the aperture for its transit, acting in a lateral direction,(d) will dilate yet more the vessel at the seat of the plug. This dilatation progressing, the disturbance of equilibrium between the force of the circulating fluid and the arterial walls augmenting, a disposition to paralysis of the coats of the vessel from over-distension and prolonged pressure, and consequent loss of contractility and elasticity, must ensue (especially if the size of the plug is maintained or increased by fresh exogenous accretions of fibrin from the surrounding blood); and this the more if the parietes of the vessel become structurally affected by actions resulting from adhesion of the plug to its inner surface and organic fusion therewith, or again if the tunics of the vessel have been previously diseased owing to their occupation by atheroma, or calcareous, or oily material. Of course, the tendency to dilatation or the formation of aneurism would be proportionate to the yielding character of surrounding structures and their looseness of connection.

(c) I alluded to the experiment on the ass described above, and to the impression which it left upon my mind, when relating to the Pathological Society a case of aneurism of the superior mesenteric artery May 5, 1857. (See the *Transactions* of the Society, vol. viii., page 168.) In this case, in addition to the aneurism discovered, soft recently-formed granulations of fibrine were found attached to the aortic and mitral valve-flaps of the heart.

(d) An action by the concurrence of which, in part at least, an aneurism, under certain conditions, tends to burst externally.

Such is the process to which I have conceived the formation of aneurisms may, in certain cases, and chiefly in small arterial trunks, especially those of the viscera, be referred; and this, to my mind, has specially seemed to apply to the formation of aneurisms on the intra-cranial and the coronary or cardiac arteries. I have repeatedly been struck in considering such cases with the immunity from other disease which the affected vessel showed; and, in truth, in any instance wherein a single non-traumatic aneurism in any small artery exists (especially if it be from its position particularly free from liability to outward injury)(e) no disease of the coats of this, or, perhaps, of any other arterial vessel existing, we find it a puzzling matter to offer any plausible account of its production. Of such conditions we have one or two instances in the St. George's Hospital Pathological Museum. Thus preparation No. 129, series vi., shows an aneurism of the posterior tibial artery full of laminated coagulum, whose walls are remarkably smooth and healthy. The patient died with symptoms of *heart disease*, and after death the aortic and mitral valve-flaps were found to have extensive fibrinous deposits attached to them. Another case is the one, which I have previously quoted in a foot-note, of aneurism of the superior mesenteric artery, in which similar deposits were found on the same cardiac valves. (See preparation 115 in the same series.)

I cannot help thinking that in proportion as an aneurism occurs in a vessel which elsewhere and in every way is quite natural, and at a part where bifurcation exists, or subsidiary branches are given off (a part—*i.e.*, at which fibrinous masses would most likely be arrested in their transit), or in a subject free from other lesions of the arterial system, and of an age and sex at which aneurismal formations are least wont to appear—I say in proportion as these conditions obtain, I cannot help thinking that we have sufficiently reasonable grounds for conjecturing that a fibrinous plug, embolic or thrombic, may have been the ground of the mischief. This position would also be strengthened by evidence that the valvular apparatus or some part of the inner surface of the heart had been the seat of fibrinous deposit, or that the patient had been the subject of rheumatic fever.

I have ventured to make the above suggestions regarding the possible mode of formation of aneurisms, and to commend them to the attention of pathologists, hoping that the observations and experience of others may correct or substantiate them.

NOTE ON ACUPRESSURE.

By Mr. LAWSON TAIT.

A few days ago Sir James Simpson showed me a case where he had removed the breast for a scirrhus tumour. The result is so successful that I do not remember ever having seen or heard of its parallel. The patient was only 28 years of age, and very cachectic-looking before the operation—indeed, on the whole, a rather unlikely subject for a large wound to heal by first intention.

The operation differed in some respects from the ordinary method of excision of the mammæ. In the first place, the direction of the wound was at right angles to the direction of the fibres of the great pectoral muscle, while most operators prefer that the direction of the wound should be parallel with that of those fibres. Why this latter should be the usually adopted method I have often asked, and always met with the answer—"Because in that direction the pectoral muscles can exert no evil influence by tearing up adhesions." It does not seem likely that a patient with such a large wound in her breast will exert her pectoral muscles to any great extent; and although I have watched often for it, I never saw any spontaneous movements in them under such circumstances. Besides, the result of this case will show that such a reason is useless; while the direction of the wound across the muscular fibres affords exit at the depending end for the oozing, and prevents the large baggy wound from remaining full of fluid, which rapidly decomposes. This seems to me an important point in this case; but there were others more important—

(e) The *Transactions* of our London Pathological Society contain the records of two cases of aneurism bursting *in the substance* of the brain, one being the case of an aneurism of the posterior cerebral artery, related by Dr. V. der Byl, vol. viii., p. 129; the other of the right superior cerebellar artery, related by Dr. Bristowe, vol. x., p. 4. Dr. Crisp also relates a case of aneurism of the right anterior cerebral artery which burst in the anterior lobe of the brain. (See his work on the Bloodvessels, 1847, p. 165.)

viz., acupressure was employed. The stitches were deep, being introduced by a handled needle, and embracing a large amount of muscular substance. Again, there was no dressing employed—none whatever, and the wound *was not allowed to be fingered:* the only interference with it being that when it felt hot or uncomfortable it was blown upon gently by an ordinary pair of bellows. It was on the thirteenth day that I saw it, and the wound then was perfectly healed—glued together by *primary adhesion* in the strictest sense of the term; and there never had been a drop of pus. Some one who saw it said that he thought it would have been the better for a few sloughs; but had the lady been his wife, I question if this would have been his opinion.

Last week there occurred a case of scalp wound, where the temporal artery was divided by a blow from a paraffin lamp. The wound was closed with two stitches, and the hæmorrhage was checked by a long needle. The wound was healed and the man at his work on the second day, when, as the needle was annoying him by catching in his cap, he removed it himself, without the occurrence of any secondary hæmorrhage. The pressure exerted by the needle in this case must have been very slight, as there was a large extent of skin involved, fully an inch from the entrance of the needle to its exit.

On Saturday night another wound of a branch of the temporal turned up, and was secured in the usual way. I removed the needle in fifteen hours, when the wound was quite closed, and it has remained so up till now.

Bathgate.

REPORTS OF HOSPITAL PRACTICE
IN
MEDICINE AND SURGERY.

SPECIAL REPORT ON THE EXISTING TREATMENT OF FRACTURES IN THE LONDON HOSPITALS.

In reporting on the treatment of fractures, no independent description of the various forms of splints need be given. These will be most conveniently noticed under the head of the particular fractures for which they are required. There are, however, two important accessories in the management of fractures which may be referred to in our first paper—namely, beds, and the so-called stiff apparatus.

That a mechanical contrivance to come into general use must be simple in its construction and easy of application is well illustrated by what is at present the fact with respect to beds (and we may add, in passing, to splints also) in the Hospitals of London.

It is remarkable, and, at the same time, to those who are engaged in practice where what is elaborate cannot be secured, reassuring, that although several of the Hospitals are in no way pinched for funds, although any kind of bed or apparatus could be had almost for the asking, there are very few instances indeed in which any but the common French bedstead(a), or the simplest forms of iron or wood splints are in use. This but indorses Mr. Erichsen's statement that "a Surgeon of ordinary ingenuity and mechanical skill may be fully prepared to treat successfully every fracture to which he can be called by having at hand a smooth deal plank half an inch in thickness, a sheet of gutta-percha, undressed sole-leather, or paste-board, to cut into splints as required."(b)

BEDS.

It is often very difficult in private practice to get a suitable bed on which to place a patient who has sustained a fracture. The ordinary sleeping beds, which come first to hand, are wholly unfit for the purpose. Feather beds are not, as far as we have seen, used in a single London Hospital. A sufficient reason for this, no doubt, is that they are very expensive; but were they cheap they would be equally discarded. A good fracture-bed (1) must be firm, so that it does not sink in under the weight of the patient; (2) it must not become knotty or uneven. It must remain in such a state that the patient can lie as well in one part of it as another.

1. The firmness of a bed depends chiefly on what supports it beneath. We find three contrivances in common use:—

(*a*) Strong webbing tightly strained to the framework of the bedstead by strong cordage. We venture to think this is open to objection. It is liable to yield to some degree under the weight of a heavy person, so that the bed 'sags' in the middle.

(*b*) Iron laths placed longitudinally and transversely.

(*c*) Wood laths lying transversely. These last two are very satisfactory—unyielding, durable, and easily cleaned. It is usual where the webbing is employed to place a board, like the spare leaf of a dining table, under the mattress, to secure the requisite firmness.

2. The evenness of a bed rests with the material of which it is made. The following substances are in use:—

(*a*) Horsehair.—This is allowed to be the best of all. It does not readily become knotty; it has a considerable resiliency under pressure; it is durable, and it can be cleaned. It is, however, expensive: an ordinary Hospital horsehair mattrass, we are told, costs 30s.

(*b*) Flock.—This is the material of which a very great majority of beds are made. It has the advantage of being cheap: a flock bed costs, without the tick, about 5s. 6d.

(*c*) In a few instances straw is used for ordinary cases, but there is frequently placed above the straw mattress a thin flock bed.

It is a curious fact, which all may not have observed, that perspiration from a person collects, not on the upper surface of the bed, next the patient, but on the under aspect, where it may sometimes be seen standing in drops. It is therefore necessary, in examining the condition of a mattress, to look to its under surface. The upper half-thickness, of which we should judge by passing the hand beneath the patient, may be dry and in a fair condition, while the under half is wet and unfit for longer use. A stout person, who perspires freely, will rot a mattress in a month.

We shall now describe the method of making up a bed for a patient with fracture which we found in use in Mr. Paget's accident ward at St. Bartholomew's Hospital. We are aware that those who have had fractures to manage will have mastered details of this kind for themselves; indeed, we must often refer to points with which many readers are quite familiar; even to such, however, it may not be uninteresting to know exactly what means are, by those in authority, considered best for the accomplishment of certain ends. In the case of fractures of the femur and of many severe fractures of other bones, a board, such as was mentioned above, is placed beneath the mattress. The mattress is of horsehair. Upon this are placed a blanket and a sheet. The sheet is very carefully strained tight, and tucked in as far as possible beneath the mattrass, in order that there may be no 'rucks' or 'creases' in it. This seemingly trivial matter is of great importance—the starting-point of a bed sore has frequently been a crease or a coarse seam in the sheet. Covering the patient are a sheet, blankets according to the season, and a coverlet. Pillows are sparingly allowed: they are single, and only wide enough for the head and neck. Patients, if left to themselves, always place their shoulders upon the pillow: when this is the case, the body is in a sloping posture, and so has a tendency to slide down towards the foot of the bed. It would probably be an advantage if it could be made customary for patients to dispense altogether with pillows.

In many instances it is desirable to change the bottom sheet with as little movement of the patient as possible. It may be done thus:—The sheet to be removed is "untucked" at one side of the bed and rolled inwards close up to the side of the body. The fresh sheet is rolled up for half its width, after the fashion of a window blind (or it may be narrowly folded up), and the roll is placed side by side with that of the soiled sheet. The two rolls together are then carefully and gradually pushed beneath the patient, when the one can be removed while the other is put in order.

The way of managing the action of the bowels when the patient is not in a condition to sit up in bed is very important. Here Hospital nursing, where plenty of help is at hand, has, as is so often the case, a great advantage over that in private houses, where everything must be done by one person. In some of the Hospitals the evacuation is passed into a draw-sheet, or into a hollowed-out mass of tow, which is then removed, the skin being afterwards washed and carefully

(a) We shall notice the beds named respectively after Luke, Earle, and Arnott when we refer to the fractures for which they are most often used.

(b) "Science and Art of Surgery," 1861, p. 204.

dried. In the generality of cases, however, some kind of bed-pan is used. This utensil, which is best constructed in the form of a wedge, should be as shallow as possible, since it can then be readily slipped into place when the patient is slightly rolled over upon the side. The "Liverpool slipper" and a very good pan made by Weiss are constructed upon this principle.

STIFF APPARATUS.

We find that there are in the practice of different Surgeons three distinct periods at which fractures are put up in the stiff apparatus. 1. As soon as possible after the accident. This applies, however, with the great majority of Surgeons(c), only to the most uncomplicated cases, in which there is simply a breaking of the bone, with little or no displacement of the fragments, and little injury of the soft parts. 2. After the lapse of ten days or a fortnight (splints having in the meantime been used), when all spasmodic action of the muscles has passed off, and all swelling has subsided. 3. At the end of a month or five weeks in the case of the bones of the leg, after a longer interval in the case of the femur, and when union is becoming tolerably firm. There can be no doubt that the stiff apparatus is perfectly adapted for simple fractures of single bones, as the fibula, and also for the more uncomplicated fractures of two contiguous bones, such as the tibia and fibula.

There are some details in the application and management of the stiff apparatus, whatever material is used in making it, which we may refer to. The limb should be washed with soap and water, thoroughly dried, and dusted with starch powder, in order that the skin may be in as good a state as possible to resist the ill effects of long-confined perspiration. A thick sheet of cotton wool, or a flannel roller, in one or two layers as the case may be, should be applied first as a padding beneath the stiff splint. As few turns or reverses as possible should be made in laying on the bandage containing the stiffening material. These, if present, are apt to form ridges, which are a source of irritation to the parts beneath. If the free edge of the bandage is stiffened it is likely to excoriate the skin, especially above the heel; a margin of half an inch should, therefore, be left unstiffened. In some instances the stiff splint is cut up as soon as it has "set," and is afterwards reapplied by means of straps as a bandage. Both the glue and the starch casing mentioned below are readily so managed. This method, although it has the advantage of allowing a more close watching of the repair of the fracture, is not generally followed; the splint is commonly left entire as at first applied. Seutin's pliers (d) are the most convenient instrument with which to cut up the plaster-of-Paris bandage, but strong scissors, or an old pair of cutting bone forceps answer almost equally well. It is worth mentioning that it is as well to introduce a broad tape longitudinally under the first or flannel bandage next the skin, with its ends projecting above and below, so that when the casing is slit up, either with stout scissors or Seutin's shears, the skin may not be wounded.

Four materials chiefly are used in making a stiff apparatus —namely, plaster of Paris, gum and chalk, starch, and glue. *Plaster of Paris* is recommended by the following circumstances:—It is very cheap—good plaster costs 6s. per cwt.; it keeps good if placed in a *dry* atmosphere for almost any time; it forms a very strong and light splint, and it "sets" very quickly. A great deal of the success which attends the use of this apparatus turns on (*a*) the material of which the bandage is made,—this should be coarse soft muslin, or cotton of very open texture; common flannel or cotton rollers are unsuitable; (*b*) the "preparation" of the bandage,—this consists of rubbing as much as possible of the dry plaster powder into the meshes of the bandage through its whole extent. The application is thus made:—One bowl of cold water and another of dry plaster being at hand, two or three feet of the prepared bandage are evenly rolled upon the limb in a single layer; this applied portion is then thoroughly wetted, and some of the dry powder, taken in the hand, is well rubbed into it; more bandage is applied, and the same process of wetting and rubbing in of fresh plaster is gone through. A single thickness of the bandage is of sufficient strength in many cases, but more may be added if it is thought desirable.

Gum and Chalk.—The mixture is readily formed by making equal parts of powdered gum and finely-powdered prepared chalk into the consistence of thick batter by the gradual addition of water; or powdered chalk may be stirred to the requisite amount into a moderately thick solution of gum in water. It is applied by being painted into the meshes of an ordinary roller.

The starch bandage, as at present in very common use, is so fully described by Mr. Erichsen(e) that we need not specially dwell on it.

Glue.—This is the best commercial French glue. It is first softened by being soaked in cold water, and is afterwards heated over the fire till it liquifies. A fifth or an eighth part of methylated spirit is added in order that it may "set" more rapidly. This substance makes a very good stiff splint—light, strong, durable, and when carefully put on, very presentable in appearance.

Leather and gutta percha are in very general use for the lighter kinds of splints. We need only say of leather that it is frequently not soaked long enough. It should be kept in cold water for several days, or in moderately warm water for some hours before it is used. It will then be thoroughly softened, and rendered mobile in its texture, so that it can be turned evenly round a prominence, or be fitted to an angle or into a depression. Gutta percha should be of sufficient substance. A good deal that is in the market for other purposes is not stout enough for splints; that which answers best is about one-eighth of an inch in thickness. In making large splints of either of these substances—as, for example, for hip disease in children—holes may be here and there punched to allow of ventilation.

A "leather-felt" splint (a patent of Mr. Hides, of Mortimer-street) has lately been introduced into some of the Hospitals. It is made of thick felt lined with wash-leather. The felt, being first moulded to the limb, is stiffened by the application to it of a mixture which is sold with it. It is a very convenient material, and sets very quickly.

E. B., F. H. M.

(To be continued.)

(c) Mr. Erichsen ("Science and Art of Surgery," 1864, p. 229) says:—"During many years, however, I have followed Seutin's plan in some hundreds of fractures of all kinds, putting the limb up in the starched apparatus *immediately* after the reduction of the fracture, and have found the practice an extremely useful one, even in fractures of the thigh. . ." We shall hope to give some results of Mr. Erichsen's practice when we notice particular fractures.

Medical Times and Gazette.

SATURDAY, FEBRUARY 24.

PROFESSOR GAMGEE ON THE CATTLE PLAGUE.

We recently alluded to the investigations that were being carried on with the object of making out, as far as possible, all that could be of the nature of Rinderpest. We have now to notice the labours up to the present in this direction of no less an authority than Professor Gamgee. The volume(f) he publishes containing the results of his investigations appears most opportunely at a time when the public acts of the country are rendering a tardy testimony to the sound wisdom and clear foresight of the measures he has so long advocated in the face of so much opposition.

(e) "Science and Art of Surgery," p. 205.

(f) "The Cattle Plague." By John Gamgee, Principal of the Albert Veterinary College, London, etc., etc. Pp. 859. London: Robert Hardwicke. 1866.

The work is divided into three parts; of which, however, the first and second only refer immediately to the cattle plague. The official Reports of the International Veterinary Congresses held, one in Hamburg in 1863, and the other in Vienna in 1865, form the third part of the work. These Reports, which are published for the first time in this country, contain much matter referring to the prevention of the spread of Rinderpest.

A definition of the disease opens the first part. Cattle plague is a specific, malignant, and highly contagious fever; it never originates spontaneously beyond the Russian frontiers, and within these it is probably not generated at any time *de novo*. It is essentially a bovine disease; it never attacks any animal more than once. Its period of incubation does not exceed ten days. Among the symptoms is mentioned fever-heat preceding all other symptoms. The skin affection is defined as a "scaly eruption on the back and loins, and a characteristic eruption on the inside of the thighs and on the mammæ."

Bearing on the statement that it is a specific malignant fever, we find these passages at p. 80 in the admirable dissertation on the nature of the disease:—"The cattle plague is not a local disorder; it is not an affection of any special organ or group of organs. It is a systemic disease—a fever in which the mucous membranes and skin are specially implicated. . . . It is, however, something different, and something more than an inflammation of the breathing, or digestive, or generative systems. The cell growth, fatty and molecular disintegrations, desquamation, and discharge of the epithelial and epidermic cells, are typical of this disease. In this way it can only be classified amongst general diseases, with fevers of a specific kind, and which originate from specific causes, run a definite course, manifest a singular periodicity in their progress, and have a marked tendency to destroy life."

At page 79 we are told that it never attacks men, horses, dogs, and the great majority of warm-blooded animals. The poison does pass through the system of some ruminants besides those of the bovine race, but it appears to be deprived of much of its force until it returns to members of the ox-tribe. Concerning the proposition that from some peculiarities of the soil of the Steppes, or of the Russian breeds of cattle the cattle plague may be generated *de novo*, the author remarks, when treating of the causes of the disease, that "as yet no one has demonstrated that in the Steppes cattle can be placed under such circumstances, apart from being subjected to the influence of contagion, as can induce the disorder;" that "the disease is always there, roving to and fro, winter and summer, amongst cattle of all kinds, sometimes killing many, and at other times attacking few." "There are periods of recrudescence," he states, "which are to a great extent accounted for by periodic and extraordinary movements of stock, as in times of war or by an activated cattle trade; but neither cold nor heat, rain nor drought, storms nor severe frosts, affect the propagation of the malady, except in so far as they affect the movements of people and the traffic in cattle."

We have mentioned among the characters selected by the author for defining the disease fever-heat preceding all other symptoms. We have in this symptom another proof of the value of the use of the thermometer in disease, to which we have directed our readers' attention elsewhere. To the experimental inquiries of Dr. Arthur Gamgee and the author of the work before us we believe we owe our first knowledge of the important fact that a rise in the temperature of the animal attacked with Rinderpest takes place, and that before any other symptom is manifested. The subject is of so much interest, and not only so, but of so much practical importance, that we give the following extract from the author's remarks:

"A delicate thermometer indicates an elevation of temperature in the earliest stage of the disease, varying from 1° to 4° Fahr. The elevation precedes the acceleration of the pulse and every other symptom. I have usually inserted the bulb, and about two inches of the stem, of the thermometer, within the vagina or rectum, and kept it in a couple of minutes, using the precaution of dipping the instrument in water at 100° Fahr. between each observation, so as to prevent discrepancies. When one of Casella's registering thermometers is used, the warm water into which the thermometer is dipped should not exceed 90° Fahr., and I commonly add a little Condy's fluid to the water so as to disinfect the instrument. The normal temperature varies from 100° to 101°, and may rise to 102°. It is not uncommon to find it in healthy animals varying one or two degrees at different periods of the day, so that reliable observations can only be made on a number of cattle at the same time, obeying in all the same conditions as to the instrument used, the part in which the observation is made, whether it be the rectum or vagina, and the length of time the instrument is inserted, &c. Sometimes, when animals are excited on a hot day, and are hurried into a shed from a field, the thermometer may rise one or two-tenths more than usual; but if a whole stock be examined, any animals suffering, however slightly, from the disease, indicate an elevation amounting even to 5° or 6°. Such an exaltation of temperature is generally incompatible with health, and the only exception yet known to this rule is that observed during œstrum or sexual excitement; the temperature then rises 3° or 4°, and the same may be seen just after parturition. It is probably preferable to introduce the thermometer into the rectum, as animals are restive when the bulb is inserted in the vagina."

In the section treating of the symptoms, we read at p. 50, that "in favourable cases we find a cutaneous eruption on various parts;" that "we sometimes find a desquamation of the epidermis which indicates a morbid process of the skin, similar to that affecting the mucous membranes;" that "the surface of the skin over the neck and withers is often moist or greasy from an abundant sebaceous secretion;" that "there are no vesicles, and an entire absence, as a rule, of pustules."

The changes undergone by the blood, milk, and urine in Rinderpest, according to the experiments of Dr. Arthur Gamgee, made some months ago, form a valuable part of the book. From these experiments it appears that the amount of serum is remarkably diminished, the amount of fibrin and corpuscles is increased; that of the latter in a very decided manner. The great increase in the quantity of the corpuscles Dr. Gamgee thinks can only partially be accounted for. It seems to us, however, that the increase of the corpuscles, and the diminution of the serum, *in a given quantity of blood*, are only different expressions of the same fact—an altered ratio of one of these matters to the other. It would require us to know the total amount of blood in the animal's body to enable us to decide whether the absolute quantity of corpuscles had been increased or diminished by the disease.

The examination of the milk showed principally a remarkable diminution in the amount of sugar, and an enormous increase of butter. These results, we may remark, must be taken in connection with the fact that the total yield of evening milk was only a few ounces. The conclusion to be drawn is, that in this disease the secretion of sugar is checked the most, that of butter the least, of the ingredients of milk.

As he could not obtain the whole of the urine passed in twenty-four hours, Dr. Gamgee has not been able to ascertain the actual quantities of the different constituents of this fluid passed daily. He records the presence of albumen in varying quantity, of bile-colouring matters, and of traces of bile-acids.

In an addendum to the section on the nature of the disease, the author gives a detailed confutation of Dr. Murchison's small-pox theory. A full account of the preventive and curative treatments that have been proposed are also given; but we need hardly add that the author has no belief that any successful method has been, or is likely to be, discovered.

The section on the prevention of the cattle plague gives a full account of the measures to be adopted to arrest its spread, and a long and important account of the effects of inoculation. The Government measures for the prevention of cattle plague

and the First Report of the Commissioners complete the first part.

Part II. gives a full and exhaustive history of the cattle plague, both in past times and during its present outbreak in this country. The history of the Revel cargo is given, and on such evidence as will surely satisfy any impartial reader, that by this cargo the disease was introduced into this country.

The account which we have given can afford but an imperfect notion of the valuable contents of this volume; but we have already exceeded the limits of our space. We confidently recommend it as a contribution to the history of Steppe-murrain, and a record of its present visitation to this country, not likely to be surpassed.

NOVEL PHASE OF MEDICINE.

We frequently hear it stated in extra-professional circles that Medical men are not men of business—that a Professional training is a bar to success in the mercantile world—that if Doctors are taken out of their Profession and placed in the mart or exchange they will generally be found unfitted for pushing their way and making their fortunes by commerce or speculation. We own that we have felt, on the whole, flattered by such criticisms. A profession, we have said, is certainly not a trade. It exists for higher ends than mere money-making. It cultivates higher intellectual powers than are required for calculating profits, and appeals to higher moral faculties than are of necessity developed in the shop or counting-house. Certain facts, however, are from time to time forced upon public notice which seem to prove that the general opinion which we have quoted, like many other general opinions, may be quite wrong, and that our estimate of the character which Medical training and practice develope is becoming antiquated and Quixotic. So far from a Medical man not being a good man of business, he is found in actual practice to be so sharp that those acute bodies, the railway companies, avail themselves of his talents to conduct the delicate monetary arrangements which their misfortunes may render necessary, between those of Her Majesty's subjects whom they have mangled or shaken and their shareholders, in preference to the abilities of subtle lawyers or specially trained agents. Take, for instance, the report of a trial which we publish this week under the head of "Legal Intelligence." What a perfect picture of commercial art it exhibits, the artist being a diploma'd Surgeon. The evidence gives us the Medical man who "represents" the Midland Railway pursuing his avocations. It is Sunday, and his ministrations, combining those of agent and Doctor, take a benevolent tinge, befitting the character of the day. His errand is to one of the victims of the Colney Hatch accident. Storing with blank cheques his pocket-book, which he appears to use sometimes as an instrument of diagnosis and sometimes, like Mr. Ralph Nickleby did his cash-box, as a delicate allurement, he calls on the patient. In what honeyed terms he introduces the subject of compensation; how, to pave the way, he assures the patient of the deep sympathy which the company, collectively and individually, feel for his sufferings; and then, after the requisite degree of softening is supposed to have been produced, how he gently slides into the subject which he has at heart. It is only for the sake of the peace of mind of the sufferer—only for the sake of the marvellous effect that it must certainly have in hastening his recovery, that he, as a Medical man, ventures to allude to it. Then lightly descending from his Professional eminence, how gracefully and condescendingly he takes his stand on the same level with the Custom-house officer. He touchingly appeals to their common humanity, and talks to him as "man to man." He, as a Surgeon, keeps a carriage; the railway company keep a number; if his carriage had knocked out the poor man's teeth, what compensation would be due? The responsibilities of the railway company are exactly those of his own coachman, and on this fair and honest basis between "man and man" why could they not come to an agreement? To our minds, the whole thing shows a masterly acquaintance not only with the laws of commerce, but with those of diplomacy. As Medical critics, we might demur to the statement that injury of the spine is always accompanied by fixed pain, and that impairment of its functions is always followed by paralysis; but any mere scientific misgiving of this sort is completely overcome by our admiration for the transcendent genius for *finesse* displayed by the Medical representative of the Midland Railway.

THE THERMOMETER IN DISEASE.

It has been seen that the only constant symptom of fever is preternatural heat, and that the other symptoms are calculated to mislead us in many cases. A disease in one part of its course may have strongly marked and characteristic symptoms. These may all disappear except the preternatural heat, and thus, unless the temperature be noted, a very erroneous impression regarding the condition of the patient will be formed. This sometimes occurs in ague.

The following case illustrates our remarks:—A young man, 18 years of age, was admitted into Hospital. He suffered from well-marked tertian ague. The symptoms of the cold, hot, and sweating stages were strongly developed. His spleen was greatly enlarged. He was very anæmic. The fits occurred in the middle of the day and lasted several hours. After resting in bed a few days all his symptoms disappeared, and at no period of the day did he feel ill. His appetite, which had been bad, returned. He got up daily. He was convinced that the fits had ceased. In a few days' time he was kept in bed, that his temperature might be observed. This was found to rise as formerly, and to reach a point equal to that attained when the symptoms were all present and were well marked. Many such cases are on record. Quinine not unfrequently disassociates the symptoms from the disease, while the fever, tested by the thermometer, still continues. Sometimes it makes the disease very irregular in its course, so that it conforms neither to the quotidian, tertian, nor quartan type.

Such elevation of the temperature with the absence of the other symptoms in ague, continues for a considerable time. Probably this fact partly accounts for those cases, apparently cured, in which, however, on a return to work, exposure to the weather, or to other causes, the symptoms return.

It is obvious, therefore, that the temperature is the only true guide to the condition of the patient, and that the patient must be kept under treatment if the temperature continues to rise above the standard of health.

Sometimes quinine, when given to persons ill with ague, removes the symptoms and greatly lessens the daily elevation of the temperature. But some elevation occurs. In such cases from slight causes, the disease returns with its original severity. Such patients cannot be pronounced to be cured.

What amount of elevation is sufficient to show that the disease continues? It is necessary to remember that in *health* there occurs a daily elevation of the temperature. Such an elevation often amounts to 2° or 2·5° Fah. The minimum temperature often falls to 97°, and the maximum rises to 99° or 99·5° Fah. The daily variations of the temperature in health are greater in young people than in adults.

The lowest temperature is reached usually between 12 p.m. and 4 a.m. After the latter hour the temperature again rises, and reaches its maximum usually about 12 at noon. Hence a mere rise does not prove the continuance of the ague. It must attain a point higher than the maximum temperature of health. If a temperature of 100° or higher be marked by the thermometer, the patient is not cured.

The following case shows that a frequent pulse (which, apart from the temperature, is the most important symptom) cannot be relied on as evidence of fever:—

A girl, aged 18, was admitted into Hospital in the following

condition :—She lay in an apparently insensible state; when roused, she would answer questions; she spoke in a whisper; her lips and teeth were covered with sordes; her tongue was dry and brown; the pulse beat 160 in the minute; she had a peculiar movement of both hands, which disappeared when she slept. From the peculiarity of her manner, from the whispering tone of her voice, and the strange movement of her hands, hysteria was suspected. But was this the only condition present? Did the frequent pulse, the dry lips and tongue, and apparent prostration indicate fever? By the aid of the thermometer her temperature was proved to be normal, and thus all febrile diseases were excluded. By the use of galvanism she was at once cured, and the pulse was reduced greatly in frequency, though it continued to beat about 108 in the minute for some days longer.

On the other hand, a pulse of the frequency of health by no means proves that fever is absent. Thus, not unfrequently whilst the pulse beats with the frequency of health the temperature may be 103° or 105° Fah.

A case has lately been narrated by Dr. F. W. Gibson where the pulse beat only 52 in the minute, and the temperature of the body was judged by the Physician in attendance, who relied on his touch, to be normal. By the thermometer this was found to be 103° Fah. This was a case of acute jaundice.

The chief causes of a frequent pulse are,—1st, General weakness; 2nd, Fever. There is no character of the pulse by which it can be told to which of these causes the increase in frequency is due. When elevation of the temperature of the body occurs, the pulse is mostly increased in frequency. Such increase is proportionate to the amount of the elevation of the temperature; that is—the higher the temperature, the more frequent the pulse. If the pulse beat very quickly, if its increased frequency cannot be accounted for by the rise in the temperature of the body, the other cause—namely, weakness—is present, and hence information in respect of treatment is obtained.

But the frequency of the pulse is greatly dependent on age, temperament, sex, etc., and thus it is difficult to lay down exact rules respecting its relative frequency to the temperature of the body. But if, the temperature continuing the same, the pulse increases in frequency, we learn that the patient has become more prostrate, and we learn that stimulants are required.

A rapid and considerable increase of the beats of the pulse in febrile patients, while the height to which the temperature daily rises remains the same, is always a most serious symptom, and often precedes and foretels the death of the patient. We need hardly mention that the excitement caused by the visit of the Medical attendant may considerably accelerate the pulse.

The circumstances that influence the pulse are—1. The condition of the heart. 2. The condition of the arteries. 3. The amount of blood. The state of the arteries influences the size of the pulse. If there be want of tonicity the pulse is large; if, on the other hand, they are contracted, the pulse is small. The arteries generally sympathise with the general condition of the system. When this is weak, their coats are relaxed, and the pulse is large. Thus a large pulse often indicates the reverse of a vigorous condition of system. But on the heart depends the strength of the pulse; from it the blood receives its impulse.

The heart, like the arteries, sympathises with the condition of the system. When this is weak, the heart beats proportionately feebly, and the pulse, though it may be of considerable size, is easily compressed. If the system be vigorous the heart beats strongly, and the pulse is compressed and arrested with difficulty. It is, therefore, compressibility that gives us the greatest information respecting the general condition of the patient. Thus in febrile patients the two circumstances to be carefully looked to are, the relative frequency of the pulse to the temperature and its compressibility.

Neither alone is to be constantly relied on; they mutually correct or confirm one another. From these two circumstances we gain most important information in respect of the prognosis and treatment of the patient—whether stimulants should be given or withheld—whether they should be given sparingly or freely. The question the Physician has to decide is—given a disease of a certain duration and intensity, has the patient sufficient strength to withstand the disease. The pulse, judged in the manner just mentioned, estimates the strength of the patient. We have seen that the temperature affords an exact measure of the intensity of the disease, and we shall find subsequently that it also gives much information in respect of the duration of the attack. The nature of the disease must also be borne in mind, as diseases of a different nature, which may produce the same degree of elevation of the temperature, may vary greatly in their danger.

It is to be hoped that the sphygmograph, by virtue of the information it will give regarding the condition of the pulse, may make our knowledge in this respect still more exact.

All of our readers will be able to call to mind the difficulty they have experienced to decide whether a patient was suffering from hysteria or was the victim of a serious disease. It is true that those most experienced can usually detect the true nature of the case. Nevertheless, cases occur where hysteria so closely simulates other disease that a diagnosis is at first impossible. Such a case has been already given. Here there were many symptoms that were suggestive that the patient was the victim of fever. But by the use of the thermometer the error made from the symptoms that were present was corrected. The instrument is often of service in other cases of hysteria.

Hysteria often simulates inflammatory disease, but the temperature of the body of persons suffering from acute inflammation is always raised. *The temperature of hysterical patients is normal.* Hence we possess a means of discriminating between these two conditions. If the temperature be normal the patient is not the subject of an acute inflammatory disease.

THE WEEK.

DR. RICHARDSON'S METHOD FOR LOCAL ANÆSTHESIA.

Dr. Richardson's process for local anæsthesia, first described in this journal on February 3rd of the present year, has been successfully carried out several times this week. Dr. Richardson has used it at nine operations of various kinds, and several others have had recourse to it. The operations in which it has been successful have been fistula in ano and removal of polypus from anal orifice by Mr. Gowland; phymosis, by Mr. Erichsen; incision of an abscess of the breast and eversion of a diseased nail, by Mr. H. Thomson; and removal of a tumour from the sole of the foot, by Mr. W. Adams. In the last-named case the tumour removed was about the size of a large walnut, and had been a cause of much suffering. The incision was carried round the tumour, the extent of skin surface divided being over two inches, and the dissection being carried downwards nearly to bone. The patient, a lady, thought she was conscious of the line the knife took through the skin, but said it caused no pain whatever. During the deep dissection she felt nothing at all. The results, so far, of this new method are satisfactory beyond expectation; but we learn that Dr. Richardson is still actively engaged in devising further improvements with the view specially of making the process applicable to more important operations.

PROPOSED PENSION TO THE WIDOW OF THE LATE DR. R. D. THOMSON.

Some months ago we had the gratification of announcing to our readers that Lord Palmerston had promised to recommend Her Majesty to grant a pension to the widow of the late Dr.

R. Dundas Thomson, not as an eleemosynary gift, but as a recognition of the deeeased Physician's lifelong devotion to science, and of much unpaid labour in the publie serviee. For example,—during several years he analysed the waters supplied by the various water eompanies to London, and furnished the Registrar-General with the results for publieation in his Weekly Returns. A better thing for the public health was never done; and these analyses are now eontinued both by Professor Frankland, on behalf of the Registrar-General, and by Dr. Letheby, on behalf of the Medieal Offieers of Health of the Metropolis. But such analyses are worth two hundred and fifty pounds per annum at a very moderate computation. We learn with regret that Earl Russell, not being, perhaps, suffieiently informed of the nature of Dr. Thomson's elaim, has expressed doubts as to his ability to carry out his predeeessor's good intentions; but we are sure that such of our readers as have been interested in the progress of Medical scienee and of sanitary reform will join us in hoping that Earl Russell will consent to pay this graeeful tribute to the memory of a man whose labours benefited others more than himself.

INDIA-RUBBER ENEMA APPARATUS.

On looking through an illustrated eatalogue of Surgieal and obstetrieal instruments and appliances which we have received from the Messrs. Maw, we are struck with the immense advanee made during the last few years in the ehcapness and exeellence of many articles which are indispensable to the health and eomfort of invalids. Of all human inventions, there is scarce one more serviceable than the enema. Some time ago we happened to be attending an Eton boy of ten years old, the son of an eminent statesman sinee deeeased, and proposed that he should have an enema. The child roared at the supposed indignity, when his mother said, "Don't be so silly and frightened, for I know that your papa does so every day before he goes to his offiee." What the particular eonnection between the posterior region of humanity and the brain may be we do not pretend to say; but we know that it is impossible to give undivided attention to business or study when the reetum is irritated with what it ean't readily expel, and that health and comfort of mind, and body, and temper may be promoted by the simple operation of washing out with a pint of cold water(a). If this were done more frequently, we suspect that St. Mark's Hospital would lose half its patients. It is a great objeet, therefore, that enema apparatus should be eheap, easily worked, able to be used in private, and effective. Now, as to cheapness. A few years ago no enema apparatus eould be got for less than 10s. to 20s. Now they can be had at from 3s. to 6s. Formerly, the brass syringes in common use required to be put together and taken to pieees, and required three hands for comfortable administration, whether to self or others—*i.e.*, two hands for the pump and one for the delivery pipe. Now, Higginson's india-rubber enemas are workable with one hand, and the construetion requiring a simple act of expansion and eontraction, like a reptile's heart. Formerly if a seedy creature, staying perhaps in a strange house, wished to perform sueh an act for himself, he must go to a great expense to get a "fountain reservoir" enema, which he could put into his poeket. Now, with one of Higginson's, which cost 3s. 6d, he ean twist it up and put it into his pocket, and with a mere jug of water has all he requires. These are small matters, courteous reader, but a good many people's eomfort depends on them nevertheless. Whilst we are on the subject, let us advise the Messrs. Maw, and all other manufacturers of enema maehines, to take particular pains with that pipe whieh is inserted into the orifice of the bowel, for the shape of many in eommon use, and especially of those attaehed to india-rubber bottles for children, is the reverse of what it should be. They ought to be inverted eones—made of the smoothest metal, and largest at the extremity, so that when introdueed through the sphincter they may not slip out readily.

(a) There is somewhere an ancedote that Voltaire one evening, in conversation with a friend, appeared very miserable, and said he should hang himself. In the morning the friend called to inquire if he had put the threat into execution. "Not so," was the answer. "*Mon lavement a bien operé ce matin.*"

FROM ABROAD.—NULLITY OF MARRIAGE IN THE INSANE—MORTALITY AT MATERNITIES.

M Legrand du Saulle relates an interesting ease in whieh a marriage was reeently annulled by the *Cour Impériale de Paris*, in consequence of the intervention of a Medical Practitioner. M. J., formerly a eaptain of engineers, having at various periods of life exhibited remarkable eeeentricities, when 46 years of age, after a reverse of fortune, left Franee for Mexico in 1860, aecompanied by his servant, Eliza S. Some months after he had an attaek of aeute delirium, which quite shattered his faculties, so that from that time he beeame the victim of hallueinations of the senses and mystical ideas. Sometimes, too, he was immersed in ambitious projeets, and at others, plunged into the depths of despondency, yielding like a child or a sick person. In November, 1861, he twice attempted suicide, his mental disturbanee still continuing after he had recovered from the effects of these attempts. In less than a month after he was married at Mexieo to Eliza S., who, not satisfied with a legacy of 40,000 fr., bequeathed by a prior will, induced him to present her with a marriage gift of 25,000 fr., and eventually to declare her universal legatee. Immediately after the marriage, Dr. Sehultz applied at the French Legation at Mexico, declaring that he had long attended M. J., suffering from insanity, with threatening paralysis, and that in his opinion advantage had been taken of his state of mind to induce him to marry his servant, against whieh marriage he consequently entered this protest. In January, 1862, M. J. resolved to return to France, and during the voyage was eonstantly thinking of drowning himself. When he arrived in Paris (Mareh, 1862) he was pronounced by competent Practitioners to be suffering under dementia and general paralysis, and was placed in an Asylum. Proceedings having been taken on the part of his friends to deelare his marriage with S. null and void, the civil tribunal of the Seine, in July, 1863, pronouneed the marriage valid. This led to renewed Medieal investigations being made at Mexico as to his state at the time of marriage, and, by a judgment of the *Cour Impériale* in 1865, M. J. was pronouneed at the time of, and prior to, his marriage to have been in a state of dementia, and the marriage eonsequently declared void.

"It is evident, therefore," says M. Legrand, "that a marriage may be dissolved in France, and we must admit that this is only justiee. In faee of so equitable a decision, and of an attitude so loyal and courageous on the part of M. Schultz, we ean only regret that it should unfortunately be so diffieult to oftener protect the interests and honour of families. We very frequently, in fact, find individuals contraeting disproportionate, unreasonable, scandalous, or infamous marriages under the certain influence of the aeeidents whieh herald in the commencement of general paralysis. In sueh cases the marriage contract is drawn up entirely in favour of the woman, and, before long, the husband dying, his fortune passes into such unworthy hands. Should the contraet eontain some restrictive elauses, a will is quiekly suggested, and still more eagerly accepted. The same occurrences are also observed during the suspensory phases of general paralysis, which have been termed *remissions*, and which, in a Medico-legal point of view, are so well deserving of the attention of Medical Praetitioners and magistrates. It is well known that as soon as, under the influence of senility or disease, a man begins to lose his mental faculties, he beeomes the objeet of eupidity. Spoliative measures are projected, robbery is organised around him, intimidation is exercised over his weakness, and all resistanee is in vain. Is it possible to effieaciously remedy such a state of things? Yes. To this end let not the Practitioner aeeord too pre-

ponderating a part to theoretical superfluities and micrographical subtleties, let him employ himself less with therapeutical experiments on his patient, and endeavour to acquire a more exact recognition of the precise state of his intellect. He will then no longer see these catastrophes taking place, which have brought ruin to more than one domestic hearth, without recording his protest. Is this to ask too much at his hands? Surely not, as he then may, in imitation of Dr. Schultz, secure the triumph of science and truth."

At the request of the Société de Chirurgie, M. Le Fort gave some account of his new work on Maternity Hospitals, the result of the visits he has paid to the various establishments of this kind in Europe. His conclusions are based upon 1,800,000 accouchements, 883,312 of the number having been effected in Hospitals, and 934,781 at the patients' own houses. The difference in the mortality is most striking, for while in the former category it amounts to 1 death in 30 deliveries, in the latter it is only 1 in 150, or 200, or even less still. So great is the difference in Paris itself, that in the years 1862-63-64 the charitable lying-in institutions only return a mortality of 1 in 187, while the Paris Maternité, during 1860-64, lost 1226 women of 9886 who were delivered within its walls—*i.e.*, 1 in 8! Although less marked, this difference is also found throughout Europe. This excessive mortality in maternities is chiefly due to the great development of puerperal fever which takes place, the appearance of the disease seeming but very little influenced by season, climate, concomitant epidemics, individual conditions, or the amount of concentration of the patients. The epidemics which arise are, moreover, not due to germs diffused through the atmosphere or meteorological conditions, for the sanitary condition of two neighbouring maternities in the same town may be very different. While the Paris Maternité was ravaged by frightful epidemics, and that for more than a year, the mortality at the Clinique continued below its ordinary mean. The same facts have been observed in the two maternities at St. Petersburg, and in those of Vienna—where they are situated within the same Hospital, without, however, any personal communication with each other, the one being attended by Medical students and the other by midwives.

On the occasion of the presentation of M. Le Fort's work to the Academy of Sciences, General Morin observed that the Consulting Hospital Committee of the Ministry of the Interior had been occupied with this question, and had arrived at the same conclusion as M. Le Fort's figures led to, that it was preferable that women should be delivered *à domicile;* but, as many of these women had no homes, it was impossible, even for their sakes, that maternities should be suppressed. The most that could be done was to ameliorate their condition by diminishing the number of beds and very much enlarging the space occupied by each. The plan, too, found so efficacious at Dublin will also be adopted—viz., the assigning four wards, each capable of holding ten beds, to thirty patients, so that there shall always be an empty ward, which, in its turn, is cleansed and whitewashed. He added that public opinion had suffered a great shock from this frightful mortality at lying-in establishments, and that it was very important that it should be made acquainted with the solicitude with which the administration was endeavouring to remedy so sad a state of things. M. Velpeau observed that the reform had been commenced by opening a lying-in ward in every Hospital, and deliveries had been even allowed, in spite of the regulations, to take place in the ordinary wards, in the midst of other patients. He also pointed out that the *morale* of the patient had as much to do with her recovery as the hygienic condition of the patient. Delivered *à domicile*, she was surrounded by the faces of those she knew and hearts she loved, while her abandoned state when in the Hospital, and her anxiety as to the fate of herself and child, singularly aggravated the redoubtable crisis she had to pass through. The women who were delivered at home recovered in spite of the deplorable conditions their misery may have reduced them to.

PARLIAMENTARY.—THE SEWAGE OF LARGE TOWNS—CATTLE DISEASES BILL—THE STATISTICS OF FOOD—THE REMOVAL OF THE BRITISH MUSEUM COLLECTIONS—DWELLINGS FOR THE LABOURING CLASSES.

On Thursday, February 16, in the House of Commons,

Mr. Schreiber asked whether it was the intention of Government to propose any additional legislation with regard to the sewage of large towns?

Sir G. Grey said that the Government did not entertain any such intention, and that for this reason. In the course of last Session an Act was passed to give municipal authorities power to acquire land, and a Commission was also appointed to inquire into the state of rivers in the United Kingdom. Until some experience had been obtained of the operation of that Act, and until a report had been received from the Commission named, the Government did not think it expedient to propose any further legislation on the subject.

The Cattle Diseases Bill was committed. Various verbal amendments were made in the earlier clauses without much discussion, and on Clause 13, which relates to the slaughter of diseased animals and the compensation to be given to the owners,

Mr. Bright renewed his protest against indiscriminate slaughter and against the principle of compensation out of rates raised from the whole community, particularly to the extent proposed by the Bill. He objected altogether to retrospective compensation, and urged the Government to reconsider the compensation clauses.

The Chancellor of the Exchequer proposed to alter the clause so as to provide that compensation may be given up to one-half the value of the animal when sound, the amount not to exceed £20.

After considerable discussion this amendment was agreed to.

On the 16th clause, which gives discretionary power to the local authorities to order the slaughter of cattle herded with diseased animals,

Mr. Bright proposed an amendment to the effect that this slaughter should not take place without the consent of the owners. He read a letter describing the successful treatment of Baron Rothschild's cattle at Mentmore by Mr. Worms' process.

Sir G. Grey said that the authorities in many cases insisted that the slaughter of these animals was quite as important as that of the diseased cattle.

Mr. Hunt warned the House not to trust too much to these remedies, which had hitherto proved delusive.

Mr. Tollemache informed the House that Mr. Worms' remedy had been tried on his and his brother's farm in Cheshire, and had proved a failure.

Some further discussion took place, and on a division the amendment was rejected by 388 to 50.

On the motion of Sir G. Grey a proviso was added to Clause 17 excluding from compensation persons who have violated the orders.

The clause relating to retrospective compensation was negatived with a view to its reconsideration.

On Clause 21, which relates to the movement of cattle,

Mr. Hunt moved the first of a series of amendments prohibiting the total removal of cattle until March 25, and announced that if he carried it he should then propose to insert in the clause a string of exceptions to this general rule.

Sir George Grey objected to the proposal, on the ground that sufficient facilities did not exist for the supply of dead meat to the great centres of population, and he feared, therefore that it would have the effect of raising the price of the food of the people.

Mr. Henley believed that the amendment, on the whole, would be attended with the least inconvenience.

Mr. Headlam referred to the case of Newcastle to show what inconvenience the total prohibition would cause in the great towns.

Mr. Lowe pointed out that the question was not with what degree of strictness or laxity the movement of cattle should be permitted, but whether Parliament should not embody in this Bill the regulations under which it thought this movement should be permitted, instead of leaving them to be settled by a number of local authorities. He earnestly exhorted the House not to let slip the present opportunity of checking the disease, and warned them that if it were not checked by the middle of April the calamity would exceed the worst apprehensions.

The discussion was continued by Captain Jervis, Lord

Elcho, Mr. H. A. Bruce, Sir J. Simeon, and Mr. Weguelin; and on a division the amendment was carried by 264 to 181.

On the suggestion of Mr. Bouverie, the Chairman was ordered to report progress.

In the House of Lords on Friday,

The Earl of Ellenborough asked Earl Granville whether he would consent to lay on the table a copy of a letter which had been published in the newspapers, he apprehended by the authority of the Government, about three weeks after the plague first broke out. It was from the Consul at Warsaw, stating that a disease had broken out in Poland in 1857, such as was represented now to exist in this country, but in no case did it extend itself to any part of the country where the water was impregnated with iron, and cures had been effected in other parts of the country by giving animals water in iron vessels. He was astonished to find that a letter so remarkable had failed to attract public attention, and that so simple a method of treatment had not been resorted to, at all events, experimentally.

Earl Granville promised that the noble lord's suggestion should not be forgotten, but did not anticipate any very favourable results from the course of treatment indicated in the letter.

In the House of Commons, in answer to a question from Mr. Hunt,

Sir George Grey said that the Government would acquiesce in the decision of the House last night, and the mode in which they proposed to carry it out was by embodying in one bill the provisions as to compulsory slaughter, compensation, and the rates to be levied for that purpose, and Mr. Hunt's amendment absolutely prohibiting the removal of cattle by railway. This would leave the movement of cattle by road and the exceptions to be dealt with in a separate bill. He acquiesced in the committal of Mr. Hunt's bill *pro formâ*.

The House then went into committee on Sir G. Grey's bill.

After a long discussion on the compensation clauses,

A clause was added, enabling the Queen in Council to suspend at any time the operation of the Act as regards the slaughter of animals.

The Bill was ordered to be reported on Saturday, and the Chancellor of the Exchequer intimated that he should ask the House to read it a third time.

Mr. Hunt's Bill was committed *pro formâ*.

On Saturday Sir George Grey's Bill was read a first time in the House of Lords and a third time in the House of Commons, and passed in the Lower House.

In the House of Lords on Monday the Bill was read a second and third time, and passed.

The House of Commons went into Committee on Mr. Hunt's Cattle Plague Bill.

Mr. Hunt explained the exceptions to the general prohibition of the removal of cattle which the Bill proposed to allow.

On Tuesday, in the House of Lords,

The Royal Assent was given by commission to the Cattle Diseases Bill.

After some conversation respecting various points in connection with the cattle plague,

Lord Derby inquired what measures had been taken to prevent the spread of the small-pox in sheep which had recently broken out in Northamptonshire.

Lord Granville replied that measures had been adopted which it was hoped would prevent the extension of the disease; and, in answer to further questions, he stated that at present it had not been precisely ascertained whether the disease had been imported from abroad.

In the House of Commons,

Sir S. Northcote asked the President of the Board of Trade what amount of information the Government could give respecting the consumption of articles of food, especially corn and meat, at various periods in the present century.

Mr. Milner Gibson: I am sure that any estimate that could be furnished of the quantity of corn and meat consumed either now or at any former period during the present century would be very loose and unsatisfactory. We have returns of the importations of foreign corn which may be depended on, but we have no returns of the home-grown corn consumed, and no statistics of the extent of land under cultivation. We are now taking a cattle census, and it is possible, if it be true that one-fourth of the cattle are annually slaughtered, and if we get this census completed, we may be able to estimate the consumption of butcher's meat. But with respect to corn, those acquainted with the subject tell us that no information which can be depended on exists.

Mr. C. Bentinck asked the Chancellor of the Exchequer what course Her Majesty's Government intended to pursue relative to the vacant ground at South Kensington, and the erection of a building there; and whether any bill was to be introduced this session for the removal of any of the collections now forming part of the British Museum.

The Chancellor of the Exchequer: The intention of Her Majesty's Government, as I think my hon. friend will perceive from the Civil Estimates which will very shortly be laid upon the table, is to propose two votes for the disposal in part of the site at South Kensington, one of which will apply to the reception of certain collections of the British Museum, and the other to patents. With respect to the introduction of any bill this Session for the removal of those collections, that would not come on until we have disposed of the vote. It must necessarily follow; but until I know how that question has been disposed of I am not able to speak of the time when the bill will be introduced.

Mr. M'Cullagh Torrens, in moving for leave to bring in a bill to provide better dwellings for artisans and labourers, described at some length the straits to which working men were put in the metropolis and other large towns to obtain house accommodation, and the evils which resulted from overcrowding, and showed that hitherto private speculation and private charity had failed to supply anything like an adequate remedy. He explained that the Bill would give power to the Home Secretary, when he had reason to suspect, or was informed by a corporate body, or by a certain number of ratepayers, that any district by reason of overcrowding was exposed to the danger of pestilence, to cause that district to be inspected, and an estimate of the expense of the necessary removals and rebuildings to be drawn up; and it also would empower the Public Works Commissioners to advance money for the purpose of carrying the necessary improvements out, on the security of the local rates.

Mr. Locke seconded the motion, which was supported by Mr. Kinnaird, and after a few words from Mr. Childers, leave was given to bring in the Bill.

MEDICAL MANNERS IN THE NINETEENTH CENTURY.

Practitioners of the present day have no small reason to congratulate themselves upon the change which has taken place of late years in Medical manners; or, perhaps, it would be more correct to say upon the gradual decay of Medical mannerism. There was a time when more thought was bestowed by the fashionable Doctor upon his external appearance, figure, behaviour, and manner than upon the ills of his patients; and even now many a rising Doctor feels more anxiety as to the impression his mere manner may produce upon his patients, and his capability of pleasing them, than he does concerning his practical experience in the treatment of disease, or his Professional knowledge and skill. In former days a man might, indeed, learn the art of satisfying his patients by studying mankind as it was then, far better than by working in Medical schools, or watching the treatment of the sick in the wards of a Hospital. In former days the public could judge of us solely by our manner, and they looked for a particular manner in their Medical adviser, and if they found it not they were dissatisfied; but all this has changed. Not that manner is not required in these days, or that it is a thing to be trifled with or entirely disregarded by any one who aims at even a moderate share of Professional success; but it is no longer the *one thing only required* to ensure success. Nay, in these days high acquirements, associated with bad manner, may command some success, while the most perfect manner, with only an empty head to support it, will pretty certainly bring failure to its possessor. We all have our little peculiarities of manner; but these are far more indicative of the individual gentleman than was formerly the case, and they are often natural peculiarities rather than cultivated conventional oddities or ridiculous caprices. We seem to aim at being thought gentlemen and being real Doctors, instead of affecting to play the Doctor, and studying how to impress the patient with the profundity of our wisdom, although painfully conscious of our deficient information. In short, it is quite certain that in these days there is far greater simplicity and honesty of purpose in Professional manner than was formerly

the case. We really do more, and think more, while we pretend to very much less. We seek to gain the confidence of people rather by conveying information than by clever acting, or boasting of power over disease which no mortal can possess, and taking every opportunity of puffing ourselves in a manner which would now be considered vulgar, even by not very sensitive persons

A type of Practitioner occasionally to be met with early in the present century was the following:—A very stout, but ignorant, bustling person, who spoke in a loud, blustering, authoritative tone, and gained the confidence of his patients by a system of terrorism—"It is well that you sent for me, ma'am, when you did, for had you delayed but another day there would have been little chance of saving you." The Professional knowledge of such a Doctor, and his powers of diagnosis, may be easily estimated. Plenty of self-confidence rendered real knowledge to him a worthless superfluity, and not a little bluster soon overawed patients who asked unpleasantly minute questions about the nature of their cases. As may be supposed, our friend was a terrible coward at heart, and when he supposed himself ill he appeared what he was—a cringing ignoramus—and laid aside for the time the character of an offensive bully. Happily, the type is gone, there being no further demand in these days for the sort of article, nor for the shrewd discerning sort of Professional adviser with very decided manner, who, when asked respectfully by his timid patient if he might eat beef, said "Beef! d—— it, Sir, no." If for "beef" he had said mutton, or chicken, or port, or sherry, or claret, the answer would have varied only in the repetition of the word. A generation or two has passed since then Medical mannerism is completely changed, and most assuredly neither the Profession nor the public has lost by the altered fashion.

Gold-headed canes, with the vinaigrettes, have likewise long since disappeared, and the last pair of Hessian boots, after lingering for some time in solitary lustre, finally vanished. But one solitary Jabot (frill) erects its unblemished crest in Medical London, and its respected owner, who was never wrong in his opinion, forms the only remaining link which connects free and progressive Medical science of the present day with the unyielding Medical rigidity of the past.

The individual peculiarities now noticed among the different classes of Practitioners, although often laughable enough, seldom amount to actual bad taste. They seem rather to partake of harmless affectation, and for the most part might be indulged in by other than Professional men, and are therefore not peculiar to Medical practice. Still, slight differences of manner may be observed among existing Physicians, Surgeons, and general Practitioners. Thus, one walks into his patient's room, hat in hand, with a dignified air, and slow, measured step; another in the quickest possible manner, with every limb dancing about as if it were hung upon wires, and every muscle of expression nervously quivering and twitching with emotion excited by the extreme interest he takes in the condition of his patient. One enters the patient's room in his overcoat; another leaves it in the ante-room; a third leaves his hat and coat in the hall, like the singing master; but there is now no rule in this matter, although some masters of Professional etiquette think it a breach of good taste to enter a ladies' room with a great coat on their back. Another frowns and looks severely upon the patient, or very grave and thoughtful; some appear pompous, and a few jaunty. And when the patient begins to detail his or her aches and pains how one Doctor's face lights up, another's appears imperturbable; another looks knowing; some bland, some obsequious, some expressive of superior wisdom or calm dignity.

What ample room is there for the display of individual Medical peculiarity in the mode of receiving a patient in the consultation-room! One Doctor rises and courteously offers the patient a seat; another appears overwhelmed with business, and without raising his hand from the letter he is writing says, curtly, "Be seated, sir," or "Sit down;" a third dances about, shakes the patient by the hand, tells him how very glad he is to see him, stirs up the fire, and hopes there is not much the matter, etc., and after entering into conversation a little, pats him on the back, and assures him he can give him a little tonic which will just brace up his nerves and set him quite to rights. Some of us give definite and rigidly exact directions in a few carefully-worded sentences; others write down on paper the number of teaspoonfuls of water that should be added to the one of wine; some go over and over the same ground in order to impress the patient more strongly with the importance of this or that recommendation, and succeed in sending him away in a happy state of confusion; some talk in a gossiping way, and give no directions after all; some detail the number of cases of the same kind brought under their notice before, and tell the patient how Lord or Lady B.'s case differed in this or that point from his own.

Occasionally Doctors give complete clinical lectures to their patients, some adopting the familiar, others the grandiloquent style of imparting knowledge. Some try to give the patient the impression of being cheery and hopeful about his ease; others give him the notion of being doubtful; some are actually dismal, and a few—obviously never intended by nature to be Doctors at all—seem to be utterly uninterested with every particular piece of information afforded by the patient.

One Doctor exhibits the greatest interest in secretions, and deems it of pressing necessity to examine with the greatest attention the quality and quantity of the excrementitious matters in all cases; another Practitioner considers this attention important only in some cases. Some take the actual vessels in their own hands; others allow the nurse to perform this part of the operation, while they look intently and perhaps smell and test the compound. On the other hand, a highly-eminent Practitioner regarded all this as very unnecessary, and the lifting the vessel in his own hands so derogatory to his Professional dignity, that he wrote two letters to prove that this was actually the nurse's and not the Doctor's business. The most sensitive and elegant of Doctors would, however, scarcely consider it right to run the chance of allowing hæmorrhage from kidney or bowels to escape observation.

And how differently we signify to the patient that we have actually listened to what he has to tell us. Some say "Yes," although the patient asked no question whatever, or "Yes, I see," or "Yes, quite so;" some, "Indeed!" some, "Ah!" some, "Oh!" some, "'hm;" some give a slight cough; some grunt, and correct it a little too late by a benignant smile. And while all this is going on, some of us stand up with back to the fire, some sit down. Some, whether sitting or standing, maintain an erect stiff posture, never rotating the head without turning the body, and bend as if all the vertebræ were anchylosed; while others incessantly nod the head and assent to ten times as many statements as have been made, seeming to have understood the whole story even before the preliminary and introductory matters have been gone over. Some gently incline the head at a particularly graceful angle, others nod in a common-place style. Some listen to every word with the utmost attention, so that when called upon to rejoin they may afford evidence to the patient that each minute particular has been weighed and considered in its proper order, and will not be lost sight of in the elaborate prescription about to be written. Others, of a more cogitating and less amiable disposition, who perhaps have been a little more accustomed to real thought, sit near to the patient and display the most imperturbable patience, because they have learned the art of travelling a long, long way off till the story is finished, trusting to their well-practised intelligence to seize important points, or to their ingenuity to supply any links in the story they have neglectfully lost.

Although conventional manners are for the most part unnecessary in our day, it cannot be denied that the success of some Practitioners is to be attributed more to their confident manner and self-assertion than to any higher or more desirable qualifications. But as the education of all classes advances, Medical vulgarisms will become less patent, and patients will be no more influenced by vulgar boasts than they would have been by gold-headed canes. We shall be more free to exercise our natural manner, and less disposed to study mannerism for the mere purpose of pleasing silly people. We may hope that their taste will improve, and that they will cease to require us to talk nonsense. At any rate, we may feel sure that among the rising Physicians, Surgeons, and General Practitioners are men earnest and thoughtful, with manners like those of other gentlemen, who are determined to leave to the quacks all the profits to be derived from vulgar boastings and common-place mannerism.

REVIEWS.

Guy's Hospital Reports. Third Series. Vol. XI. London: John Churchill and Sons. 1865. Pp. 466.

Nobody, we imagine, requires to be told that the new volume of these Reports maintains the character established by its predecessors. The Guy's Hospital Reports are now again one of our Professional institutions, and we all look for the issue of the annual volume as certainly as we look for the arrival of Christmas. There is no fear of their suspension again. The only suggestion for improvement in the plan of the Reports that we should wish to make is, that there should be added a general summary of *all* the cases treated, such as it might be the duty of the Registrar to draw up; and this upon a system and in a form to give practical results, and to be uniform with registers kept and published by other London Hospitals. This is no new suggestion of ours. We have over and over again pressed the importance of such uniformity upon the managing authorities of the Metropolitan Hospitals; and we sincerely hope that some agreement upon this subject may be come to in the course of the next year. Dr. Wilks and Mr. Bryant are the largest contributors to the new volume; but we recognise also nearly all the familiar names. Two of the most important papers are, to our mind, those of Dr. G. O. Rees and Dr. Sutton, who have recorded a number of cases of rheumatic fever, complicated and simple, treated without recourse to active medicines. We say "treated" because we hold that rest, a regulated diet and temperature, together with due attention to the state of the bowels, such as should be had in health, and the general system of management of sick persons in a well-conducted Hospital, are no mean or inefficient aids to recovery in any acute disease. Although hating from the bottom of our hearts, and detesting with all our mind and soul every form of "pathy," every deception practised upon the uninformed or half-informed in the name of Physic, we yet hold that there is something in each of the quackish systems now in vogue—let us add that ever has been in vogue—which legitimate Practitioners may draw a lesson from. None of us forget, we presume, and are not likely to forget, the outburst of wrath which some years ago fell upon the head of that accomplished and benevolent Physician, Dr. Forbes, when he published in his Review the startling article on "Homœopathy, Allopathy, and Young Physic." Since then the author has been gathered to his fathers; but the seed that he then sowed has germinated in the soil in which he deposited it; the young plant has grown rapidly and vigorously, and its fruit is seen in the daily increasing dependence of British Practitioners, Physicians and Surgeons, upon the restorative powers of nature, in the triumphs of Conservative Surgery, and in the acceptance met with by such works as that of Mr. Hilton on Pain and Rest. No one can compare the simplicity of Medical and Surgical practice in the present day with what that practice was even when some of us were students in the Hospitals a quarter of a century ago without being struck with the revolution that has been undergone. We do not give Dr. Forbes credit for the whole of this, but his advocacy of a logical reconsideration of our therapeutical system went very far to rouse the Profession to the selection of a new and better path than it was then pursuing. Holding, then, such views as these, and valuing above all things every effort to establish what Dr. Forbes termed the "natural history" of disease, we shall be pardoned if, on the present occasion, we seize upon this one characteristic of the volume before us, and point out what it has to tell us of nature's cures.

But first of all let us do a little stock-taking, and see in the practice of Physic alone what advances we have made in the direction of natural therapeutics. 1. As to the exanthemata, such as small-pox, measles, and scarlatina. We are not about to depreciate the endeavours of those who are striving to discover an agent which will counteract the specific cause of these diseases. We say to such, go on and prosper. You have a noble and legitimate object in view, and whether you find what you are looking for in ammonia, or among the class of antiseptics, or elsewhere, we shall be among the first to welcome your discovery. But in the meanwhile, let us recognise the truth that these maladies are admitted to exhibit a spontaneous evolution naturally terminating in health; that unless life is endangered by some remarkable depression of vital force, the Physician of the present day contents himself in the cure with watching for the earliest indication of lowered vitality, and confines his administration of drugs to the relief of such disturbances of natural functions as his experience teaches him tend powerfully to reduce the powers of life. 2. The same may be said of our modern treatment of the continued fevers. Unless some special reason is seen for more active interference—and this rarely occurs—all that the Physician has to do is to take care that his patient has as much as he requires of such appropriate nourishment as his weakened digestive powers can manage; and he looks for recovery in uncomplicated cases almost as a matter of course. We have no nervous fear in such cases now of leaving nature (not unaided by hygiene) to work out her own cure in her own way. 3. Then there is among inflammatory diseases of internal organs the typical disease pneumonia, which we used to treat first by taking away the blood which we supposed in our ignorance fed the flames raging within, and then by half poisoning our patient with tartar emetic and calomel. Who in his senses would dream of pursuing such a practice now, unless in cases as exceptional as they are dangerous? Who does not know that the majority of pneumonic patients, notwithstanding the temporary inconvenience they suffer, will get well when kept in bed in a regulated temperature and with a regulated diet, and get strong again, too, and fit for their daily labour in a far shorter time than they did when pneumonia was regarded as inevitably fatal unless knocked down by the powerful weapons wielded by the resolute hand of the Doctor? 4. And may not something of the same revolution be seen in our management of peritonitis, and some similarly acute diseases? True, we give opium commonly and largely to many a peritonitic patient, but how many mild cases there are that are cured with nothing or little else besides rest and external applications. And when we do give opium, is it so much because we believe that it has any powerful influence upon the pathological changes in the membrane, as because it is the most effectual means we possess of ensuring rest? And this sort of treatment is, so far as we can see, quite as effectual, and far safer for the patient, as the repeated full bloodlettings and mercurialising till the gums were sore, which we regarded as necessary elements of our treatment in our younger days. We might carry on our demonstration into the domain of non-inflammatory and chronic maladies. But it is, in view of the present volume of Reports, with acute disease that we have only to do at present, because in the papers of Dr. Recs and Dr. Sutton we have to record an additional proof of the powers of the *vis medicatrix naturæ*.

Dr. Gull and Dr. Rees, be it known to all that it may concern, have been treating acute rheumatism successfully with mint water. We wonder whether mint water ever produced symptoms resembling acute rheumatism; perhaps the homœopaths can tell us, for, if not, then they must look to the stability of their theory. Details of Dr. Gull's cases, sufficiently full for the purpose of establishing his point, are given in twenty-one instances by Dr. Sutton, and four cases are detailed by Dr. Rees. The following is Dr. Sutton's summary of results as affects the duration of the disease:—"The average duration of the acute symptoms in the first seven cases, in which there was no evidence of the heart being involved, the abstracts of which have been just given, was 8·5 days, while in the last six cases, in which the heart was evidently affected, the average duration was 23·6 days. The recorded experience of other Hospital Physicians confirms what is here shown, that cases in which there is not, on admission into the Hospital, evidence of much heart affection, tend to get well in from six to fourteen days, that is, within twenty days; cases, however, in which there are very early indications of severe heart affection, tend to last over twenty days. In the cases with little or no cardiac disease, the shortest duration of the acute symptoms was six days; the longest sixteen days. Where the cardiac disease was great, the shortest duration of acute symptoms was seven days; the longest thirty-eight days. The cases marked No. 1, 5, and 12 in males, and No. 6, 9, 7, and 17 in the females, tend to confirm the experience, as late years have shown, that acute rheumatic pericarditis does not, as regards the recovery of the patient and the successful termination of the disease within a reasonable time, require any special treatment, and more than that, it shows that a patient may have rheumatic inflammation of both pleuræ and effusion into the right; the heart also may be involved; yet in thirteen days all the acute changes may subside and the patient be convalescent, and out of bed on the twenty-fourth day, and the only treatment adopted be a grain of extract of opium every night, and mint julep with extract of dandelion three times a day. Such facts also tend to teach that acute rheumatic pericarditis may

subside without any treatment except rest in bed and careful diet in fourteen days; that rheumatic pericarditis, complicated with albuminous urine, may, without medicine, except mint julep and a grain of opium for one night only, have so far recovered as scarcely to be detected on the seventh day of treatment; and the patient afterwards continued steadily to improve and able to go out of the Hospital within a month."—P. 413. Now, although these cases do not show that rheumatic fever ought to be treated in all cases without medicine (and it has yet to be demonstrated what effect such abstinence from active medication has upon consecutive heart maiming), we think that Dr. Sutton has established this—viz., "That the best treatment for rheumatic fever has still to be determined, and that it is absolutely necessary to understand the natural progress of the disease before any conclusion can be arrived at concerning the operation of remedies. The cases show that too much importance has been attached to the use of medicine, especially in those acute cases where the tendency to a natural cure is the greatest."—P. 428. Dr. Rees says—"For my own part, the results have firmly impressed me with the belief that the old plan of treatment, consisting in the exhibition of calomel, opium, and antimony, and the free use of colchicum, did great harm (might not Dr. Rees include blood-letting?), not only by retarding recovery, but by leaving the patient greatly debilitated. The duration of cases of acute rheumatism when I first became a student at Guy's Hospital was certainly far longer than at present, when, whatever may be the treatment adopted, it partakes less of the heroic character than that which was practised by our predecessors."—P. 430. We are told that a series of comparative observations are about being instituted by Dr. Rees upon the relative efficacy of mint-water, alkalies, lemon juice, etc., in the treatment of this disease. We await the result with some impatience.

Clinical Lectures and Reports by the Medical and Surgical Staff of the London Hospital. Vol. II., 1865. Churchill and Sons, 1865. Pp. 415.

We have much pleasure in reviewing the second volume of the "London Hospital Reports." The contributors to it are Mr. Adams, Mr. Curling, Dr. Letheby, Mr. Heekford, Dr. Fraser, Dr. Davies, Mr. Hutchinson, Mr. Maunder, Mr. Couper, Dr. Woodman, Dr. Hughlings Jackson, and Mr. Little, and in addition to the papers and lectures of these gentlemen there is a series of cases recorded by the gold medallists of the Clinical School, Messrs. Walker, Llewellyn, Rogerson, and Thorp. We do not propose to notice here all these papers, although none are devoid of such interest as will induce our readers to study them. We shall allude only to a few which have specially attracted our own attention.

Mr. Curling has appended to his admirable paper upon the Treatment of Painful Cancer of the Rectum a tabular statement of ten cases in which the colon was opened in the loin. One of the patients lived for two and a half years afterwards, one for nine months, one for eight months, one for five months, one for three months, one for two months, one for five weeks, and one for three weeks. All these died from exhaustion consequent on the disease. One died on the thirteenth day of exhaustion from persistent vomiting due to chloroform, and the remaining patient from peritonitis set up before the operation. We quote some of Mr. Curling's final remarks:—"That an artificial anus in the loin is not a constant source of trouble and annoyance, as many persons imagine, is amply shown by several of the cases in the table, and by others in which the patients have lived for years after the operation. The bowels act at regular periods, and the escape of flatus and feculent matter at other times can be prevented by a well-adjusted pad and bandage. When diarrhœa occurs, or when unhealthy gases are generated, then annoyance is experienced. The chief inconvenience liable to occur arises from prolapsus of the upper part of the colon, which occasionally happened and gave trouble in the case detailed in this paper. . . . Indeed, prolapsus rarely occurred in this case after a proper pad and bandage had been constructed and kept applied. . . . As a minor matter in connection with these cases, though not unimportant, I must call attention to the remarkable efficacy of iodine lotion in rendering the feculent discharges inodorous, and in keeping the wound sweet. The lotion used was composed of about four drachms of the compound tincture to eight ounces of water. Some spongiopiline wetted with this lotion and applied over the wound soaked up the feculent matter, and kept the part tolerably clean as well as sweet, and the lotion was injected into all recesses and sinuses."—P. 12.

A very suggestive paper is furnished by Dr. Letheby on liquid diffusion in relation to physiology and practical toxicology. We strongly recommend its study to our readers.

By far the largest contributor to this volume is Mr. Hutchinson, who publishes here no fewer than six instructive papers. We shall notice some of them. One relates to a case of fibroplastic tumour of the scalp, in removal of which a tourniquet was employed around the head, being placed just above the ears, with a compress upon the right temporal artery, in order to restrain hemorrhage. In an excellent paper upon Lupus, Mr. Hutchinson gives a statistical summary of conclusions obtained from the collection of notes of seventy-seven cases which have come under his own observation. We cannot refrain from copying this summary:—"*Age at which the disease began.*—The average age for the whole seventy-six cases is sixteen years. The youngest patient was six months, and the oldest fifty-six years. *Duration of the disease.*—The average duration of the cases when seen by me was nearly seven years. This fact well demonstrates the very chronic nature of the inflammation. *Sex of patient.*—Thirty-one of the patients were males and forty-six females. *State of health of the patient.*—Dividing the cases into three classes, as "good," "medium," and "decidedly feeble and cachectic," we assign thirty-three to the first, twelve to the second, and eleven to the last. In twenty-one cases the notes are defective. *Tubercular diathesis.*—There was proof of active tubercular dyscrasia in one in every six of those in whom this fact is noted. *History of tubercular diathesis in the patients' family.*—In sixteen cases there was the history of phthisis in the patients' nearest relatives (parents, or brothers, or sisters). In fourteen cases I have not kept any note on this point. *Local injury assigned as a cause.*—In eighteen cases the patients stated that the disease had followed local damage to the part. *Was the disease single or multiple in its manifestations?*—In thirty-four cases only a single part had suffered, that is, there was only one lupus patch. In forty-one cases there were several patches, and in two cases the notes are indefinite on the point. *Other symptoms of struma present in the patient.*—In eighteen cases there were present other diseases of the kind usually classed as "strumous," but in nearly half of the seventy-seven cases I have no positive information on this point. *Inherited syphilis as a cause.*—In only two of the cases was there reason for believing the patient to be the subject of inherited syphilis. *Position of the patient in his or her family.*—In seventeen cases I have no note on this point. Of the remaining fifty-eight, the patient was the eldest born in eleven instances, the second in fourteen, the third in nine, the fourth in seven, the fifth in five, the sixth in two, the seventh in four, and a yet higher position in the remaining four."—P. 137.

Another very important contribution by the same writer is entitled "New Facts and Opinions as to Inherited Syphilis." After giving a summary of his views respecting the indications of inherited syphilis furnished by the shape of the upper incisor teeth, the physiognomy, and the occurrence of chronic interstitial keratitis, on which his diagnosis of inherited syphilis is habitually based, he proceeds to discuss the following points:—"Can syphilis be transmitted to the third generation?" Of the cases he relates bearing on this question, there are seven in which the offspring of persons with inherited taint manifested no syphilitic symptoms. In only one case were they observed, but the facts of it are so extraordinary that he cannot avoid concluding that some source of error was present. "To what extent does the diathesis of inherited syphilis protect against subsequent contagion or modify its results?" The general conclusion is that when such persons acquire the disease anew it occurs after a very different fashion to what is met with in others, and that such subjects are not liable to contract the indurated form of chancre. "Severe organic disease in connexion with inherited syphilis." Mr. Hutchinson maintains that heredito-syphilis does not in any way predispose to phthisis. He then discusses the subject of "Diseases of the bones in connexion with inherited syphilis," and next the question "Do the symptoms presented by infants bear any close relation to the stage of the disease in the parent?" The pith of his entire answer is conveyed in the sentence, "It matters little what may have been the stage of the disease in the parent, the offspring will present first symptoms of the secondary class, and only at a much later period of life those of the tertiary group." As regards the question, "Will the mercurial treatment of a syphilitic parent increase

the chance that his offspring will escape?" the reply of the writer is in the affirmative. "I should have no hesitation in advising the parent of a syphilitic child to at once submit himself to an efficient and prolonged course." Then follow sections "On the phenomena of latency in respect to inherited taint," "On the forms of lupus which occur in connexion with inherited syphilis," "Cases of ulcerative destruction of the palate, etc.," and, lastly, "A contrasted parallel between the course of symptoms in acquired and inherited syphilis." In the course of this last subject Mr. Hutchinson discusses the question, "Why chancres differ?" He thus explains his views of the origin of the soft non-infecting sore in the indurated chancre:—"If we may be permitted to suppose a time when the true virus—that which produces the indurated sore and secondary symptoms—was the only one extant, the following results might be predicated:—Certain individuals who had already had true syphilis would contract the disease a second time, and in these the sore would not assume its typical characters. Some of these would probably transmit this modified sore to others who were, like themselves, already protected, and thus a second diminution in power of the virus would result, and we should, after a few such inter-communications, have a virus quite incapable even in a healthy person of producing anything more than a local sore. Exactly the same chain of events would occur in those whose protection was the result of inherited disease. Keeping these probabilities in mind, we can easily explain the origin of the virus by which 'soft sores' are produced, and can also readily suggest reasons why there should be, as there are, many varieties of these."—P. 203. We might with advantage to our readers almost confine this review to Mr. Hutchinson's contributions, but must with regret pass by the remainder in order to do some justice to his colleagues.

Mr. Heckford has a paper on "Circumcision as a remedial measure in certain cases of epilepsy, chorea, etc.," alluding, of course, to those cases (especially of children) where these maladies originate in masturbation. He insists, not only on the free removal of the prepuce, but on delaying the process of healing as long as possible.

There is a capital statistical paper by Dr. Fraser on "Stimulation *versus* Depletion," showing that at the London Hospital there has, for some years past, been a steady rise in the employment of stimulants in the treatment of disease and injuries. Dr. Fraser adds, that "Whatever be the cause, we may rest assured that the practice is imperative and needful, for it would be a monstrous assumption that a whole staff could be blindly following an objectless routine."

A lecture by Dr. Herbert Davies gives "The results of the Blister Treatment in Fifty Cases of Rheumatic Fever." We are disposed to regard this as rather a merciful treatment, for really the pain of the blistering is not to be compared with the inconvenience arising from the local lesions, and whatever its effect may be in shortening the duration of the disease and preventing cardiac complication (about which we would reserve our opinion until the results of the comparative experiments at Guy's Hospital are published), there is little question that the condition of the patient is rendered on the whole more tolerable.

In Mr. Maunders' paper "On the Removal of Cartilage in Operations about Joints" he makes the following remarks:—"The large share in predisposing to pyæmia, which I think the protracted healing of a large wound may take, induces me to offer the suggestion that Hospital Surgeons, in selecting a method of operation in any particular case, should, in unhealthy seasons and in unfavourable subjects, choose that plan which will insure the most rapid closing of the wound rather than one which might, all other circumstances being favourable, be deemed slightly preferable. Thus amputation of the thigh should be performed rather than excision of the knee; tibio-tarsal amputation instead of excision of the ankle-joint. In this way the deterioration of a patient's health, by shortening his stay in the Hospital, is reduced to a minimum, and the prospect of a successful issue is increased. . . . In selecting a special case for the attempted preservation of the cartilage, the Surgeon would be guided by the size of the articular extremity of the bone, preferring the smaller to the larger—*e.g.*, that of the tibia to that of the femur; but if the patient be a bad one for surgical operation, or the season unhealthy, he will do well to cut away the cartilage with the adjacent layer of bone, in order to expedite the closure of the wound. *I believe confinement in the unwholesome atmosphere of a Hospital to be more prolific of blood poisoning than the presence of open cancelli in a wound.*"—P. 213.

Dr. Woodman has an interesting paper headed "Cases of Malingering, with remarks," in which he maintains the following propositions:—"1. That nearly all those who feign diseases or accidents are really in some way or other in ill-health, or, in other words, that a basis of truth underlies most attempts at malingering. 2. That the difficulties in the detection of these cases are only to be fully met by a comprehensive knowledge of the real diseases, and by a constant study of human motives and actions. 3. That the resources of our art have been of late years so enriched by the microscope, ophthalmoscope, stethoscope, and laryngoscope, and other aids to physical diagnosis, and the apparatus of the chemist, that the detection of frauds is now much easier than before. But that, 4, in all cases of doubt it is better to assume for the time that the patient's statements are true than to run the risk of maltreating or neglecting a real case of disease."—P. 257. The same writer supplies a table of fifty-five cases of hernia operated on between October, 1860, and January, 1862, inclusive, during which period no official record was kept, and no statistics were published.

Dr. Hughlings Jackson publishes some instructive "Lectures on Hemiplegia." We cannot speak too highly of them as a sample of the teachings at the London Hospital.

The volume concludes with a list of the more important preparations added to the Museum during the past year, and a statistical Medical Report by Dr. Woodman, followed by one by Mr. Maunder, "On the Major Operations performed for the year 1864."

Electro-Therapie, mit Besonderer Rücksicht auf Nervenkrankheiten. Von Dr. Carl Frommhold, in Pesth. Pesth: 1865. Pp. 418.

Electro-Therapeutics, with Special Regard to Nervous Affections. By Dr. Carl Frommhold.

A Medical book from Hungary is such a *rara avis*, that we should feel inclined to notice it even if there were no great intrinsic merits in the performance of the author. Hungary, although entirely dependent upon Germany for its Medical information and instruction, yet boasts of a good national University, and a few Medical periodicals written in the national language. For some time past extraordinary efforts have been made by Hungarian patriots to destroy the German monopoly of science, and to show to the world that there is scientific as well as physical and political vigour in this small but high-spirited nation. Unfortunately, few people out of Hungary will be found willing to endeavour to master the difficulties of the idiom, and authors are therefore obliged to resort to the German language if desirous of addressing a large audience. The present work is one of this class, and we have much pleasure in stating that it is highly creditable to the author, who has evidently taken great pains to produce a good sound treatise on his subject.

A really useful literature on Medical electricity has only commenced to exist within the last ten years, for it is not too much to say that all books published prior to 1855 were devoid of scientific or practical value. In that year, M. Duchenne published his researches on the effects of the induced current, and succeeded in thoroughly rousing Professional attention to the study of Medical electricity. He was soon afterwards followed by Professor Remak, of Berlin, who investigated chiefly the properties of the continuous galvanic current. Both these authors were staunch partisans of the special form of electricity to which they had devoted their attention, professing the greatest contempt for any other forms, and giving their own pet agents an undue prominence in a therapeutical point of view. Dr. Althaus was the first who contrived to keep aloof from the enthusiasm in which specialists are apt to indulge, and applying much critical acumen to the question, restricted the use of galvanism considerably, and made the *rationale* of its beneficial action in certain diseases intelligible to the Profession. Since then a number of other treatises have appeared on the same subject, but it cannot be said that any very decided progress has been made. Dr. Frommhold, without ignoring the labours of his predecessors, has applied considerable originality and research to the study of these questions; but as he is not a great adept in literary composition, his book is very difficult reading; moreover, he has committed the mistake, while entering sometimes with a tedious detail into matters which would have only required a passing notice, to hurry over more important subjects about which we should liked to have received full information. Thus, for instance, he describes a new proceeding for treating aneurisms by the

continuous galvanic current, and which looks very plausible on paper; he goes on to say that such operations were performed on patients by Dr. Balassa, the Professor of Surgery at the University of Pesth, yet he does not detail a single case, nor does he inform us of the ultimate result of these operations. With these and other drawbacks, the work is one of real value, and will be read with interest by those who are engaged in the therapeutical application of electricity.

The contents of the book are arranged as follows:—Physics and electro-physiology occupy the first hundred pages, after which the author discusses the subject of electrolysis with special reference to the treatment of aneurisms, and describes some new appliances for using the galvanic cautery. The body of the work is taken up with a consideration of the Medical use of galvanism in hyperæsthesia, spasm, paralysis, gout, rheumatism, and deafness.

A System of Instruction in Quantitative Chemical Analysis. By Dr. C. Remigius Fresenius. Fourth edition. Edited by J. Lloyd Bullock, F.C.S., and Arthur Vacher, F.C.S. London: John Churchill and Sons. 1865.

This, the fourth English edition of Dr. Fresenius's classical work on Quantitative Analysis, extends over pp. 782, exclusive of tables of contents and index, Mr. Bullock says of this, as compared with the earlier editions, that it is almost a new work, and a brief comparative examination is sufficient to convince us that he is correct. The work, however, remains the same in method and principle; its renovation having been performed for the almost sole purpose of making it accurately represent the present condition of the quantitative department of analysis. Many new processes and improved modes of procedure have been introduced, together with "not fewer than fifty" additional engravings of instruments and apparatus. The processes may often appear to be tedious, and even complex in their execution, but it must be borne in mind that the author only gives those methods which yield as nearly as possible accurate results, and that, unfortunately, in many cases, processes combining accuracy with simplicity and rapidity of execution, are as yet unknown. The methods described have been invented by many chemists, but all, we believe, have been submitted to careful trial by the author before they have received admission into his work, so that they carry with them additional authority, due to his own verification of their correctness. It is an excellent work, having no equal in our language.

REPORTS OF SOCIETIES.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Tuesday, February 13.

Dr. Alderson, F.R.S., President.

Mr. Henry Thompson related a case of

PHOSPHATIC CALCULUS IN THE MALE BLADDER, WITH A NUCLEUS OF BONE (PROBABLY A SEQUESTRUM DETACHED FROM THE INNOMINATE BONE).

A man, aged 40, was sent to the care of Mr. Thompson, at University College Hospital, by Dr. R. Uvedale West, of Alford, Lincolnshire, in June, 1865, for a urinary affection of two years' standing. On examination a stricture near the orifice of the urethra and a stone in the bladder were found. On June 27 the stricture was divided by the bistoury, and the first crushing was performed on that day. All going on well, the stone was again crushed on the 30th. On this occasion the *débris* withdrawn in the jaws of the lithotrite was remarked at the time to be unusual in character, but was not then minutely examined. Four days after this, retention was caused by a fragment impacted in the urethra; this was withdrawn by means of the forceps, and it was at once seen to be a fragment of bone. Other small pieces followed, and the patient went out cured on July 15. He remains perfectly well at the present time. It was not until after the appearance of the bone that a minute history of the case was taken. The following circumstances were then elicited:—The patient had had severe pain in the right hip seventeen years ago, and was lame for more than a year. Then an abscess broke externally, the cicatrix of which, among many others, is seen about the joint. Another attack took place three or four years after, from which several abscesses and much pain and lameness resulted. Two years ago another attack laid him up for several weeks, but no external abscess resulted. When recovering from this, he became the subject of some pain and frequency in micturition; and finally the ordinary symptoms of stone appeared, and continued up to the time of his admission. The author made reference to some analogous but not precisely similar cases, no example of the latter having been at present discovered. The conclusion which he arrived at after full investigation was, that the origin of the calculous formation in this case was the existence of disease in a part of the os innominatum, resulting in necrosis of a small portion; and that this portion ultimately exfoliated and detached itself, to be extruded, not externally by the surface of the body—not by means of abscess which should follow the usual course along the tracks of muscles or vessels, but by one which communicated directly with the bladder, so that the sequestrum made its way into that cavity, and formed the nucleus of the phosphatic stone for which the patient was subsequently successfully operated on by lithotrity.

Mr. William Lawrence communicated a paper by Mr. Joseph Allen, on a

CASE OF LITHOTOMY—MULBERRY CALCULUS WEIGHING EIGHT OUNCES AND A QUARTER—DEATH.

The author was summoned to the Rev. T. C——, a thin spare man, of nervous temperament, aged 56 years, on November 16, 1864, and found him suffering great pain and irritability of the bladder. He was a married man, of temperate habits. Had been married seventeen years and a-half, and had three children growing up. A few days previously he had caught cold whilst performing the funeral service at the cemetery, and had suffered considerable pain in the body since, accompanied with frequent and painful micturition. He had tried several remedies without avail. Opiates and other anodynes, etc., were prescribed, but with only temporary relief. His history was as follows:—He was born in Surrey, and from his boyhood was fond of exercise, running, jumping, etc., but frequently suffered great pain afterwards, and often passed blood in his urine; this he concealed lest he should be debarred from such pursuits. As a young man, hunting had the same effect, but his love for the sport was too great to allow him to give it up. He resided at Calais for eleven years, and enjoyed good health all the time. He afterwards spent seven years in London. He was ill for about three weeks shortly before leaving London with inflammation of the bladder, according to his account. Has resided in Norwich about five years. His health generally has been good, dyspepsia being his chief ailment, which a little carbonate of soda mostly removed. He confessed, however, to great irritability of his bladder for some years past, having been compelled whilst in London to micturate every two hours, and latterly had been unable to retain the urine more than one hour, so that he was compelled to time his visits in the parish accordingly. On December 5, 1864, he was sounded by the author in the presence of Dr. Eade, having previously refused to permit it through false delicacy. The sound, immediately on entering the bladder, came in contact with a large and hard stone. The urine contained lithic acid in considerable quantity, also pus-globules. It was determined to perform lithotomy, which was accordingly done on December 8. The ordinary lateral incision was made, and the stone readily seized with the forceps. On attempting to extract it, however, it was found to be one of no ordinary size. Larger forceps were then introduced, and a firm grasp obtained, but without avail. In order, therefore, to avoid laceration of the parts as much as possible, the fibres of fascia on either side were carefully cut with a blunt-pointed bistoury by Mr. Cadge, traction being made on the stone at the same time. The perineum was enormously distended during the extraction of the stone. After a short time a mulberry calculus, weighing eight ounces and a-quarter, was removed. There was scarcely any hæmorrhage, and very little laceration of the parts. The patient was remarkably well after the operation, and for a time progressed most favourably, the wound presenting a healthy appearance, and gradually closing. He was able to retain his urine in the bladder for three hours, a thing he had never done before for years. After a time, however, his spirits began to flag, and he became fidgety and impatient; and although well supplied with nourishment and stimulants from the first, he gradually became weaker, and at last sunk from exhaustion on Jan. 20, 1865, six weeks after the operation.

Mr. Holmes Coote said the case related by Mr. Henry Thompson was worthy of great consideration. There was one point, however, on which information was desirable, viz., as to the microscopic structure of the nucleus of the calculus. This would remove the possibility of doubt as to its being bone. Mr. Thompson had said that there was no specimen in the museum of St. Bartholomew's Hospital of a calculus with a nucleus of bone. He (Mr. Coote) remembered a case in which Mr. Lawrence had removed a calculus from the bladder of a woman. In this instance the bone was that of a sheep, and, of course, had been introduced from without. He could scarcely understand how the piece of bone in Mr. Henry Thompson's patient's case could have got into the bladder in the way suggested by the author, with so little irritation. Mr. Coote then spoke in eulogistic terms of the operation in the case brought forward by Mr. Allen. It was probably the largest oxalate of lime calculus that had been removed by the lateral operation of lithotomy. Mr. Coote also remarked that although Mr. Allen had not alluded to the fact, the history of the case clearly showed that the patient did not die of the mere operation. That was skilfully performed, and reflected the greatest credit on the operator. Had there been an autopsy, he (Mr. Coote) had no doubt it would have revealed other diseases as the cause of death. The coma pointed to renal disease. Mr. Coote concluded by saying that the operator was worthy of great praise.

Mr. Erichsen agreed in the main with Mr. Coote. He thought it a matter of great importance to distinguish cases of stones in the male and female bladder as regards the source of their nuclei. We know, he said, that in the female bladder the nuclei may be most various substances introduced from without; but a piece of bone was scarcely likely to be introduced by the male urethra. He agreed with Mr. Thompson that it most probably came from the pelvic bone in his patient's case. With reference to the second case, Mr. Erichsen said the stone was very large, although he was not prepared to say that it was the largest oxalate of lime calculus which had been removed by lithotomy. The case was of importance as regards the question of removing a stone through the prostate. In cases in which we hear of such great difficulty in removal, he could not help thinking the gland had been divided beyond its limits. The case introduced the question of small and large incisions in the prostate. No doubt in Mr. Allen's case the best method of getting the stone out was adopted; but he could not think it could have passed through the lateral lobe without extending beyond its limits. Mr. Erichsen concluded his remarks by expressing his opinion that death was caused by renal disease, and not by the operation.

Mr. Charles Hawkins had no difficulty in coming to the same conclusion as Mr. Thompson had; he had very little doubt that a foreign body could make its way into the bladder from other parts of the body. He referred to a case in the practice of Sir Benjamin Brodie, in which the nucleus of a calculus removed from the bladder of a female consisted of a small portion of bone and two imperfectly-formed teeth, and to another case in which large quantities of hair, covered with calcareous matter, had been passed. Mr. Hawkins believed that these foreign bodies had come from tumours connected with the ovaries. Mr. Hawkins then referred to cases in which fæcal matter had found its way into the bladder, and gave brief particulars of a case of calculus in the bladder, the nucleus of which calculus was some vegetable substance derived, he believed, from fæces. In this case, Mr. Hawkins had removed the calculus by lithotrity with success.

Mr. Spencer Wells said that, without in the smallest degree criticising the mode in which the very large oxalate of lime calculus had been removed—feeling, indeed, that the operation was a very creditable one to the Surgeons concerned—he still wished to ask the author of the paper, simply as a guide to future practice in a similar case, whether it would not give a patient a better chance of recovery, in a case where a stone was known or be believed to be unusually large, either to perform the high operation, or to be prepared with some powerful crushing apparatus, by which, after the bladder had been laid open, the stone might be broken and removed in fragments. Either of these plans would seem to be less hazardous than the forcible dilatation or the large incisions necessary for the removal of a very large unbroken stone by the lateral or bi-lateral perineal operation. With regard to the curious substances found as the nucleus of calculi, he (Mr. Wells) might add that he had recently removed a phosphatic calculus from the bladder of a patient who had undergone an operation for vesico-vaginal fistula, and a loop of silver wire which had got into the bladder had formed the nucleus of the calculus.

Mr. Henry Lee said that Mr. Erichsen implied in his remarks that the best plan to deal with large stones was to cut them out, rather than to tear them out. In this opinion he (Mr. Lee) concurred. Mr. Lee then referred to a case of lithotomy of his own at St. George's for the removal of a very large stone. In this instance he cut, no doubt, beyond the limits of the prostate, and the result of the case showed that the practice did not always lead to bad results. The calculus was phosphatic, and weighed four ounces and a quarter, and there was another stone in the bladder, extracted at the same time, which weighed a quarter of an ounce.

Mr. Propert said that twenty-five years ago he had under his care a young gentleman who had a knack of driving things up his urethra. At last he passed up a long piece of sealing-wax. The specimen of wax afterwards removed from the bladder would be found in the museum of St. George's Hospital. Sir B. Brodie, who was consulted, could not discover any foreign body in the bladder, and the patient went to India. After remaining in India some time, symptoms of stone in the bladder came on, and the patient came home for operation. Sir B. Brodie operated, and removed a calculus, the nucleus of which was a piece of sealing-wax. The patient recovered, and went out again to India, when, unfortunately, he was drowned.

Mr. Moore had had under his care at the Middlesex Hospital a patient, above 30 years of age, who had a similar strange fancy for passing foreign bodies into his urethra. He one day introduced a piece of sealing-wax. He afterwards had mucous and phosphatic urine, and suffered so much that lithotomy was performed. The piece of sealing-wax was removed and placed in the museum. The fragment was bent on itself, and had the ordinary flattened oval shape of a calculus. It was creased and compressed, as if it had been squeezed into its form by the contractions of the bladder. As regards the source of the nucleus in Mr. Henry Thompson's patient's case, he could not conceive that there could be any great difficulty in the way of the belief that it had been detached from the pelvic bone, and had made its way into the bladder. He did not think the passage of purulent matter from an abscess into the bladder was likely to produce any injurious consequences, and he referred to cases which served to show that the action of urine on abscesses communicating with the bladder did not affect them injuriously; on the contrary, the stimulating effects of the urine appeared to produce salutary effects.

In reply to a remark by Mr. Holmes Coote, Mr. Moore said that he did not mean that pelvic abscesses were not serious, but that the mere entering of matter from an abscess into the bladder was not serious.

Mr. Solly agreed with the other speaker as to the great probability that the bone was an exfoliation from the ischium, and he agreed with Mr. Moore that an abscess might empty into the bladder without producing any striking disturbances. In illustration, he referred to the case of a patient lately under his care in St. Thomas's Hospital, who had paralysis of the legs consequent on disease of the spine, and who had quite recovered, after having passed much purulent matter in the urine. The case related by Mr. Allen introduced the question whether it would not be better to crush a stone when it was found to be so large, as in that case, before attempting to extract it. On one occasion he had had prepared beforehand an instrument for this purpose, but it turned out that the stone was not so large as had been expected. He thought the Surgeon ought to be prepared with a crushing apparatus, in order to break up the stone when it was very large.

Mr. Charles Hawkins described an instrument—a pair of strong forceps with large teeth—made by the direction of Sir B. Brodie for use in a case of lithotomy, but the instrument was not required, as the stone did not prove to be as large as was expected.

Mr. Solly said the instrument he had had made was like the one spoken of by Mr. Hawkins.

Mr. Thompson thought the evidence all but complete that the bone had had its origin in the body of the patient himself. Still he should be glad to submit the fragment to microscopical analysis to determine accurately that point. He was, of course, quite alive to the various sources of error on this point. It was not long since he performed lithotomy for the removal of sealing-wax introduced by a patient into his own bladder, and he had more recently removed a hair-pin from the bladder of a male, who had so introduced it. With reference

to the important and interesting case of Mr. Allen, there were two points well worthy to be considered with regard to it. First, was it possible to crush that stone through the wound, and so withdraw the fragments, instead of enlarging it? He had seen no instrument which he thought capable of crushing a large oxalate of lime stone, certainly none by way of compression. He had cut a gentleman last summer and removed an oxalate of lime stone weighing 3½ oz. Before withdrawing it he had applied forceps of great strength, and with a powerful screw in their handles, and he had screwed the handles together, bending the iron, but no impression was made on the stone. The best method he had seen was one employed by Civiale, who, after trying it and perfecting it on twelve or thirteen cases, had just introduced it to the Academy of Medicine at Paris. Mr. Thompson had seen all those calculi so crushed and removed, and considered it a very valuable instrument. It was accomplished by means of perforation by a drill, which split up the stone. Secondly, there was the question of the high operation for such a stone. Could it have been ascertained to be so large—and no doubt such information it was possible to attain—he believed the high operation would have been preferable. The bladder was nearer to the surface above the pubes in a thin individual such as this patient was; less important parts were in the way than in the perineum, and the depth of this region, which is exceedingly embarrassing with so large and spherical a stone, was avoided by that procedure. Altogether it was well worthy of consideration whether such stones should not be removed by the high or supra-pubic rather than by the lateral operation. He inclined to the belief that the former was preferable for these cases.

Mr. Joseph Allen explained how it happened that leave to make a post-mortem could not be obtained. Although the post-mortem might have revealed renal disease, there had been no positive evidence of it during life. The patient seemed to sink from nervous depression. As regards the prostate, as no post-mortem examination had been obtained it was impossible to speak positively. He was glad to find that Mr. Henry Thompson, in his reply, had relieved him (Mr. Allen) of the necessity of replying to several questions which had been put to him. Mr. Allen said that the largest stone—not an oxalate—which had been removed in Norwich had been removed by the lateral operation, and the patient recovered. For this reason he did not think of the high operation; moreover, it was not easy to ascertain the size of a stone before the operation.

NEW ARTIFICIAL ARM.

After the meeting, Mr. Uren, of Cornwall, exhibited an artificial arm which he had invented, and which had been made by Messrs. Weiss and Son. This seems to be as useful an artificial arm as any we have yet seen. Movement of the elbow, opening and closing of the fingers, are maintained by the movement of the stump of the upper arm acting on some cords which are connected to the arm and to straps across the trunk. The man who wore it said it was comfortable, and that it was of considerable use to him.

LEGAL INTELLIGENCE.

COURT OF EXCHEQUER.—Feb. 20.

(*Sittings at Nisi Prius, at Guildhall, before the* Lord Chief Baron *and a Special Jury.*)

MEAKIN *v.* THE MIDLAND RAILWAY COMPANY.

Mr. Montagu Chambers, Q.C., Mr. Horace Lloyd, and Mr. Waddy were counsel for the pliantiff; Mr. Bovill, Q.C., and Mr. Alfred Wills, appeared for the Company.

This case was resumed. The plaintiff is a gauger in the Customs, and receives a salary of £250 a-year. Last year he was travelling on the defendants' line of railway, and was in the collision at Colney-hatch, when 300 passengers were more or less injured. The plaintiff had his lip cut and some teeth damaged, and was for a short time rendered insensible. On his arrival at King's-cross he was taken home and placed under Medical charge. The defendants admitted that the accident had resulted from the negligence of their servants, and the only question for the jury was the amount of damages the plaintiff was entitled to under the circumstances. The plaintiff was described as having been previous to the accident a man of vigour both in mind and in body, an active member of the Customs Volunteer Corps, and an occasional contributor to literature. The plaintiff was entitled under the rules for Civil Service pensions to an annuity in the event of his retiring from office of £62, calculated upon his present salary. He is a clerk in the third class, and could, should circumstances favour him, rise to a salary of £400 per annum. The plaintiff appeared to be suffering very severely from the effects of the accident, and had great difficulty in using his legs at all. Several Medical gentlemen of great eminence—Mr. Ingolby, Mr. Hutchison, Mr. Sweeting, Mr. Hall, and Mr. Adams—were called, and described the plaintiff's case as a very serious one, and of course the evidence differed a little as to what was likely to prove the result of the plaintiff's injuries. They all agreed that he had been very seriously injured, and that some very considerable time must elapse before he would be able to resume his duties at the Custom House, if he ever could, as one or two said, resume them at all. It appears that if an officer of Customs is incapacitated from doing his work from ill-health he is usually allowed six months' leave of absence upon full pay, and if he is not then sufficiently recovered to resume his duties the term is extended another six months, but the pay is reduced by one-half. The plaintiff's wife said that the accident had made him a wreck of what he formerly was. An effort the plaintiff made to resume his duties was ineffectual, and after some days he was obliged again to lie up. The plaintiff was said to have received an injury to the spine, and was otherwise so seriously hurt as to make it a mere matter of speculation whether he ever could resume his duties, failing which, after the expiration of one year, the Board of Customs would remove him from the list of effective officers and force him to retire on his pay of £62 per annum.

On the part of the defendants, Mr. Skelding, a Surgeon, was called, and swore that he had examined the plaintiff, and was of opinion that the plaintiff's brain had received no lasting injury, neither was there any injury to the spine. There was no reason why the plaintiff after a few months should not return to his work and be as good a man as ever he was in his life.

In cross-examination the witness said that he was in the employ of the defendants. He called upon the plaintiff to examine him, and he said that he was requested to say that the company desired to express their sympathy with him, and afterwards touched upon the matter of compensation, and put the case to the plaintiff thus:—"Suppose my carriage had caused the mischief, what do you think it right between man and man that you ought to receive under the circumstances?" The plaintiff replied that as the day was Sunday such a matter had better not be mentioned. To this the witness said that he should not have mentioned the matter had not Mr. Hall, the plaintiff's medical adviser, consented to his doing so, and rather wished him to do so, under the belief that the question of compensation might be weighing upon the plaintiff and would retard his recovery. The witness said he had settled many compensation cases with patients. It was part of his duty. He always put the case as between "man and man." He carried cheques in his pocket for the purpose of settling cases, and had some with him then. The plaintiff had never complained twice of pain in the same place. He had asked the plaintiff to point out the seat of pain, and the spot indicated by the patient he had put his pocket-book upon, and then asked him again where the pain was, and the plaintiff had fixed upon another spot, and so he had gone on from place to place. The pains were "flying pains." Any impairment in the functions of the spine was followed by paralysis. In injury to the spine the pain was constant.

Mr. Barnard Holt, the eminent Surgeon of Saville-row, examined the plaintiff on behalf of the Railway Passengers' Insurance Company, and he now stated that, after a thorough examination of the plaintiff, he had no hesitation in saying that, with quiet and fresh air, he would in the course of a very few months be sufficiently restored to health to return to and discharge his duties, and that the plaintiff's ultimate recovery was not very far distant. The lameness the plaintiff exhibited was the result of want of power in the muscles of the leg, brought about by the injury the leg had received. The plaintiff's pulse was uniform, and the same volume on both sides. The plaintiff had undressed himself for the examination, and he used both arms with freedom. There was no doubt that the excitement as to the result of the trial retarded his recovery.

Mr. Haynes Walton, also a Surgeon of high position, entertained the same opinion as Mr. Holt. He saw no reason at all why the plaintiff should not entirely recover from the accident, but of course he could not say when. The plaintiff

might in the course of three or four months be reasonably fit to resume his work.

A certificate written by Dr. Jeffreson, who declined to appear as a witness, was read. The Doctor was particularly guarded in the expressions he used. He said, after having examined the plaintiff, he saw no reason why he should not "eventually" recover. Of course, if the plaintiff should not recover within the time allowed by the Customs for leave of absence, he would be struck off the roll of effectives, and compelled to retire on the £62 a year, when he is only about 43 years of age, and be obliged to seek other employment to make up the great difference between his £250 a year and his pension.

Mr. Bovill summed up the defendants' evidence, and urged that the Medical testimony he had called must have satisfied the jury that the injuries sustained by the plaintiff were not of a permanent character. The mode adopted by the company as to settling compensation was done out of kindness to the injured parties, as it removed as soon as could be done all anxiety that men would naturally have as to what was likely to be in a money sense the result of their case, and when that anxiety was once removed it did a great deal towards the patient's recovery.

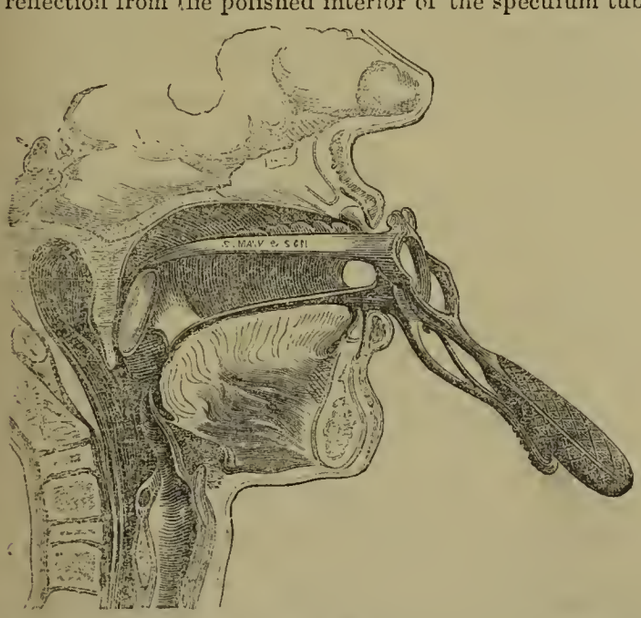
Mr. Chambers, in the course of an admirable reply, ridiculed the notion of the company, from feelings of compassion, having the cheque-book produced to an injured man, in the moments of his agony as a means of soothing his pain, relieving his anxieties, and pushing him on to recovery. He supposed the offer of £30 or £40, or even 100 guineas, was given as a golden pill, the "heal-all" and "cure-all" of the company. As to the notion of the petitioner suffering from flying pains, he was poked here with the pocket-book, "Does that hurt you?" Then somewhere else—"Does that hurt you?" Then another poke—"Does that hurt?" And because the poor man said "Yes" to the questions, then the jury were asked to believe that all his pains were flying ones, and that he had no permanent pains at all.

After the Lord Chief Baron had summed up, leaving the question of damages to the jury, they retired, and after a short absence returned into court, assessing the damages at £800.

NEW INVENTIONS.

NEW BI-VALVE SPECULUM FOR EXAMINING THE LARYNX, INVENTED AND PATENTED BY DR. LABORDETTE, OF LISIEUX.

We have received from Messrs. S. Maw and Son, of Aldersgate-street, a specimen of the instrument whose use is depicted in the accompanying wood-cut. It will be seen that it combines the functions of mirror and depressor of the tongue in one instrument; that the handle is placed out of the way of the eyes; that a great deal of light is economised by reflection from the polished interior of the speculum tube.



The description of the instrument given by the inventor is as follows:—

"The posterior blade, which is curved to fit closely the back of the mouth, descends more or less deeply into the pharynx; the inferior blade, which is shorter, penetrates as far as the base of the tongue, which it depresses by means of the lever spring fixed to the handle.

"The instrument, introduced into the mouth, is pushed as far back as possible; the posterior blade being in the pharynx serves as a point d'appui; the tongue is then immediately depressed in the manner before described by means of the lever-spring acting upon the anterior blade, and exposes the orifice of the larynx reflected in the mirror.

"There are two sizes, one for children and one for adults, which may be obtained, price 31s. each, through most chemists, or direct from S. Maw and Son, 11, Aldersgate-street, E.C."

So far as our own short and hasty trial goes, we have found no difficulty in warming the instrument, or in cleaning it after use; and for autolaryngoscopy we should consider it less fatiguing than the ordinary laryngoscope. But on these points we shall be glad to hear what is said by such of our readers as are adepts in the art of laryngoscopy.

BOOKS RECEIVED.

The Dublin Quarterly Journal of Medical Science. No. 81. February, 1866. Dublin: Fannin and Co. 5s.

*** Contains ten original communications, all apparently of great value. In addition to a translation by Dr. Moore of a paper by Donders on Food and its Relation to Heat and Work, Mr. Porter gives some observations on crushing stone in the bladder; Dr. Smyly, some notes in Medicine and Surgery, including a case of ovariotomy, of strangulated hernia, forcible flexion of the knee-joint, compound fracture of the clavicle, and a new mode of fixing the larynx in laryngoscopy. But we must tell Dr. Smyly that Dr. Labordette's instrument does in one piece what his invention does in two. Dr. Hayden gives cases of typhoid pneumonia with a striking photograph. Dr. Stokes speaks of the treatment of granular ophthalmia by pressure, with figures of pressure instruments. Mr. Colles has a paper on Injuries of the Larger Joints. Dr. M'Clintock gives cases of scarlatina complicating childbed—a coincidence which we shudder at on this side of the Channel. Dr. Wynn Foot publishes a very scholarly thesis on chromidrosis; Dr. Gordon, an examination of the inside of the pleura by the endoscope; Dr. Fleming, some remarks on lithotomy and lithotrity; and Dr. Baxter, on sunstroke. In his opinion sunstroke does not depend upon heat absolutely, but upon that kind of atmosphere which opposes perspiration.

Where Shall We Get Meat? The Food Supplies of Western Europe. By Joseph Fisher. London: Longmans.

*** An account of a tour over the greater part of Europe by a man who went to see the quantity and quality of animal food procurable.

The Dropped Arm, a paper read before the Brighton and Sussex Medico-Chirurgical Society, Dec. 7, 1865. By J. A. Hingeston, M.R.C.S., L.S.A., Registered Practitioner. Author of "Topics of the Day," etc. etc. Brighton: Wakeling, 1866. Price 6d.

*** The writer treats of muscular debility of the arm from granular degeneration of the spinal cord.

On the Anatomy of Vertebrates, vol. 1, Fishes, and Reptiles. By R. Owen. London: Longmans and Co.

*** This is the first volume of a work on the vertebrates, to rank with that on the invertebrates. It shall be reviewed soon.

The Magnetic Purification of River Water, and the Report of the Sewage Committee of 1864. By Thomas Spencer, F.C.S., etc. Third edition. London: Stanford, 1865. One shilling.

*** One of our contributors is preparing an account of Mr. Spencer's process for purifying water, which has not attracted the attention it merits.

Noveau Treatment de l'Angine Couenneuse des Croup et des autres Localisations de la Diphthérie, par le Baume de Copabu, et le Poivre Cubèbe, Medication anti Catarrhale, Substitutive Générale. Par M. H. Trideau. Paris: J. B. Baillière et Fills, 1866. Pp. 32.

*** Recommends copaiba, or cubebs suspended in emulsion, for diphtheria.

Cincinnati Journal of Medicine. Edited by George C. Blackman, M.D., Theophilus Parvin, M.D., and Robert Bartholo, M.D.

*** The editors of this journal have borrowed without acknowledgment the device of a bunch of grapes with the motto "*fructû cognoscitur arbor*," which appear on the title-page on a "Report on Cheap Wine" from the pen of one of our contributors. We do not think that an article on spermatorrhœa is the sort of fruit that speaks well of the tree whence springs the *Cincinnati Journal of Medicine*.

The Australian Medical Journal. December, 1865.

*** Two cases of the falsely-called hydatids of the uterus by Dr. Gunning, and a good practical paper on homœopathy by Dr. Bird.

Journal of the Scottish Meteorological Society. January, 1866. Edinburgh: Blackwood. 2s. 6d.

*** An interesting paper on the popular weather prognostics of Scotland.

Pharmaceutical Journal. February, 1866

*** Unusually full of interesting and useful matter.

Introductory Address Delivered at the Opening of the Winter Session at St. Thomas's Hospital. By Wm. M. Ord, M.B.

First Annual Report of the Borough of Newcastle Pauper Lunatic Asylum, 1865.

Report of the Health of Liverpool during the December Quarter of the Year 1865. By W. S. Trench, M.D.

Observations on the Present Epidemic of Typhus. By R. Perry, M.D. Glasgow: W. Mackenzie.
Braithwaite's Retrospect of Medicine, vol. 52. London: Simpkin and Co.

MEDICAL NEWS.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—At a general meeting of the Fellows held on Monday, February 19, the following gentlemen, having undergone the necessary Examination, and satisfied the College of their proficiency in the science and practice of Medicine, Surgery, and Midwifery, were duly admitted to practise Physic as Licentiates of the College:—

Joseph Burn, Bourne; Henry Cribb, Bishop's Stortford; Hamilton De Tatham, 40, Dorset-square; George Edgelow, Kensington-square; George Jackson, Plymouth; John Morrill, Guy's Hospital; John Holden Webb, St. Mary's Hospital.

At the same meeting, the following gentlemen were reported by the Examiners to have passed their Primary Examination for the Licence:—

William Perceval Magor Boyle, Guy's Hospital; Henry Cheesman, Guy's Hospital; Charles Gôte Gurdon, Guy's Hospital; James Robert Hill, St. Mary's Hospital; William George Kemp, St. Bartholomew's Hospital; George Welland Mackenzie, London Hospital; John William Morris, Guy's Hospital; Arthur Wolcot Nankivell, University College; John Ockenden, St. Mary's Hospital; John Robert Perkins, King's College; John James Ridge, St. Thomas's Hospital; Eldred Noble Smith, St. Mary's Hospital; John Davies Thomas, University College; William James Todd, King's College; Arthur Tudor Humphreys Trevor, King's College.

APOTHECARIES' HALL.—Names of gentlemen who passed their Examination in the Science and Practice of Medicine, and received Certificates to Practise, on Thursday, February 15, 1866:—

Charles George Edmonds, Southampton-street, Camberwell; Robert Andrew Bolt, Blackman-street, S.E.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.—Names of Candidates who passed the Major Examination Feb. 21, 1866, as Pharmaceutical Chemists:—

Thomas Fitzgerald Bulmer, Preston; Osborn Chubb, Taunton; Thos. Harris Cruse, Warminster; Walter Dyson, Pendleton; Arthur Thomas Horton, Scarborough; Edward Jones, Ryde; Andrew MacInnes; Ardrossan; James Stewart, Kirkcaldy.

APPOINTMENTS.

*** The Editor will thank gentlemen to forward to the Publishing-office, as early as possible, information as to any new Appointments that take place.

BIRD, WILLIAM V., M.D., has been appointed Honorary Surgeon to the Bootle Dispensary, Liverpool.

FOSTER, BALTHAZAR W., M.D., has been elected Physician to the Birmingham General Dispensary.

KNOX, JOHN, M.B., has been elected Physician and Surgeon to the Bakewell Dispensary, and Surgeon-Accoucheur to the Ladies' Charity.

EVEY, JOHN, M.D., has been elected Medical Officer to the Workhouse of the Bailieborough Union.

MAPLESON, HORSLEY T., M.R.C.S. Eng., has been elected Medical Officer in ordinary to the St. Marylebone Resident Dispensary.

PODE, CHARLES C., Mr., B.A., of Exeter Coll., has been elected Radcliffe Travelling Fellow.

REED, WALTER HUGO, M.R.C.S. Eng., has been appointed Assistant Medical Officer to the Derby County Asylum.

HORP, D., L.R.C.P. Edin, has been elected Resident Surgeon-Accoucheur at the General Dispensary, Birmingham.

THORP, HENLEY, M.D. St. And, has been elected Medical Officer to the Letterkenny Union Workhouse.

BIRTHS.

BORMAN.—On January 30, at Derby, the wife of Allan Borman, M.R.C.S. Eng., of a daughter.

BRISTOWE.—On February 19, at 2, Queen-square, S.W., the wife of John S. Bristowe, M.D., of a daughter.

BROSTER.—On February 17, at Marland-place, Southampton, the wife of Edward B. Broster, Assistant-Surgeon, R.N., prematurely of a daughter.

BRUNTON.—On February 13, at 207, Caledonian-road, the wife of John Brunton, M.D., of a daughter.

GAINS.—On January 21, at Newcastle, Jamaica, the wife of George E. Gains, M.R.C.S. Eng., Surgeon 6th Royals, of a daughter.

GREENWOOD.—On February 13, at Penryn, Cornwall, the wife of N. Greenwood, L.R.C.P.L., of a son.

GRIMSHAW.—On February 2, at Molesworth-street, Dublin, the wife of T. W. Grimshaw, M.B., of a son.

HICKS.—On February 13, at Old-street-road, the wife of Dr. G. Borlase Hicks, of a son.

JONES.—On February 6, at Dolgelly, the wife of Edward Jones, M.D., of a son.

LONG.—On February 16, at Barham House, Leamington, the wife of C. F. Long, M.D., of a daughter.

MACKAY.—On February 10, at Elgin, N.B., the wife of J. W. N. Mackay, M.D., of a daughter.

OGLE.—On February 9, at 13, Upper Brook-street, W., the wife of John A. Ogle, M.D., of a son.

RIDING.—On February 16, at 36, Euston-square, N.W., the wife of Dr. Riding, of a daughter.

SWIFT.—On February 7, at St. Helen's-park-crescent, Southsea, the wife of Dr. B. Swift, Surgeon-Major 14th Regiment, of a son.

TIZARD.—On February 10, at Weymouth, the wife of Henry Tizard, M.D., of a daughter, prematurely.

WALKER.—On February 16, at Peterborough, the wife of Dr. T. J. Walker, of a daughter.

WATKINS.—On February 17, at 11, Chandos-street, W.C., the wife of C. S. Watkins, M.R.C.S. Eng., of a son, stillborn.

MARRIAGES.

CURTIS—ASHBY.—At Staines Church, Albert Curtis, M.R.C.S. Eng., to Augusta, daughter of the late Charles Ashby, Esq.

GARSTANG—WARDLEY—On February 14, at Over Darwen, Lancashire, Walter Garstang, M.D., to Matilda Mary, second daughter of James Wardley, Esq.

MCKELLAR — WHITE. — On November 16, at Umballa, India, Edward McKellar, Staff-Surgeon 10th Bengal Cavalry, to Elizabeth, only daughter of the late Colonel White.

MOUNCEY—WILSON.—On February 13, at St. George's, Hanover-square, James A. Mouncey, Surgeon, to Emily Georgina, eldest daughter of William Wilson, Esq.

ROSS—NIGHTINGALE. — On February 17, at St. Michael's Church, St. Martin's-in-the-Fields, John T. Ross, M.R.C.S., R.N., to Mary Julia, second daughter of the late Thomas Nightingale, Esq.

RUSSELL—TIM.—On February 13, at Eccleshall Church, Sheffield, John Russell, M.R.C.S. Eng., to Elizabeth Mary, eldest daughter of Charles Tim, M.D.

DEATHS.

ADAIR, PONSONBY K., M.R.C.S. Eng., at Kurrachee, India, Medical Superintendent Indo-European Telegraph Establishment, on January 18, aged 28.

GRIFFIN, WILLIAM H., M.R.C.S. Eng., at Banbury, Oxon, on February 5, aged 26.

HENDERSON, ALEXANDER, H.M. Bombay Medical Service, at Church-hill, Edinburgh, on February 6.

HOBSON, THOMAS, L.S.A., at Kirk, Ella, Hull, on February 1, aged 55.

LEACH, HENRY, M.R.C.S. Eng., at Leigh, Essex, formerly of Sandgate, on February 20.

MCGLASHAN, JOHN, L.F.P.S. Glasg., at 46, Wilson-street, Middlesborough, on February 15.

MORRIS, WILLIAM, M.D. St. And., at Newbury, Berks, on February 20, aged 33.

POLLARD, TEMPEST, M.R.C.S. Eng., at St. Helier's, Jersey, on January 31, aged 46.

SARASIN, FELIX W., M.D., at Bale, Switzerland, on February 12.

STEDMAN, SILAS S., M.D. Lond., at Christchurch, Canterbury, New Zealand, on December 4, aged 45.

SUTCLIFFE, CHARLES, M.R.C.S. Eng., at Todmorden, Lancashire, on February 12, aged 44.

POOR-LAW MEDICAL SERVICE.

*** The area of each district is stated in acres. The population is computed according to the last census.

RESIGNATIONS.

Basford Union.—Mr. John H. Osborne has resigned the Calverton District; area 7430; population 3101; salary £25 per annum.

Birmingham Parish.—Dr. Edward White has resigned the Fourth District; salary £150 per annum. (No fees.)

Kidderminster Union—Mr. Cecil Webster has resigned the Bewdley District; area 9006; population 4141; salary £70 10s. 10d. per annum.

St. Thomas's Union.—Mr. Charles T. Tothill has resigned the Topsham District; area 4239; population 4361; salary £52 16s. per annum.

APPOINTMENTS.

Aylsham Union.—Thomas Daurant, M.R.C.S. Edin., L.S.A., to the Third District.

Droitwich Union.—Serjeant S. Roden, M.D. Edin., M.R.C.S.E., to the Hanbury District.

Nottingham Union.—Henry R. Hatherly, M.R.C.S.E., L.S.A., L.M., to the Second District.

Sheffield Union.—Wm. Skinner, jun., L.R.C.P., M.R.C.S.E., to the North District.

Great Yarmouth Parish.—Thomas H. Moxon, M.R.C.S.E., L.S.A., to the South District.

Académie de Médecine.—At the election to replace the late M. Beau in the Section of Pathological Anatomy, M. Behier was the successful candidate, polling 43 votes, against 36 given for M. Barthez.

Hyposulphite of Soda in Cattle Plague.—Mr. J. T. Noakes, of Brockley Hall, Lewisham, states that his herdsman has successfully used hyposulphite of soda as a preventive of cattle disease. He recommends that a solution of the strength of five pounds dissolved in 100 gallons of water be given as an ordinary drink to cattle. Those of his herd thus treated escaped the infection, although not isolated. The remainder died.

Cambridge. — Resignation of the Professor of Anatomy.—A meeting of the friends of Dr. Clark, who, after fifty years, has resigned the Professorship of Anatomy, was held at Christ's College Lodge on Tuesday afternoon last for the purpose of considering some mode of showing how much his long-continued services to the University and to science are appreciated. The meeting was well attended by influential members of the Senate; and the following resolution, proposed by the Master of Trinity College, was unanimously adopted: —"That, in order to recognise the great services rendered by Dr. Clark to science and to the University, a marble bust of him be offered to the Senate, to be placed in the Museum of Comparative Anatomy, and that it be suggested to the Senate that for the future the Museum of Comparative Anatomy be called the Clarkian Museum."

Cambridge. — An election to the Professorship of Anatomy, vacant by the resignation of Dr. Clark, will take place in the Senate House on the 1st of March. Dr. Humphry and Mr. Lestourgeon were candidates for the chair, but the latter having withdrawn, the former will most likely be elected without opposition. The candidates who have issued circulars offering themselves for the Professorship of Zoology and Comparative Anatomy, which has been recently established, are Dr. Drosier and Mr. Newton. The chair is open to scientific men generally. We have seen Dr. Cobbold's name mentioned as that of a probable candidate, but we believe it is not that gentleman's intention to come forward.

Fever in Whitechapel.—The Medical officer of health for the Whitechapel district, Mr. Liddle, has made a report to the Local Board of Works, in which he states that during the past year the number of deaths in the district from fever has been 167, exclusive of those which occurred in the Fever Hospital of those belonging to the district. Fever has been epidemic since 1862, in which year the number of deaths from it was 250; in 1863, the number was 158, and in 1864 it was 170. During the past year the Medical officers of the Union attended 573 cases of fever, and in the preceding year 395 cases; in the workhouse during the past year there have been 535 cases of fever. These melancholy facts, the Medical officer remarks, clearly indicate that our sanitary arrangements are very imperfect, and that much greater exertion must be made, and further scientific inquiries must be instituted if this plague is not checked.

Mr. Worms' "Cure" for the Cattle Plague.—Mr. T. Archer, of Arndean, Dollar, N.B., in a letter which appeared in the *Times* of February 22, gives the following account of his reasons for incredulity in reference to Mr. Worms' diagnosis and mode of treatment:—

"Will you kindly give me space in your columns to express my entire disbelief in Mr. Worms' so-called curé for the Rinderpest, notwithstanding the many successful applications of it that are almost daily announced in the *Times*? My incredulity is based, not alone on my own want of success in applying the remedy—which the advocates of Mr. Worms' system may attribute to my having followed his original directions contained in the letter to Lord Leigh, instead of the second prescription, where pickling onions are substituted for shallots, or the third, where I observe that one of the ingredients (assafœtida) is nearly quadrupled—but also on my experience of the disease, and on information I have been able to gather from neighbours who have been heavy sufferers.

"In the first place, I cannot detect what Mr. Worms calls the very first symptom—viz, an offensive tainted breath. I have subjected ten animals in various stages of the disease to rigid and repeated tests, and find the breath is as sweet as when they are in perfect health. From this I infer that the disease which Mr. Worms has been in the habit of treating in Ceylon is not identical with the Rinderpest, and I attribute the apparent cures to the fact that the afflicted animal will, during the first three or four days after the disease has unmistakably shown itself, occasionally rally, take its food greedily, chew its cud, and appear as if nothing ailed it.

"If, however, the attack be of a severe type, a reaction will set in and speedily dispel the hopes of the sanguine operator. Should the disease, on the contrary, be of a mild type, the animal may, doubtless, recover from it and the treatment alike. It will be interesting to learn how many can be pronounced cured in ten days, instead of twenty-four or forty-eight hours, after the Worms cure has been administered. The percentage of recoveries is now, I am glad to say, much higher in this neighbourhood than at the first outbreak of the plague. Whether this is attributable to the disease, like some other epidemics, assuming a milder form as it progresses or to a new system of management, that has very generally been adopted, I cannot say, but, in any case, I consider it a subject for congratulation that the new Act leaves the slaughtering of cattle in some degree to the discretion of local authorities."

A Gigantic Bird.—The fossil remains of a gigantic bird, estimated to have stood twenty-five feet high, have been discovered in some beds of limestone at Nelson, in New Zealand. The remains consist of a head minus the lower jaw, the dimensions of which are 3 ft. 4 in.; the orbit of the eye measured 4½ in. by 2½ in.; also a body minus the neck; the thorax is highly developed but rather flat, the tail long, and body bulky; the wings, which are well defined, are large and close to the body, and are separated by a saddle or cradle very graceful in form; the feathers covering the body are of a large size and lying close.—*Australian Paper.* The following letter on this supposed discovery from Professor Owen appeared in Thursday's *Times*:—

"Sir,—Paragraphs like that on the 'Gigantic Bird' usually include elements which the naturalist sees to be fatal to the interpretation attached to the facts; yet these may be well deserving attention and inquiry. New Zealand was undoubtedly the land of huge birds, but, like their few existing congeners in other parts of the world, the head was small; that of a Dinornis, thrice the bulk of the largest living ostrich, does not exceed eight inches in length.

"The notice of the remains found in the province of Nelson assures me that they are those of a saurian reptile, and indicate the jurassic age of the 'beds of limestone' in which they have been petrified. Parts of a Plesiosaurus were discovered in that province by Mr. J. H. Hood, of Cluny-house, Dunkeld, in 1861; but the present are of another kind.

"Should this letter appear and meet the eyes of any colonist able to grant the request, I would ask only for a single vertebra (joint of back or tail) and one of the supposed feathers of the 'gigantic bird,' and promise to return the name of the animal.

"As my table this morning gives unmistakable evidence of a coming avalanche of inquiries as to the meaning of the paragraph from the 'colonial newspaper' to which you have added your circulation, 'friends will please to accept' the above as an answer. "I am, Sir, your obedient servant,

"February 21. "Richard Owen."

The following are the last week's Cattle Plague Returns.

Census Divisions.	1. Attacked. Week ending February 10.	Week ending February 3.	Week ending January 27.	2. Result of reported Cases from the Commencement of the disease. Attacked.	Killed.	Died.	Recovered.	Unaccounted for.
1. Metropolitan Police District	23	36	26	7537	3177	3443	323	594

Note.—251 Inspectors have not sent in their reports in time for this return. The very large amount of work involved in inspection appears in some cases to be the reason of this delay. One Inspector has written to say that he inspects "upwards of 330 stocks," and that it is impossible for him to make up the return in time.

NOTES, QUERIES, AND REPLIES.

He that questioneth much shall learn much.—*Bacon.*

Special Report on Fractures.

In this week's number we publish the first of a series of Lectures on Fractures and Dislocations, which we hope to continue on alternate weeks, with the remainder of Dr. Bence Jones's Lectures. At the same time we begin to publish a set of Special Reports on the Treatment of Fractures as at present carried on in the Hospitals of London. Probably the treatment in Provincial Hospitals will follow. We are sure that every Practitioner who has passed some years in secluded Professional labour, away from Hospitals and great towns, will be glad to know the simplest, latest, and most useful methods of treating accidents such as these, which cause so much anxiety lest anything less than a comely and useful limb may be the result.

"*An Invalid.*"—The Restorative advertised with the great Surgical Baronet's name is only a quack nostrum.

W. R. S. is thanked, but it is too ticklish a subject.

Dr. Macloughlin's doctrine, that cholera is always preceded by a premonitory diarrhœa, is now sufficiently well known to the Profession.

Pulvis Jacobi.—It was in great reputo in 1750.

Mr. Addington.—A distemper among horned cattle prevailed in 1745. The offer is declined, with thanks for your courtesy.

Erinensis, Deptford.—Teige, a son of Joseph O'Cassidy, of Coole, Physician to the Princes of Fermanah in 1450.

Dr. W.—Hawkins invented the cutting gorget in 1740.

E. R., Kennington.—Mrs. Mapp, the bone-setter, visited the Grecian Coffee-house once a week in her coach and four from Epsom in 1736. Mrs. Stephens received £5000 from Parliament in 1739 for communicating the secret of her solvent for stone in the bladder.

A Country Surgeon.—The drawings of Sir Charles Bell will remain on view in the Museum of the College of Surgeons during the ensuing week, after which, in pursuance of the wishes of Lady Bell, they will be forwarded to the Royal Victoria Hospital, Netley.

Archæologist, Sheffield.—There were two Surgeons appointed by the Council to attend Henry VI. during his illness—viz., Robert Warren and John Marshall. At this time Surgery was distinct from Medicine, though united to the occupation of the barber.

The Army Medical Service.—There is a rumour that the whole batch of Medical candidates at Netley have petitioned to be allowed to exchange from the British into the Indian Medical Service. If this be true, it gives the useful hint to all who intend to compete at the next examination that they may as well go in for the Indian Service chance, and save themselves the trouble of asking afterwards for an exchange, which may not be got very easily.

Erratum.—In our report of the meeting of the Royal Medical and Chirurgical Society for February 10, *for* "Mr. Gascoyen," *read* "Mr. Gaskoin."

The late Alleged Breach of Medical Etiquette at Upton Noble (Vide "Medical Times and Gazette," January 6 and 20, 1866).

To the Editor of the Medical Times and Gazette.

Sir,—At a meeting of the Somerset Central Medical Society, held on the 8th inst., the above question was discussed by the members present, and it was unanimously resolved that the Secretary be requested to write to the *Medical Times and Gazette*, stating that in their opinion Dr. Higginbotham was entirely justified in the course he pursued on that occasion.

I am, &c. W. C. Walker, Sec. and Treas. S.C.M.S.

Shepton Mallet, February 16.

Syphilisation.

To the Editor of the Medical Times and Gazette.

Sir,—I am glad to see that after the lapse of nearly ten years from its first introduction to the British public the subject of syphilisation is now receiving its due share of attention. Permit me to observe that the earliest notices of syphilisation in Norway appeared in the *British and Foreign Medical Review* for April, 1857, p. 410; and again in 1859, January number, p. 118, the full account of Dr. Danielssen's researches was given, with an analysis of the long discussion on this curious subject, in which Professor Faye, of Christiania, took so active a part. Both these notices were written by Yours, &c. Edward Charlton, M.D.

7, Eldon-square, Newcastle-on-Tyne, Feb. 16.

The Sphygmograph.

To the Editor of the Medical Times and Gazette.

Sir,—I hope you will allow me to correct an error which occurs in a paragraph published in your last impression. Dr. B. W. Foster, of Birmingham, is therein stated to have read the first systematic paper on the use of the sphygmograph which has been heard in this country. This is rather a strange mistake, as it is well known that I read a paper, two or three months ago, at the Medical Society of London, in which I embodied the result of observations which I have been carrying out during the past year, with the assistance and advice of my friend Dr. Burdon Sanderson, to whom is due the real credit of introducing the instrument to English Physicians.

I am, &c.,

Francis Ed. Anstie, M.D., F.R.C.P.

16, Wimpole-street, Feb. 22.

Poor Law Medical Relief.

To the Editor of the Medical Times and Gazette.

Sir,—I have now in the hands of the printer the Draft of a Bill containing seventeen clauses, with a commentary on each clause pointing out the reasons for their proposition. There is also a letter addressed to the Members of Parliament bringing all the important points of the subject prominently before them. A copy will be sent to each Medical officer who has sent a subscription to the Association within the last twelve months, as well as to each Member of Parliament, as soon as the Bill is brought before the House. If any of your readers can assist me by naming a gentleman willing to undertake the charge of the Bill, I shall be glad to hear from him. The printer informs me he cannot keep the type standing, I therefore trust that those Medical officers who intend subscribing will do so without delay, so that I may order the number of copies of the pamphlet actually required for them.

I am, &c. Richard Griffin.

12, Royal-terrace, Weymouth, February 17, 1866.

List of subscriptions received by Mr. Griffin:—Norman, W., St. Columb Major, 5s.; Allen, R. R., Belper, 10s.; Eldridge, F., Andover, 20s.; Heginbotham, E., Wincanton, 10s.; Coombs, J. W., Ticehurst, 5s.; Wills, J., Sturminster. 10s.; Smart, J., Bethnal-green, 10s.; Jones, W., Wigton, 5s.; Mason, M., Sudbury, 10s.; Ledgard, J. A., Carlton, 5s.; Ransom, R., (not Union) Cambridge, 10s. 6d.; Dowse, J., Huddersfield, 5s.; Taylor, C., Melksham, 5s.; Parsons, C. H., Foleshill, 5s.; Hewett, T., Hendon, 21s.

List of subscriptions received by Mr. Prowse:—Dandy, C., Ormskirk, 20s.; Burtt, G. R., Chard, 10s.; Somerville, J. H., Walsall, 10s.; Robinson, G. S., Saffron Walden, 10s.; Williams, W., Festiniog, 10s. 6d.; Roberts, R., Festiniog, 10s. 6d.; Douglas, T. S., Cockermouth, 10s.; Sutherland, W., Billingham, 5s.; Barrett, J. S., 5s.; Holyoake, T., Seisdon, 10s.; Yelf, L. K., Shipston-on-Stowe, 10s.; T——s, 5s.; Tiley, J., Hitchin, 5s.

Ode to Dr. Marion Sims.

To the Editor of the Medical Times and Gazette.

Sir,—After reading your vigorous criticism on the recently-published work of Dr. Marion Sims, my "teeming brain" conceived the following verses, which I hasten to deliver to you, to be, as you may think best, either strangled at once, or, happier fate! received among your adopted children.

I am, &c.

H. L.

Say, what is man? An atom at the first,
Waiting its nuptial atom in the womb;
Too oft, alas, by fate untimely curst,
In place of fostering home, to find a tomb.
Grieved at the thought, a tear thine eye bedims,
Great son of Æsculapius, Marion Sims.

Swift to thine aid *inventive genius* brings
Persuasive tent or glistering hystrotome;
With these the obstructed portal open flings,
And guides the struggling sperm'tozoon home.
Thus may the wished-for union perfect be,
The mystery no human eye can see.

Sims, should these fail, thou still wilt cherish hope
To find some other cause that breeds the ill,
With learned digit, searching microscope,
Or peering speculum, exploring still;—
Nay, wizard-like, ethereal sleep wilt shed,
To win thy point, e'en o'er the nuptial bed.

Indirect Inoculation for Rinderpest.

To the Editor of the Medical Times and Gazette.

Sir,—Since the appearance of my letter in your last number, in which I spoke of a modified process of inoculation for the prevention of Rinderpest, I learnt by some remarks made by Dr. Crisp on the cattle plague at the meeting of the Pathological Society, January 16, that men employed in flaying diseased animals had often an eczematous eruption upon the arms and thighs, which sometimes continues for three and four weeks, and evidently arises, as he thinks, from the acidity of the virus affecting the skin, these men being in the habit of placing the knife between the thighs whilst so employed.

Now, if besides inoculating other species of animals with the Rinderpest virus, with the object of returning the infection in a modified form, we were also to inoculate cattle with the lymph obtained from these pustules in man, we might obtain an exanthem in cattle which would act as a safeguard against any future attack of the Rinderpest. Or better still, where an eruption happens to be contracted in man by direct or indirect communication with the diseased animal, we might avail ourselves of the opportunity, and employ the infection thus accidentally derived for the purpose of inoculation instead.

Requesting you to give the above a place in your columns,

I am, &c.

20, Clarinda-terrace, Kingstown, Feb. 20. F. E. Jencken, M.D.

To the Editor of the Medical Times and Gazette.

Sir,—The "hypothesis" of your correspondent Dr. Jencken in last week's *Medical Times and Gazette* is, I think, worthy of serious consideration. As it is an established fact that lymph from human small-pox inoculated into the cow does not produce small-pox, but cow-pox, and that this (cow-pox) lymph inoculated into the healthy human subject proves a complete prophylactic against small-pox, so the lymph from Rinderpest inoculated into the human subject does not produce Rinderpest, but herpes (*vide* Dr. Harbord's letter in *Medical Times and Gazette*, page 184); therefore, why should not this (herpetic) lymph inoculated into the healthy cow prove a complete prophylactic against Rinderpest? Reasoning from analogy, it must be so, unless there is something wrong in the premises; and, further, as there is no known cure for small-pox, so there is none for Rinderpest, and therefore the only effectual way of stopping the ravages

of the disease is to discover a prophylactic for it, such as has been discovered for small-pox.

The cow has been made subservient to the life and well being of thousands of the human race, and why should not the human race be made subservient to the life and preservation of our herds of cattle? I have no doubt there are many persons who would willingly submit to be inoculated with the lymph of Rinderpest, seeing there is no known instance (so far as I am aware of) where the matter of Rinderpest has proved fatal to the human subject. Let the thing be put to the test of experiment, and we shall soon see whether there be any value in it or not. We have, no doubt, been on the right tack in all this vaccination, but, unfortunately, we have been experimenting with the wrong sort of lymph, and therefore no good has resulted from it. I am, &c.

2, Shaw-street, Liverpool, Feb. 20. P. Leigh, M.R.C.S.

"Grease" and Variola.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

Sir,—Mr. Whately's letter is valuable, but may I ask some of your readers whether this is a new fact? Does not Jenner in his original work state that the men who tended horses suffering from "grease" if they afterwards milked the cows on the farm caused the appearance of vaccine vesicle on the cows' bags. I am, &c.

West Haddon, February 19. G. H.

List of Papers (not) read at the Meeting of the British Mutual Admiration Society.

1. On the vegetable formation of the Baldwin Islands, as suggesting a new theory of capillary attraction, by Dr. Wigsby and Mr. Beardmore.
2. On the theory and practice of ovisuction, based on the minute anatomy of the *chalaza* under high powers of the microscope; being a lecture specially dedicated to the grandmothers of England, by Dr. Bleareye, F.R.S.
3. On shirt-collars as an archetypal relic of the exoskeleton and on the gills of the tunicata, by Dr. Shelly.
4. On the composition of the milk among the Asiatic nomads as explaining the formation of cream of tartar by their revolutions on the Steppes, by Professor Dariman, of Pumpernickel.
5. Professor Wrigley on the vermiform process.
6. On the strata of native hippuric acid recently discovered at Bayswater, under the auspices of the Geological Society.
7. On the successful treatment of homicidal mania by the external application of the *Cannabis sativa*, by Dr. John Bull.
8. On nidification in the Equus caballus, by G. P. R. M. D.
9. On the paralysis producible in birds by the application of chloride of sodium to the feathers covering the posterior termination of the vertebral column, by Dr. Handy Fowler.
10. On the arrest of *tabes* in the horse by a general grumous discharge, by Professor Angreus Hercules, of the N. V. C.
11. On the psychical development of the higher quadrumana, as illustrated by the wood carvings of Gibbons, and the military organisation of mandrills, by Bulbous Roots, M.D.
12. On a new species of mouse, the *Mus remotus* (or farm-'ouse), discovered in the country round London by Tittlebat Titmouse, Esq.

At the Royal Observatory, Greenwich, the mean height of the barometer in the week was 29·342 in. The barometric pressure fell to 28·48 in. on Sunday, and rose to 29·89 in. on Saturday.

The general direction of the wind was S.W. and N.W.

* The average weekly numbers of births and deaths in each of the above towns have been corrected for increase of population from the middle of the ten years 1851-60 to the present time.

† Registration did not commence in Ireland till January 1, 1864; the average weekly number of births and deaths in Dublin are calculated therefore on the assumption that the birth-rate and death-rate in that city were the same as the averages of the rates in the other towns.

‡ The deaths in Manchester and Bristol include those of paupers belonging to these cities who died in Workhouses situated outside the municipal boundaries.

§ The mean temperature at Greenwich during the same week was 45·8°.

APPOINTMENTS FOR THE WEEK.

February 24. *Saturday* (*this day*).

Operations at St. Bartholomew's, 1½ p.m.; St. Thomas's, 9½ a.m.; King's, 2 p.m.; Charing-cross, 1 p.m.; Royal Free Hospital, 1½ p.m.

Royal Institution, 3 p.m. Prof. Westmacott, "On Art Education and How Works of Art should be Viewed."

26. *Monday*.

Operations at the Metropolitan Free Hospital, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 9 a.m. and 1.30 p.m.

27. *Tuesday*.

By Mr. Armstrong Todd—Lithotomy (a child).

ORIGINAL LECTURES.

ON GENERAL AND LOCAL CHEMICAL DISORDERS ARISING FROM MODIFIED PEROXIDATION,

AND ON THE MECHANICAL DERANGEMENTS THEY PRODUCE.

By H. BENCE JONES, M.D., F.R.S.

Part III.—Lecture X.

On Fermentations and Fevers.

There is for the chemist and for the physician no subject more anxiously waiting for perfect solution than the nature of fermentation. For animal poisonings are fermentations, including as I intend to do under this term catalytic as well as transferred actions.

Many mineral, vegetable, and animal substances have the power to exalt or change the chemical actions going on in contact with them. Thus heated spongy platinum will cause hydrogen and oxygen to combine. Phosphorus will convert oxygen into the more active ozone. Finely-divided platinum will oxidise alcohol in the air. Peculiar vegetable mycoderms will produce the same oxidising action as the spongy platinum.

Sugar, when fully oxidised, without the presence of any modifying substance, gives rise to carbonic acid and water only; when modifying substances are present the oxidation is far more complex. With yeast or wine ferment sugar gives alcohol, glycerine, succinic acid, and carbonic acid; with a different ferment lactic acid is formed; with yet another viscous fermentation occurs, and gum, mannite, water, and carbonic acid are produced. According to M. Pasteur, when animal matters are present with the sugar, oxidation at first occurs; infusoria, as monas crepusculum and bacterium termo, live until the oxygen is gone; then butyric vibrios appear, and these set up putrefaction, and the compound sugar, $C_{12}H_{12}O_{12}$, gives rise to butyric acid, $C_8H_8O_4$, carbonic acid, C_4O_8, and free hydrogen, H_4.

In the human body many different kinds of ferments occur in health. Of these zymases, four are well known: first, those that change starch into sugar, as in saliva, in pancreatic fluid, in intestinal fluid, and in the liver; secondly, those that change sugar into lactic acid, as in stomach, and in milk; thirdly, those that help to make the albuminous part of the food soluble, as in the pepsine of the stomach; fourthly, substances that cause the fine division or emulsion of fat in the body, as in bile, in pancreatic and intestinal fluid.

Moreover, many other chemical actions in the human body depend in health on some kind of contact action, or action by presence. The whole process of assimilation in each part of the body: the food becoming blood, the blood becoming part of each organ and texture, identical in composition with the substance already there, gives evidence of the highest amount of contact action, on which clear ideas are as yet wanting.

At present our knowledge of the chemistry of fermentation is insufficient for the full solution of the comparatively simple problems of the making of bread or the putrefying of urine; how far short, then, must it be from giving us the explanation of the chemistry of assimilation?—far less can it help us now to comprehend the great problem of reproduction.

I am unable here to enter into the multitude of questions connected with fermentation in general. I am obliged to limit myself to a few points connected with fermentation, and I shall take that of the urine, on which I have some facts which I wish to bring before you.

First, on acid fermentation in the urine.

For the last twenty years it has been a received opinion that there is an acid fermentation in the urine.(a) Scherer thinks that after it has been passed an increase of acidity may be observed, and the deposit of uric acid and of acid urates he holds to be well explained by this after formation of acid. When making my experiments on the variations of the acidity of the urine by carefully determining the amount of acid in the urine at different periods after the water was passed, I was led to doubt the existence of this acid fermentation, and to satisfy myself I made the following experiments on the so-called acid fermentation.

I endeavoured to measure the increase of acidity in the urine, first by a standard solution of soda, and secondly, by watching the time when the uric acid crystallised out. A very dilute standard solution of soda was prepared, and eighteen different experiments on healthy urine were made. The acidity was determined when the urine was first made in a fixed quantity of water, 50 or 100 c.c., and the acidity was again and again noted from time to time on different days in the same urine. The results are given in the following table: —

	Expt. 1st.	Expt. 2nd.	Expt. 3rd.	Expt. 4th.	Expt. 5th.	Expt. 6th.	Expt. 7th.	Expt. 8th.	Expt. 9th.	Expt. 10th.	Expt. 11th.	Expt. 12th.	Expt. 13th.	Expt. 14th.	Expt. 15th.	Expt. 16th.	Expt. 17th.	Expt. 18th.
1st day ..	..	..	..	..	..	..	..	..	..	..	..	..	..	..	..	..	no incr.	..
2nd day ..	..	no incr.	no incr.	no incr.	slight incr.	..	..	..	..	no incr.	slight incr.	..	..	..	no incr.	slight incr.	..	slight incr.
3rd day ..	no incr.	..	..	..	..	slight incr.	slight incr.	decr.	incr.	..	..	..	..	..	..	..	no incr.	..
4th day ..	..	..	..	no incr.	no incr.	..	..	..	..	no incr.	slight incr.	..	..	..	..	..	..	..
5th day ..	no incr.	no incr.	..	..	..	slight incr.	slight incr.	slight incr.	..	..	..	slight decr.	strong decr.	..	..	..	..	..
6th day ..	..	..	..	no incr.	..	..	..	..	decr.	decr.	slight incr.	..	..	no incr.	..	..	no incr.	..
7th day ..	no incr.	no incr.	..	..	no incr.	slight decr.	..	decr.	..	..	..	..	..	..	..	..	..	..
8th day ..	..	..	..	..	..	..	..	..	..	decr.	..	..	..	..	..	..	decr.	..
9th day ..	..	..	..	..	..	slight incr.	..	same	..	..	..	..	..	..	..	..	..	..
10th day ..	decr.	..	..	..	decr.	..	..	..	..	..	..	..	..	..	..	..	..	..

Thus, in all these experiments there is not one that showed any decided increase of acidity. There was either no increase of acidity at all, or it was so slight that the increase was not beyond the possible error of observation consequent on the process. Failing by direct measurement, I tried whether any conclusion could be arrived at by noting the time when free uric acid crystallised out, because the crystallising out of free uric acid is the most delicate test of the free acidity of the urine. Forty-nine different urines were observed daily without any filtration to determine the day when the uric acid crystallised out. In 32 no crystals were found; in 17 they were found.

In these 17 urines crystals were seen 5 times on the 2nd day.
" " " " 5 " 3rd "
" " " " 2 " 5th "
" " " " 1 " 6th "
" " " " 2 " 7th "
" " " " 1 " 11th "
" " " " 1 " 12th "

Twenty different urines were filtered immediately after they were passed, and in these only ten times were crystals of uric acid found.

In these 10 urines crystals were seen 3 times on the 3rd day.
" " " " 3 " 4th "
" " " " 3 " 5th "
" " " " 1 " 7th "

It follows, then, that there is no evidence of any increase of acidity at any fixed short period after the urine is made. No proof of fermentation can be drawn from these observations of the days of appearance of uric acid crystals in the urine.

When Professor Brucke observed that in health small quantities of sugar were found in the urine, it seemed to me very desirable to try whether this sugar disappeared when the urine was kept. Three litres of urine were divided into two perfectly equal portions. One part had the sugar determined immediately; it gave 2·4 grains of sugar. The other part was kept until it became feebly alkaline in twenty-five days. Then the sugar present in it was determined by the same process, and found to be 1·9 grains.

Hence I can find no distinct evidence of an acid fermentation in the urine. The more or less rapid crystallisation of

(a) *Scherer Beitrage zur Pathologischen Chemie; Annalen der Chemie und Pharmacie*, vol. xlii., p. 176.

free uric acid depends on the amount of liberating acid that is secreted by the kidney and on the more or less acid urates that exist in the urine, and on the influence of other salts present at the same time. Highly acid urates are decomposed, setting free uric acid, when washed with water or salt and water alone; while they are not decomposed if washed with the urine from which they were precipitated. Less acid urates liberate uric acid when washed with dilute solutions of acid or of pure acid phosphate of soda more or less quickly, according to the amount of dilute acid or acid phosphate of soda present, and according to the temperature and the time the action is continued. Even in the ordinary method of determining with strong hydrochloric acid the amount of uric acid in the urine, twenty-four hours are, as Dr. Hassall has shown, insufficient to allow all the uric acid to crystallise out.

Secondly, on the alkaline fermentation in the urine.

It has been said, and repeated over and over again, that the mucus in the urine is the ferment that effects this change from acid to alkali; but this is not the fact, as the following experiments, not made for this object, will show you.

In November the fresh urine was filtered carefully through a fine filter, and twenty observations were made from day to day. Seven times the urine became neutral or alkaline on the following days:—Ninth day, 1; tenth day, 2; eleventh day, 3; sixteenth day, 1.

In February the unfiltered urine was observed twenty-two times. Nine times it became neutral or alkaline on the following days:—Fifth day, 1; sixth day, 1; eighth day, 1; ninth day, 2; tenth day, 1; eleventh day, 1; thirteenth day, 1; fourteenth day, 1.

In June the unfiltered urine was observed twenty-seven times. Eighteen times it became neutral or alkaline on the following days: Fourth day, 1; fifth day, 1; sixth day, 2; seventh day, 3; eighth day, 4; tenth day, 2; eleventh day, 5.

Hence, filtered 7 in 20 become neutral or alkaline during observation, most on the eleventh day; unfiltered, 9 in 22, most on the ninth day; in summer, unfiltered, 18 in 27, most on the eleventh day. So that there is no decided difference between filtered and unfiltered urine as regards alkaline fermentation. The mucus that is separable by the filter is not the ferment that changes the urea into carbonate of ammonia, $C_2H_4N_2O_2 + 4HO = 2(NH_4O.CO_2)$.

Moreover, vibrios are not the cause of the alkalescence; for I have several times met with urine that was exceedingly foul in smell at the moment of passing, and so ropy that the drops adhered as they were poured from the vessel, quite distinctly tailing. Yet test paper showed that this water was highly acid, and it remained so in one case in July for seven days. With the microscope, multitudes of active vibrios were found within a few minutes of the water leaving the bladder.

That these vibrios are formed within the bladder the following case proves:—

A boy, eight years of age, was brought to me with the following history:—A native of India, just arrived, sickly, thin, sallow, languid. When four and a-half some unusual smell was first perceived in the urine; but little was thought of it until he embarked for England, when the water was observed to be passed in large quantities, and frequently to be so abominably offensive as to render his cabin intolerable to those with him. The mother remarked that she had observed the offensive smell to be always most perceptible when the bowels were most constipated. When the bowels were well evacuated the urine was not fœtid. Generally fifty to sixty-five ounces were passed in twenty-four hours. At one evacuation of the bladder he did pass thirty-three ounces; specific gravity 1008; slightly acid; with albumen and pus, and no casts of tubes. Specific gravity sometimes as low as 1004. Dr. Prout, who examined the patient, considered the smell was distinctly that of sulphuretted hydrogen. Two months after I saw him he caught a bad cold in Ireland and died. The kidneys and bladder were sent to London for examination. The right kidney was one and a-quarter inch long, one inch broad, and the ureter impervious. The left kidney was large, with abscesses in it. The pelvis was dilated and the ureter dilated. The bladder was very much dilated. The right ureter opened by wide mouth into the bladder. At its entrance it admitted a large catheter, and it swelled, when blown up, to four times the size it had when collapsed, presenting very much the appearance of an inflated small intestine. It was twice the size of the other ureter, and was four inches long. During life the urine was caught on a glass at the microscope, and the focus being right the infusoria were seen instantly in activity in four seconds. As many as fourteen divisions were counted in one moving string; monads were also present, and some pus globules and blood globules.

M. Pasteur considers that he has proved that the germs of these vibrios come from the atmosphere, and that they will not form unless all the oxygen present is first taken away by other kinds of infusoria; then the vibrios set up intense putrefaction, and without the access of germs and absence of oxygen no putrefaction occurs. When air is present, he says, in twenty-four hours monads and bacteria abstract oxygen, and grow on the surface in contact with the air, forming a pellicle, which gets thicker and thicker until it falls to the bottom, and thus prevents oxygen getting to the lowest part of the liquid. There the vibrios can live and do set up putrefaction, transforming nitrogenised into simpler, but still complex compounds. Bacteria burn these products, and reduce them to the simplest forms—water, ammonia, and carbonic acid.

The alkaline fermentation of the urine and putrefaction in the bladder are not explained by these facts of M. Pasteur. If it be possible that monads or vibrios may make the urea change to carbonate of ammonia, then the germs of the monas and of the vibrio, at least sometimes, must be formed in the bladder. The putrid abscesses found in the liver; in contact with bone; in the cellular tissue and in other parts where no germs can be carried by the access of air must either prove that vibrios are not necessary to putrefaction or that the germs of infusoria must during life pass into all our textures and start into activity when circumstances permit. At present, notwithstanding M. Pasteur's high authority, the possibility of the production of infusoria without germs entering the body must be considered an open question.

If we are not able yet to comprehend the alkaline fermentation of the urine and the putrefactions that occur in the bladder (b), how can we yet expect to obtain an explanation of other more complex fermentations that may arise within the body? For example—

M. Davine has shown that the Charbon contageux or sang du rate or malignant pustule depends on the development of bacteria in the blood; if the disease is local, it gives rise to carbuncle, or diffuse erysipelas; or if general, it affects the whole blood. The infusoria are analagous to those which produce butyric fermentation. Fourteen inoculations on rabbits proved that the blood was affected. In four hours the rabbits died. The blood was decomposed and full of infusoria. The organs, as, for example, the liver, &c., were decomposing, and ecchymosis and effusions were found in the serous cavities. In man the disease has been attributed to inoculation by bites from flies fed on putrid matter.

Consequences of Ammoniacal Urine.

The effect of this change of urea into carbonate of ammonia in the urine has been the cause of great confusion. It was exalted into a disease, and the chemical inability of carbonate of ammonia to dissolve earthy phosphates in the urine was called the phosphatic diathesis; and to make the confusion still worse, as the amount of earthy phosphate precipitable depends on the amount of earths present, when much magnesia and lime were in the ammoniacal urine the phosphatic diathesis was considered very marked and very slight when a small amount of earthy matter was present. Carbonate of ammonia and earthy salts in the urine give rise to all the appearances that have been attributed to disease, and the cause of the phosphatic diathesis disappears in the cause of ammoniacal urine—in other words, it depends only on the alkaline fermentation which we have just been considering.

The Symptoms Resulting from Ammoniacal Urine.

The bladder in health contains a feebly acid saline fluid. If the acid or salts vary greatly on either side of the usual amount the bladder is irritated by the unaccustomed stimulus

(b) Since this was written M. Béchamp, in the *Comptes Rendus* for 27th February and 7th August, 1865, states that he has insulated by alcohol the ferment from the urine. He names it Néfrozymase, and he traces its variations in healthy and diseased states. It is a soluble organic albuminous substance, void of all organisation, capable, though to a much less degree, like sialozymase or diastase, to change starch into dextrin and sugar. It is altered by boiling, and then loses the property of acting on starch or on urea. This may be shown to be the case even in healthy urine, without any separation of the néfrozymase. Thus M. Béchamp brings us back again to chemical changes taking place in a peculiar albumen, as the cause of the decomposition of urea in the urine, whilst M. Pasteur holds that living vibrios effect this change. Between a highly complex organic substance undergoing chemical change, and the chemical actions going on in living plants and animals lies our future knowledge of fermentation and putrefaction. Most probably it will ultimately be proved that when in living or in dead animal or vegetable albuminous matter certain kinds of increased chemical action are set up, the various kinds of fermentation or putrefaction are produced, according to the kind of chemical action that exists in the so-called living or dead albumen.

of pure water or excess of salt. Thus a very strong solution of salts in the urine, or very dilute almost watery urine, cause irritation. Highly acid urine and, above all, ammoniacal urine have the same effect. Increased irritation causes increased secretion, and the mucus cells when thrown out in quantity acted on by the carbonate of ammonia become ropy and adhesive; like the ordinary alkaline mucus from other mucous membranes, as from the nostrils. If the irritation is continued pus is formed, and these cells also when acted on by carbonate of ammonia become ropy, and this has also been included under the term of ropy mucus. According as more or less earthy phosphates are present—that is, according as more or less magnesia or lime is taken into the system, more or less phosphatic precipitate is mixed with the ropy mucus or ropy pus, and this chemical error mounts up to the formation of mechanical masses of mortar-like or stoney substances, which cause excessive pain either in passing through the irritated urethra or in scraping the inflamed surface of the bladder, or even by precipitation within the mucous membrane of the bladder itself.

The constant muscular contraction to expel the irritant is more disturbing to sleep than the cough of bronchitis; and hence loss of rest becomes sometimes the most serious consequence of the complaint. Next to this is the extension of the inflammation upwards to the pelvis of the kidney. The ureters may show or not show that they have been inflamed; sometimes no trace can be found of the passage of the inflammation upwards, but pyelitis and tubular nephritis producing pus throughout the kidneys and uræmia throughout the body may put an end to the progress of the disease by destroying life.

The inflammation may spread downwards, and then the urethra suffers, and often violent orchitis is set up.

If the neck of the bladder and the prostate get thickened by interstitial deposit of fibrin, the bladder is unable to empty itself, and the fluid that remains is in a variable state of more or less complete putrefaction. If the fundus is chiefly thickened by deposit and increase of the muscular coat it will contain less and less fluid as the thickening increases; from either cause the frequency of the calls increase, and when ulceration takes place the amount of pain with each contraction becomes excessive.

(To be continued.)

ORIGINAL COMMUNICATIONS.

ON SOME FORMS OF DYSPHAGIA (a),

WITH SPECIAL REFERENCE TO NEW METHODS OF TREATMENT.

By MORELL MACKENZIE, M.D. Lond., M.R.C.P.,
Physician to the Hospital for Diseases of the Throat.

Dysphagia, though strictly speaking only a symptom of disease—an impairment or arrest of function—is attended with such serious consequences to health and life, that it appears to me to deserve especial and independent consideration. So many diseases, both local and general, give rise to dysphagia, that in a paper like this it would be impossible to pass them in review, except in so far as they are concerned in the production of a common phenomenon. On these grounds, it seems to me desirable to bring a symptom of disease under your notice, rather than such an aggregate of symptoms as would constitute a single disease. This method of investigation not only brings a great variety of causes under consideration, but it favours the application of differential diagnosis, and enables us to give prominence to the various methods of treatment suitable under different circumstances. Before bringing under your consideration the causes which make the act of swallowing difficult, it is well briefly to describe the normal mode in which the function is effected.

The food, after being sufficiently softened by the saliva, is thrown into the pharynx by the pressure of the tongue against the roof of the mouth; the communication between the pharynx and the posterior-nares being cut off by the approximation of the posterior pillars and the action of the uvula. When the food has passed from the mouth, this cavity is closed posteriorly by the approximation of the anterior pillars. The base of the tongue being now elevated and directed backwards, whilst the larynx is raised and slightly advanced, the epiglottis is pressed down over the laryngeal aperture. This movement of the valve is likewise assisted by the passage of the morsel of food over its lingual surface, and by the contraction of the glosso-epiglottidean fibres. The closure of the larynx is further effected by successive approximations of the ventricular bands and the vocal cords. Propelled from the pharynx into the œsophagus by the contraction of the middle and inferior constrictors, the pellet of food mechanically dilates the tube and stimulates its lining membrane; successive contractions of the muscular coat in successive portions of the canal carry the food into the stomach. The action of swallowing becomes purely involuntary, when the isthmus of the fauces has been passed. This brief analysis will make it evident that dysphagia may be caused by morbid conditions of any of the parts concerned in the act of deglutition, whether the disease of these parts be of a purely local character or depend on central or reflex causes. Dysphagia may be due either to the pain occasioned by the act of swallowing, or to an actual obstruction in the food-tract; and some authors have endeavoured to classify all forms of dysphagia under these two heads. As, however, this arrangement ignores the influence of paralysis and spasm, I do not see the utility of its application. The various causes of dysphagia are therefore:—

1st. Diseases of the tongue.
2nd. Diseases of the pharynx.
3rd. Diseases of the larynx and trachea.
4th. Diseases of the œsophagus.
5th. Diseases of the parts contiguous to the food-tract, by which the calibre of the canal is narrowed.

It is especially with reference to new methods of treatment that I bring the subject of this paper under your notice, and I shall only refer to the nature and symptoms of the various diseases giving rise to dysphagia, in so far as they may affect the question of therapeutics.

1. *Diseases of the Tongue.*—Inflammation, ulceration, ranula, paralysis, simple hypertrophy or cancer of the tongue may cause dysphagia. It is only in the last named disease, however, that this symptom is really serious, and here it sometimes causes death; excision is the last resource. The experience of Mr. Syme in his last operation is most important. No Surgeon would think of performing the operation without making himself thoroughly acquainted with all that the Scotch Professor has written on the subject; at the same time, I may be allowed briefly to remind you that the success of Mr. Syme's last operation was due to the performance of the operation in such a manner, that deglutition could afterwards be effected physiologically. In previous cases, after the operation, the elevation and advance of the larynx in swallowing could not be properly performed, in consequence of the division of all those muscles by which this movement is effected. In his last operation, Mr. Syme left the mylo-hyoidei and genio-hyoidei muscles entire. The result was that after the operation, the action of the larynx in deglutition remained normal. In previous cases, pulmonary inflammation had proved the sequel to laryngeal disease, the latter having been caused by the passage of food into the larynx. The non-closure of the epiglottis was due to the larynx not being raised in the normal way. In the last operation none of the untoward symptoms occurred, and before the end of three weeks, the patient declared that "he had never felt better in his life."

2. *Diseases of the Pharynx.*—Amongst the causes here situated are enlarged tonsils, whether of an acute or chronic character, general inflammation of the mucous membrane of the pharynx, diphtheria, ulcers of the mucous membrane, more especially when situated on the posterior wall of the pharynx just behind the uvula, polypi of the fauces, spasm or paralysis of the pharynx, and the action of corrosive poisons. When acute inflammation of the tonsils (commonly called quinsey) has reached a certain grade, it generally runs a definite course, whatever treatment be adopted. When seen at an early stage, however—that is, before the substance of the glands is affected, and whilst the disease is confined to the superjacent mucous membrane—I have found the local action of guaiacum most beneficial. "Instar specifici in hoc morbo operatur," says Home in his "Principia Medicinæ," (pars iii., sec. iv.) I tried this remedy internally and as a local application—that is to say, I powdered the affected part with it—but it did not prove serviceable in my hands until Dr. Crompton, of Manchester, explained to me his way of employing it. This consists in allowing the patient to place on his tongue and slowly suck away four or five grains every three, four, five, or six hours, according to the urgency of the symptoms. In cases of incipient quinsey—that is to say,

(a) This paper was originally read before the Medical Society of London.

where the patient has not felt any uneasiness for more than forty-eight hours—and in cases of general congestion of the mucous membrane of the fauces and soft palate, even of a very high degree, I have found that it almost invariably cuts short the crescent inflammation. Very often within twenty-four hours the patient is entirely relieved. I have employed it now in several hundred cases, so that I do not speak without some experience. In 4 per cent. of the cases it caused griping and diarrhœa, but the favourable results were not due to the latter symptom; indeed, where there was any intestinal irritation the drug was at once discontinued,—in most cases before any good effects had resulted. Whilst I am on the subject I may take occasion to observe that the local application of guaiacum has proved very useful in cases of chronic congestion of the mucous membrane dependent on constitutional syphilis. The dislike which some patients expressed to sucking the guaiacum induced me to have the powdered resin made into lozenges. After a good many trials Messrs. Bullock and Reynolds succeeded in manufacturing an excellent lozenge, in which the guaiacum is very nicely combined with the juice of the black currant. There are four grains of guaiacum in each lozenge, and though they exert a peculiar pungent effect on the back of the throat, they are not disagreeable. I have found them not less effectual than the powder. In bringing this remedy under your notice I ought perhaps to recommend it as a means of warding off one form of dysphagia rather than of overcoming it when present. It need scarcely be observed that the guaiacum is of no use when the gland-substance of the tonsil has become affected. When pus has been formed the dysphagia, if present, should be relieved by making an incision in the tonsil with a guarded bistoury; a very minute and superficial opening is generally sufficient to allow the complete and rapid escape of the matter.

Chronic enlargement of the tonsils sometimes gives rise to dysphagia. It is only in the case of children, however, that this symptom becomes serious. Here the small calibre of the throat, and the large size to which the glands attain, sometimes gives rise to a chronic form of dysphagia, in which the food is constantly swallowed with some difficulty. Under these circumstances, the glands may be excised. Many parents, however, object to having cutting operations performed on their children; in these cases, London paste, an escharotic consisting of unslaked lime and caustic soda moistened with a little alcohol, will be found a useful agent for destroying the glands. The largest tonsils can generally be reduced to a convenient size in three weeks or a month. The caustic can be applied either with a glass rod or with a little instrument I have had made for the purpose. The latter is made of vulcanite, and it has a kind of shallow, circular spoon, which is provided with a cover. The closed instrument is introduced into the mouth, and when opposite the tonsil the cover of the spoon is drawn back, and the caustic comes in contact with the enlarged tonsil. The application of the caustic causes the formation of a slough, which separates in three or four days. The caustic can then be applied again, and so on until the gland is reduced to a convenient size. Vienna paste has been used for this purpose by Dr. Fournié, of Paris, but I am not aware that the caustic which I have introduced, and which is in every way more manageable than the potash caustic, has ever before been employed in Surgery. It is prepared for me by Messrs. Bullock and Reynolds.(b)

Ulcers in the pharynx are especially likely to give rise to dysphagia when situated on the posterior wall of the pharynx behind the uvula. Their presence here causes the pressure backwards of the uvula, which occurs at the commencement of deglutition, to be accompanied with uneasiness; the uvula, therefore, gives way, the act of deglutition is baulked, and the food or drink sometimes passes up into the nares. Some months ago I saw a case in consultation where the cause of the dysphagia had not been detected. I found that the symptom was occasioned by a small circular ulcer about three lines in diameter, situated on the posterior wall of the pharynx, on a level with the base of the uvula. These ulcers, whether of simple or specific character, are generally easily healed by the application of caustics. In dysphagia dependent on general hyperæmia of the mucous membrane, the sucking of ice is often attended with very satisfactory results.

Polypi of the pharynx and posterior nares sometimes give rise to dysphagia, but it is not necessary to enter into the various modes of treating these affections.

(b) For further details see my pamphlet on "Enlarged Tonsils." (London: Lewis.)

The forms of dysphagia dependent on spasm or paralysis are very distressing. Spasm of the pharynx is due,—First, to nervous irritability; secondly, to the poison of hydrophobia; thirdly, to the disease of the cervical portion of the spinal cord.

The nervous irritability may be simply a form of hysteria, or it may occur without any symptom of that disease being present. It is frequently the sequel of some local injury to the mucous membrane of the pharynx, thus:—A bone sticks in the throat, but is afterwards dislodged and passes into the stomach. The sensation of the foreign body remains, however, and the patient cannot be convinced that the bone is no longer there. This persistent incredulity on the part of patients may have given rise to the story of a Practitioner who in such cases, it is said, always provided himself with a fish-bone before he used the probang. The production of the bone can alone persuade the patient that it is no longer in the throat. When the sensation remains in the œsophagus it is called œsophagism. Wherever the situation of the disease, I have found the best effects follow from the internal application of galvanism.

Ordinary cases of spasm of the pharynx may be best treated locally by one of two methods,—by one plan, ice may be brought into continuous contact with the mucous membrane, whilst counter irritation is persistently applied to the neck externally; in the other, a sedative and relaxing mode of treatment may be carried out. Should the latter method be adopted, steam inhalations with a small quantity of chloroform and conium will be found useful. Whatever local treatment be adopted, suitable constitutional remedies must be used. It is not necessary to enter into details concerning the best hygienic means for strengthening a weakened nervous system, nor to explain the suitable mental or moral treatment of such cases.

2. In hydrophobia, dysphagia forms the pathognomenic symptom of the disease. The ætiology and pathology of the disease are obscure enough, but the main features are, alas, far too marked. The spasm of the pharynx is too evident to escape attention. Few of us have the misfortune to meet with cases of this disease, and it may perhaps seem unnecessary to some to make any remarks on the treatment of its most fatal symptom. A careful examination of all the reported cases, will not, I think, fail to convince most people that death is almost invariably due to exhaustion. The prostration is no doubt in a great measure due to the extraordinary influence of the poison on the nervous system, but still it must be in part caused by the entire arrest of the supply of nutriment. Should a case of this sort come under my care, I should look to the introduction of food and stimulants with the stomach-tube as the most important feature in the treatment of the case. I need not say that the latter instrument would have to be used under the influence of chloroform.

3. Injuries of the cervical portion of the spinal cord sometimes give rise to spasm of the pharynx; it is, however, generally quickly followed by paralysis.

(To be continued.)

DESCRIPTION OF SOME UNDESCRIBED APPEARANCES IN THE WALLS OF OVARIAN CYSTS.

By FRANCIS BOWEN, M.D.,

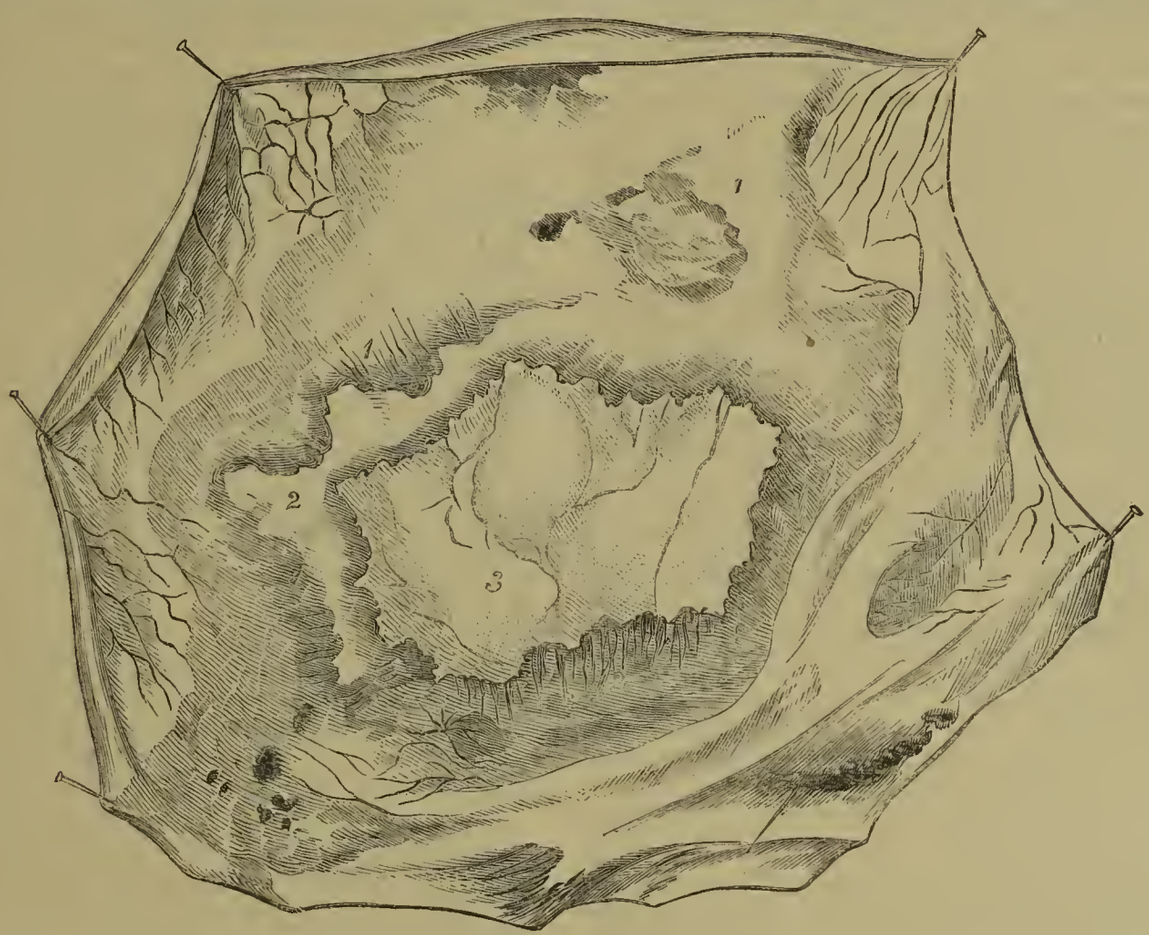
Formerly Resident Surgeon to the Royal Maternity Hospital, Edinburgh, and late Surgeon to the Royal Hibernian Military School, Phœnix Park, Dublin.

Patches of a lustreless yellow or dull brownish colour, generally supposed to be indicative of fatty tissue, are of frequent occurrence in the walls of ovarian cysts. With a view to their examination, Mr. T. Spencer Wells, with his usual courtesy and kindness, supplied me with numerous cysts of this class, which he removed by operation; and Dr. James Bell Pettigrew, of the Royal College of Surgeons, aided my investigations by every means in his power.

The multilocular ovarian cyst from which a portion of the principal cyst wall (ten by twelve inches) was taken, was one of very rapid growth in a young and unmarried Jewess. The fluid evacuated at the time of the operation measured twenty-one pints, and the emptied cyst weighed one pound four ounces. A report of the case appears in the *Medical Times and Gazette* of February 10, 1866, page 145.

This cyst wall displayed several irregular patches of a dull

yellow or brownish colour. On examination by the microscope, the patches in question were found to consist principally of white fibrous tissue, but no traces of fat could be detected. The colour was probably due to non-vascularity, the patches being deprived of a vascular supply owing to the vessels being filled with clot, and being more or less obliterated. The non-vascularity of the patches is worthy of attention, and was no doubt due to congestion of the vessels in the immediate neighbourhood, resulting in rupture and extravasation. This seems likely, from the circumstance that the cyst wall, as a whole, was beautifully injected with blood, the portions only surrounding the patches showing extravasation. The extravasated points formed two circumvallated lines, as shown in the accompanying woodcut. The vessels leading to the



Accurate view of the appearances from within observed in portion of the wall of a large cyst removed by Mr. T. Spencer Well by ovariotomy at the Samaritan Hospital on January 10, 1866. Reduced one-half.

outer circumvallation were large and numerous, those leading to the inner circumvallation being smaller and fewer in number. The patches with the circumvallated lines may be said to form three distinct areas.

1. An area where the vessels were numerous and large, and where great quantities of blood of a bright florid colour was effused.

2. An area where the vessels were smaller and partially emptied of their contents, and where the effusion was less highly coloured and less distinctly marked.

3. An area in which the remnants only of vessels could be traced, and where no effusion was perceptible.

This third or central area was of a dull yellow, running into a dull brownish tint, and contrasted strongly with the delicate hue of the second area.

These appearances are described as seen from within the cyst wall.

That portion of the cyst wall corresponding to the non-vascular area varied in thickness, and not unfrequently became extremely thin, and it is probable that when the cyst ruptures it occurs at the points indicated. That the thinner portions referred to may give way is extremely likely on account of distinct or well-defined perforations of various sizes occurring in the walls between the smaller enclosed cysts. The non-vascular area, in all probability, degenerates, and results in thinning and subsequent perforation. If this view be correct, rupture is due to degeneration in the bloodvessels in the first instance.

62, Upper Berkeley-street, W.

We learn that on Tuesday next Messrs. Puttick and Simpson will sell by auction the Professional and private library of the late Dr. Robert Ferguson, Physician to the Queen,

CASE OF CONCUSSION OF THE SPINE, WITH REMARKS.

By D. DYCE BROWN, M.A., M.D.,

Fellow of the Obstetrical Society of London.

W. C., aged 18, a gentleman's servant, of a slim figure, was vaulting behind his master's house on August 24, 1865, when he fell, inclining to the right side, upon the sacrum. He found immediately that he had lost the use of his lower limbs, and had to be carried into the house. I was asked to see him next day, when I found he could move neither lower limb in the least, and on attempting to do so suffered considerable pain in both, especially the right limb. This pain was most severe in the muscles of the anterior part of the thigh. The legs were subject to involuntary startings, and felt numb and cold at times, though not constantly. He was unable to turn in bed without assistance; complained of pain and tenderness in the upper part of the sacrum; no fracture. Feeling of constriction across abdomen, increased much on attempting any movement of the legs. Pulse natural; tongue clean; passed his urine; no priapism; no head symptoms of any kind. He was ordered to have perfect rest in bed, a purgative, and six leeches to be applied to the upper part of the sacrum. This to be followed by poultices.

26th.—Pain and tenderness in back and limbs relieved, especially in left limb; can move the left leg a little. Soon after yesterday's visit both legs felt perfectly cold (though the weather at the time was extremely hot), the feeling of heat being gradually restored by warm blankets. Had passed no urine for the last twenty hours, and though he felt no uneasiness I passed the catheter. The passage of the instrument seemed to give the nesessary stimulus, for as soon as it

was fairly in the bladder, and the urine began to flow, the remainder did not run in a dead stream, but was forced out at the sides of the tube, as well as through it, by the contractive force of the bladder.

27th.—To-day complains of much pain over lumbar and lower dorsal regions of spine, which are tender to the touch. Says his limbs are "stiffer" and more pained than yesterday, but he can move the right leg a little and the left more. Passes urine now freely. I ordered other six leeches to the tender portion of the spine, to be followed by poultices; also a mixture containing small doses of bichloride of mercury and tincture of belladonna.

28th.—Pain and tenderness almost gone from back. Can move the left leg well, and the right much better than yesterday.

29th.—Pain and tenderness in back entirely gone; pain in limbs much better. Feeling of constriction in the abdomen gone; moves both legs well.

31st.—Yesterday he rose from bed, and walked out into the garden with the help of a stick. To-day he walked up to my my house, having his stick in his hand, but not using it. Feels well; no pain anywhere; left leg quite recovered; right leg feels a little stiff, but not painful. Walks well, but on looking at him from behind the right leg drags very slightly. I have frequently seen him since, perfectly recovered in every respect.

Remarks.—My reason for bringing this case before the notice of the Profession is its twofold interest:—1. Its comparative rarity; and 2. Its Medico-legal importance. As to the first point, a case so marked where there could be no mistake about the diagnosis, where the paraplegia was so complete, and yet the recovery perfect in a week's time, where there were no head symptoms from *contre-coup*, and where, considering the small height from which the patient fell, one would have expected only a very slight injury, is, I think, extremely interesting and instructive. On the question of the pathology of concussion of the spine—whether there is any real organic change, however minute, in the cord or not—I do not now enter, as there is not sufficient known at present to decide the question. But whatever "concussion" really is, this must be set down as a case of it, for, since there was no fracture, had the symptoms been caused by the presence of a clot of extravasated blood recovery in a week would have been impossible. It will be observed that there was a disposition to reaction and irritation, most of the symptoms, such as the spinal tenderness, pain and startings in the legs, etc., indicating this. The treatment which seemed to do most good was the rest, leeching, and poulticing. As to the assistance given in the cure by the medicine I am doubtful, as the relief to all the symptoms followed too rapidly on the second leeching to justify my attributing a large share, if any, to the medicine. It is interesting to observe that though both legs were involved, the right one was much more so than the left, and was longer in recovering, and it will be remembered that the lad distinctly stated that he fell inclining to the right side; also the fact that most severe pain was situated in the anterior portion of the muscles of the thigh is worthy of observation, the abnormity of sensation not consisting in numbness or want of sensation, but in hyperæsthesia. This condition is occasionally seen in such cases. Secondly, the case is interesting in its Medico-legal aspect. The attention of the Profession has been much drawn lately to the subject of injuries to the nervous system from railway accidents, and as, on the one hand, most severe and lasting injuries to the nervous system can be caused by accidents which leave little or no external marks, and on the other, most of the symptoms and sensations can be feigned by impostors, the motive for imposition—namely, recovery of damages—being always a ground of suspicion, it behoves Medical men to be careful lest in their evidence they err on the side of credulity or of incredulity. Had the injury in the above case occurred from a railway accident—say from being thrown out of a carriage—and had it been proved that the patient had fallen only from the height of probably a yard and a-half, was not otherwise ill, but simply said he could not move his legs, and complained of the other feelings which my patient had, but nevertheless had completely recovered in a week, the suspicion with which such a case would be looked at would not improbably result in its being considered a case of imposition for the purpose of obtaining damages, or if the unfortunate sufferer happened to be a woman, perhaps a combination of imposition, fright, and hysteria would have been the verdict.

REPORTS OF HOSPITAL PRACTICE
IN
MEDICINE AND SURGERY.

ST. BARTHOLOMEW'S HOSPITAL.

DISEASE OF THE ANKLE-JOINT—AMPUTATION.

(Extract from a Clinical Lecture delivered by Mr. HOLMES COOTE, Surgeon to the Hospital.)

Diseases of the ankle-joint are not mentioned with the fulness that such a subject merits, chiefly because the study of deformities has been excluded from general consideration. I amputated the foot and ankle of a man aged 36 last Saturday, with the conviction that any further attempt to preserve the limb would be useless; and the examination of the morbid parts justifies that conviction.

The ankle-joint is a compound joint. The articulation between the tibia, the fibula, and the astragalus is but one of the many which give to the foot its proper amount of movement. In the present specimen we find two of these joints diseased; first, that already mentioned; and secondly, that between the astragalus and the calcaneo-scaphoid ligament,—in other words, the joints both on the upper and the under surface of the astragalus. The bone itself is soft and preternaturally vascular, and the cartilage on both surfaces is loose and partially absorbed; the remains of the synovial membrane are thickened.

Look well at the foot; observe how the arch has sunk. It is a confirmed case of talipes valgus, wherein the support supplied by the calcaneo-scaphoid ligament has been lost; the head of the astragalus has come to the ground, and the weight of the body has been transmitted to it from the tibia.

The disease commenced in the astragalus, and was transmitted throughout its whole substance; general chronic inflammation and softening of the bone ensued, the cartilage became "shed," and the synovial membrane thickened as already described.

After many years of rest, of treatment, and of constant care, this patient might perhaps have recovered with a stiff ankle. But the necessary conditions were not attainable. You all know how rarely cases of confirmed disease of the ankle-joint recover with osseous anchylosis.

Now, what is the course which should have been adopted in the present case? When the arch of the foot first sank, it should have been at once raised by a thin elastic pad, and the ankle kept at its right bearing by an outside iron, attached to the boot, and a leather strap. The head of the astragalus would not then have pressed upon the ground, the bone would not have become diseased, and most of the ulterior symptoms would, in all probability, have been avoided.

As it is, the foot has been removed, an operation attended with no great amount of danger to life; but the patient is mutilated. I operate at the lower third or fourth of the limb,—in short, I divide the bone where it is smallest. You then have a conical stump, which is the form best suited for an artificial foot.

I closed this wound with strapping. That mode of dressing is preferable to suture when the flaps are thin and long. A great amount of support is given to the detached structures, and the warmth is of use in maintaining circulation.

The patient is convalescent.

KING'S COLLEGE HOSPITAL.

CASES OF EXCISION OF THE KNEE.

(Under the care of Mr. HENRY SMITH.)

The following cases represent very fairly (Mr. Smith remarked) the particular instances in which the operation of excision of the knee-joint should be substituted for amputation. In the first case detailed acute disease was going on to such an extent as to threaten the life of this patient, who had, in fact, left another institution because she would not submit to the loss of her limb, which had been suggested as the only resource. The only thing that induced hesitation to adopt excision was the suspicion that tuberculous disease of the lung existed, but stethoscopic examination revealed so little mischief, that Mr. Smith considered he was not justified in amputating the thigh. The fatal result was solely due to pyæmia, which, as is well

known, is too liable to destroy patients after any Surgical operation. It is a matter for regret that it was found necessary to remove the limb from the splint a few days after the operation; it is not improbable that the disturbance of the parts may have been productive of pyæmia.

In the second case the operation was performed for the sole purpose of rectifying deformity and making an entirely useless limb of some service to the boy. Mr. Smith was induced to perform excision here in consequence of the wasted and semi-paralysed condition of the limb; for it is well known now that when a firm anchylosis is brought about not only does the power of motion become restored, but the limb gets a considerable increase in bulk and power.

In the third case we are presented with an instance where perhaps the circumstances are as favourable for an operation as they could possibly be, and where even perhaps the most obstinate opponent to excision of the knee would consider it justifiable; for not only was there a perfectly useless limb, but disease which had been going on for six years with more or less severity was adding suffering, and there was really no other remedy short of amputation, for any attempt to break up the very tough anchylosis would have been out of the question, as the force required would have probably been productive of further serious mischief. In this case, as in that of the boy, the perfect absence of the slightest unfavourable symptom after so severe a proceeding was remarkable, and the fact of the patient being able to be put upon his crutches a month after the operation with a straight limb and the parts at the site of operation firmly knit together, is perhaps unparalleled in the history of this operation.

Case 1.—M. B., aged 30, admitted September 6, 1865, a tolerably healthy-looking woman; pain and slight swelling commenced in right knee-joint about a year before; shortly after this she was confined, and this appeared to aggravate the symptoms. She applied to one of the London Hospitals, where they recommended amputation at the thigh.

On admission, the knee-joint was much swollen, very painful on pressure and slightly flexed; a back splint ordered to keep the joint still, and tonics.

On October 21 excision by a lunated transverse incision was performed; the greater part of the condyles of the femur and a slice of about one half an inch in thickness of the tibia being removed; the patella also was taken away. There was extensive pulpy degeneration of the synovial membrane of the joint; cartilages here and there slightly ulcerated; the bony tissue of the femur was perfectly healthy, and that of the tibia somewhat softened.

25th.—The patient became very restless and low, and required large quantities of stimuli. Forty-eight hours after the operation she had rallied well, and although the pulse was very rapid (130), she had no bad symptoms, but took her nourishment, beef-tea, etc., well, besides 8 oz. of brandy. Yesterday there was a good deal of puffiness about the front of the knee, and on dressing the part carefully a large quantity of purulent matter escaped, and it was discovered that the end of the femur was riding considerably over the tibia. Mr. Smith, therefore, gave her chloroform, and took the limb off the splint, and making extension got the parts into good position.

26th.—Slightly delirious; great discharge; ordered brandy 10 oz. The pulse increased up to 140 up till the 31st, and she had severe rigors. Pyæmic symptoms set in about this date, and became more and more severe until she died November 8. A most prominent symptom for forty-eight hours before death was excruciating pain at the back of the head, causing her to scream loudly.

At a post-mortem examination it was found, forty-one hours after death, the body pale and emaciated, and on opening the brain pus was found deposited under the membranes in front of the cerebellum, also in the right ventricle and corpus striatum; there was also pus in the left and fourth ventricles; on opening the joint the bones were in very good position, they were infiltrated with purulent matter, and the tissues surrounding them disorganised; no abscesses found in other joints; there were two or three circumscribed abscesses on the surfaces of both lungs; tubercles in both lungs; abdominal viscera healthy.

Case 2.—F. B., aged 8, admitted September 28, with strumous disease of left knee-joint. Disease had been existing about seven years. The joint much thickened, semiflexed, and partially anchylosed. The leg was much wasted and entirely useless. All active disease in the joint had ceased. The lad was very healthy, and in a good state for operation.

On October 7, excision performed by a single lunated incision horizontally across the joint, the lower end of the femur and part of the head of the tibia being removed, leaving as much as possible of the epiphysis as possible; the patella also was removed. The joint was entirely disorganised, and the lower end of the femur was impacted in the head of the tibia, which was immensely thickened.

The boy had not a single bad symptom, and by the 24th the wound had nearly healed.

On November 4, on being taken out of bed and placed on his feet, it was found that the leg was nearly straight; the union, however, was not at all firm, and, considering the amount of diseased bone taken away, there was very little shortening, and when standing perfectly upright he was able to touch the ground with ease with the toes of the limb operated on.

29th.—Discharged.

Case 3.—W. H., aged 30, a marine, admitted December 24, 1865. First noticed pain in left knee-joint whilst on duty in the summer of 1860. Shortly after this abscesses formed, and burst about the joint. On admission the joint was anchylosed, semiflexed, and the tibia slightly dislocated backwards, and there were several scars of old abscesses about the joint. Complained of considerable pain when an attempt was made to use the limb.

On January 6, the joint was excised by a single transverse lunated incision. The lower end of the femur, patella, and heads of the fibia and fibula were found to be firmly pressed together; a large wedge-shaped piece of bone was removed, including the whole of the anchylosed parts; a thin slice from the head of the tibia was subsequently removed, as a small cavity containing tuberculous matter was found in it. The ends of the bones came well into apposition. The limb was put up in an ordinary excision splint and swung. The patient did wonderfully well, and did not have a single bad symptom. Splint removed on the 30th. Wound almost entirely healed.

On February 9, the patient got up and was allowed to go about the ward on crutches. There was very little shortening and very firm union, and the patient in perfect health.

A case of excision of the knee-joint has been recently under Mr. Wood's care, and has turned out successfully, the patient being a lad of about 5 years of age. The disease had commenced in the synovial membrane, the joint itself only being secondarily affected. The epiphysis of the tibia was removed and also a thin slice of the femur. The case healed well and there was but little shortening. [We are compelled to postpone the full account of this case until next week.]

UNIVERSITY COLLEGE HOSPITAL.

INCLUDED CARIES AND NECROSIS OF THE HUMERUS—CHRONIC OSTRITIS OF THE ULNA—CLINICAL REMARKS.

(Under the care of Mr. ERICHSEN.)

We are indebted to Mr. F. B. Nunneley for these cases.

Case 1.—T. E., aged 22, sailor. Patient has had good health generally. Two years ago he had a slight blow on the elbow; a month after there was pain just above the joint, and swelling, which gradually increased. Eight months ago the pain became very severe and gnawing, especially at night. On admission, the lower end of the humerus was found considerably enlarged, and the shaft of the bone was thickened for some distance above; just above the level of the condyles were two spots, which were extremely tender; the elbow-joint was not involved in the disease. In accordance with his diagnosis—that there was either an abscess or included caries—Mr. Erichsen made a T incision down to the bone and applied the trephine. A carious cavity was found, and gouged out, and the arm placed on a splint. Since the operation the patient has been entirely free from his old pain, and is now gradually recovering.

Case 2.—H. B., aged 27. Patient has had symptoms of both secondary and tertiary syphilis. A year ago he had pain in the right elbow, which was worse at night; since then the pain has become most severe, so much so at night as to deprive him of sleep. When admitted (November 13) there was considerable enlargement of the upper end of the ulna, the swelling was exquisitely tender at one spot; the elbow-joint was free. 15th.—Mr. Erichsen made a longitudinal incision three inches long down to the bone, the structures over which were greatly thickened with plastic matter, as also was the

periosteum. He then made a cut with Hey's saw about one and a-half inches long into the substance of the bone, not quite deeply enough to open up its cancellous structure. The patient passed the night after the operation free from the wearying pain, which has not returned since.

Mr. Erichsen remarked that it was a definite rule in Surgery to use the trephine when there was considerable enlargement of the head of one of the bones entering into the knee or elbow-joint, with nocturnal exacerbations of pain, and especially if there were one or two tender spots; the cases met with having these symptoms, being either (1) chronic osteritis, or (2) included central caries and necrosis, or (3) included abscess. He further mentioned a fourth case, in which he had found it necessary to use the trephine:—A patient had an enlargement of the humerus occupying the external condyle; there was tensive pain, but no crackling on manipulating the swelling. On trephining, a large cavity lined with a smooth membrane and containing an ounce of clear serous fluid was found. In connexion with these cases of disease about the elbow-joint, Mr. Erichsen further alluded to a case which had been in the Hospital some time ago, and which presented several points of interest. The case was that of a sailor, who had struck his elbow several times accidentally before coming into the Hospital; but for two years there had been pain and impaired movement of the joint. On admission, the patient, who seemed to be in good health, complained of pain in the left elbow. On examination, the lower end of the humerus was found to be three times its natural size. There was tenderness over the swelling, the joint was free, the glands in the axilla were not enlarged. At one part of the expanded bone was more or less egg-shell crackling and a semi-elastic feeling. Mr. Erichsen made a diagnosis of myeloid tumour of the humerus, and disarticulated at the shoulder-joint, thus amputating above the diseased bone. The patient made a very good recovery.

Another case of chronic ostritis of the ulna has been recently admitted. The case is that of a woman, aged 31. She states that a year ago she strained her right arm whilst lifting a heavy weight. Since then she has had pain, latterly very severe, over the upper third of the back of the ulna. There was here on admission a swelling two inches long, resembling a node, with one very tender spot. Mr. Erichsen made a saw-cut an inch and a-half long longitudinally into the enlarged bone. After the operation the patient expressed herself quite relieved from the pain, and slept well during the night.

SOUTHWARK OPHTHALMIC HOSPITAL.

ON THE CORRECTION BY CYLINDRICAL LENSES OF ASTIGMATISM AFTER THE EXTRACTION OF CATARACT.

(By ROBERT A. C. MOON, House-Surgeon to the Ophthalmic Hospital, Southwark.)

William V., aged 53, was admitted at the Ophthalmic Hospital, Southwark, under the care of Mr. Laurence, October 16, 1865. The lens of the right eye was densely opaque and that of the left was faintly striated. With the right eye he possessed merely quantitative perception of light; with the left he could read No. 2 (Jäger) when his presbyopia was corrected with a 12-inch convex glass.

On October 20 Mr. Laurence removed the right lens by the "traction" operation, during which everything went perfectly smoothly. Five days afterwards there was slight iritis, but by November 17 all reaction had disappeared. The pupillary area was occupied by a thin layer of opaque capsule, which was removed by a needle operation.

Upon leaving the Hospital he was supplied with $2\frac{1}{2}$ and $4\frac{1}{2}$ inch convex lenses, they being the spherical glasses which afforded him the greatest benefit. On February 8, 1866, he returned to the Hospital, stating that his sight was still very defective. With + $4\frac{1}{2}$ he read C (Snellen) at 20 feet; with + $2\frac{1}{2}$ he read No. 6 (Jäger).

Finding that there was no material obstruction to the rays of light, the pupil being perfectly clear and the fundus being distinctly visible with the ophthalmoscope, we tested the eye for astigmatism with the following results:—

1. With + $4\frac{1}{2}$ on horizontal arc a little clearer than vertical lines. Lines disposed obliquely / / / are invisible, but a similar set at right angles to these are distinctly seen.

2. With a 20-inch convex cylindrical lens, the axis directed upwards and slightly outwards, at an angle of about 10° from the perpendicular, in addition to his spherical + $4\frac{1}{2}$, he reads L well, and XL imperfectly at 20 feet; *so that his visual power was more than doubled.* With the cylindrical lens, in addition to his spherical + $2\frac{1}{2}$, he reads No. 1 with perfect ease.

From these observations we conclude that this patient is the subject of hypermetropic astigmatism in an oblique meridian of the cornea. Whether this irregularity of curvature existed prior to the extraction or whether it was the result of the operation it would be difficult to determine.

The object in publishing the present report is to show the necessity of a careful investigation of the optical condition of all patients who have undergone operations for cataract. The loose way in which the optical investigation is sometimes conducted in such cases is greatly to be deprecated. As remarked by Dr. Mackenzie (*Ophthalmic Review*, vol. ii.), patients who have been operated on for cataract are in many instances sent back to their homes with convex lenses of $4\frac{1}{2}$ inches focus for distant objects and $2\frac{1}{2}$ for near objects, very little care being taken to see that these are the glasses which will afford them the greatest assistance.

Although the vision of many eyes after extraction of the lens cannot by any optical contrivance be raised above a certain point, yet a very large quota, of which the above case is a representative, will be found to be astigmatic. Therefore if spherical glasses do not completely restore the visual power to the normal standard, the suspicion should at once arise that the eye is astigmatic, and any abnormal refraction of the meridians of the cornea should be ascertained and corrected by cylindrical glasses.

SATURDAY, MARCH 3.

THE REPORT OF THE COMMISSION AT THE ADMIRALTY.

We print in another column a full abstract of this important document, so far as it relates to the Army. That part relating to the Navy shall appear next week. It evidently seems as if the Committee had been actuated by the sincerest desire to remove every grievance which the Medical officers of either Service could reasonably complain of. Although not long, the Report is exhaustive, and deals with every question that could fairly come under consideration; such as military status, rank, pay, and promotion.

It will be evident that the Committee have tacitly condemned many points in the existing system; and that they have equally endorsed the complaints which we in this journal have from time to time given expression to, on the part of the Medical Services. On this point we believe that the combatant and executive members of the Committee were unanimous,—that they showed the best feeling, and only required to have the sentiments of the Profession and the facts of the case temperately laid before them. We have good reason to know, further, that the civilian Medical members, Dr. Markham and Mr. Busk, did their duty towards their naval and military brethren in a way to earn their warmest acknowledgments.

We gather, however, from our military brethren that they wish the Committee could have gone a little further in one

respect; and we conceive that their sentiments are much as follows:—
