VOL. XXV.

CHICAGO, JULY 6, 1895.

No. 1.

ADDRESS.

CONCERNING STONE IN THE KIDNEY AND ITS OPERATIVE TREATMENT, WITH REPORT OF CASES.

CHAIRMAN'S ADDRESS.

Delivered before the Section on Surgery and Anatomy at the Forty-sixth
Annual Meeting of the American Medical Association, at
Baltimore, Md., May 7-10, 1895.

BY JOSEPH RANSOHOFF, M.D., F.R.C.S.

PROFESSOR OF ANATOMY AND CLINICAL SURGERY MEDICAL COLLEGE
OF OHIO, CINCINNATI.

The first, the easy, the pleasant part of my task, is to express my appreciation of the honor of being permitted to preside over your deliberations. The distinction is not lessened by the surgical achievements, past and present, of the city in which we are convened. It was in Baltimore that the common iliac artery was first tied by William Gibson before he was called to shed luster on the surgery of Philadelphia. It was here that Jameson first in the history of surgery made a nearly complete excision of the upper jaw. It was here that the son, worthy of a worthy father, Nathan Rhyno Smith, for nearly half a century fostered surgical growth. His surgical anatomy of the arteries did much toward elevating American surgery of the second quarter of the century to the high plane then occupied by that of France and of England. For a simple and efficient method of suspending an extremity are we likewise indebted to this Nestor among American surgeons. The mantles of such worthy peers have not been laid aside; they are worn with dignity and grace by younger scions. *Nomina sunt odiosa*. Great as were the early surgeons of Baltimore, they did not venture, like those of to-day, to remove the Gasserian ganglion, lay bladder, ureter and kidney open to inspection, and last but not least, extend the hope of all but absolute relief to the woman with cancer of the breast.

The rule of the ASSOCIATION calling for an annual address on surgery, fortunately relieves the Chairman of your Section of the burden of presenting in formal review the progress made. It gives him the option to limit his remarks to a single topic of surgical interest. Of this privilege I beg to avail myself, the subject of my choice being, "Concerning stone in the kidney and its operative treatment."

Clearness in the diagnosis and skill in the operative treatment of surgical diseases of the kidney are among the latest, though not the least, of the conquests of the closing decades of our century. Thorough chemic, microscopic and bacteriologic examination of the urine, cystoscopy, catheterization of the ureters, and probatory incisions, have done much to bring affections of these organs within the range of diagnostic certainty. The relative values of symp-

oms are becoming fixed, and in the operative technique many questions are definitely settled and more are fast nearing solution. Yet there are not a few problems pertaining to renal surgery which collective statistics alone can solve, since from the comparative rarity of the affection the experience of the individual must be greatly restricted. Such problems pertain to the diagnosis and treatment of primary stone in the kidney. To more clearly elucidate the questions to be submitted for consideration, I beg to present the following seven cases in which the kidney was explored for stone:

Case 1.—M. L., age, 27, seen with Drs. Phelps and Comegys. A robust young man under treatment for gonorrhoea, for which the balsamic oils had been freely administered. Has had repeated sharp attacks of pain in the back and the left groin, but never required treatment for them. On April 1, 1892, he was seized with violent pain in the left side, radiating to the testicle. Micturition frequent. The urine was of high specific gravity and contained a large amount of blood. Three days after the inception of the attack there was a severe rigor, followed by febrile elevations of temperature of from 2 to 3 degrees, which continued until April 22. The symptoms were referred to the bladder. Dysuria was the marked subjective symptom. The quantity of urine was greatly reduced, until the quantity passed in twenty-four hours was between six and eight ounces. The patient had become irresponsive and somnolent. The tongue was dry. The urine secreted had to be removed by catheterization. Bimanual examination of the left lumbar region showed increased resistance. On deep inspiration a very decided enlargement of the left kidney, could be detected. The examination elicited pain in the region of the kidney, radiating toward the bladder. Diagnosis: pyelitis and oliguria, probably of calculus origin.

Operation, April 22; chloroform narcosis; incision of the costo-iliac interval parallel to the last rib and exposure of kidney. The organ was apparently twice its normal size, of a dark purplish color. Exploratory aspiration revealed pus. Incision through the posterior wall of the kidney substance into the pelvis gave vent to about two ounces of foul pus. In the lower end of the pelvis a small oxalate of lime calculus was found impacted; weight eight grains. The cavity of the kidney was thoroughly irrigated with sterilized water, drainage tube inserted and wound partly packed. With the relief of intra-renal tension afforded by the operation, both kidneys resumed their function; the urine passed by the bladder and through the wound was, as near as could be estimated, about equal in quantity. The temperature subsided to the normal within a week, and it looked, during the first week after the operation, as though the patient would make an uninterrupted recovery. Without discernible cause a rigor supervened on May 23. It was followed by a train of uremic symptoms identical with those of his first seizure. The urine ceased altogether to flow *per vias naturales*, and the quantity discharged from the fistula of the left side was reduced to from six to eight ounces in the twenty-four hours. On May 26 four ounces were passed from the wound. From that time to May 28 the condition of total anuria existed. Pain was complained of in the right lumbar region and palpation revealed a slight enlargement of the kidney.

May 29, 37 days after the first operation, nephrotomy was made on the right side. About one ounce of fetid pus was removed, but prolonged and careful exploration of the pelvis and ureter failed to reveal the presence of a calculus. The wound was treated as in the first instance by drainage. Within twenty-four hours the patient *quoad vitam* was on the road to recovery. The left kidney at once resumed its function and during the three years which have passed has per-

formed three-fourths of the work of both glands. The right kidney has never resumed its full functional activity. It is easy to estimate the excreting capacity of the two glands, since the patient has a renal fistula on each side, for the relief of which he will allow no effort to be made. During the last year not an ounce of urine has entered the bladder. Except for the inconvenience of carrying a urinal, the patient would consider himself restored to perfect health.

Case 2.—Jewish Hospital, June 28, 1892. J. I., age 28, salesman, of temperate habits, during three years had had frequent attacks of severe pain in the region of right kidney. During the last year these attacks were followed by hematuria. Milder attacks followed each other at intervals of one or two weeks. During the last seizure he was seen by my assistant, Dr. Evans, who pronounced it of unusual severity. Present condition: robust adult, below average height, but very obese. Physical examination negative. Bimanual examination of right kidney very painful. Kidney can not be distinctly palpated. Urine passed in twenty-four hours, forty-five ounces, reddish in color, specific gravity 1026. Microscopic examination showed a few white blood corpuscles, and oxalate of lime crystals. Diagnosis: nephrolithiasis dextra.

Operation June 30, 1892. Oblique incision. Panniculus adiposus very largely developed. Examination of the kidney difficult, owing to enormous development of fat capsule, much of which had to be removed with scissors and forceps. Kidney loosened and drawn into the wound. Palpation and acupuncture negative as to stone. Incision along convexity and digital exploration likewise negative. The hemorrhage during the search having been rather profuse, the kidney wound contused, and the search in the hope of reward having been rather prolonged, the renal wound was partly closed with sutures and a drainage tube carried into the pelvis. Nephrorrhaphy with catgut sutures. Owing to the excision of retro-renal fat masses, the avoidance of a cavity was not practicable. During seventy-two hours the patient suffered excruciatingly from renal pains, which subsided with the removal of the drainage tube. The wound healed by primary union, except for a renal fistula, which healed spontaneously within three months. During six months after operation, patient suffered from no attacks. An opportunity to see him since has not been had.

Case 3.—M. C., age 35, seamstress; entered Good Samaritan Hospital Nov. 9, 1892. States that for two years she has been suffering from lumbar pains, followed in the course of time by a constant soreness in the left side. The urine became cloudy, filled, according to her statement, with mucus and pus, and often presenting large quantities of blood. She states that sand was often passed, and in September last she passed a calculus the size of a pea. In urinating, pain is always present, and the stream is suddenly checked. She also states that she sometimes has pain down to the heel of the left foot, and that it is often of a shooting character. She had hemoptysis and cough three years ago and has frequently suffered from night sweats. Present condition: patient in poor condition, having lost about twenty to twenty-five pounds; appearance somewhat emaciated; urinalysis shows urine to be normal the greater portion of the time, but after sustaining severe pains in the bladder it contains either enough blood to tinge it or to appear in the form of clots on sedimentation. Cystoscopic examination made by a specialist indicated the presence of a neoplasm in the anterior wall of the bladder. Whereas this was far from distinct, the suprapubic incision for exploratory purposes was determined upon.

April 16, suprapubic incision displayed a bladder normal in every regard. No hemorrhage was visible at the examination. The ureters were carefully examined at the time, and nothing in the way of blood was found to come from them. Since the operation was negative in its results, the bladder wound was closed at once by Lembert sutures and the incision through the parietes packed. The wound in the bladder healed by primary intention, temperature and pulse always remaining normal. Patient was discharged from the hospital June 6, 1893, with the wound perfectly healed.

Patient re-entered the hospital March 8, 1894, and complains of severe pain in the region of the left kidney, shooting toward the groin and the leg; is also very tender to pressure over the left kidney; again has blood in the urine at intervals, especially after the pain is severe. March 28. Says that she passed a stone last night while urinating, but it was lost in the closet; no one saw it. The patient insists upon an exploration of the left kidney. April 10. Oblique incision in the left costo-iliac interval; exposure of the left

kidney. The kidney was drawn into the wound and carefully palpated with negative results. Incision in the convex surface large enough to admit the finger, with exploration of the calices, likewise negative. The incision was prolonged therefore into both poles and the kidney subjected to ocular inspection. Nothing abnormal was found. The hemorrhage was relatively slight and ceased entirely after the insertion of four deep and five superficial catgut sutures. After the kidney was fixed in its position with silk-worm gut, external wound was closed. By May 1 the patient had recovered without any trouble from the operation, and on June 5 was discharged. There was no further hematuria or pain of any consequence. Four months after the operation the patient presented herself at the office with a needle underneath the skin of Scarpa's triangle on the left side. This was removed, the patient claiming to have no knowledge as to how it came there.

Oct. 8, 1894. Patient visited hospital to-day; is in good health and has had no return of her trouble.

Case 4.—Good Samaritan Hospital, Sept. 20, 1894. Mrs. W., age 43, married. About seven years ago patient was sick with acute renal pains, followed by discharge of pus and blood with the urine. Since the first these attacks were invariably limited to the left side. The present attack, like previous ones, began suddenly with the sense of weight and fullness, and the detection of a swelling. Present condition: Fairly nourished woman. Temperature in the morning normal; in the evening 100 degrees; pulse varying between 80 and 100. On the left side, the kidney enlarged to the size of a double fist, can be clearly outlined in its lower segment. It presents itself as a rather movable tumor in the costo-iliac interval, not reaching the iliac crest. Urinalysis: urine often examined is turbid, light in color and containing a sediment rich in pus cells and crystals of oxalate of lime; a few red blood discs in every specimen. Very many examinations failed to reveal the bacillus of tuberculosis. Diagnosis: movable kidney, with recurring pyonephrosis, probably of calculus origin. Right kidney determined to be normal by cystoscopic examination.

Operation, September 28. Chloroform-morphia narcosis. Incision parallel to last rib. Exposure and fixation of kidney. Removal by incision of about a pint of fetid pus. Kidney sacculated. In lower portion an adherent calculus was found and removed with some difficulty. Irrigation and drainage. The patient's temperature varied from 101 to 102.5 degrees from the third day for a week. Profuse discharge necessitated daily dressing.

November 27. Patient discharged in good condition, with renal fistula and drainage tube.

Since the operation I have seen the patient once for renal distension, from displacement of tube. Nephrectomy will eventually become necessary.

The presence of an oxalate of lime calculus (weight 17 grains), with the history, makes it probable that nephrolithiasis was the first condition, followed by recurrent hydronephrosis and in turn by mobility of the kidney. Suppuration was probably a late factor in the case, which earlier interference would have prevented.

Case 5.—L. S., male, age 25, admitted to Avondale Hospital with diagnosis of recurrent appendicitis. States that except for hip disease, from which he suffered early in life, he was well until eight months prior to admission, when he was suddenly seized with severe colicky pain in region of appendix, associated with vomiting. Was free of pain for six weeks, when he suffered a second attack of great severity, which confined him to his bed during four weeks. He has never recovered entirely from this attack. States that he is always in pain, for which he has habituated himself to the use of morphia, of which he takes about three-quarters of a grain in the twenty-four hours. Present condition: well developed male. Ankylosis of right hip and complementary pelvic inclination. Complexion rather sallow. Pain more or less constant in the region of the appendix. Three times within the month the pain was severe enough to require the administration of morphia by injection. During these attacks the temperature rose to 100 degrees; at other times normal. Careful palpation fails to reveal tenderness over the appendix. Physical examination of the abdomen negative. Pressure over the last rib toward the kidney always elicited severe pain. Urinalysis: during six weeks, urinalysis made twice each week. Urine always contained in the neighborhood of .5 per cent. of albumin. It was generally light

straw color, slightly turbid, always acid. Microscopic examination always revealed pus cells and a few red blood corpuscles, and bladder epithelia. Crystals were never found. Repeated examination by centrifugation failed to reveal tubercle bacilli, the presence of which would not have been surprising with the previous history of long-standing tubercular disease of the hip.

November 4. Cystoscopic examination under cocain. Bladder normal; stream from right ureter was turbid; across the field slight flakes of white material passed from time to time. The left ureter discharges clear urine. Diagnosis: nephrolithiasis dextra.

Operation November 11. Oblique incision through the right costo-iliac interval. Exposure of the kidney, which seems normal in color and size. In the posterior wall, near the hilum, an induration distinctly palpable. Acupuncture proves it to be due to a stone. Radial incision in the line of the blood supply, followed by the easy removal of a stone, uric acid, weight 60 grains. The stone was in the substance of the gland, only slightly projecting into the pelvis. The wound in the kidney was closed by three catgut sutures. Palpation of the kidney for other stones negative. Fixation of the kidney by two silkworm gut sutures. Drainage with strands of silkworm gut.

November 12. Patient passed a restless night. Severe pain in the back, right groin and testicle. Urine very bloody and containing many clots. Quantity passed in twenty-four hours, thirty ounces. Temperature 100 degrees; pulse, 90.

November 13. Pain less severe. Passed forty ounces of urine; last samples slightly tinged with blood. Temperature normal; pulse normal.

From this time the patient's recovery was uninterrupted. The drainage was removed with the first dressing, on the tenth day. Union perfect. December 4. Patient discharged well. April 4. Patient presented himself to-day, perfectly restored to health. The urine normal in every respect.

Case 6.—Martin L., aged 28, single. Entered Good Samaritan Hospital Feb. 26, 1894. History for the past five years: has had severe pains in the region of the left kidney. Very frequently he has suffered from severe pains shooting down the groin and the left testicle and into the leg. These attacks are usually followed by the appearance of blood in larger and smaller quantity in the urine. These attacks last from one to three days. Present condition: well-nourished man of short stature. Pressure over the left last rib very painful. No enlargement of the kidney discernible. Urinates three to four times during the night. The urine turbid, specific gravity 1040, rich in albumin and red blood corpuscles. Contains also oxalate of lime crystals.

March 3. The patient just passed a very bad night, has suffered intensely from an attack of renal colic. Urine passed frequently and containing large quantities of blood. Morphia administered in grs. $\frac{1}{4}$ doses at 3 in the morning and again at 9. Diagnosis: renal calculus.

March 10, operation. Oblique incision over the left kidney from the middle of the last rib toward crest of ilium. Kidney exposed and brought into the wound. In the pelvis of the kidney a number of loose calculi were felt. Incision one inch long through convex border, circulation being controlled by the finger of an assistant. Hemorrhage slight, but drainage of a considerable quantity of urine. Three stones were easily removed from the pelvis. Two smaller ones adherent to the calices removed by blunt curette. Suture of the kidney wound by three deep and two superficial catgut sutures and sewing of the kidney to the deep fascia. For purpose of drainage, there having been considerable oozing from the peri-renal tissue, the wound was very firmly packed with gauze. March 11. Patient passed a very bad night, vomited considerably and complained of some abdominal pain. Passed from the bladder twenty ounces of bloody urine. Ordered a teaspoonful of Epsom salts every two hours. Dressings changed and gauze removed. No drainage of urine from the wound. Wound looks healthy. March 12. Evidences of intestinal obstruction, vomiting recurring at intervals of half an hour has assumed the form of regurgitation. Bowels have not moved. Abdominal distension very marked. Temperature 100; pulse between 120 and 130; quantity of urine in twenty-four hours, twenty-seven ounces. March 13. Patient passed a very bad night. Regurgitation more marked. Temperature 96; pulse 160; 11:30 p.m., patient died.

March 14. Autopsy. Abdomen very much dis-

tended. Upon opening the abdomen the intestines, from the descending colon upward, including all of the small intestine to the duodenum, very much distended; peritoneal vessels, mesenteric and intestinal, are very much injected. There is no pus present, nor are there any flocculi of lymph to be found. Very thorough search of the peritoneum over the kidney fails to reveal any wound of this tunic. Left kidney presents a wound along its convex border quite firmly agglutinated. About the incision some infiltration of blood in the cortex of the kidney. Right kidney normal.

Case 7.—D. K. G., male, age 47; observed with Dr. Forchheimer. Family history good; has never been seriously ill, except three years before he came under observation, when he was confined to his bed with severe pain in the left lumbar and inguinal regions, which was ascribed to ileo-colitis. Within the last year he has suffered a number of times from chills followed by febrile elevations. These seizures would keep him indoors for twenty-four or forty-eight hours only. During these attacks he would frequently vomit. He has not lost in weight. His greatest complaint has been pain in the back, which would awaken him in the night. The pain has never been severe enough to necessitate the use of morphia. It has been limited to the left side, and never assumed the form of renal colic. Has twice been examined for bladder trouble and each examination was followed within an hour by a rise of temperature to 104 degrees. Within twenty-four hours the temperature subsided to the normal. This patient was under my observation during six months. He was enabled to follow his vocation, and except for pains at night, and what he believed to be malarial seizures, suffered comparatively little. On the part of the urinary tract there were no subjective symptoms. Micturition was neither abnormally frequent nor painful at any time. Physical examination negative, except for a very marked tenderness over the left kidney, which could always be evoked by deep pressure against the last rib. Bimanual examination failed to reveal any enlargement of the kidney, nor were referred pains ever elicited. Urinalysis. During six months his urine was examined at least once a week. It was always slightly turbid when passed, a little paler than normal, acid in reaction and of normal specific gravity. Every specimen contained a trace of albumin, a number of pus cells and a few red blood discs. At no time during the prolonged period of observation did the specimens obtained by centrifugation contain either crystals or tubercle bacilli. During the last month prior to operation, the pyuria increased notably.

November 25. Cystoscopic examination under cocain. Bladder normal. Ureters brought into view, and streams of urine found alike on the two sides. About the left ureteral orifice, there was an area of redness, extending apparently a half inch toward the urethra. Hemorrhage was not observed. The examination, though made with every precaution to the contrary, was followed within two hours by a chill and a rise of temperature to 104 degrees. In three days the patient was again about his work. Diagnosis: nephrolithiasis sinistra.

Operation, at Christ Hospital, Jan. 22, 1895. Morphina and chloroform anesthesia. Oblique incision through costo-iliac interval. Exposure of kidney through *capsula adiposa* of moderate thickness. Kidney, apparently of abnormal length, drawn into the wound and carefully palpated with negative results. Acupuncture resorted to without locating a stone. With digital compression of the renal pedicle, the autopsy cut was made and the interior of the gland subjected to palpation and inspection. The incision was attended by very little hemorrhage; nor was any pus evacuated. The kidney structure was normal. In the lowermost portion of the pelvis an elongated stone was found, opposite the beginning of the ureter. An effort to remove it through the incision in the kidney failed. Therefore the pelvis was opened by a longitudinal incision. The stone was easily removed. Wound in pelvis closed by two catgut Lembert sutures. For the closure of the kidney wound, three deep and four superficial sutures were used. After fixation of the kidney with silkworm gut sutures, the wound was closed, a strand of gut being used for drainage. An uninterrupted recovery followed the operation. During seventy-two hours the urine contained considerable blood, and the colicky pains were severe enough to necessitate the use of morphia. Hemorrhage from the kidney ceased on the third day. The

highest temperature reached was 100 degrees. The quantity of urine was twelve and one-half ounces the first twenty-four hours; twenty-one ounces during the second; thirty-seven ounces during the third, after which the quantity was normal. The patient has had no attack of pain since the operation. The urine still contains a few pus corpuscles, but red blood discs are not to be found. First dressing and drainage was removed on the tenth day; sutures at the end of two weeks. Primary union along the entire line. The patient left the hospital after five weeks, well, except for the presence of pus cells in the urine. In four examinations made since his departure from the hospital, blood discs were not found. In two examinations of urine recently made, oxalate of lime crystals were found.

Stone in the kidney is far from being a rare affection, if the records of autopsies are to be judged from. In the majority of cases thus found, they were unattended by tangible symptoms. On the other hand, no other affection of the kidney is so often erroneously supposed to be present as stone. Of the seven nephrotomies here recorded and made for stone, the search proved fruitless in two. In 1886 Gross¹ was already enabled to collect twenty-nine cases of unsuccessful operations for stone, all of which recovered. A few years later McCosh² found five additional cases of which two were fatal. These were cases of Chavasse,³ and in both calculi were found at the autopsy. Similar unfruitful explorations have since been made, twice by Keyes⁴ and Parkes,⁵ once by Guyon,⁶ Bruce Clark,⁷ Tiffany⁸ and Israel⁹. While it is probable that in some of these cases a small concretion was overlooked, the thorough exploration after incision made by such competent operators must lead us to believe that there is a condition of the kidneys, other than lithiasis, which is expressed by the symptomatic tripod of renal calculus before destructive changes have been produced, namely, lumbar pains, renal colic and hematuria. The term "nephralgie hematurique," proposed by Sabatier¹⁰, describes the cardinal symptoms but does not explain the condition which varies with the varying causes of hyperacidity of the urine, syphilitic cicatrices, mobility of the kidney and consequent intermittent hydronephrosis or hemiphilia with renal expression of its presence. In a nephrectomy done for hematuria by Senator,¹¹ the kidney was found absolutely normal. For diagnostic purposes, catheterization of the left ureter was made by Nitze through a suprapubic incision, and the source of the hematuria, if not its cause, satisfactorily determined. In one of my own cases, although the kidney was not removed, the hematuria was doubtless of like hemaphilic origin, for the kidney upon section was found absolutely normal. (Case 3.)

An array of forty-four recorded cases of failure to find a stone may be of importance in damage suits arising from such failure. They demonstrate that the diagnosis can be only approximately made. The record is equally significant in showing the safety of such explorations since only two deaths are recorded, and in both cases stones were found at the autopsy. It is equally noteworthy that in many of the cases thus operated upon, permanent relief was afforded by the exploratory incision, either in consequence of section of the lumbar nerves or of relief of intra-capsular tension, the severance of adhesions or the fixation of a previously movable kidney. In not a few, however, has there been recurrence of symptoms in from a few weeks to a year.

In the diagnosis of kidney stone, writers have for many years pointed to the presence of abnormal

constituents in the urine. First, crystals indicative of the character of the stone; and second, blood in quantities appreciable to the unaided eye. The hemorrhage, it is said, is rarely as profuse as in malignant disease, but yet is present in considerable quantity. In both regards, observations often and carefully made will be negative. In two of the cases very accurate examinations for a period of from one to six months were made and crystals were not found. Except when a stone is in the process of growth, the presence of crystals can hardly be expected. Furthermore, to be of clinical significance, the crystals must be proved to be passed with the urine, and not to have been formed later. In only one of the cases of successful nephrotomy for stone recorded above, was the hematuria apparent. Far more important, however, it appears to me, is the presence of red blood discs at every microscopic examination made. In three of the cases the examination extended over a period of from one to six months, without out failure to find a few discs in every specimen examined. In all of these cases the microscopic hematuria was associated with acid pyuria. The aseptic character of the latter in two of the cases was repeatedly demonstrated by centrifuging. Mechanical irritation, pressure, necrosis of the renal epithelium and minimal erosions of capillaries produced by a renal calculus accounted for the slight hematuria and the pyuria, aseptic in its character.

This does not accord altogether with the views, particularly of the French school, as expressed by Tuffier regarding the ability of the kidneys to entertain without any reaction, aseptic bodies of even large size, and that when septic infection does ensue, it is the result of upward extension of like processes from bladder and urethra, either from a gonorrhoea, or unclean catheterization. Large and small stones by their presence produce pressure, atrophy and cirrhosis. In the specimens here presented, of two kidneys in which large primary calculi are found, the area of atrophy will be seen just a little larger than the measurements of the concrements, which by pressure on the vessels had induced an aseptic infarct and secondary atrophy of the contiguous kidney tissue. The kidneys, as a whole, present the picture of interstitial nephritis. Although growing into the ureters and filling the pelvis, the stones have produced no destruction of either. Yet the inspection of these kidneys assures us that had plerone-pneumonia not claimed the individual, death must have resulted soon from renal changes which, slow, mechanical and aseptic, were none the less destructive to the secreting elements. Regarding the history of this case, nothing is known, although it is almost inconceivable that an examination of the urine would have failed to detect evidence of renal disease.

Regarding the channels of septic invasion in renal lithiasis, it appears to be far from certain that the usual route is from below upward, as it doubtless is in the typical surgical kidney developing in the course of primary lesions of the lower urinary tract. In two of the recorded cases there never had been a gonorrhoea. In three of them, instrumentation of the bladder had not been practiced until after the discovery of the pyuria. Posner and Lewin¹² have recently made very interesting experimental observations which establish the auto-infective nature of many suppurative processes of the urinary passages, and which throw much light upon the cause of sup-

uration in cases of stone in the kidney where instrumentation had not been practiced. The source of infection is the intestinal canal and the channel the general circulation. The eliminative function of the kidney has been shown for other infectious diseases. In the case of suppurative processes, thus produced experimentally by ligating the ureters and obstructing the intestine, the bacillus found in the kidney was almost always the gas-forming organism belonging to the bacterium coli group. Pyuria from stone may, therefore, be aseptic; or, if septic, be the result of infection from the lower urinary tract, or caused by the eliminative function of the kidney.

The value of cystoscopic examination, as an auxiliary to the diagnosis of renal calculus can not be questioned. The presence of two discharging ureteral mouths assures us better than any other method can, of the presence of two active kidneys. It can not exclude the possible existence of a horse-shoe or placental kidney with double ureters. The certainty of the non-existence of vesical disease, as established by the cystoscope of Nitze or of Kelly, often makes it certain that the symptoms in a given case are of renal origin. In two of the three cases in which it was used, the information was of absolute value in excluding the bladder as the source of the disease and fixing the site of the latter. In one of the cases a turbid stream with a few flocculi was ejected from the right ureteral cone, while the urine from the left side was very clear. In a second case the left ureteral mouth presented an irritated appearance entirely at variance with the picture of the right side. In the third case, one of profuse hematuria, cystoscopic examinations were entirely negative. With a wider knowledge of direct catheterization of the ureters, as practiced by Pawlik, and of the better method of direct illumination of the bladder, as practiced by Kelly, the elucidation of obscure renal disease will doubtless be made comparatively easy. In the male it may be justifiable to resort to suprapubic incision and direct catheterization of the ureters for diagnostic purpose. Quite recently, Nitze has added the ureteral catheter to his cystoscope. It is not probable that many will become experts in its use. Unfortunately, the cystoscope is of no value in cases where it would be most needed; those in which there is an *indicatio vitalis* for operative interference, particularly on account of hematuria and anuria.

Anuria is by far the most interesting, as it is also the most fatal, complication of kidney stone. Of fifty-six cases collected by Legueu,¹⁸ treated conservatively, sixteen recovered in from three to twenty days; forty or 71.5 per cent., died in from four to twenty-five days. Autopsies were made in thirty cases. In twenty-three, the ureter was found blocked by a stone, while in seven a gross mechanical obstruction was not present. In three cases there was only one kidney. In six, both ureters were blocked by a calculus. In fourteen additional cases, both kidneys contained stones. In six, there were other evidences of disease, chiefly suppuration, and in one case the kidney was normal. In sixteen cases of anuria, nephrotomy was followed by recovery in ten, the mortality being 37 per cent., as against 71.5 per cent., in cases left to nature. Such statistics justify the division of nephro-lithotomies into those of choice and those of necessity. The conditions may well be likened to those of hernia. In the unobstructed, we may choose the time for operative interference; in

the strangulated, delay means death. Anuria in calculus disease may be the result of a simultaneous obstruction of both ureters, a condition which is quite unusual. It generally depends upon obstruction of the ureter of one kidney, and reflex arrestation of function of its fellow, which in the majority of cases is likewise found to be diseased. That primary anuria or oliguria may be the result of inhibition of a normal kidney through reflex channels from obstruction in its diseased fellow, or after nephrectomy, has been positively settled by experimental as well as by clinical observations. Among the most striking of the latter was one made by Israel¹⁴ in a case of hydronephrosis of intermittent type. With each recurrence of increased intra-renal tension in the diseased kidney, the secretion of normal urine was reduced to a minimum. Tapping of the hydronephrotic side was immediately followed by the flow of the normal amount of urine from the healthy kidney. Pressure upon the kidney tissue or irritation by packing or ligation of the pedicle after nephrectomy, may bring about the same reflex diminution of function of the remaining gland.

Death follows nephrectomy from uremia in nearly 50 per cent. of cases, (Madelung¹⁵ eight out of seventeen). In most of these it has been presumed that there existed but one kidney. For such cases in the future it will be obligatory to explore the side not previously operated upon, and if a kidney be found, to make an exploratory incision. It is more than probable that the sudden increase in function of the remaining gland is associated with a degree of hyperemia incompatible with excretion from the glomeruli, for which the local depletion of nephrotomy could only be of benefit.

Since Bardenheuer's¹⁶ case of nephrotomy for anuria after operation on one kidney was published in 1882, a number of most brilliant successes have been recorded by Lange,¹⁷ Clement Lucas,¹⁸ Meyer,¹⁹ Kirkham,²⁰ Godley,²¹ Israel²² and Cabot.²³ In most cases, as in my own, the operator was relieved of the difficulty of determining the side for operation by the previous clinical history, the limitation of pain to one side, by the presence of tenderness or tumor, or by the previous removal of one kidney. Except for the certainty give by the condition last named, there must always be some doubt as to the side to be operated upon. In a case of anuria, Israel operated on a hydronephrotic left kidney. The patient was not relieved. Twenty-four hours later the right kidney was explored and a stone located in the ureter too low for removal at the time. The patient did not rally, the anuria having continued nine days. Tuffier has properly pointed out that operation should not be deferred on account of doubt as to the side of obstruction, since the chances are always 50 per cent. that the diseased kidney will be found, and it might be added, if the chance fails an immediate exploration of the opposite side should be made. I have been enabled to find only one case of simultaneous bilateral nephrotomy for calculus anuria. The patient died eleven days after the operation.²⁴

In the surgical treatment of renal calculus, choice must be made between simple incision and extirpation or partial resection of the kidney. The localized conditions demanding the latter must of necessity be so rare that for present considerations they may be disregarded. Nor would any one resort to the more drastic operation with a comparatively normal

condition of the kidney and a small calculus. It is in the presence of multiple or of large branched calculi and of a kidney more or less converted into an abscess cavity that the question becomes embarrassing. Neither the size, conformation nor multiplicity of the calculus ought to weigh in favor of nephrectomy, since with the longitudinal incision along the renal convexity, ample room for manipulation can be obtained. Nor does the dread of a renal fistula remaining after nephrotomy for calculus pyonephrosis render nephrectomy justifiable, except when cystoscopic examination or the voidance of clean urine renders unimpeachable evidence of the presence of a normal kidney; for in seventy-six fatal cases of renal calculus, Legueu found the disease bilateral in thirty-eight and in only four instances was the remaining kidney normal. Edel,²⁵ Clement Lucas,²⁶ Shepherd²⁷ reported cases where nephrectomy was followed after four and five respectively, by fatal calculous pyelitis of the remaining kidney. These considerations are weighty, irrespective of the inherent dangers of the two procedures, nephrotomy and nephrectomy, the mortality of which is decidedly in favor of nephrotomy (nephrotomy 31 per cent., nephrectomy 41 per cent.).

With increasing confidence in the relative safety of exploratory nephrotomy, cases of renal calculus will doubtless be earlier subjected to operation and before those destructive changes have ensued which, at the time of operation, force upon surgeons the choice between incision and excision of the kidney. With proper care regarding hemorrhage and sepsis, a nephrolithotomy on an otherwise healthy kidney ought to be attended by a mortality of not more than 5 per cent. The unequalled tabulation of Newman, in 1888, of forty-two cases without a death, could not be maintained. Tait lost one case out of fourteen. Within the last three years, deaths have occurred in the hands of such expert operators as Butler-Smythe, Jacobson, Knowsley Thornton, Godlee and Israel. The immediate mortality of nephrotomy for calculus pyelitis is 33 per cent. A stronger plea than these statistics could not be made for an early operation in real or supposed cases of renal calculus.

In the technique of the nephrotomies above recorded, I have had an opportunity of comparing the relative values of the oblique and the transverse incisions. The advantages of the former have been so decided that I have used it to the exclusion of the other in all of my recent operations on the kidney from the loin. Through an ample incision from the middle of the last rib toward the iliac crest, the entire kidney can be drawn into the wound, the pelvis, both surfaces and poles, explored by the finger, and the circulation through it absolutely controlled. By continuing the incision downward and forward, all of the suprapelvic portion of the ureter can be brought into view and, if need be, subjected to operative treatment.

The renal calculi which I have presented are all small, the heaviest weighing sixty grains. In this regard the collection may be interesting, since in all of the cases of which they are the trophies, except one, the exploratory needle was used and without any results. In none of my cases was the detection of the stone accomplished by using the needle. A stone weighing 556 grains, as removed by Tiffany,²⁸ or one weighing nearly five ounces, as removed by Shepherd,²⁹ and another by Gay,³⁰ can easily be felt

through a puncture with a needle. Here acupuncture is superfluous, since such stones can be felt through the hardened kidney substance by the examining finger. For the detection of small stones a success from acupuncture would be a matter of chance, and therefore, in my judgment, should be discontinued as wasteful of time and fraught with the danger of wounding a larger branch of the renal vessels. Palpation of the kidney drawn well into the wound between the thumb and finger on opposite surfaces, will reduce the danger of overlooking a calculus to a minimum. In this manner all of the kidney, except possibly the superior pole on the left side, can be thoroughly felt. If the calculus even then escapes detection it must be small indeed, deeply imbedded, and discoverable only by incision into the kidney substance.

How and where shall this incision be made? In answering this question two considerations must guide us: hemorrhage and the final result as to a cure without a renal fistula. Hyrtl³¹, as long ago as 1869, demonstrated by corrosive preparations that the kidney is naturally divisible into anterior and posterior segments, the blood supply of each being independent of that of the other, after the vessels supplying them have been given off from the main trunk of the renal artery. Along the convexity of the gland, therefore, the longitudinal section made as in an autopsy would be least likely to wound a larger vessel. In four operations in which I have resorted to this sectional incision the hemorrhage, while free, was parenchymatous in all. To reduce even this to a minimum the incision should not be made longer than is needful for the introduction of the exploring finger, until the kidney has been brought far enough into the wound to make feasible the compression of its pedicle by padded clamp, or preferably by the fingers of an assistant. This makes the hemorrhage *nil*, while the search for the stone progresses. Such compression has been experimentally maintained for half an hour (Tuffier) in animals without other effect than a transitory albuminuria. In an operation for stone, compression would rarely be needed during more than five minutes. The length of the incision must vary with the difficulties encountered in searching for and removing the stone. With a finger introduced into a kidney through a small incision in the center of its convexity, or two incisions nearer the poles, the separate calices can be as methodically explored as are the fingers of a glove. Only after failure of this method to find a stone does the complete division of the kidney from end to end, for ocular inspection, as in a post-mortem examination seem justifiable. Incisions into the renal pelvis for exploration alone are to be avoided because of the obviously greater danger of hemorrhage and the dread of lacerating the pelvic wall beyond repair.

Renal fistulæ are seen oftener after incisions into the pelvis than after nephrotomy proper, the ratio being as 20 to 3. Therefore, stones found in the pelvis of the kidney should, wherever possible, be removed through an incision in the cortex. In one of my cases a stone was found embedded near the posterior surface. In such a case a radial incision on to the stone, passing between the blood vessels, is ample for its removal and not attended by severe hemorrhage.

For operative wounds of the kidney, primary union should be aimed for, as scrupulously as in wounds elsewhere. Drainage of the kidney is therefore un-

called for except for pyonephrosis, where the ureter is manifestly incompetent. In one of my cases the presence of a drainage tube gave rise during seventy-two hours to very severe pain, and was the direct cause of a fistula which continued to discharge during three months before it finally closed. In nephrolithotomy on an otherwise normal kidney, the ideal operation is terminated by closely suturing the wound in the kidney with alternate deep and superficial catgut sutures, traction on which should only be sufficient to keep the edges in apposition. Experimentally and clinically, such sutures have been shown to be practically innocuous to the kidney at large, and that the resulting scar involves only the immediate vicinity of the line of incision and of the sutures, provided larger vessels are not included. Experiments by Paoli,³² Tuffier³³ and Barth³⁵ have shown that, particularly in the incision along the convexity, secondary degenerative changes are reduced to a minimum. Griefenhagen³⁵ had an opportunity to examine two kidneys treated by sutures after operation. A linear and depressed cicatrix narrowing toward the pelvis and firmly adherent to the capsule was present in each kidney as the only vestige of a previous incision. One patient died of apoplexy six months after the operation. In the other, the kidney had become movable and at times incarcerated in a ventral hernia making nephrectomy necessary. Suture of the kidney first practiced by LeDentu,³⁶ in 1889, has been performed successfully by Morris, Israel, Fenger, Bernays, Tuffier, Garard, Marchant and Rose.

Primary union should likewise be sought for when the pelvis or ureter has been incised; catgut Lembert suturing being used. The probability of success is less than in nephrotomy proper. In one of my cases thus treated the result was perfect. Meyer and Sanger have recently reported similar successes. A slight objection to primary suture is the severe pain of a colicky nature entailed by the passage of small blood clots through the ureters and lasting from twenty-four to forty-eight hours.

The only fatal result which I have had to record from my nephrotomies for stone was directly attributable to intestinal obstruction from excessive packing of the wound with gauze. This obstruction was the result of paralysis from pressure on the intestinal nerves in their course in the meso-colon and behind the posterior parietal layer of the peritoneum. This is the second case of this nature to be recorded; the other occurred in the hands of Israel. There probably have been other deaths erroneously ascribed to peritonitis after operation on the kidney and in which wounding and infection of the peritoneum have been supposed to be the causes of death. In two of the cases operated on since this unfortunate result, I have contented myself with such drainage as could be obtained by a strand of silk-worm gut removed with the first dressing.

The concluding act of every operation upon the kidney must look toward fixation of the gland in its normal position. Where the fat capsule has not been interfered with much and the kidney has been little disturbed in its relations in the process of searching for and removing the stone, nature can be relied upon to secure its proper fixation. In every case, however, in which the gland has been removed from its bed and drawn into the wound, either for purposes of exploration or operation, a *sine qua non* of an undisturbed and lasting recovery is the fixation of the

kidney in its position by a number of catgut or, preferably, of silk-worm sutures. A number of recent writers have suggested that the sutures used for closing the renal incision can likewise be employed for the fixation of the gland. My own preference has been for the silk-worm gut. By two sutures through the kidney, the capsule proper, and the fat capsule on the one hand, and the lumbar fascia and the peritoneum of the last rib on the other, the kidney can be firmly and satisfactorily anchored until such time as post-operative adhesions result. One of the safeguards against mobility of a kidney is, in my judgment, prolonged rest in bed of at least five to six weeks before the patient resumes the erect posture. In the triumph of finding a stone, the precautions against a movable kidney might readily be overlooked. The danger of allowing the gland to take care of itself has been shown in a number of cases, and notably in the one of Griefenhagen already referred to, where secondary nephrectomy became necessary.

In conclusion, the following theses are presented for your consideration:

1. An absolute diagnosis of stone can not be made.
2. Nephro-lithotomies may be divided into those of necessity and those of choice. In anuria and profuse hematuria delay is fatal.
3. Pyuria and microscopic hematuria as indications of beginning destructive changes, are positive indications for operative exploration.
4. The oblique incision is to be preferred for the ease with which it permits the exploration of the entire kidney.
5. Acupuncture is not to be relied upon.
6. Incisions should be made along the convex border and only when the circulation is controlled by digital compression.
7. Incisions into the pelvis for exploration and for removing a stone are to be avoided.
8. Primary nephrectomy for stone should be reserved for extreme cases.
9. Primary union by suture, where feasible, makes nephro-lithotomy an ideal operation.
10. Tight packing of the kidney wound and perirenal space endangers the nerve supply of the colon.
11. Nephrorrhaphy should form the closing act of every operation which has seriously disturbed the relations of the kidney.

CONSERVATIVE SURGERY ON THE BATTLE-FIELD AND FIRST AID TO THE WOUNDED.

BY N. SENN, M.D., Ph.D., LL.D.

COLONEL AND SURGEON-GENERAL OF THE ILLINOIS NATIONAL GUARD;
 PRESIDENT OF ASSOCIATION OF MILITARY SURGEONS OF ILLINOIS;
 EX-PRESIDENT OF THE ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES.
 CHICAGO.

Conservatism will characterize the military surgery of the future. The two great sources of danger that face the wounded soldier upon the battle-field—hemorrhage and infection—will be greatly diminished by additional and improved hemostatic measures, and the more general and effective application of the principles of aseptic and antiseptic surgery.

FIG. 1.—Elevation of the upper extremity in the treatment of hemorrhage.

Mutilating primary operations will be limited to injuries with extensive destruction of the soft parts and complications involving large vessels and nerves which in themselves are sufficient to arrest the nutrition of the injured limb. Gunshot injuries of bones and joints will no longer determine the propriety of primary resection and amputation, and the danger of penetrating wounds of any of the large cavities of the body will be greatly diminished by the prompt employment of measures calculated to prevent septic infection, and other immediate and remote complications. I take it for granted, that I am expected on this occasion to discuss briefly the salient

topics which will engage the attention of the military surgeons of future wars, and which will enable them to reduce the death rate, diminish suffering, save limbs, and prevent painful remote complications in case of bullet and other wounds which heretofore demanded primary mutilating operations, or, if treated upon conservative plans, subjected the soldier to imminent danger to life from septic complications.

Conservative surgery on the battle-field consists in rendering prompt and efficient aid to the wounded. To accomplish this successfully is the desire and aim of the military surgeons of all civilized nations. A well-trained hospital corps is now looked upon as an essential constituent of every modern military body. In our own country the Army and Navy, as well as the National Guards of the different States, are making ample preparations for effective first aid to the wounded, in the event of war, by the careful training of soldiers selected for Hospital Corps service. The practice of conservative surgery upon the battle-field will, of necessity, be intrusted largely to the educated, well-trained, non-combatant soldier. It is the char-

FIG. 2.—Gun-stack for elevation of the lower extremity.

acter and efficiency of his work that will determine the fate of the wounded. I shall limit my remarks to the discussion on the work to be done by the surgeon and his helpmates, the members of the Hospital Corps, in caring for the wounded upon the battle-field, which will embrace: 1, the treatment of hemorrhage; 2, to counteract shock; 3, primary dressing; 4, immobilization; 5, transportation.

Temporary Hemostasis.—A large percentage of deaths upon the battle-field has been caused by the immediate result of hemorrhage. It is to be expected that the small calibre bullet, owing to its greater velocity and penetrating power, will cause death more frequently from primary acute hemor-

rhage than the round or large conical bullet of the past, because the wounds inflicted by it resemble more nearly incised than contused wounds as was formerly the case. There can be but little doubt that the old weapon produced wounds which were more liable to be followed by secondary hemorrhage, induced by the sloughing of the large area of contused tissue surrounding the tubular wound made by the bullet. The absence of this extensive area of contusion and laceration in wounds of large blood vessels made by the new bullet will increase the danger from primary hemorrhage, and will, consequently, demand more frequently and urgently in their treatment the employment of prompt and efficient hemostatic measures. The treatment of hemorrhage upon the battle-field will be governed by the size and character of the vessel wounded and the part or organ injured. A distinction between arterial and venous hemorrhage is impracticable as far as the immediate treatment by non-professional assistants is concerned. Ligation of a blood vessel upon the battle-field, either at the point of injury or in its continuity, will be done only in exceptional cases. In

FIG. 3.—Digital compression of brachial artery.

the majority of instances this part of the treatment will be consigned to the surgeons in charge of the first dressing station or the field hospital. In rendering the first aid to the wounded, hemorrhage should be diminished or arrested by such means and measures as are always at hand, or that can be readily extemporized and can be safely and efficiently applied by members of the Hospital Corps.

Elevation of Limb.—The force of gravitation answers an exceedingly useful purpose in arresting hemorrhage from the smaller vessels of the extremities. By placing the injured limb in a vertical position, intravascular pressure is so much diminished that spontaneous arrest of hemorrhage is often effected by this simple procedure, even when a vessel the size of the palmar arches is injured, but its greatest value and widest range of application will be in the treatment of venous and parenchymatous hemorrhage. The elevated position should be maintained for some time after the hemorrhage has ceased, or until more efficient measures can be employed. The

manner of effecting and maintaining elevation as a hemostatic agent is shown in Figs. 1 and 2.

Digital Compression.—In the treatment of hemorrhage from large vessels accessible to digital compression, this method offers a reliable means of controlling hemorrhage. The members of the Hospital Corps are familiarized with the exact location of the principal arteries of the extremities and the method of arresting hemorrhage by digital compression.

The compression must be continued uninterruptedly until the bleeding vessel can be tied, or pressure can be replaced by elastic constriction or the antiseptic tampon.

Flexion.—Forced flexion as an hemostatic agent was introduced by Adelman. Genuflexion is a prompt and efficient method of arresting hemorrhage from the popliteal artery and its branches. Brachial hyperflexion answers the same purpose in the treatment of hemorrhage from the brachial artery from a point opposite the elbow joint or any of its branches below this point.

In making genuflexion, the belt, suspender, gun-strap, or triangular bandage should be passed

FIG. 4.—Digital compression of femoral artery.

through a slit in the shoe or boot above the heel, after which the ends are firmly tied over the base of the thigh where it is fastened to the pants or drawers with a safety pin. Forced flexion of the forearm can be made with an ordinary handkerchief.

Elastic Constriction.—Elastic constriction, properly applied, is a safe and absolutely reliable hemostatic agent in preventing and controlling hemorrhage from any of the vessels of the extremities. Introduced and popularized by the greatest military surgeon of the present time, von Eschmarch, it is applied wherever surgery is practiced, but its employment is of special value upon the battle-field. The elastic constrictor has displaced almost entirely the ordinary tourniquet. Preliminary compression of the limb by an elastic bandage is unnecessary, as simple elevation continued for a few moments will render the limb sufficiently bloodless for all practical purposes. The harmful effects of elastic constriction improperly applied are temporary, and even permanent paralysis of one or more of the principal nerves injured by the

linear compression. To prevent such a complication it is necessary to compress the limb at a point where the main nerves are adequately protected by muscles and to bring to bear no more pressure than is necessary to realize the object for which the constriction is made—to interrupt completely both the venous and arterial circulation. The arm should be constricted at a point corresponding with the middle of the deltoid muscle or over the top of the shoulder and the thigh near its base.

To avoid harmful linear constriction it is advisable to use an elastic band at least an inch in width or a suspender, and if the constrictor encircles the limb more than once, to bring each turn separately down upon the surface of the limb and not overlap each other. An assistant should hold the limb firmly in a vertical position when the constrictor is applied over the side of the limb where the large blood vessels are located, and the constriction quickly and firmly made so as to interrupt at once, completely, both the arterial and venous circulation. How long is it safe to exclude from a limb the circulation by elastic constriction? This is an important question which presents itself with special force in the practice of military surgery. I made, a few years ago, an interesting series of experiments on

to twelve hours without any obvious harmful results. From the results of my own experiments and the clinical data on elastic constriction as a hemostatic resource, I am satisfied that it is safe to exclude the circulation from a limb for four to six hours without incurring any special risks of gangrene or permanent damage to large nerve trunks. The exact limit of prolonged constriction in man has not been determined, and I should consider it unwise to continue it beyond the time specified. In the majority of cases during this time the wounded will be brought to the attention of surgeons when the injured vessel is exposed and tied, or elastic constriction is replaced by direct compression.

FIG. 5.—Genuflexion in the treatment of hemorrhage from the popliteal artery and its branches.

dogs for the purpose of formulating an authoritative answer to this question. Elastic constriction was applied by using rubber tubes the size of an ordinary lead pencil, and the constriction was continued from one to twenty-six hours. Temporary paralysis was observed in a number of cases. Gangrene of the limb below the point of constriction resulted only in one case, and in this instance the constriction was continued for twenty-four hours, while the dog in which the constriction was continued for twenty-six hours recovered in a short time perfect use of the limb. The blood contained in the arteries and veins below the point of constriction remained fluid and retained its intrinsic functional properties for this length of time after complete exclusion from the general circulation. Elastic constriction is not attended by any special danger from this source. Every surgeon has had cases in which elastic constriction was continued for several hours, in the performance of difficult and tedious operations, without witnessing any untoward, immediate or remote results from the prolonged interruption of the circulation. I have learned of a number of cases of railway injuries in which elastic constriction was continued for seven

FIG. 6.—Forced flexion of forearm in arresting hemorrhage from the brachial artery opposite the elbow joint or any of its branches below this point.

Antiseptic Tampon.—The antiseptic tampon is a convenient and very useful hemostatic agent in the treatment of accidental hemorrhage. The antiseptic package with which every soldier of civilized warfare will be supplied can be used advantageously for this purpose. It will prove of special value in the arrest of hemorrhage from the vessels of the scalp, face and intercostal arteries, and in the treatment of open lacerated and sabre wounds. The surface to be compressed should be dusted with the antiseptic powder contained in the package, and with the hygroscopic antiseptic material composing the balance of the package a graduated compress is made, the apex of which is placed in contact with the bleeding vessel, and the necessary degree of pressure secured by a circular bandage with or without the use of an extemporized splint according to the location of the vessel, or the relations of the injured vessel to the underlying bone.

Vessel injuries treated by antiseptic tamponade will seldom require ligation as the tampon, if the wound remains aseptic, is allowed to remain until the lumen of the vessel has become obliterated permanently by thrombosis and cicatrization.

Internal Hemorrhage.—The prompt and proper treatment of internal hemorrhage will constitute one of the crowning triumphs of surgery upon the battle-field. The direct treatment of the injured vessels by early invasion of any of the three large cavities of the body will be the means of saving many lives which heretofore were doomed to certain death. This part of the surgeon's work will be done at the first dressing station or the field hospital.

What can be done behind the fighting line in such cases to bridge over the time until such services can be rendered to the injured? In hemorrhage from the intracranial vessels caused by bullet wounds, it would be dangerous to plug the wounds of entrance and exit as the accumulation of blood in the cranial cavity would result in death from cerebral compression. The escape of blood should be favored by inserting into the track made by the bullet a strip of aseptic or iodoform gauze. This will not only serve a useful purpose as a capillary drain, but by bringing in contact with the injured vessels an aseptic foreign substance the spontaneous arrest of hemorrhage by thrombosis is favored. The gauze drain should

FIG. 7.—Elastic constriction of upper extremity. (After Seydel.)

be secured on the surface of the wound with a safety pin and the wound or wounds protected against infection by an antiseptic dressing retained in place by the triangular bandage. By this treatment many cases will reach the field hospital for a timely intracranial operation. In bullet and stab wounds of the chest, complicated by hemorrhage from the intercostal arteries, the antiseptic tampon is the proper treatment. Packing of the tubular wound with an antiseptic hygroscopic material will not only succeed in arresting the hemorrhage, but will serve at the same time as an efficient capillary drain and protect the cavity of the chest and its contents against infection. In hemorrhage from injuries of the organs of the chest, firm circular compression of the chest directly over the wound already protected against infection by an antiseptic dressing constitutes a valuable indirect hemostatic measure.

Immobilization of the chest wall by circular compression diminishes the functional activity of the lungs, and in doing so exerts a favorable influence in arresting hemorrhage from this organ. The cartridge

belt or gunstrap can be used to the greatest advantage in limiting the respiratory movements of the chest. I believe that this conservative treatment of penetrating wounds of the chest will yield better results than injection of filtered air, absorbable aseptic solutions, or treatment by rib resection, free incision, and attempts to ligate the bleeding vessels. In penetrating wounds of the abdomen the prime indication in the future treatment of such injuries will be to prevent death from hemorrhage. Visceral wounds of the abdominal organs, notably the liver, spleen and mesentery, usually give rise to profuse and often fatal hemorrhage. The hemorrhage is more frequently venous and parenchymatous than arterial. In my address last year before this Association, I urged the importance of early operative interference in such cases, and mentioned hemorrhage and the direct treatment of visceral wounds as ample indications to justify prompt, active interference. In in-

FIG. 7 a.—Suspender constriction of arm.

juries of vessels below the bifurcation of the abdominal aorta, attempts should be made to prevent death from hemorrhage upon the battle-field by resorting to the use of some sort of compression with a view to interrupting the circulation in the aorta above the bleeding point. Esmarch's method, shown in Fig. 11, can be extemporized in a few moments, as it requires no instrument of special construction and meets the indications more completely than the various instruments devised for this purpose.

The method of Brandis is equally simple and efficacious. As hemorrhage from any of the vascular organs and large vessels of the abdominal organs requires prompt treatment, and as in large engagements a considerable length of time will necessarily intervene between the first aid and the permanent arrest of hemorrhage by laparotomy, and as in many instances the location of the wound is outside of the range of successful treatment by compression of the abdominal aorta, it appears to me that in such cases

it would be good treatment to resort to direct and circular compression as has been described in connection with penetrating wounds of the chest. The wound of entrance and exit, if the latter exists, should be protected by an antiseptic dressing. Over the wound corresponding with the yielding part of the abdominal wall a large compress which may be composed of a compress made of a blanket, an article of clothing, a cartridge belt, or canteen should be

FIG. 8.—Elastic constriction of lower extremity. (After Seydel.)

placed and over it firm circular compression made with a belt or gunstrap. The direct compression made in the direction of the track of the bullet will do much toward diminishing the vascularity of the underlying injured parts, while the circular compression will immobilize the abdominal wall at the seat of injury and limit the movements of abdominal organs, conditions which can not fail in materially diminishing the risks of hemorrhage and in aiding thrombosis, nature's resource, in effecting spontaneous arrest of hemorrhage.

FIG. 8 a.—Elastic constriction of thigh.

PERMANENT HEMOSTASIS.—*Forcippresure.*—The best and most successful military surgeon is the one who accomplishes the most with the least number of instruments. Complicated instrument cases look well and make a favorable impression upon laymen, and can be used to advantage in a well-equipped hospital; they are out of place on the battle-field. The fewer the instruments in the

treatment of emergency cases, the less the danger of infection. The writer has recently devised an operating pocket case which contains all the instruments a military surgeon is expected to use when in active service. It contains among the instruments needed for emergency work seven hemostatic forceps, by the use of which he is in a position to meet the emergencies incident to hemorrhage upon the battle-field. The use of aseptic hemostatic forceps upon the battle-field will meet the indications successfully in many cases in which other hemostatic measures are inapplicable. If the bleeding vessel is so located that it can be grasped with hemostatic forceps, but can not be ligated without performing a formidable operation, the forceps should be allowed to remain and should be incorporated in the antiseptic dressing and a note made to this effect on the diagnosis tag.

FIG. 9.—Antiseptic tamponade of wound of deep palmar arch.

Ligature.—Ligation of blood vessels, arteries and veins will usually be done upon the battle-field after temporary hemostasis by other means, either at the first dressing station or, more frequently, at the field hospital. Silk is the proper ligature material in military service. Silk can be sterilized repeatedly by boiling and is, consequently, a much safer material than catgut in emergency practice. Aseptic silk in an aseptic wound invariably becomes encysted. Catgut sterilized in Boeckmann's sterilizer and kept ready for use in sterilized envelopes, as advised by Boeckmann, could be made serviceable for military surgery. As a rule, the vessel should be tied at the seat of injury by enlarging the existing wound and using it as a guide to the injured vessel. Cases,

however, will present themselves in which it is impossible to apply this rule, and where the artery has to be tied in its continuity in a more accessible place on the proximal side of the bleeding point. Antiseptic precautions in the treatment of wounds and the employment of the aseptic ligature will materially diminish, if not entirely overcome, the risk of secondary hemorrhage, which proved such a terror to the surgeons, and such a frequent source of danger and death to the injured during the great War of the Rebellion. The ligature should never be tied sufficiently tight to rupture any of the tunics of the vessel. All that is necessary to obtain an ideal permanent obliteration of the vessel is to approximate and hold in uninterrupted contact the intima. If the vessel requiring ligature in its continuity is a large one, a double ligature with a bloodless space between the two ligatures is preferable, as the space interposed between them offers the most favorable conditions for an early and permanent obliteration

of the vessel in the same manner as in closing an intestinal wound by Lembert's sutures.

Hot Water and Styptics.—Hot water at a temperature of 120 to 130 degrees F. coagulates the albumin upon the surface of the wound and in doing so seals the orifices of small vessels, and on this account has become a popular hemostatic in arresting parenchymatous bleeding in parts and organs accessible to this method of treatment. The employment of styptics in arresting hemorrhage, on the whole, should be discountenanced, as their use interferes with an ideal healing of the wound. Their application can only come in question in the treatment of bleeding wounds of the mouth and pharynx where antiseptic tamponade is impracticable.

Saline Infusion.—Patients who have become debilitated by hemorrhage to the extent of endangering life, require restoration of a normal degree of intracardiac and intravascular pressure by saline infusion. Transfusion of blood, whole or debrinated, has been proved clinically and experimentally a failure in preventing death from the immediate and remote results of dangerous hemorrhage. The transfused morphologic elements of the blood do not retain their vitality and are destined to be removed from the receiver sooner or later, by elimination through some of the excretory organs. von Bergmann and others have shown that the immediate cause of death from acute hemorrhage, subnormal intracardiac and intravascular pressure can be avoided more successfully by substituting for animal or human blood a physiologic solution of common salt.

FIG. 10.—Treatment of penetrating wound of chest by antiseptic tamponade and immobilization by circular compression.

FIG. 11.—Compression of abdominal aorta. (After Esmarch.)

of the lumen of the vessel. Under aseptic and antiseptic precautions the ligation of large veins is as safe a procedure as ligation of the accompanying arteries.

Vein Suture and Lateral Ligature.—In small wounds of large veins, lateral ligature and suturing with fine silk or catgut secures permanent hemostasis with preservation of the lumen of the vein, and for these reasons should receive in this kind of vein injuries the preference to ligation in continuity. This method of treatment receives particular value in the case of wounds of the superior longitudinal sinus and the large veins at the base of the neck in the axillæ and the groins, as well as the large veins in the abdominal cavity. The lateral ligature is applied by seizing the margins of the vein wound with a sharp tenaculum and tying the base of the cone with a fine silk or catgut ligature. In suturing of vein wounds the margins are inverted toward the lumen

Every field outfit should be supplied with a definite quantity of salt from which the solution can be prepared in a few moments when required. Szumann's solution is the one usually preferred. It consists of:

Natr. chlorat	6.0
Natr. carbon	1.0
Aq. distillat	1000.0

The chloride and carbonate of soda in the above proportion should be carried in every pannier so as to be available in all cases in which a saline infusion may become necessary. The simplest apparatus for making a saline transfusion is a glass or hard rubber funnel with two or more feet of rubber tubing and a small glass tube with a tapering point. The median basilic vein is usually selected for making the injection. The vein is exposed by a small incision after having rendered it turgid by proximal compression in the same manner as in performing phlebotomy. After exposure of the vein it is incised transversely.

and the point of the glass tube is inserted and fastened in place by a ligature previously inserted. Before inserting the glass tube the precaution is taken to fill it and the rubber tube with the saline solution to prevent the introduction of air. The saline solution to be used should be heated to the temperature of the body and infection is prevented by using only sterilized water for the solution.

The quantity of solution to be used to fulfill the therapeutic indications will vary from 500 to 1,500 grams, 1,000 grams being a fair average dose, and for the preparation of which the necessary quantity of powder should be kept in readiness. If the symptoms of improvement which follow the employment of a saline infusion should come to a standstill or disappear, it may become necessary to repeat the intravenous injection in the course of an hour or more. The same object gained by intravenous injections of salt solution is attained more indirectly and with greater loss of time by copious hypodermatic and rectal injections.

(To be continued.)

MODERN URETHROSCOPY AND CYSTOSCOPY —CATHETERIZATION OF THE URETERS AND INTRAVESICAL REMOVAL OF TUMORS.

Read in the Section on Surgery and Anatomy, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY FERD. C. VALENTINE, M.D.
NEW YORK.

Even those who have not gone very deeply into the recent literature of genito-urinary surgery, can not fail to be impressed with the correct idea that the title of this paper encompasses more than can be said in the time allotted at any meeting. Indeed, the title suggests volumes, conjures up visions of a very large library and actually covers a vast experience on the part of those who have given special attention to this most important branch of the healing art. The greater portion of this experience can not be written, for it depends upon practice of the hand and eye. For these reasons this paper can practically be little more than a demonstration of instruments.

I beg leave to divide this demonstration into four parts, omitting historical considerations entirely.

1. *Modern Urethroscopy.*—The instruments I have the privilege of showing are:

The Posner urethroscope is the simplest form of those now in use. It is practically a prolongation of the old meatoscope, except that it has no obturator and has a tube eight and one-half centimeters long. It is of glass, silvered within and blackened without. It is made in two forms; one with the tube vertically cut off, the other terminating obliquely. In practice, after being lubricated, preferably with glycerin, it is inserted into the urethra and any moisture obstructing vision is dipped out with either metal or wooden applicators wound with absorbent cotton. The illuminating source for the use of the Posner urethroscope may be either a head-mirror and lamp, or gas, or an electric light thrown in at the top of the funnel.

While the Posner urethroscope is necessarily limited in use by its inevitable shortness and other causes to be mentioned later on, it is certainly a very useful substitute in circumstances in which more

extensive apparatus is not at hand. One case is vividly before my mind in which it served as well as any more complicated instrument possibly could have done. It was shown me last winter by Dr. Arthur Lewis, Professor Posner's assistant at the Berliner Allgemeine Poliklinik. This patient had had a urethral discharge for eight years following an attack of urethritis. All manner of treatment proved unavailing. The patient, an artistic designer, had fallen into that mental depression we so frequently find associated with and resultant upon affections of the genito-urinary apparatus. The man's mind was certainly in a state of decided melancholia. The first attempt at illuminating the urethra revealed a superficial ulcer about one centimeter long by half a centimeter wide, situated about five and one-half centimeters behind the fossa navicularis. Two applications of silver nitrate a week apart, sufficed to entirely cure the case.

Grünfeld, of Vienna, devised an urethroscope about one-fifth longer than Posner's. It differs also in being of metal, blackened within and having an easily removable obturator.

The Casper urethroscope is a more extensive apparatus, based, however, essentially upon the same optical principles as are nearly all other instruments for urethral exploration. The tubes are of metal and longer than those designed by Posner; they have an obturator and at their visual end have a rim fitting into a handle, provided with an ingenious arrangement of condensers and prism by which electric light is reflected into the urethra. This entails quite a weighty handle, which I do not doubt will be remedied in the future by its designer.

One objection to the use of this instrument is that it must be learned. The beginner is obliged to exclude reflexes and to overcome the hazy mist which at first presents to his vision, and only when he has overcome these can he see the urethra.

The requirement of a light, easily manageable handle, seems to have been anticipated in William K. Otis' most cleverly devised urethroscope. It has been recently described in several journals, and therefore need not be again discussed here. With no desire to sin on the score of excessive patriotism, I can not but be pleased with the marked evidences of American ingenuity Otis' instrument presents.

Posner, Grünfeld and Casper use wooden "Tupfer" for the purpose of removing excessive moisture from the field of vision. These "Tupfer" consist of "wood wire," which is nothing but the sticks drawn for matches, but not cut into match length. Cotton wound around their ends, complete this part of the apparatus.

The instrument, however, which seems to cover all the requirements of modern urethroscopy, is the Nitze-Oberlaender urethroscope. It consists, essentially, of a battery which provides light urethral tubes of various calibers and a light-carrier which is inserted into these tubes.

By means of the light-carrier, the source of illumination is placed at the points to be examined, thus fulfilling the essential requirement, in obedience to the law that visual acuity is in proportion to intensity of illumination. It must be self-evident that the nearer the object to be seen is to the source of light, the more clearly it is perceived. To enable the urethra to hold an unprotected electric light within it, an ingenious arrangement of two small

tubes allows a current of cold water to flow around the light. Kollmann, of Leipzig, experimentally determined that in the first thirty seconds after insertion of the light, the temperature of the urethra rises one and a half degrees and there remains stationary. This gives no discomfort whatever to the patient. A simple rheostat governs the amount of light required in each case. The only objection which can be properly urged against this instrument is that excessive moisture can not be dipped from the urethra except by previously removing the light-bearer. This, however, is so trifling a matter, that it hardly merits serious consideration.

The space occupied by the light-bearer in the urethral tube is so small that it practically does not obstruct vision. Moreover, the light being within the urethra at the very tip of the tube, enables the use of a much longer instrument; indeed, there is no difficulty whatever in using the ordinary Oberlaender tubes for examination of the posterior urethra, practically a species of cystoscopy.

Since Nitze devoted his remarkable genius more to the development of cystoscopy, from which so many astonishing things have arisen, some of the profession concluded that urethroscopy was thereby condemned as a mere scientific diversion. But Oberlaender showed that the urethra is still a most important organ, fully meriting the profound study he gave it. The improvements he wrought led to a recognition of the pathologic significance of the details, such as gaping gland orifices, changes in color, lack of striation, smoothing out of folds in the mucous membrane, etc., and made it possible to view intelligently that bugbear of specialists, chronic gonorrhoea. The far-reaching results of gonorrhoea, both to the patient himself and to women, need but be mentioned here.

If Oberlaender had done nothing else than describe urethral pathology, modify the Otis dilator and offer further methods for the treatment of urethral diseases, the merit of his work would be incalculable. At a proper time I hope to enter more fully into the details of this matter, which can be but sketched here.

2. *Cystoscopy*.—It is too late in the scientific day to discuss the value of cystoscopy. No one can deny that visual exploration of the interior of the bladder is of incalculable diagnostic advantage beyond palpation with tactile instruments. The instrument which Nitze devised has a very short beak, consisting of a removable Edison mignon-lamp. This is attached to the shaft, immediately beyond where it has a prism adjusted with such optical neatness as to throw the illuminated image directly into the line of vision.

The optical arrangement of lenses within the shaft and at the visual end of the Nitze cystoscope, are calculated to give a clear image, not only of the vesical mucous membrane, but also of neoplasms as well as stones within the bladder. Several cases present themselves to memory in which stones were so encapsulated or held by trabeculae that even the most delicately managed sound could not reveal them. They could readily be located by means of the cystoscope.

In renal diseases, however, the cystoscope is of surpassing importance. The fact that a patient passes blood or pus from the kidneys with the urine, by no means indicates whether the right or left kidney is diseased. Watching the mouth of the ureters

through the cystoscope, will show which kidney extrudes the vitiated urine and thus save unnecessary nephrotomy. One case especially, among those in which I had the pleasure of assisting Nitze, demonstrated the extraordinary value of cystoscopy. This was an apparently healthy, vigorous man, who occasionally passed bloody urine. The surgeons who had explored his bladder found no cause for this symptom. Palpation of the renal regions revealed nothing. At one time, when the patient bled, his bladder was cystoscoped and it was found that the blood came from the right ureter. An exploratory operation at first exposed no kidney; search revealed that its lower pole was *above* the upper margin of the twelfth rib, rendering palpation impossible. On drawing down the organ and removing it, it proved to be three times its normal size. Microscopic examination showed it to be carcinomatous in all its parts. When I left Berlin on April 9, the patient was making an eventless recovery. Were this the only case of the kind, it would suffice to establish the very great importance of cystoscopy for diagnostic purposes.

The one opportunity for error in cystoscopy lies in the possibility of exaggeration. The optical apparatus necessarily magnifies, and therefore when the tip of the instrument is too far removed from the point or object under examination it appears enlarged. This, however, may also be advantageously employed in determining the character of a pathologic product or foreign body. How clearly these are visible is well shown by the beautiful pictures in Nitze's "*Kystoskopographischer Atlas*." These were taken by his photographing cystoscope.

The technique of cystoscopy is very simple, albeit wearisome. Very few cases can be properly prepared and examined in less than half an hour. The bladder is washed with a boric acid solution until the wash water flowing out through the catheter is perfectly clear; this may require a very long time. Then the bladder is filled with 100 to 250 grams of boric acid solution and the cystoscope, being sterilized and lubricated with glycerin is inserted in the same manner as the Mercier catheter is used. In sensitive cases the insertion of the cystoscope may be preceded by an injection of cocain in a weak solution. By then gradually advancing the rheostat of the light battery a sufficiency of light is obtained. Rapidly turning on the light endangers the lamp, which from excessive current may suddenly burn out and require an entire repetition of all the steps of the procedure.

Several modifications of the Nitze cystoscope have recently been placed upon the market. Among these Lohnstein's with a doubly curved beak, appears to unnecessarily increase the intravesical length of the instrument and to make the distance between the point examined and the prism too great. Winter's cystoscope for the female bladder is merely a shorter cystoscope than Nitze's.

3. *Catheterization of the Ureters*.—When Dr. Max Nitze, of Berlin, claimed priority in successful catheterization of the ureters in the male in No. 9 of the *Centralblatt für Chirurgie* for 1895, he reserved for himself a discussion of the present and future diagnostic and therapeutic value of urethral catheterization. In view thereof, and in view of the magnificent work done by Howard A. Kelly, of Baltimore, little beyond a demonstration of the instruments remains to be said here.

Kelly's and Pawlik's methods have rendered catheterization of the ureters in the female rather easy. But the efforts made in the male by Brenner, Poirier and Boisseau du Rocher, have by no means proved executable with any degree of security.

Nitze's cystoscope for catheterizing the ureters, roughly described is a small-sized (Charrière 19) cystoscope running through and easily turning in a larger tube. The latter is open at the outer angle of the knee of its Mercier bend. Near the visual end of the outer tube a small, short one enters it. This is just sufficiently large to permit the catheter or sound for the ureter to pass through it and the larger tube, from the tip of which it can be protruded. It is inserted into the bladder closed entirely. When in place, the knob on the outer rim, indicating as with other cystoscopes, the position of the beak, the inner tube, or small cystoscope which contains the lamp and prism, is pushed forward, and the whole apparatus turned until the mouth of the ureter is clearly seen through the visual end. The catheter is then propelled by the fingers until its point enters the mouth of the ureter. This is the most difficult part of the whole procedure. Once accomplished, the catheter can be easily pushed into the ureter, on toward the pelvis of the kidney. Then holding it firmly in place, cutting off the light, drawing the inner cystoscope into the outer tube, the metal part of the apparatus can be withdrawn, leaving the catheter in the ureter, projecting through the bladder and the urethra. In normal cases the urine, free from vesical secretions, will then spurt or drip from the orifice of the catheter, two to five drops every minute, minute and a half, or two minutes.

Incidentally it may be mentioned here, that the inner tube, before described, can be used for cystoscoping children's bladders.

Casper's cystoscope for catheterizing the ureters is a somewhat more complicated and heavier instrument than Nitze's. Its beak is doubly curved, somewhat like Lohnstein's modification of Nitze's instrument. The lamp and terminal prism are considerably larger than Nitze's, for which the author claims a wider visual field. The ocular end of the shaft has an extra set of prisms in the optical apparatus, which places it beneath the shaft. Thus the opening directly into the shaft is left free for the entrance of the catheter. When it has penetrated the ureter to the desired degree, a bit of rubber tubing at the orifice of its entrance is removed. Then a ring at upper part of the instrument is drawn toward the operator. It is attached to a thin metal slide, which forms the upper third of the catheter canal. On removing this entirely, the catheter is held by the ureter above; the part lying in the bladder is then freed and supporting the end projecting from the meatus, the cystoscope is withdrawn. Thus the catheter is left *in situ*.

4. *The Intravesical Removal of Tumors.*—Unfortunately, through circumstances unnecessary to relate here, the manufacturer of Nitze's instruments could not provide me with an operating cystoscope in time to demonstrate it at this meeting. I am therefore obliged to crave your indulgence for being compelled to use a drawing, which, at best, is an unsatisfactory substitute.

It is a cystoscope with wires to snare off tumors within the bladder. The wire can be used cold, by mere constriction, or it can be rendered incandescent

to sear as it strangulates. The tip of the instrument has a small platinum coil which can be rendered incandescent also, and thus used to cauterize the bases of tumors, arrest hemorrhage, etc. The instrument also has diminutive forceps, by which small fragments of tumors, or stones, or other foreign bodies can be grasped and withdrawn.

Other genito-urinary instruments and procedures, not being within the scope of this paper, I shall take pleasure in demonstrating privately to those interested. Among these are Nitze's irrigation and lithotomy cystoscopes, Oberlaender and Kollmann's urethral instruments, Janet's intravesical injector without a catheter, for the treatment of gonorrhoea, and many other new genito-urinary devices.

This being the first occasion which I have had to publicly express my gratitude for many special attentions shown me in Germany, it affords me great pleasure to convey most sincere thanks to the eminent genito-urinary specialists there for all they did to advance my studies. I must mention particularly among these gentlemen, Prof. Carl Posner, Dr. Max Nitze, Dr. Leopold Casper, Dr. Hans Wossidlo, Dr. Arthur Lewin, Dr. Ernest R. W. Frank, of Berlin; Dr. Arthur Kollmann, of Leipzig, and Dr. F. M. Oberlaender, of Dresden.

THE RADICAL CURE OF HYDROCELE.

Read in the Section on Surgery and Anatomy, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY D. C. HAWLEY, A.B., M.D.

ATTENDING SURGEON MARY FLETCHER HOSPITAL; ATTENDING SURGEON FANNIE ALLEN HOSPITAL; SECRETARY VERMONT STATE MEDICAL SOCIETY.
BURLINGTON, VT.

The only known method of effecting a certain, absolute and permanent cure of a hydrocele, is to bring about the complete obliteration of the cavity of the tunica vaginalis.¹

The methods usually employed by surgeons at the present time for the radical cure of hydrocele, are the injection method and the method by open incision. The treatment by injection fails in some cases, from the fact, no doubt, of its being improperly or poorly done. Again, it often fails in cases of very large hydrocele, and invariably in cases in which there is much thickening of the tunic, thereby preventing perfect collapse of the same.

Treatment by iodine injection is usually painful, and is attended with intense swelling and tenderness of the scrotum. Three to five days must be spent in bed, and three or four weeks are often necessary for perfect recovery.

Injection of carbolic acid is, in my experience, less painful and more efficacious, but requires about the same length of time for a cure.

In the operation by incision, as usually practiced and as described in the text-books, an incision about two inches long is made along the anterior surface of the tumor, which thoroughly opens and drains the sac. The edges of the tunica vaginalis are stitched to the skin by catgut or silk sutures, and a rubber drainage tube is inserted, or the cavity is packed with gauze.

The after treatment consists in a daily dressing, when the tube is gradually shortened or the packing is renewed. The patient must remain in bed for ten or twelve days, and eighteen to twenty-eight days or

¹ Treves.

more are required for a cure in most cases of operation by incision.

I wish now to describe, briefly, a method which I have employed for two or three years past, in my service in the Mary Fletcher Hospital and in private practice. I consider it almost unnecessary to say, at the present day, that the operation must be done aseptically.

The usual incision, two to three inches in length, is made along the anterior surface of the tumor, taking care always not to injure the testicle. The fluid is allowed to escape and the sac is irrigated. The margin of the tunic is stitched to the skin by six or eight black silk sutures. I use black silk, as it can be more readily found and removed. The interior of the sac is now irritated over every part of its surface by being rubbed with the finger tips. This is not done roughly, but gently and thoroughly. The sac is packed with strips of iodoform gauze, the usual dressings applied and the patient kept in bed. At the end of twenty-four hours the strips of gauze are removed and the cavity is irrigated. The entire surface of the tunica vaginalis will now be found to be covered with inflammatory lymph. Further packing or drainage is not used.

The opposing surfaces of the sac are now brought into thorough coaptation by compression, applied by means of strips of adhesive plaster. A light dressing of gauze is placed over the wound of incision and the adhesive strips are applied systematically around the scrotum over this dressing, so as to produce firm and even compression. The dressing should be inspected occasionally at first to see that it does not become loosened. If it does so, it must be reapplied at once. At the end of four or five days the dressing is taken off and the silk sutures removed.

At this time the cavity of the sac will be found to have been obliterated, the opposing surfaces having united by adhesive inflammation. Should a sinus be found, which, however, has happened but once in any of my cases, it should be treated on general principles and allowed to heal from the bottom. The wound is again dressed and mild compression continued. Two or three more dressings are all that are required, and at the end of six to twelve days the wound will be entirely healed. A slight dressing may be necessary for a few days to prevent chafing, and a suspensory should be worn for several weeks.

The strips of gauze used for packing should be counted and a note made of the number, to avoid the possibility of one of them being left at the time of the first dressing. But little swelling follows the operation, and I have seen no cases in which orchitis has supervened. The patient need be kept in bed but three or four days, but the scrotum should be suspended whenever he is allowed to get up.

Case 1.—George W., age 54, carpenter by trade, was admitted to the Mary Fletcher Hospital with a history of double hydrocele having existed for ten or twelve years. Both had been tapped several times. On Oct. 16, 1894, I operated on him under ether, in the manner described. The left hydrocele contained a pint of fluid and the right more than a pint. The case was dressed the next day, when the packing was removed and the surfaces of the sacs were brought together and held in apposition by a well-fitting dressing. This was left five days and on October 22, six days from the time of operation, the case was again dressed and both sides were found entirely healed, excepting the incisions through the scrotal tissues. There was no pus. Dressed again on October 24, or the eighth day, and the patient allowed to go home as he resided in the city, with instructions to return in four days. He returned as directed on October 28, when

both incisions were found entirely healed, and he was discharged cured—twelve days from the date of operation. He went to work at once at his trade, having lost less than two weeks' time. At the present writing he is perfectly well, with no sign of a return of the trouble.

Another case of single hydrocele containing a half pint of fluid was operated on by the same method nearly two years ago, and was well in six days, and no sign of a return of the hydrocele up to the present time. In one case, a small sinus was found at the second dressing, which was one inch in depth and a little larger than a good-sized probe. This closed perfectly in three or four days.

Every case operated on thus far, by this method, has been successful.

The advantages claimed for this operation over any other, in all cases of old or large hydrocele, are the shorter duration of the treatment, together with the probability of a radical cure in every case.

The treatment by the injection method requires a long time for the restoration of the parts to their normal condition, while at the same time the result is uncertain, for the reason that the inflammatory process set up by the injection may not be sufficient to produce a cure. On the other hand, it may be so severe as to cause extreme swelling and much suffering.

The special objection to the open incision method is the long duration of the treatment. The patient must remain in bed from six to twelve days, which time measures the duration of the treatment by the method I have described.

This method is, I believe, applicable to all cases requiring an operation. It is not open to the objection that the patient must take an anesthetic, for if there is any special reason why he may not do so, or if he will not submit to it, the operation may be done with cocain.

RECENT INVESTIGATIONS UPON THE POISONOUS PROPERTY IN EXPIRED AIR.

BY HANNAH B. CLARK, (UNIVERSITY OF CHICAGO).

"Expired air consists chiefly of watery vapor, carbonic dioxide (CO₂), and organic matter. CO₂ in large quantities is a deadly poison, and popular opinion looks upon this as the dangerous element in foul air. But specialists do not deem the CO₂ even in the worst ventilated rooms really dangerous. . . .

"What then constitutes the danger from foul air? It is the organic matter present in it. The lungs and skin exhale a powerful poison. The quantity is very small, but where two or three persons are together in a confined space, it is sufficient to infect the air quickly. While the exact nature of this organic matter is a subject of dispute, it is evident that the human miasma is the really dangerous element in expired air. . . .

"The amount is generally proportional to the amount of expired air, and the CO₂ measures the amount of expired air. Hence, the CO₂, although comparatively harmless itself, is a good index of the impurities of the air."¹

In this extract from Dr. Burnham's admirable monograph we have a clear statement of the position taken by physiologists in the second stage of the discussion regarding the toxicity of expired air, the view which appears in almost every work on hygiene

¹ *Outlines of School Hygiene*, W. H. Burnham, Ph.D. Pedagogical Seminary, June, 1892, pp. 22, 23.

published within the last five or six years. During this time, however, continued investigation has furnished us with a body of new evidence which is so weighty and, on one point so decisive that it involves an entire re-statement of the case. To this end a review of the course of discussion seems called for.

The "popular opinion" to which Dr. Burnham refers, that looks upon CO₂ as the dangerous element in expired air, is but the conservative survival of what, in the first phase of the investigation, was the general scientific opinion. In searching for the cause of those phenomena so common in crowded, ill-ventilated rooms—headache, fainting, nausea, etc., the earliest students of the problem naturally had their suspicions directed to the one conspicuous element of expired air whose poisonous properties, when in large quantities, were well known, and carbon dioxide continued to bear this odium until experiments showed what a small amount of the gas is present in even the most impure air. Any evil effect from it seemed impossible and, as its presence did not explain the phenomena under consideration, some other poison must be sought.

In 1870, Ransome published his studies of "The Organic Matter of the Human Breath,"² which led the way in a long series of investigations. Ransome tested the breath for free and organic ammonia and estimated the organic matters given off in twenty-four hours at 0.2 gm. or 3 grs. He found in the breath, cells of various kinds, portions of epithelia, etc., and concluded that "they simply show the readiness with which the aqueous vapor of the breath ferments or putrefies, and the consequent danger of over-crowding, and the paramount importance of ventilation."

More practical experiments were made by Hermans³ in 1883, when he attempted to answer the question, whether there is in inhabited rooms an accumulation of combustible material which leads to evil results, and whether, if a gaseous organic matter is exhaled, it is harmful. He reached the conclusion that sound men breathe out no appreciable amount of volatile organic matter. By another series of experiments in which he placed a man in an airtight chamber and examined the air from time to time, he found that unpleasant symptoms appeared when the CO₂ rose to 3 per cent. His attempts to discover some trace of organic matter in the fluid formed by condensed exhalations were fruitless.

This negative result was an incentive to further studies of the same question, such as those of Uffelmann,⁴ who determined the amount of CO₂ in atmospheric air at from 3 to 4 parts per 10,000. Since Hermans' experiments placed the danger point for CO₂ at 3 per cent., and other investigators had reported less than 100 parts per 10,000 in the worst ventilated rooms, the evidence seemed to be conclusive that CO₂ is not the dangerous element. Uffelmann also states that it is not the infallible test of the toxicity of the air that it had been assumed to be, for he often found it low when the latter, *i. e.*, when the organic matter was high.

Into the midst of these partially negative discussions with their lack of finality came certain statements from Brown-Séquard and d'Arsonval⁵ which

aroused the keenest interest because of their apparent decisiveness.

These investigators had obtained a sort of solution of expired air both by pouring water into the bronchial tubes of an animal and withdrawing it after it had mixed with the air from the lungs, and by condensing breath. With the liquid thus obtained they injected rabbits and dogs, the doses varying from 4 to 25 grs. The resulting symptoms of illness differ only in intensity according to the increase in the dose. They were invariably, dilation of the pupils, quickened respiration, paralytic weakness and variations of temperature, followed in extreme cases by death. After death the venous blood was found to be red. These results led the writers to conclude that, "the lungs of men, dogs and rabbits, in a healthy condition, produce an extremely energetic poison. . . . It is extremely probable, if not certain, that this is the toxic agent which renders confined air dangerous."

The poison, they said, is probably a volatile alkaloid, "leucomaine," judging by its extreme alkalinity, its persistence after heating to boiling in a closed vessel, and the resemblance between the phenomena caused by injections of condensed breath and those caused by other alkaloids.

There was an immediate attempt made to obtain results which would corroborate those of Brown-Séquard and his fellow worker. Dastre and Laye⁶ succeeded in producing the same symptoms in animals, but only when they injected very large quantities of the fluid, and they afterward found that a similar quantity of pure water produced the same effects!

Entirely negative results were reached by Lehmann and Jensen,⁷ and also by Hoffmann-Wellenhof.⁸ No trace of the alkaloid could be discovered.

Brown-Séquard and d'Arsonval returned no direct answer, but a little later in the same year they reported a still more striking series of experiments in which they employed the so-called ventilation method. A number of rabbits were confined in glass cages so connected that only the first animal received fresh air, each of the others being obliged to breathe the exhalations of those preceding it. The death of the animals took place in regular order, beginning with the one farthest from the fresh air. Moreover, they stated the amount of CO₂ present at any time was very small, not more than 1 or 2 per cent., and when a tube of sulphuric acid was placed between any two cages, the rabbit beyond it, farthest from the source of air, lived.

All of these facts they regarded as greatly strengthening the theory of a volatile organic poison, since the small amount of CO₂ could not cause death, and the security of the animal which received its air through H₂ SO₄ pointed to a probable union of the alkaloid and the acid.

This second challenge to investigators was taken up as quickly as the first had been. The vexed question seemed on the point of solution. Its confirmation was apparently given by Merkel⁹ who in 1892 repeated Brown-Séquard's experiments. Trying first the method of injection, he failed as the other would-be verifiers had done, but when he used the ventilation method his confirmation of the earlier results

⁹ Arch. f. Hygiene, Bd. xv.

appeared complete. There were the deaths in the same order, with the same exception in the case of an animal protected by the H_2SO_4 , and the same small amount of CO_2 . The remark that the symptoms of illness could not be distinguished from those of carbonic acid poisoning is apparently made by Merkel as an observer rather than as a logician. He ignores it in his conclusions.

Merkel next followed out the suggestion as to a basic substance, and attempted to unite it with various acids, sulphuric, hydrochloric and acetic. After passing expired air through the acid he evaporated the solution and injected the sediment into rabbits. Only the most transient symptoms of disturbance followed.

The conclusion was therefore drawn that the organic poison exists,—as proved by the test of caged rabbits breathing expired air; that it is a base, as Brown-Séguard believed, and that it loses its toxicity when it enters into combination with an acid.

For a time the position thus taken by Merkel and Brown-Séguard and d'Arsonval was unassailed, and their view was even incorporated in the current works on hygiene as of final authority. But the doubts had not all been laid; they were repeatedly revived by other observers who wished to see the proofs in their own laboratories, until the accumulated evidence entirely altered the aspect of the question.

Benu, like Lehmann and Jessen, obtained only negative results from injection. With the ventilation method there was a repetition of the phenomena Merkel had seen, but there were also several obvious causes which rendered unnecessary any reference to an obscure poison. Excessive moisture, sudden changes of temperature, and lack of oxygen were the factors which explained all the effects. Without ignoring the organic matter present, Benu considered it too small in amount to cause any trouble, and he found no proof of a specific poison.

Thus far all the control experiments had been with animals, but Haldane and Smith¹⁰ now made a valuable contribution to general knowledge in the record of investigations made with human subjects. They constructed an air-tight chamber in which the subject remained from seven to twelve hours at four different times. In the first two experiments the CO_2 increased from the normal to 5.8 per cent. and 6.39 per cent. In the second two the CO_2 was absorbed and reached only 0.6 and 1.4 per cent. General discomfort, quickened respiration and a headache on coming out were the symptoms experienced by the subject in the first two; in the last two only the slightest discomfort. In no case was an odor perceptible in the chamber at the close of the experiment, though it had been occupied for hours.

In order to estimate the relative part played by excessive CO_2 and insufficient O, another series of tests was made which showed that the diminution of O had comparatively little effect, since hyperpnoea began when the CO_2 reached about 5 per cent. whether the amount of O was greater or less than the normal.

The conclusions which the authors draw are of interest:

1. "The immediate dangers from breathing air highly vitiated by respiration arise entirely from the excess of carbonic acid and the deficiency of oxygen, and not from any specific poison.

2. "The hyperpnoea is due to excess of CO_2 and is not apparently affected by the corresponding deficiency of O. The hyperpnoea begins to appear when the CO_2 rises from 3 per cent. to 4 per cent. At about 10 per cent. there is extreme distress.

3. "Excess of CO_2 is likewise the cause, or at least one cause of the frontal headache produced by highly vitiated air.

4. "Hyperpnoea from defect of O begins to be appreciable when the O in the air breathed has fallen to a point which seems to differ in different individuals. In the case of one of ourselves the hyperpnoea became appreciable at about 12 per cent. and excessive at about 6 per cent."

In a later experiment¹¹ the same observers repeated the ventilation tests of Merkel, but only to conclude that "these experiments are distinctly against the theory that a volatile poison, other than carbonic acid, exists in expired air."

The amount of CO_2 was larger than that found by Merkel, and the presence of an absorption tube produced no effect; that is, there was no union of the acid with the hypothetical base.

The latest testimony on the subject of a volatile poison is presented by Rauer,¹² who, at the suggestion of Professor Flügge, undertook to repeat the work of Brown-Séguard and d'Arsonval with the most careful exclusion of all possible sources of error. Like Haldane and Smith, he found that the CO_2 in the cages was far in excess of that reported by Brown-Séguard, a fact which throws suspicion upon the latter's air-pump or tubing. He also failed to agree with the latter as to the effects of H_2SO_4 . The absorption tube was no protection to the animal whose air supply came through it. Furthermore, the rapid recovery of the animals when the experiment was stopped was very different from the behavior of those poisoned by any known alkaloid. On the other hand, all the symptoms were those of carbonic acid poisoning, and direct proof that death was caused only by the CO_2 is afforded by the fact that when an animal breathed through a tube containing KOH, which removed the CO_2 , it continued perfectly well.

Finally, the amount of organic matter present in expired air corresponds so closely to that in atmospheric air that it can not be looked upon as of any appreciable importance, even if a slight excess exists.

In this work of Rauer, we have the last reported investigations of the question under discussion. Taking these in connection with the conclusions reached by Benu and the many other observers who sought to verify Brown-Séguard's results, we may confidently affirm a final judgment on one point—the theory that there is a volatile organic poison in expired air is ruled out of court; it will not be questioned again in the face of such overwhelming denial. But the problem still remains, What is the poisonous property in badly ventilated rooms which renders the air dangerous?

There is general agreement among investigators that until the amount of CO_2 rises to 3 per cent. or 4 per cent. no harm results. But the worst ventilated rooms show less than 1 per cent., therefore it can not be responsible for those phenomena of crowded rooms which are commonly ascribed to bad air. Whether long continued exposure to air containing an excess

¹¹ Jour. of Pathol. and Bact., February, 1893.

¹² Zeitschr. f. Hygiene u. Inf., Bd. XI, Heft. I.

¹⁰ Jour. of Path. and Bact., October, 1892.

of CO₂ above the normal, even if it be below the danger limit, affects in any way physical well-being, is a question too elusive to be easily answered, if indeed it admits of an empirical answer.

The suggestions which have been recently made regarding the cause of the phenomena in question tend toward the view that no single cause, but rather a combination of causes is to be expected, and that these may possibly be related to the physical condition of the air quite as much as to its chemic composition.

In a crowded, ill-ventilated room, several abnormal factors are to be noticed. Aside from the excess of carbonic dioxid, there is an increase of moisture, a very considerable rise of temperature, and, very often, unpleasant odors, some of them due to bodily uncleanness. All of these must receive consideration in the further study of the practical problem, and be weighed both alone and in combination.

The difficulties in the way of these complicated experiments, increased as they must be by attention to the subjective element, the nervous strain felt by sensitive persons in a crowd, are so many that no complete solution of the question can be looked for in the immediate future. We may, however, hope to learn something definite about the effects of temperature and cleanliness, factors which have a very direct bearing upon the efficiency of all systems of ventilation.

Two recent series of investigations on subjects allied to the one discussed above contain some interesting suggestions. In the *Centralblatt für Bakteriologie*, February, 1894, Alessi reports certain experiments which he has made on sewer gas as a predisposing cause of typhoid infection. He found that the animals which breathed sewer air, a mixture of various gases, were rendered peculiarly susceptible to infection, but that no one of the gases taken alone produced any effect, nor, most significant of all, did an artificial mixture of the more familiar gases of decomposition such as H₂S, CH₄, NH₃, etc. He apparently failed in some way to reproduce all the elements of natural "sewer gas."

Geilmuyden, (*Arch. f. Hygiene*, Bd. XXI, Hft. 11) who studied the products of illuminating gas, asserts that the poisonous properties of air in crowded rooms are certain, but that chemically they can not be shown or determined.

By a study of animals he reached the same conclusion that Haldane and Smith, Hermans and others had reached, that CO₂ is not dangerous until it amounts to 3 per cent. or 4 per cent. Illuminating gas increased the CO₂ in well-ventilated rooms 0.2 per cent. to 0.3 per cent.; in badly ventilated rooms 0.6 per cent. to 0.7 per cent. The gas increases the moisture slightly, the temperature very considerably. And the latter part he regards as a very significant one in considering the injurious influence of the air.

SOCIETY PROCEEDINGS.

Association of American Medical Colleges.

Sixth Annual Meeting, held at the Club House of the Hotel Rennert, Baltimore.

(Continued from page 1014.)

It is my opinion that medical jurisprudence should be taught during the third or fourth years of the four years' course. It should be a compulsory study, including at least

thirty-two hours of time. The instruction can best be afforded in lectures and recitations. It should not include toxicology, except from a legal standpoint. A few hours can, with profit, be spent in the laboratory in a study of blood in its medico-legal aspects. I would suggest that instruction include work in the following topics in the subjoined order:

HISTORY OF MEDICAL JURISPRUDENCE.

Legal procedure, the coroner's jury; the justice or municipal courts; the grand jury; the trial court; the court of review or supreme court.

Evidence, witness of fact; witness of opinion or expert; dying declarations.

Phenomena and signs of death; molecular death; somatic death; causes of death; signs of death; medico-legal investigations in cases of death; the post-mortem etc.

Presumption of death; presumption of survivorship; personal identity; the causes producing violent death; examination of blood stains; burns and scalds.

Death in different forms of asphyxia; from suffocation; from strangulation; from hanging; from drowning.

Death by lightning; death from heat and cold; death by starvation; death from poisoning; toxicology.

Toxicology from a medico-legal standpoint; malingering; pregnancy; criminal abortion.

Infanticide; legitimacy; inheritance; rape; insanity; medical malpractice; civil malpractice; life insurance.

DR. N. S. DAVIS, Dean and Professor of the Practice of Medicine Chicago Medical College, presented the subject of

THE HISTORY OF MEDICINE AND MEDICAL ETHICS.

The importance of a more systematic study of the history of medicine and its relations to all other coincident branches of human learning through the past centuries, is well illustrated by the following saying of Hippocrates: "The physician must know what his predecessors have known, if he does not wish to deceive both himself and others."

Having delivered a course of lectures to the senior class in the Northwestern University Medical School, each of the last three years, on the history of medicine and medical ethics, I am more than ever before convinced that the subjects named are of so much importance that they should be placed in the curriculum of a medical school. They should be taught with a reasonable degree of thoroughness. Guided by my own experience, I am induced to think that a fair discussion of the origin, progress and more important events pertaining to the history of medicine can not be given in less than fifteen or sixteen lectures or lessons of one hour each.

SYLLABUS OF WORK.

Lecture 1. All the earliest historical and mythological data prior to, and at the time of Hippocrates; between the fourth and fifth centuries, B. C.

Lecture 2. The characteristics of Hippocrates and his works, and their relations to co-existing systems of philosophy and religion.

Lecture 3. The progress of medicine from the death of Hippocrates to the establishment of the Grecian or Alexandrian School and Library, to the overthrow 100 B. C.

Lecture 4. The effects of the Roman conquests, and the transference of medical institutions to Rome and their progress to the time of Galen about 200 A. D.

Lecture 5. Medical progress from the death of Galen to the overthrow of the Roman empire; the establishment of Arabian medical schools, to the return of medicine with the Saracens to Europe, covering a period of ten or twelve centuries.

Lecture 6. The reestablishment of medical schools at Salerno, Bologna, and other points in Europe, from the thirteenth century to the end of the fifteenth century, during which chemistry and anatomy became distinct branches of science, and the arts of printing is discovered.

Lecture 7. Progress of medicine during the sixteenth and seventeenth centuries, with the influence upon it of the thirty years of religious wars.

Lecture 8. Progress during the eighteenth century—the era of medical theories and dogmas, as well as of scientific discussions.

Lecture 9. The important discoveries and progress during the first half of the nineteenth century.

Lecture 10. The condition and progress of medicine and medical institutions in the American colonies from their settlement to the close of the War of Independence.

Lecture 11. The progress of medicine and of medical institutions in the United States.

Lecture 12. Progress in the development of minute anat-

omy, pathology, etiology and experimental therapeutics, closing the second half of the nineteenth century, and its relation to coincident progress in the other departments of science.

Lecture 13. The important discoveries and their application in all practical departments of medicine, during second half of the nineteenth century.

Lecture 14. The present status of the science and art of medicine and surgery, the effect of its segregation into specialties, and the principles that should guide our efforts for future progress.

Lecture 15. A candid statement of the origin and distinctive characteristic features and claims of homeopathy, Thompsonianism, eclecticism, physio-medicalism, etc., which still remain as an eighteenth century excrement or dogmas in the domain of medicine.

In presenting a fair discussion of medical ethics, I have found it necessary to give four lectures, to-wit:

Lecture 1. The origin of medical ethics, including the Hippocratic oath, the volumes by Thomas Percival in 1803, and the framing of the American Code by the National Medical Convention in 1846 and 1847.

Lecture 2. The adoption of the American Code by the AMERICAN MEDICAL ASSOCIATION and nearly all the State medical societies. The duties of the physician to his patient and of the patient to the physician.

Lecture 3. The Code as applied to the relations existing between physicians and to the profession at large.

Lecture 4. The Code, defining the duties of the physician to the public and of the public to the profession, with the explanatory preamble and resolutions appended thereto, with such comments may be deemed proper.

The most appropriate place in the medical course of study is the fourth year, and certainly not earlier than the third year; as the more advanced the student is in the current medicine of the day, the better he will appreciate all that relates to its past history; and the more certainly it will guard him against entertaining extravagant ideas of the importance and permanence of the popular doctrines and practices in which he is being educated.

We would recommend as the minimum amount of work for four years, courses to consist of eight months each as follows:

For the third year men, thirty recitations, twenty didactic lectures, ten practical lessons in physical diagnosis, and three review examinations.

For the Seniors (that is for the fourth year men) we recommend thirty recitations, twenty didactic lectures, ten lessons in practical physical diagnosis, thirty clinical lectures, and three review examinations. Although we have recommended this as a minimum, we think it would be a fair average. There would be no objection to adding a few more hours if other subjects permitted.

The work of the Juniors should comprise recitations on physical diagnosis, and on all of the common diseases of the heart and lungs, and didactic lectures on the more important diseases of the thorax.

The work of the Seniors should comprise recitations on practically all of the diseases of the thorax, except those of very rare occurrence, with didactic lectures on all of the principal diseases, and clinical lectures on such cases as might be presented. Practical physical diagnosis would necessarily have to be much the same for the two classes, but the Juniors should study thoroughly the normal chest. By this arrangement all subjects are gone over twice in one way or another, and we believe it necessary that they should be so considered, in order to fit the men for work as general physicians. We have not specified the particular diseases, thinking it would require more space than you would care to devote to this branch, but we will do so if it is your desire. Respectfully submitted,

E. FLETCHER INGALS,
Chairman Rush Medical College.

DR. HENRY P. BOWDITCH, Professor of Physiology at Harvard Medical College, said, on the subject of

PHYSIOLOGY.

I feel much hesitation in undertaking the work you have asked me to perform; since no one person can have an adequate idea of the conditions under which medical instruction is taught in various medical schools of the country. An ideal course of instruction should be arranged so as to bring the instruction in physiology subsequent to that of anatomy; but this is rarely, if ever, possible, owing to the small number of subjects which can be properly taught the first year.

With regard to this, the fifth point in your circular letter, I would say that, in my opinion, it would be unwise to make any general rule to regulate the practice of medical schools with regard to giving credit for work done in other schools. Each school should judge of this for itself. It seems that the object of this committee will be secured if the aid of various national societies of specialists is invoked. The preparation of a syllabus of lectures in physiology, for instance, could be intrusted to a committee of the American Physiological Society, and if indorsed by the society would command the confidence of the various medical faculties of the country. A result would be reached more slowly by this way but it would, I think, be worth waiting for.

DR. ROSWELL PARK, of New York, discussed the subject of

BACTERIOLOGY.

Basing the following plan upon a four years' course of not less than eight months each, my suggestion would be as follows: I think that bacteriology ought to be taught in a way differing from that in which it is at present generally taught, and I would divide the subject in accordance with these views. During the first year, when the men are doing their preliminary work on the fundamental studies—at the time, in other words, when they are studying anatomy, physiology and biology, which I assume they are also to be taught—I would have systematic instruction in cryptogamic botany, devoted in a large measure to morphology and the classification of the various forms of vegetable life, with which they will later have to become more familiar as disease germs. This instruction at such time would be essentially didactic, with illustration by diagrams and, if possible, by a certain amount of acquaintance with the appearance of these minute forms of life through the microscope. This didactic instruction should be partly by the way of lectures, partly by way of recitation, and might profitably consume eight or ten hours of actual work. Incidentally, I would put in also instruction upon the lowest forms of animal life—the sporozoa, etc. This might possibly be done before they take up the other forms of animal life which are parasitic, that is, the entozoa.

During the second year, or at such time as the men are taught organic chemistry, and along with the study of the alkaloids, or in appropriate places, I would have instruction inserted, concerning the ptomaines and other poisonous alkaloids which are the products of bacterial life; and, again, when they are dealing with the albuminoids, I would insert so much as can be taught with any definiteness about the albuminoid poisons of the same origin. This would require a careful arrangement of these and their insertion at proper points, with a reference backward to morphologic studies and a strong impetus forward in the direction of a practical application of what they have learned during these two years, which should come in during the fourth year in the way of laboratory investigation.

I am taking it for granted that teachers in the various departments who have to deal with infectious diseases would make, now and again, the statement that such and such a disease is due to such and such an organism, and would give such demonstration of this as they might see fit. This would be both an illustration of the importance of remembering the isolated facts already gathered, and would serve to keep the student alive to the importance of such knowledge.

It would be difficult to assign a definite number of hours to this work in organic chemistry *in toto*. I should say that at least three or four hours ought to be devoted to this particular part of the work during the season's instruction in chemistry, perhaps more.

Finally, during the fourth year, I would have courses of practical instruction in a bacteriologic laboratory, arranged to last at least six weeks, preferably eight, during which at least three hours of continuous work should be devoted to this each day, this to be like laboratory instruction in other respects. The men should be taught to make the culture media, and to go through all the various manipulations which are included in the study of bacteriology. They should be taught to differentiate between different forms, and to recognize pathogenic organisms; and at least a certain amount of work upon living animals should also be insisted upon. They should also be taught the use of the microscope in the recognition of bacteria and their differentiation, as well as their detection in various morbid products—sputum, urine, etc.

It seems to me that in this way, men would go out from college, not experts, but intelligent scholars, having already in their possession the knowledge which would incite them to further study, or at least make them intelligent readers and students.

First year. Instruction in cryptogamic botany and morphology.

Second year. Instruction in the chemistry of the bacterial products.

Fourth year. Laboratory exercises and instruction in the cultivation and detection of the bacteria, and methods of experimental study.

DR. HOWARD KELLY, Johns Hopkins Hospital, said, on the subject of

GYNECOLOGY.

(One hundred hours.)

1. Gynecology is a specialty and not one of the fundamental branches. If it is to be mastered, this must be done by post-graduate study. The time recommended is sufficient to give a general practical knowledge, but not to fit a man to perform any important operations. This time should be divided about as follows: Didactic lectures, thirty hours; clinical instruction, thirty hours; touch course, fifteen hours; pathologic laboratory demonstrations from recent specimens, fifteen hours; recitations, ten hours. One hundred hours in all.

2. These lectures should be arranged as follows: Topographical anatomy, two; gynecologic examination, two; diseases of external genitals and operations, eight; diseases of urinary system, four; diseases of uterus, tubes and ovaries, general principles of gynecologic operations, after-treatment of abdominal cases, fourteen. Total, thirty.

3. This branch should be given the last year with other special branches.

4. No special preliminary studies are necessary, except such as are naturally included in a well-arranged course with thorough teaching in anatomy and pathology.

5. I consider an examination the only proper method of admitting men to advanced standing. If the standard is high, this is but fair to the other students.

7. Topographical anatomy, two lectures. General principles of gynecologic operations, two lectures.

Touch course of ten hours. Examination of normal pelvic organs: vulva, vagina, uterus, tubes, ovaries, broad ligaments, urethra, bladder, ureters, anus, rectum, sigmoid flexure. Two lectures; fifteen hours practice.

Minor gynecology and diseases of vulva, vagina and cervix: inflammatory, neoplasms, cysts, lacerations, fistulae. Eight lectures.

Diseases of urethra, bladder and ureters: inflammatory, strictures, fistulae, calculi, neoplasms, cysts. Four lectures; four hours clinical instruction.

Diseases of uterus, tubes, ovaries and broad ligaments: inflammatory, neoplasms, cysts. Ten lectures.

After-treatment of abdominal cases. Two lectures.

NOTE.—Clinical instruction will have to be given to the class as the material is available.

1. For satisfactory gynecologic teaching, the class should be divided into small sections of five and ten.

2. Not more than five should be admitted to a touch course at one time.

3. In didactic teaching, the whole class should be united.

4. It is important, as far as practicable, to establish the plan of teaching several minor gynecologic operations upon the cadaver.

Order of instruction: one didactic lecture weekly, thirty hours. Demonstrations from recent specimens in pathologic laboratory, one hour every second week, fifteen hours. (Touch course to class by sections throughout term, fifteen hours each.) Recitations, one hour every third week, ten hours. Clinical instruction, one hour weekly, thirty hours. Total, eighty-five hours. Adding touch course, fifteen hours; total, one hundred hours.

PROFESSOR VICTOR C. VAUGHAN, of the University of Michigan, presented a

SYLLABUS OF LECTURES ON HYGIENE—NOT INCLUDING BACTERIOLOGY.

(Seventy-eight hours.)

Part I.—Individual Hygiene.

Lecture 1.—Food, definition, classification.

Lecture 2.—Force value of foods. Cyclical changes in matter, actual and potential energy. Foods for plants. How plants obtain their carbon, hydrogen, oxygen, nitrogen, phosphorus and sulphur.

Lecture 2.—Food principles; water, inorganic salts, proteids, carbohydrates and fats. The amount of each food principle required by healthy persons daily.

Lecture 4.—The economic value of foods. The percentage composition of the most important foods.

Lecture 5.—The construction of diet tables for the healthy. Rations for prisoners, for workingmen, for students.

Lecture 6.—Meats. General statements concerning the use of meats as foods. Is man suited to an exclusive vegetable diet? This question is answered from the anatomic, physiologic, chemic and experimental data known.

Lecture 7.—Meats (continued). General rules which should govern the selection of meats. Digestibility and food value of meats from different animals. Influence of season, of previous feeding, of age, of exercise just before death, and of methods of slaughtering and dressing on the food values of meats.

Lecture 8.—Meats (continued). The transmission of animal parasites to man in meats. Trichinae, echinococci, teniae.

Lecture 9.—Meats (continued). The transmission of bacterial diseases to man through the flesh of diseased animals. Anthrax, tuberculosis, foot-and-mouth disease, etc.

Lecture 10.—The inspection of animals before slaughtering. The hygiene of slaughtering houses.

Lecture 11.—Meats infected with non-specific toxicogenic germs. Historical review of cases of mass poisoning of this kind.

Lecture 12.—The examination of meats suspected of producing untoward effects. Chemic and bacteriologic examination.

Lecture 13.—Milk. Its physical and chemic properties. Adulterations. Detection of adulterations.

Lecture 14.—Milk (continued). Comparison of woman's and cow's milk. Changes in cow's milk to make it correspond more closely with that of woman. Infants' foods.

Lecture 15.—Milk (continued). A vehicle for the spread of tuberculosis, typhoid fever and other diseases.

Lecture 16.—The relation of infected milk to the summer diarrheas of infancy. The formation of poisonous ptomaines and proteids in milk.

Lecture 17.—Rules to govern the dairy farm, milking, the cooling and transportation of milk.

Lecture 18.—Sterilization and Pasteurization of milk.

Lecture 19.—Butter. Its food value. Methods of preparation. Influence of bacteria in the production of butter. Adulterations and methods of detecting the same.

Lecture 20.—Cheese. Methods of preparation. Action of rennet. Action of bacteria. Hygiene of the factory and curing room. Adulterations and methods of detecting the same.

Lecture 21.—Varieties of cheese. Food value. Cheese poisons.

Lecture 22.—The starches and starchy foods. Their value. Their digestibility. Effects of excess of starchy foods. Digestion of cellulose. Fermentation in the intestines.

Lecture 23.—Sugars and syrups. Kinds of sugar. Distinctions. Commercial methods of preparation. Confectionery. Adulterations of sugars, syrups and confectionery.

Lecture 24.—The cereals. Their food value. Varieties. Wheat, rye, barley, corn, etc. Methods of conversion into foods. Ergotism. Maidismus, lathyrismus, tayopyrismus.

Lecture 25.—Flours and meals. Tests of the bread-making value of flours. Food value. Estimation of gluten contents. Food values of flours and meals.

Lecture 26.—Bread. Methods of making. The leavening of bread, with yeast, with baking powder, with compressed air and other gases. Adulterations of bread. Impure yeast. Adulterated baking powders. The use of coloring matters in cakes. Short weight loaves.

Lecture 27.—Fresh fruits and vegetables. Their food value. Scurvy, its history in the past, its occurrence at present and its prevention.

Lecture 28.—Dried and preserved fruits. Their preparation. Adulterations. Poisoning from canned vegetables and fruits. Jellies and their adulterations.

Lecture 29.—Condiments. The extent to which salt should be used in food. The use of pepper, mustard and spices. Their adulterations.

Lecture 30.—Non-alcoholic beverages. Coffee, tea, maté, cocoa, chocolate, etc. Their food value. Their stimulating effects. Active principles. Physiologic and toxicologic effects. Adulterations.

Lecture 31.—Alcoholic beverages. Fermented and distilled; cider, wine, beer, porter, brandy, whisky, rum, gin, liquors, etc. Percentage of alcohol. Other constituents. Food values. Adulterations.

Lecture 32.—Alcoholic beverages (continued). The physiologic and pathologic effects of alcohol. Its effects on digestion, the circulation, nervous system, etc. Its use in health and disease.

Lecture 33.—Baths and bathing. The necessity of frequent bathing. Excretion through the skin. The temperature of baths. The morning bath. The shower bath and cold plunge. The warm bath. Mineral baths. Sun bathing. Swimming as a means of exercise. The resuscitation of the apparently drowned.

Lecture 34.—Clothing. Fibers used in the manufacture of clothing. Silk, wool, cotton, flax, hemp and jute. The properties of each. Their durability and adaptability. Influence of season on clothing; color. The use of fur, leather and rubber as articles of clothing.

Lecture 35.—The adjustment of clothing. Advice to patients in regard to their clothing in various diseases, such as Bright's disease and tuberculosis.

Lecture 36.—Physical exercise. Its value. Pulmonary and systemic respiration. Oxygen in the blood is physiologically still outside of the body. It must be carried into the tissues and this can be done only by activity of the tissue. Kinds of exercise. Conditions necessary to make it of value.

Lecture 37.—Mental hygiene. Activity necessary to brain development. Mental work does not kill, worry may. Train the judgment. Take some line of work and make yourself master of every detail. Study must be begun early in life. One who takes up a new line of work after 40 is likely to make a failure of it. Methods of study. Hours of study.

Lecture 38.—Rest. Recreation. Physical rest. Mental rest. Change in work. Evidences of need of rest. Rest in sleep, in recreation and in work.

Part II—The Hygiene of the Family.

Lecture 39.—Healthful homes. The selection of a site. The nature of the soil and the surroundings. The construction of the cellar, the walls, the decorations of the walls, floors, carpets and rugs, doors, windows, etc.

Lecture 40.—The arrangement of the rooms. The living, sleeping and dining rooms. The pantry and kitchen. Closets, bath room, etc.

Lecture 41.—The heating and ventilation of residences. Heating with open fire, stove, hot air, steam and hot water. The inlets for fresh air and outlets for the foul. Patent systems of ventilating houses. Simple methods.

Lecture 42.—The disposal of excreta and garbage in villages and country places. Privy vaults, dry earth closets, cesspools. The disposal of kitchen waste. Private water supplies.

Part III—School Hygiene.

Lecture 43.—Location of the building. Hill and stair climbing good exercise. The size of rooms. Air space per student. Cloak rooms. Study and recitation rooms. Lighting, heating, ventilating, blackboards, etc.

Lecture 44.—School age. The kindergarten and its methods. The study of language and mathematics. Hours of study in school and at home. Methods of study and of teaching. The influence of school life on growth and health.

Lecture 45.—The diseases of school life. Myopia and various forms of nervous disturbance. The duties of teacher, parent and health officer when epidemics appear in schools. Disinfection of school rooms.

Part IV—Industrial Hygiene.

Lecture 46.—Diseases due to the inhalation of dust. Bronchial catarrh. Pulmonary emphysema. Bronchiectasia. Deposition in the lungs of coal dust, of finely pulverized metals, of sand, tobacco dust, etc. Influence of an atmosphere filled with dust on the digestive organs. Statistics.

Lecture 47.—Diseases most frequently observed among those who work in cotton, wool, silk, hair and feather manufactories. Among those working in glass factories, in ultramarine, etc. General rules for the protection of workmen against dust inhalation.

Lecture 48.—Diseases common among those who work with poisons. Diseases of the respiratory organs. Diseases of the abdominal viscera. Phosphorus, arsenic, lead, zinc, mercury and antimony poisoning.

Lecture 49.—Working with organic poisons. Cyanogen compounds. Anilin and its derivatives. Carbolic acid. Poisonous plants. Animal poisons. General rules for the protection of these working men.

Lecture 50.—Special diseases of the skin as influenced by occupation, of the circulatory organs, of the muscles, bones, joints, of the nervous system, of the organs of special sense.

Lecture 51.—Injuries common in certain occupations. Mechanical and chemical injuries. First help to the injured. General rules for the special protection of parts of the body exposed to danger.

Part V—Municipal Hygiene.

Lecture 52.—Water supply. Sources. Cistern, surface and subterranean waters. The pollution of streams and lakes. The self-purification of rivers. The artificial purification of water; by subsidence, by precipitation, by filtration.

Lecture 53.—Waterborne diseases. Typhoid fever, cholera, dysentery.

Lecture 54.—The chemie examination of drinking water. The determination of sodium chlorid, free and albuminoid ammonia, nitrates and nitrites. The value of chemie analyses.

Lecture 55.—The microscopic and bacteriologic examination of drinking water. Objects found by microscopic examination. Methods of bacteriologic study. Counting the number of germs. Determining the toxicogenic properties of the germs.

Lecture 56.—Sewers. The single and double systems. The house connections. Traps, ventilating pipes, etc.

Lecture 57.—The disposal of sewage. Discharge into bodies of water. Sewer farms. The purification of sewage.

Lecture 58.—The disposal of garbage. Dumping into water. Burying. Burning. The utilization of garbage.

Lecture 59.—Streets, pavements, parks, public baths. The sanitation of tenements, lodging houses, places of amusement, etc. The sanitary inspection of buildings.

Lecture 60.—Sanitary supervision of the markets. Meat and milk inspection. The detection of gross adulterations.

Lecture 61.—The duties of the municipal health authorities. The notification of infectious diseases. Isolation. Disinfection. Sanitary police regulations.

Part VI—State Hygiene.

Lecture 62.—State sanitary service. State Boards of Health. Plans of organization. Duties. Relations to local and city boards. Comity between State and provincial boards. Inter-State notification of diseases dangerous to the public health.

Lecture 63.—The State Board of Health as an executive body, as an advisory board, and as a promoter of scientific investigations.

Lecture 64.—A State sanitary inspector, his duties and responsibilities. His relation to the Board of Health. A State analyst. The duties of such an officer.

Lecture 65.—The sanitary laws of different States. The means provided for their enforcement, etc.

Part VII—National Hygiene.

Lecture 66.—The National Health Service. Has our country any such service? What should be done in this direction by our government? History of national sanitary legislation in this country? In other countries?

Lecture 67.—What means are now used to protect against the importation of disease from other countries? Quarantine, disinfection, inspection. What should be done? Should the national government undertake scientific sanitary investigations?

Part VIII—The Influence of Climate on Health.

Lecture 68.—What is meant by climate? Comparison of climatic and local conditions? The geographical distribution of tuberculosis and the lessons to be learned therefrom?

Lecture 69.—The geographical distribution of diphtheria, scarlet fever and measles.

Lecture 70.—The geographical distribution of influenza, yellow fever, dengue and malaria.

Lecture 71.—The geographical distribution of typhoid, typhus, plague; etc. Lessons to be learned from these facts.

Part IX—The Hygiene of the Sick Room.

Lecture 72.—The prevention of the spread of the infectious diseases in private practice. The selection of the sick room. Its furniture. The nurse. Isolation of the sick. What must the physician do to prevent his carrying the disease to others?

Lecture 73.—Hospitals. Their location, construction, heating, ventilation, management, etc.

Lecture 74.—Contagious disease hospitals. Hospitals and sanitarium for special diseases, as smallpox, diphtheria, tuberculosis, etc.

Part X—Immunity.

Lecture 75.—Natural and acquired immunity. How is immunity secured? Vaccination; history and statistics.

Lecture 76.—Vaccination against anthrax, chicken cholera, swine plague, etc. Immunity secured by the chemie products of germs.

Part XI—Miscellaneous.

Lecture 77.—Military hygiene. The soldier. His clothing and food. The camp. Barracks. Hospitals, etc.

Lecture 78.—Marine hygiene. The ship. Its construction and ventilation. The food and clothing of sailors. The diseases and accidents to which they are specially liable.

Lecture 79.—The disposal of the dead.

DR. H. GRADLE, of Chicago, presented a paper on

OTOLOGY.

After comparison of the courses in otology in American and foreign medical schools, the undersigned would recommend as the minimum requirement: the daily attendance in small classes at a well-organized ear clinic or dispensary, where the students can closely examine the patients for a period of at least four weeks—or what amounts to the same thing, the distribution of the twenty-four clinical hours throughout a whole semester, and either in connection with this clinic or separately, a course of at least eight systematic lectures on diseases of the ear. The only conclusive evidence that a student has not merely attended this course, but profited by it, is his ability to examine clinically and interpret correctly when put in front of new patients.

Otology should not be taught before the third year, and it would seem more logical to have it follow the training in general medicine and surgery. It would be well to have otology follow a course in rhinology.

If the various colleges belonging to the Association agree on a standard of minimum requirements in any one branch, there is no good reason why a student who presents evidence that he has passed in this branch in an equivalent medical school should not get credit for his work. But if he comes from an institution which has not adopted the same standard, justice would require a re-examination. In otology, as well as in any other branch of clinical medicine, a practical test of the student's ability to form a diagnosis and prognosis, when placed before a series of patients, is a much more correct mode of gauging his knowledge than a theoretical examination.

DR. EDWARD L. HOLMES presented the report of the sub-committee on

OPHTHALMOLOGY.

This committee presents a syllabus of minimum instruction in ophthalmology, which it believes every medical college should provide for its students. It does not suggest, much less advocate, a course for the education of students in college as specialists; simply that they should study with care fundamental principles; that those, especially, who began practice in small towns and villages, may skillfully examine and treat the ordinary diseases and injuries of the eye in patients who are utterly dependent upon them for aid; that they may, without dangerous delay, advise intelligently, patients when to seek the skill of the specialist; that they may comprehend the structure and use of common optical instruments and appliances, and, finally, that they may be able to pursue advantageously after graduation this special study if they choose.

I.

During the last four months of the second year, one lesson a week should be devoted to demonstrations of the following subjects, in classes of not more than thirty students, under the direction of instructors in properly equipped laboratories.

1. The anatomy of all the tissues by means of human eyes and the eyes of animals, at least one eye being provided for each five students, and by means of microscopic preparations.

2. The physiology of each structure.

3. In the laboratory of medical physics, a study with appropriate apparatus of the primary principles of optics.

4. Reflection of light from plain, convex, concave surfaces, with a sufficient number of small mirrors for each student to perform all necessary experiments.

5. Refraction of light by media with parallel, plain, curved surfaces; by prisms and by convex and concave lenses, each five students being furnished with lenses and a small camera, filled with smoke, that he may make his own demonstrations.

Every student should be strictly required to study approved books in connection with the laboratory exercises, and be subjected to thorough examinations.

II.

For the fourth year

1. One clinic a week through the year.

2. Sixteen didactic lectures, chiefly on the following topics: The cornea, the conjunctiva, the uveal tract, the optic nerve and retina, the lens, the lacrymal apparatus, the muscles, the lids, the orbit, with special emphasis upon purulent conjunc-

titis, glaucoma, iritis, sympathetic ophthalmitis and myopia.

3. Review of the laboratory work of the second year in the reflection and refraction of light.

4. Fifteen hours devoted to practice in the use of the ophthalmoscope, with suitable artificial eyes; emmetropic, hypermetropic and myopic, with the eyes of patients and of the students themselves.

5. Examination by focal illumination.

6. Fitting glasses, tests for color perception and tests for malingering.

7. Study of gross pathologic specimens.

8. Although the class may have passed the general examinations in materia medica and therapeutics, students should be required to study in review, at least, the following list of remedies and to write upon the blackboard at the clinics and other exercises, prescriptions in proper form for diseases of the eye.

Four mydriatics: coca, boron, silver, copper. Two myotics: mercury, zinc.

In the opinion of this committee, no student in college should be exempt from the above courses, even if he shall have taken them previously in another college.

It will be observed that, in accordance with this syllabus, the number of purely didactic lectures is reduced to a minimum, and that the teaching is in a great measure by "manual training." With this kind of individual training, and with ample clinical observation, the study of a suitable book and regular recitations from it become a most important mode of instruction. By recitations, the student gains knowledge and retains it. Unfortunately, no book has been written which is fully adapted to the requirements of this syllabus.

It is assured in this report that the college curriculum extends through four years, with a term of study each year of eight months.

Kentucky State Medical Society.

Abstract of the Proceedings of the Fortieth Annual Meeting, held at Harrodsburg, June 12, 13 and 14, 1895.

(Continued from page 1016.)

DR. FRANK C. WILSON, of Louisville, read a paper entitled THE DANGERS OF CHLOROFORM ANESTHESIA, HOW TO AVOID AND OVERCOME THEM.

The frequent occurrence of death during the administration of anesthetics forcibly impressed upon us the dangers incurred and the importance of a careful review of the subject. Dangers may arise: 1, from impurity in the anesthetic used; 2, from administering it to improper subjects, or to those not properly prepared; 3, from administering it in an improper manner; 4, if accidents occur, the danger will be vastly increased by a failure to detect the earliest indications and to properly institute measures of resuscitation; 5, danger is increased in proportion to the prolongation of anesthesia. As by far the greater number of deaths occur from the administration of chloroform, the author directed most of his attention to a consideration of the dangers incident to its use. Every patient should be carefully examined. The condition of the heart and lungs known, and that of the kidneys ascertained by a test of the urine. Simple uncomplicated disease of the heart does not necessarily preclude the use of chloroform, but ether is safer unless there be present bronchial inflammation, or disease of the kidneys. If there be found affections of the brain, chloroform is best. In the use of chloroform with the cone and with many of the inhalers it is impossible to estimate the amount of chloroform the patient actually inhales. It is not the amount of chloroform which has been poured upon the cone, but the quantity which has passed into the circulation which is the vital question. In order to obviate this difficulty the author has adopted a plan of vaporizing the anesthetic from an atomizer, the bottle being so graduated as to indicate, at a glance, exactly how much is being used. As chloroform is drawn into the inhaler or cone none is wasted, but all passes directly to the lungs and there can be no uncertainty as to the amount used. The author then dwelt upon the means of resuscitation when needed.

DR. J. H. BAUGHMAN, of Flat Lick, read a paper entitled "A Few Crumbs about Typhoid Fever."

Adjourned until 8 P.M.

SECOND DAY—EVENING SESSION.

The Society reassembled at 8 P.M. at the Harrodsburg Opera House, and was called to order by DR. J. N. BAUGHMAN, Second Vice-President.

DR. A. W. HITT, of Louisville, gave a lecture on "Leprosy," which was illustrated by means of the stereopticon. He stated that we were indebted to the Bible for the earliest reports of this disease. The popular belief that leprosy is a disease limited to the lower classes is not true. The author cited cases of kings and other members of the nobility who were afflicted with and died of the disease. There are 19,000 leper islands in all England; in France 2,000. These leper islands represented millions of cases of the disease. There were 522 cases of leprosy in the United States. One-tenth of the population of the Sandwich Islands had leprosy. The author then considered the anesthetic and tubercular forms of the disease.

DR. LYMAN BEECHER TODD, of Lexington, was introduced, and delivered an eloquent, yet touching and impressive address entitled "A Generation of Kentucky Physicians—A Reminiscence." He graphically portrayed the great work that had been done by Gross, McDowell and others and paid eloquent tributes to them. He said the Kentuckians cherished their names and highly appreciated their contributions to medicine and surgery—contributions that were preserved in libraries and considered a precious inheritance. They were the shining stars of the medical firmament, and had practiced medicine and surgery so skillfully and successfully in small towns and hamlets that it made the past generation of Kentucky physicians worthy of remembrance and emulation.

DR. DUDLEY S. REYNOLDS, of Louisville, followed Dr. Todd with an address entitled "The Ethics of the Medical Profession." This address was listened to with marked attention throughout its delivery. Among the various points brought out was this: that ethics must belong to the educated classes. It aims to establish the right conduct with respect to doctors themselves, and of their patients. He then alluded to the organization of the AMERICAN MEDICAL ASSOCIATION and its Code of Ethics, saying that the Kentucky State Medical Society was organized in 1851, at which time it adopted its code. The Kentucky State Medical Society admitted as members those physicians who were identified with local medical societies.

Adjourned till Friday, 9 A.M.

At the close of this session, the members, with their wives, daughters and friends repaired to the residence of Dr. A. D. Price, where a reception was held and a sumptuous repast served.

THIRD DAY—MORNING SESSION.

The first thing in order was the report of the Nominating Committee, which was read as follows:

To the President and Members of the Kentucky State Medical Society:—Your Nominating Committee beg leave to submit the following report:

For President, Dr. John A. Lewis, Georgetown.
 First Vice-President, Dr. H. H. Grant, Louisville.
 Second Vice-President, Dr. O. S. Kash, Moorefield.
 Permanent Secretary, Dr. Steele Bailey, Stanford.
 Treasurer, Dr. J. B. Kinnaird, Lancaster.
 Librarian, Dr. Frank Boyd, Paducah.
 Place of meeting, Lebanon, 1896.
 Chairman of Committee of Arrangements, Dr. R. C. MeChord, Lebanon.

On motion, the report was adopted.

DR. A. D. PRICE read a paper entitled

ANTEPARTUM AND POSTPARTUM HEMORRHAGE.

The author portrayed the importance of the hemorrhage that antedates the completion of labor, and there remain to be considered those of no less import that follow. There is no other class of patients in which emergencies occur so suddenly, and which demand such prompt measures of relief as those that come under the obstetrician's care. The obstetrician should have fixed principles of conduct for every accident liable to be encountered and, banishing every doubt or hesitation, boldly employ them for the saving of life. Postpartum hemorrhage follows the birth of the child, and the loss of blood is from the placental site, or from torn or lacerated vessels in vagina or cervix, or from the ruptured uterus.

The third stage of labor requires the most careful management. Delivery of the placenta, as a rule, means great danger. Too early efforts in this direction exhaust the uterine muscles and favor relaxation. Those who had witnessed a severe postpartum hemorrhage could appreciate its seriousness. Prophylaxis can accomplish much and render these cases exceedingly rare. The patient should be carefully prepared for her confinement, the surroundings being made aseptic, and by having her bladder and rectum thor-

oughly emptied. A faradic battery, one pole being applied to the lumbar region, and the other over the uterus or within its cavity, rarely fails to produce prompt and efficient contractions, and should always have a place in the obstetrician's armamentarium.

The patient's general condition will require attention. If the loss of blood has been great and the shock is severe, lower the head, elevate the limbs, apply heat to the back of the neck and head, and give rectal injections of whisky and hot coffee. If the depression is very great, hypodermics of whisky in strychnia will be demanded.

DR. JOHN G. CECIL, of Louisville, followed with a paper entitled

CRANIOTOMY, SYMPHYSIOTOMY AND CÆSAREAN SECTION.

Each of these operations has a place in obstetric surgery, and we may safely say that they are here to stay. The author believes that pelvimetry is a subject as yet little understood and still less practiced in this part of the country. It is the key to the situation in many cases demanding interference, for upon our estimation of the pelvic diameters depends the selection of the operation best indicated for relief. Craniotomy will always have its advocates, but that it must decrease while the other two must increase, is already a matter of history. Under aseptic precautions and in the hands of those familiar with the more formidable operations, it is probably the safest, that is, less destructive to maternal life, but in the light of modern surgical achievement it is not indicated upon the living child. It is indicated upon monstrosities, hydrocephalies and upon dead children; but not in any case of such extreme narrowing of the pelvic canal as would render the destruction of the child very certain, and delivery of the fragments destructive to the soft parts. Symphysiotomy is now generally admitted to be a perfectly justifiable operation. The limits are being more strictly defined as its scope is better understood. It will probably displace Cæsarean section in cases where there is only a relative indication. A proper case for it is one of occipito-posterior position which, either on account of a large fetal head or a small pelvic canal, can not be delivered by version or the forceps without such violence as would endanger the maternal structures and put the life of the child in great jeopardy. Multipara are better subjects than primipara.

Further indications for Cæsarean section are extreme cases of cervical or vaginal atresia and rupture of the womb with escape of the contents into the abdominal cavity. Considering the frightful fetal mortality, and the great risk to the life of the mother, Dr. Cecil is about prepared to say that placenta previa centralis constitutes a legitimate indication for Cæsarean section.

DR. DAVID BARROW, of Lexington, read a paper entitled

EXTRAUTERINE PREGNANCY—FOUR RECENT CASES.

The first patient was 34 years of age, married twelve years, mother of two children, one 12 and the other 9 years old.

Case 2 was a woman 28 years of age, married thirteen years: one miscarriage five years ago, no pregnancy since. In this case ruptured tubal pregnancy was diagnosed, and operation advised and performed.

Case 3, woman aged 30, married eleven years, two children living, one dead.

Case 4, woman aged 28, married five years, no children, had a miscarriage five months after marriage, and one since. She thinks she aborted at the second month.

These cases came under his care during the past five months. In all save one, the diagnosis was comparatively easy, and in every case the patient consented readily to the treatment proposed. To the prompt resort to surgery he attributes largely the successful results obtained. Extrauterine pregnancy is more frequent than is usually believed by the profession. Most physicians in active practice have met with these cases, and have often failed to recognize them, cause of death being attributed to idiopathic peritonitis or some other condition. Dr. Barrow believes and contends that more of these cases should be recognized before rupture, and if they were not put aside carelessly with the general opinion that they were cases of threatened abortion more accurate diagnoses would be made.

The treatment of extrauterine pregnancy is surgical. Electricity, injections into the sac, etc., are advocated by some, and cases are cured by these means, but he believes prompt resort to surgical interference is the only treatment worthy of consideration when the patient's consent can be obtained, and the physician is prepared to do such surgery. These patients do well after operation, if done early, and convalescence is usually rapid. We should open the abdo-

men, separate the adhesions, deliver and tie off the impregnated tube and its ovary as quickly as possible.

Dr. J. W. O'CONNOR, of Elizabethtown, read a paper entitled

ACNE ROSACEA INDURATA PUSTULOSA,

in which he reported a case. The patient, a widow 32 years of age, a native of Kentucky, the mother of two children, called at his office to consult him in regard to a skin disease of the face. She gave a history of dyspepsia and constipation. The skin disease began about two years ago, soon after the death of her husband. She first noticed a few small pimples on the nose, which gradually spread over the nose and both cheeks, with a few on the forehead. Previous to this she would often have a flushing of the face, or hot flashes, and skin of the face was always greasy. Her face was covered with bright red indurated pustules, varying in size from that of a pinhead to that of a small bean, many resembling a bean in shape, nearly all containing some pus. The integument generally was very much thickened, and pressure upon it would move the entire cheek. The capillaries were enlarged, congested and tortuous. He began treatment by opening the pustules with a sharp-pointed bistoury and squeezing out the contents, then inserting a pointed stick dipped in Monsel's solution as a cauter and germicide. After opening the pustules, he sponged the face with a 5 per cent. solution of carbolic water. He interdicted the use of all soap, and recommended bathing the face in hot water night and morning, after which rub in with a piece of flannel a 3 per cent. solution of salicylic acid. At first this is to be mixed with three parts water, and gradually made stronger and stronger until it is used pure. He gives internally 1-10 gr. doses of calomel every hour for a few days, with a pill of aloin, strychnia and belladonna. These preparations are alternated every few days with sulphur tablets 1 gr. every two hours and tablets of iron 1 gr., arsenic 1-20 gr. and strychnia 1-30 gr. every four hours. Other remedies were recommended, but he had found none so efficacious as these. The after-treatment consists in the exhibition of a general course of tonics and the mineral acids or iron, cod-liver oil or arsenic, as seems best suited to the individual case in hand.

Dr. ARCH DIXON, of Henderson, contributed a paper entitled "An Atypical Case of Appendicitis," which emphasized the necessity of early operation in all cases, whether they be acute, perforating, fulminating with general peritonitis, or acute suppurating, with local plastic peritonitis and abscess, or, in other words, as soon as the diagnosis is made, regardless of the favorability of the case. He believes appendicitis to be an infective exudative inflammation, septic in character from its incipency. The very moment the appendix takes on inflammatory action it at once proves a soil rich in character, plowed, harrowed and in every way fit for the growth of septic bacteria. In a majority of cases, if operation be performed within forty-eight hours after the onset of the symptoms, the appendix is not yet ruptured, and can be removed without pus infection of the peritoneum, an advantage of which even the boldest surgeon is pleased to avail himself. In the latter stage, if the surgeon is fortunate enough to be called at the time that the peritoneum is flooded with pus and the patient collapsed, it is his duty to perform the operation, and give the patient a chance for his life in this forlorn condition. The rule, first, last and always, should be to operate in every case of appendicitis, promising or unpromising, at the earliest possible moment.

Dr. T. C. EVANS, of Louisville, followed with a paper entitled "Adenoid Growths in the Naso-pharynx." In this paper the author desired to speak only of the abnormal condition of those masses of lymphoid tissue situated in that part of the respiratory tract, known and described as the naso-pharynx. Meyer, of Copenhagen, in 1868 was the first to describe this condition. The disease consists of an hypertrophy of the lymphoid tissue which encircles the naso-pharyngeal portion of the respiratory tract, blocking up the space and mechanically interfering with or altogether preventing nasal respiration. This hypertrophy usually involves, to a greater or less extent, the faucial tonsils and other contiguous lymphoid masses. The diagnosis is easily made from the characteristic symptoms. The treatment is either expectant or surgical. The expectant plan is at best long, tedious and uncertain, entailing years of suspense on the part of physician and patient, and subjecting the patient to dangers which, once encountered can not be corrected. Surgically, most operators now confine themselves to one of two methods: 1, removal by the post-nasal curette; and, 2, removal by post-nasal cutting forceps.

Dr. T. M. GREENE, of Lexington, read a paper entitled the "Leucocytes in Diseases of Microbic Origin." The author said the older physicians explained the etiology of diseases generally by the term *materies morbi*, of which they had no very definite idea, believing that it represented certain poisons emanating from the earth and conveyed to the system through the medium of the atmosphere, water and food. They were aware, also, that the system under certain circumstances had the power of resisting disease, also of performing cures unaided by the efforts of the physician. This was expressed in the oft-quoted aphorism, *vis medicatrix nature*. It was reserved for the modern science of bacteriology to show that *materies morbi* are really living germs, which on entering the system become pathogenic in character; also that the power of cure resides really in the white corpuscles of the blood. While engaged in this important work they are called phagocytes. Before entering upon a discussion of the progress of phagocytosis, the author dwelt upon the peculiar nature of the leucocytes themselves. There were two principal indications for treatment of all diseases of microbial origin: first to destroy the germs as soon after invasion as possible, and at their point of entrance. Second, to overcome the effects of toxins after they had been formed.

Dr. T. B. GREENLEY, of Meadow Lawn, read a paper entitled THE PREVENTION AND TREATMENT OF PULMONARY TUBERCULOSIS.

It has been the observation of the writer for many years that the majority of cases of this disease are preceded by a longer or shorter period of impaired health, apparently due to indigestion and deficient assimilation. Especially is this condition presented in those who are constitutionally predisposed to the disease. The writer entertains the opinion that if proper means were instituted sufficiently early in these cases to restore them to their ordinary health, that the disease in the majority of cases might be prevented. The means indicated consist mainly in the use of proper diet and exercise in the open air, observing at the same time sanitary environment.

As to the treatment of pulmonary tuberculosis, a great deal can be accomplished in its earliest stages by the use of proper alimentation, or the building-up system.

Dr. Greenley then outlined the plan of treatment adopted by Dr. Carasso in treating this disease. From the record it appears that every case of primary tuberculosis treated by the inhalation method of Carasso recovered, and that the fatal cases with but two exceptions were ones in which secondary tubercular lesions produced death. The average duration of the treatment in these cases was sixty days. The simplicity and harmlessness of the method, together with the remarkably successful outcome of his cases (Carasso's), recommend the method for a thorough and systematic clinical test. Perhaps the most rational as well as the truly hopeful plan of managing pulmonary tuberculosis, is before it is fully developed. Preventive means are much better than curative, but both combined in some cases are better than either alone, in order to prevent further development.

Several of the papers on the program were read by title. After the appointment of delegates to the next meeting of the AMERICAN MEDICAL ASSOCIATION, the presentation and adoption of resolutions of thanks, the Society then adjourned to meet at Lebanon in 1896.

Colorado State Medical Society.

Abstract of the Proceedings of the Twenty-fifth Annual Meeting, held at Denver, June 18 and 19, 1895.

[Special correspondence of the JOURNAL.]

THURSDAY, JUNE 18.

The meeting was called to order by the President, Dr. HUBERT WORK, of Pueblo. The reports of various officers and committees showed the society to be in a flourishing condition, with a slight net increase of membership during the past year and a balance in the treasury.

The Executive Committee reported a rule limiting readers of papers to fifteen minutes each, and remarks in discussion to five minutes, which rule being adopted and rigidly adhered to throughout the meeting, rendered possible the satisfactory completion of a full program, and added much to the success of the meeting.

"The Relationship Existing between the Eye and Diseases of the Brain," was the subject of a paper by Dr. R. F. LE MOX, of Denver. He called attention to the intimate connection of these two organs, and its clinical importance. In a case of astigmatism it is the recognition on the part of

the brain that the eye is unable to properly and comfortably do its work, that gives rise to the train of symptoms usually set up. By nervous impulses sent out from the brain are brought about the irritation, congestion and photophobia that cause the closure of the eye and suspension of its work, the train of symptoms being designed to protect the organ from more serious injury. He also urged the great diagnostic value of optic neuritis, inequality of the pupils, optic nerve atrophy, and hemianopsia in cases presenting severe headache or other indications of organic disease of the brain.

"Observations regarding Eye Strain and its Relief" were presented by DR. EDWARD JACKSON, of Philadelphia. He pointed out that ametropia and eye strain were neither identical nor necessarily connected, that either might be present in high degree without the other, that the recognition of ametropia was not essential to the diagnosis of eye strain, and did not alone establish it. He also called attention to the severe symptoms often arising from comparatively slight errors of refraction, especially those remaining after inaccurate corrections, and after middle life, when the lowest degrees of hyperopia or astigmatism were most likely to tempt their possessor to undue exertion of the ciliary muscle. The period of adaptation, during which the best fitted glasses were likely to prove unsatisfactory, and which is not sufficiently emphasized in the books, was also referred to. It was essential that the patient be forewarned of its occurrence, or he would take it as evidence of failure on the part of his adviser to find the proper glass, and lose confidence, to the detriment of both himself and his physician.

"Inflammation of the Middle Ear with Involvement of the Mastoid." DR. W. C. BANE, of Denver, stated that the majority of cases of pyogenic inflammation of the brain and its membranes were due to similar disease of the middle ear and mastoid. He reported five cases of such disease, four of which had required opening of the mastoid, and all had recovered. The first was in a man aged 59, who came for pain and dizziness. He had a small perforation in the drum membrane. Two months later he returned with a swelling below the ear half the size of a goose egg, and unhealthy pus escaping from the meatus. The removal of diseased tissue was followed by complete recovery. A man aged 27 suffered from acute purulent inflammation of the middle ear for about one month. There was a large perforation, but the mastoid became involved and rendered necessary the excavation of its entire contents. A young woman suffering from a subacute otitis media with a small perforation, the discharge having stopped, had tenderness and swelling over the mastoid requiring operation. In a boy with acute inflammation, involving the mastoid, the symptoms yielded without operation. In the fifth case, a man aged 41 with acute otitis media had severe mastoid symptoms which not being relieved by other measures, the mastoid was opened and showed that the process of disintegration had already begun.

"Laryngeal Infiltration" was the subject of a communication by DR. P. F. GILDEA, of Colorado Springs. He reported a case of severe tubercular infiltration, and pointed out that where there is much submucous tissue great infiltration occurs before there is ulceration, but where there is but little submucous tissue, ulceration takes place early.

DR. E. T. BOYD, of Leadville, exhibited an improved snare for the removal of nasal hypertrophies, etc. The improvement consisted chiefly in the addition of a pin, arranged to slide upon the canula, with which the part to be removed could be securely transfixed before tightening the snare, preventing any slipping of the loop, or the dropping of the portion removed.

REFLEX IRRITATION FOLLOWING EYE STRAIN.

DA. D. H. COOVER, in illustration of the intimate relation existing between the eye and the brain and the remote effects liable to arise from eye strain, reported a series of cases. A school girl suffered from frequent attacks characterized by general convulsions. The correction of her compound hyperopic astigmatism entirely stopped these attacks. Subsequently she lost her glasses and went five days without them during which time she had four attacks. A girl aged 11 had seizures in which she became unconscious and convulsed. She had had seven such attacks. The examination of her eyes showed two diopters of astigmatism; she was given convex 1.50 D. for constant use. For three months she did not have a seizure. Then one occurred, her glasses were changed to a full correction, and she remained entirely free from attacks ever since. A young woman who had long been subject to nausea and vomiting, especially in the morning, was entirely relieved by the correction of her compound hyperopic astigmatism. A boy of 16, working

hard at school, became affected with chorea. He was given correcting glasses, and recovered in a month. A man aged 45 had been for years troubled with a dry hollow cough, which was worse at night and worse when he was very busy. He obtained the greatest relief by going away from his business entirely. Examination of his eyes revealed compound hyperopic astigmatism. He was given correcting glasses, wore them all the time, and in three months was well of the cough.

DR. G. MELVILLE BLACK, of Denver, reported as "A Case of Angio-neurotic Edema of the Ocular Conjunctiva," the case of a man who was suddenly affected with great swelling of the conjunctiva and lids without other evidence of serious inflammation. The swelling passed away with equal rapidity. But very few similar cases were found recorded in medical literature.

DR. JOHN M. FOSTER, of Denver, exhibited a case illustrating the results obtained by "Blepharoplasty by Thiersch's Grafting." The patient had after traumatism a cicatricial contraction of the upper lid, drawing it completely away from the eyeball and preventing its closure so that the conjunctiva was suffering from continued exposure to irritants. Two operations were required. Some contraction having occurred after the first, the stitches uniting the lids after the second operation were left in place until the forty-eighth day. The result was an almost perfect restoration of the lid to its normal appearance and function.

DIAGNOSIS AND PRINCIPLES OF TREATMENT OF HIP-JOINT DISEASE.

DR. JOHN RIDLON, of Chicago, delivered an address upon this topic. He thought every physician should know enough about this disease, 1, to recognize it; 2, to understand the general principles of its treatment; and 3, to be able to recognize when it was fully cured. For diagnosis, the three early and constant symptoms are limp shrinking of the affected limb as shown by comparative measurements of the girth of the two thighs, and limitation of the movements of the joint in all directions. Other common symptoms are restlessness during sleep, with sudden crying out, particularly in the early part of the night; deformity, if the case has gone far enough; pain, which is not usually one of the early symptoms, and may be entirely absent; and abscess which is present in about 50 per cent. of cases. The differential diagnosis has to be made with reference to Pott's lumbar disease, sacro-iliac disease, congenital dislocation of the hip, and hysterical hip-joint. In the latter condition there is never any diminution in the size of the limb.

In treatment the object is to secure functional rest by preventing motion, and so far as possible removing pressure from the opposing surfaces of the joint. To prevent motion an apparatus must extend from close above the ankle to the armpits. To remove pressure the patient might be kept in bed. But this can not be continued throughout the treatment; so the only thing to do is to put a shoe on the sound limb with a heel high enough to take the weight all off the other. As to operation, he thought that the more experience the surgeon had with operating, the less was he inclined to operate. If by operation all diseased tissue could be removed, and immediate union of the wound secured, it would be right to operate. But incision and drainage were not justified; and aspiration and the injection of the abscess cavity with iodoform were not worth the pain and disturbance that attended them. In the diagnosis of cure the greatest caution must be observed. When all symptoms have been absent for six months you may think the case is getting well, but do not tell any one that you think so. Gradually relax some of the restraints of the limb, and if there is no tendency to relapse after some months give the patient slightly more freedom; and so continue until, after years of close observation of case, it may be concluded that the case is cured.

"The Treatment of Lateral Curvature of the Spine," was the subject of a paper by DR. GEO. B. PACKARD, of Denver. He advised the relief of the weakened spine from the superincumbent weight, by rest in bed for a couple of hours in the middle of the day close watching of the general health, gymnastic exercises, and the support of a properly fitted jacket.

DA. S. D. VAN METER, of Denver, urged the importance of circumcision. For very many it is needful, though some may not require it. If it were universally practiced health would be promoted, and venereal disease and reflex troubles diminished.

DR. CHAS. A. POWERS, formerly of New York, but now of Denver, read a paper on "Cancer of the Rectum and its Ex-

cision by the Method of Kraske and Modifications Thereof," with the reports of four cases, of which three had recovered and one had terminated fatally. He believed there were but comparatively few cases that could be cured by operation through the perineum. He had in these cases used the operation of Kraske, but would in future try the more recently described osteoplastic method. In cases where it was intended to preserve the anus, preliminary colotomy was indispensable. The selection of cases proper for operation was very important; and where it was found that the disease had extended too far for complete removal the attempt should not be made; but a simple colotomy resorted to, when the obstruction rendered it necessary. All cases of possible malignant disease of the rectum should have early and thorough examination. The only hope of relief lay in early recognition, and prompt and thorough excision.

DR. E. J. A. ROGERS, of Denver, reported a series of Surgical Cases, including cases of curetting of the hip and ankle joints, and one of necrosis of the great trochanter in which the diseased bone was dug out, all followed by recovery. In a case of intestinal obstruction which had lasted for several days the condition was found to be due to internal strangulation through old adhesions. In a case of chronic dilatation of the stomach in which the Murphy button was used to establish an anastomosis between the stomach and jejunum, the patient died soon after from other causes. The union was found to be perfect, the button had fallen into the stomach. He reported five cases of acute appendicitis operated on, all recovered. In one, the length of the appendix was six and a half inches. He also reported two cases of nephrectomy, and one of partial operation on an extensive abdominal sarcoma greatly benefiting the patient.

"Resection of the Femur for Angular Deformity" was discussed by DR. GEO. W. MIEL, of Denver, who reported a case. The deformity was outward from exaggeration of the natural bend of the femur by the action of the strongly attached muscles. Even with a transverse fracture and no overlapping there was shortening of three inches. He practiced and advocated a Y-shaped incision, in preference to the V-shaped, as it caused practically no loss of natural tissue, and therefore less shortening.

DR. LEONARD FREEMAN, of Denver, reported a "Case of Spontaneous Dislocation of the Hip-joint in Connection with Typhoid Fever." The patient was a girl aged 10 years. The dislocation probably occurred about the fourth week, from arthritis and malposition in bed. About the sixth or seventh week some tenderness and deformity were noticed. At the tenth week, when seen, there was shortening of one and a half to two inches, the head of the bone was on the dorsum of the ilium, and there was atrophy of the muscles about the joint. Under a general anesthetic the dislocation was reduced at the second or third attempt. The parts were kept in position and passive motion not begun until four weeks. There remained a slight but diminishing shortening of the limb, probably from lack of growth during the period of dislocation.

DR. W. W. GRANT, of Denver, reported a series of "Cases of Appendicitis," that he had operated on with recovery. In the worst case, in which the general peritoneal cavity was involved, unfavorable symptoms developing including great distension, the colon was tapped; and this was followed by prompt improvement. He believed that when the appendix was not found in the abscess cavity, adhesions should not be broken up searching for it. The most dangerous cases were those in which the appendix hung in the peritoneal cavity. He did not think that every case must be operated on; but all severe cases might require it. Relapsing cases should be operated on in the interval.

(To be continued.)

American Electro-Therapeutic Association.

Fourth Annual Meeting held in New York Academy of Medicine
New York, Sept. 25, 26, and 27, 1894.

WILLIAM J. HERDMAN, M.D., President.

(Continued from page 980.)

DR. MARGARET A. CLEAVES, of New York, read a paper on
SPECIAL HYDRO-ELECTRIC APPLICATIONS.

It seems strange that considering the time in which general hydro-electric applications have been used, advantage has not been taken of the opportunity offered by the accessible mucous cavities of the body for such applications.

So far as I am aware, nothing has been done in this regard save by the Boudet de Paris method in the treatment of intestinal occlusion, and direct application of electricity to the stomach as developed by Dr. Max Einhorn of New York. Neither have come into the prominence which their merits deserve, but this is to be explained, no doubt, by the fact that these applications require a good deal of time on the part of the operator and patient, and in the case of applications to the stomach, upon the discomfort attending the introduction and presence of the stomach electrode.

Since establishing my methods of localized hydro-electric applications to the accessible mucous cavities of the body, I have found two references with which I was not familiar before. Dr. W. S. Hedley, of Brighton, England, in his book on "Hydro-Electric Applications," refers to the possibility of applying electric douches and calls attention to their value in the event of suitable means being devised for their use; he has not, however, resorted to these measures, although he has used electric douches for an ulcerating cancer, situated externally, with marked amelioration. Beard and Rockwell in a few paragraphs call attention to hydro-electric applications and say that in accessible places, as in various cavities of the body, ulcers, sores, etc., water used as an electrode is an excellent method for applying electricity, and they further state that ordinary douches can be used for the eye, ear, stomach, rectum, uterus, etc., so long as the current is not sent out in a spray, and recommend the use of Potter's apparatus for these purposes. This apparatus I am not familiar with.

A brief resumé¹ of the development of the Boudet de Paris method and its work in intestinal occlusion can not fail to be of interest here. In surgical operations for this condition the mortality is variously given from 58 to 64 per cent.

By the work of Duchenne de Boulogne in localized electrical applications, attention was first drawn to the advantages of electricity in the treatment of obstinate constipation and intestinal obstructions. He used the induced currents almost entirely for his physiologic and pathologic studies, and others have followed in his footsteps. In 1876, however, Leroy d'Etoilles observed that unstriated muscular tissue was not excited by the excitations of an induction coil, but on the contrary, such excitations were the most powerful in causing contraction of striped muscle. Later, in 1882, Boudet de Paris insisted on this distinction and proved that only slow excitations of continuous currents could have any direct influence on intestinal contraction, and that, therefore, the constant current should be preferred to the induced current in the treatment of occlusions. But at the same time of the experiments of Boudet de Paris, the induced and constant currents were indiscriminately used in the treatment of intestinal occlusion and constipation. It has been shown, however, by many experimenters that smooth muscular fiber is excited with difficulty by induced currents. The reason is a physical one, and is explained by the fact that the induced current proceeds by shocks of very short duration, sufficient to move the striated muscle which contracts quickly, but insufficient to put in action the unstriated fiber in which the contractions are characterized by a tracing of the form of a prolonged undulation. One has but to recall the character of the graphic curve of an induced current to appreciate this fact. Experiments upon the intestinal tracts of healthy animals show that at the end of a few seconds there is an increase in the peristaltic movements, but diminishing the excitability of the intestine artificially by distension with air, the induced current within the limit of medicinal doses is found inactive. On the contrary, the continuous current under these conditions shows itself capable of causing intestinal contraction and if in place of a continuous flow in one direction, there are reversals, it is easily proved that the intestine contracts no less readily than if it were not distended. Theoretically, as in the case of intestinal occlusion, there is always more or less of paresis due to the conditions of the disease; the action of the continuous current is therefore preferable, but until the establishment of the Boudet de Paris method, there was no way by which this current could be used internally without producing a galvano-caustic action at site of the internal electrode. Such an action as this is most undesirable, and by extension of inflammation the danger of producing a stricture of the bowels is by no means small. But very small current strength could be used, and even then there remained the danger of destructive polar action. The question, however, of treating these intestinal conditions has been settled most satisfactorily by the hydro-electric

¹ Revue d'Electrotherapie, October and November, 1892, Dr. Lerat.

method of Boudet. He uses an electrode made of rubber, provided with a hollow metallic tube with a nozzle for the attachment of a fountain syringe and an attachment for the tip of the conducting cord as well. The sound is provided with an eye upon the side and about 2 centimeters from the end, or an opening situated quite at its extremity. In the latter instance, the metallic tube stops about 2 centimeters from the end of the sound.

Technique.—First the fountain syringe or irrigator should be filled with the lukewarm saturated solution of rock salt. An Apostoli pad is placed upon the abdomen and attached to the positive pole while the active electrode is introduced into the rectum as deeply as possible, in order that the mass of water constituting the injection shall pass well into the intestine, where the reflexes controlling defecation are not active. Connection is then made with the hose of the irrigator and with the negative terminal of the battery. The stop-cock governing the flow of the water is opened and half the contents of the irrigator are allowed to flow slowly in, and as the salt water flows into the intestine it becomes the electrode, carrying the current to every part of the mucous membrane with which it comes in contact. This extensive water electrode, affording as it does a large square inch area of surface, makes it possible to secure by the use of low E. M. F., a larger current strength and therefore great electrical energy without pain or discomfort. In case of pseudo strangulation and obstruction due to fecal matter, the continuous flow is sufficient, but where there is an obstacle to overcome, stronger excitations by reversing the current after the first five or six minutes are necessary. The needle should be carried back to zero, poles reversed and current turned on to former strength. This will almost always produce an intestinal contraction, accompanied by a desire to defecate. This should be resisted by the patient as much as possible until the séance is completed, but if it can not be overcome, the treatment should be suspended and the patient urged to use all the possible effort to expel the contents of the bowels. One of the three things follows: either there is an abundant evacuation, feces are expelled mixed with gas, or the water passes only slightly colored, with or without gas. In the last two instances it is necessary to repeat the electrical enema in from seven to eight hours. If indicated, at least three applications can be made in the twenty-four hours. Larat reports 70 per cent. of successful cases out of 150 in the hands of Boudet de Paris. His own results are not quite so good, viz., 101 successful cases out of 230, but still make a satisfactory showing. He remarks that his cases were all seen by his colleagues of whom at least half were doctors in the hospitals, who called him in to assist their patients. This statement is made to show that his statistics have been well tried. As to contra-indications, all insurmountable mechanical obstacles, either outside of the intestine or down within its cavity must be treated with the knife. The indications for the use of electricity are where "the obstacle can be overcome by a very strong contraction of the intestine, as in cases of 'stercorate' obstruction, intestinal palsy, 'enteroptose,' stricture from a tumor, if the astriction is not absolute, or foreign body in the intestinal cavity." It is his custom in a case of intestinal occlusion where a purgative has been tried without any result, not to insist upon its further use, but immediately to give an electric injection. In twenty-four hours, he says, this will be recognized as successful or the contrary. In the case of a failure a surgical operation should be suggested. In this way much valuable time would be saved; surgical measures would oftener be of avail while many cases would recover by the intervention of the electric douche, who would otherwise be condemned to the shock of an operation. It was supposed that peritonitis would be found to be a contra-indication to the electric douche. Larat details several cases which demonstrate very conclusively that such is not the case but where its use tended to cut short the progress of the disease.

While Larat reports a few cases in which there have been unfortunate results, his reports would seem to indicate that they were due to the disease rather than, as was suggested, to the use of the electric douche. The slowness with which the liquid of the irrigator is introduced into the intestine, would naturally seem to do away with the fear of a break in the diseased intestinal tissue with the passage of the liquid in the intestinal cavity. One would expect this accident to happen more often with the forced injections of seltzer water.

This method, however, is not only of great value in the treatment of intestinal occlusion, but in constipation and in

many of the diseased conditions of the gastro-intestinal tract as well.

For constipation the technique is the same. It is my custom to use from a quart to three quarts of lukewarm salt water according to the patient's toleration. I do not always carry the solution to the point of saturation. The negative pole is used for the active or intestinal electrode in order that its well-known stimulating properties due to the presence of the bases and hydrogen may be utilized. The C. S. varies from 5 to 10, 20 milliampères or more and reversals are made once, twice or several times, according to the needs of the case. As physiologic experiments go to prove that the stimulation of nutrition proceeds from the administration of mild currents, the higher currents are not deemed advisable. In ordinary cases, the continuous flow is sufficient, but where the response to the stimulus is not prompt, reversals are made. Sometimes I use the automatic interrupter of the continuous current, but I prefer a subsequent application of an alternating current.

Individual cases govern the amount of water used, C. S., duration of séance and frequency of application.

The applications are usually given for three successive days, when if the result is entirely satisfactory, *i. e.*, complete emptying of the bowels of fecal matter and gas, with a tendency to a return of normal peristalsis, they are discontinued and the subsequent treatment carried out by means of the Franklinic current with long percussive sparks to the lumbar and sacral plexuses, hepatic area and abdominal walls three times a week, and continued until there is complete elimination of toxins, improved metabolism, nutritional gain and normal functional activity. This is aided or not by medication, according to the case—oftener not. Cathartics are almost never given. Every hygienic and dietetic detail is considered, as well as habits and dress.

I present here a rectal electrode which was made for me at my request (with the other electrodes for the various hydro electric applications) by the Galvano-Faradic Manufacturing Company, of New York City. All of these electrodes have been constructed with platinum wire for the conducting medium, extending from the point at which the water enters the electrode to within a quarter, to a half inch, of the end of the perforated rubber tip. By the use of platinum it becomes possible at once to use not only negative but positive currents and any drug cataphorically that one may desire. At first carbon tubes were used, but as it

was found that platinum wire could be substituted without increasing the expense, this was done.

The long and curved rectal electrode is intended to pass as far as the sigmoid flexure. By its use the water can be diffused more thoroughly into the intestinal tract and consequently the current carried farther, or in the event of disease at the sigmoid flexure, a localized action may be obtained at that point either by means of the constant current douche, negative, or by cataphoric medication, utilizing any drug that may be indicated.

In the treatment of constipation by electricity there is a beneficial action upon the circulation, respiration and general nutrition. As a result of its action there is a modification of the abdominal circulation, and certain conditions of passive congestion disappear, especially as found in cases of abdominal plethora. Under its influence both the volume and the force of the muscles are increased. The atonic intestinal muscles again become capable of action, while the strength of the accessory muscles, as those of the abdominal wall, is increased.

The evil results which follow chronic constipation are legion, and every method other than drug-taking deserves careful investigation and experimentation at our hands. To establish a rational therapy, great care must be taken in discovering the cause of the condition.

Atony³ of the intestine is considered one of the most frequent causes of constipation, and may be described as a condition in which the walls of the colon have lost their tonicity and therefore are unable to expel feces at the normal rate. In all cases dependent upon atony of the muscles of the intestine or abdominal walls, the best measures are electricity, exercise, massage and hydro-therapy.

In many of the diseased conditions of the gastro-intestinal tract hydro-electric applications stand us in good stead. For instance, in intestinal catarrh, enteritis, simple, pseudo-membranous or follicular, in chronic thickening of the mucous membrane, and in chronic diarrhoea due to fermentative and putrefactive conditions. The stimulating effect of the electric current on the nervous system, and secondarily upon the muscular and glandular tissues thus localized tends to restore healthful function. The nutrition of the part is promoted by the physical properties of the current, electrolytic and cataphoric. These are conditions in which drugs fail, if depended upon alone, and which must, to a very great extent, be combated by local measures.

One of the very intractable intestinal conditions, with which we meet, namely that of pseudo-membranous enteritis, is estimated by Prof. Germain See⁴ to be found in about one-third of the patients, principally women, who are treated for gastric derangement. The pain and swelling over the colon, and gaseous fermentations are symptomatic of the condition, but the distinguishing feature of the disease is the presence in the stools of mucus, glairy and cylindrical masses. In the treatment of pseudo-membranous enteritis, I have found applications of negative currents by means of the Boudet de Paris method exceedingly valuable. Within the past two years I have treated several such cases characterized by the usual muco-membranous discharges. All had run a persistently chronic course, were characterized by irregular exacerbations, lack of marked febrile excitement, persistent derangement of the intestinal canal, mental depression and general impairment of health; also by more or less gastric disturbance, impaired appetite, repugnance to food, furred tongue, and foul breath. They were all of some years' standing, and had resisted the remedial agents administered from time to time when under the care of different physicians. At this time, however, these patients have good and normal appetites. The gastric and intestinal distress has disappeared, the bowels are regular, and the general health markedly improved and none of them have membranous casts any longer in the discharges.

After the first applications there was noted a change in the appearance of the tongue, which in the interval of the first and second treatments lost its coating and the red and irritable condition at the sides and tip. From six to eight negative applications were made in these cases with a C. S. of from 10 to 30 milliampères, the quantity of the douche varying according to the patient's toleration from one pint to three quarts. The time of the continuance of the current averaged ten minutes at each treatment. An ordinary Apostoli pad was placed over the abdomen.

In the so-called recurrent attacks of peritonitis in gouty subjects, which are really gout of the intestine and in those

cases of gastro-enteric rheumatism affecting the nerves of the alimentary tract and simulating in some cases, by the character of the pain, trouble with the pelvic organs, I have found negative hydro-electric applications of the intestinal tract of undoubted curative value. A patient under care this past winter, a gouty subject, came to me with a history of prolonged pelvic trouble (seven years, and for which she had been three months in a hospital, curetted, douched, etc., and subsequently treated by means of intra-uterine applications *a la* Apostoli) continued to have recurrent attacks of severe pain that diminished gradually, neuralgic in character, associated with bloating, tenderness, slight feverishness, great anxiety, loss of appetite and mental depression. The cycle of pain and disturbance would complete itself in from two to four weeks to be followed at intervals by another and yet another. Here intra-uterine treatment accomplished but little, in fact, I may say nothing at all, save to relieve slight sensitiveness of the endometrium, but intra-rectal negative hydro-electric douches relieved all symptoms, improved the constipation, and established the general health. In this case I shall expect a return of the symptoms when the conditions are favorable for an attack of gout, as the patient does not live in such a way, so far as diet and exercise are concerned, to lessen the chances of its recurrence.

Haig considers that many cases of colic, enteralgia, enteritis and typhlitis are really gouty manifestations located in the intestine. From my experience, the constant current used externally in chronic peritonitis, I should expect to get much better results from hydro-electric applications.

In addition to the thorough system of intestinal irrigation already practiced in cholera, positive electrolysis of suitable fluids within the intestinal tract, or diffusion of appropriate drugs into the submucous structure by means of the electric douche might prove a valuable aid.

After the electric injection, patients have sometimes complained of a burning sensation and smarting in the anus. This is not caused by the electricity, unless perchance there should be some oozing of the water between the sides of the electrode and the anal walls. It has often seemed in some cases to be due to the intense saltiness of the water. Larat has suggested where this is much complained of that Vichy might be used instead.

In using this method in the treatment of chronic constipation, I found that patients who were suffering as well from exudative material in the pelvic cavity noted an amelioration of the symptoms arising from that condition, which upon physical examination I was able to corroborate. This led me to utilize it in the treatment of pelvic exudates and also to a certain extent in other pelvic conditions, such as ovaritis, relaxed conditions of the uterus, etc. I was very glad, indeed, to avail myself of its use, as for a long time I had been extremely averse to the application of the constant current by means of the vaginal electrodes in common use. Even in the hands of the expert, I found great danger in the use of the most carefully constructed vaginal electrode of producing at point of contact, galvano-caustic action, and in the hands of those less expert I have seen very bad eschara resulting in gangrenous sloughs followed by slight hemorrhage. I was convinced that the method was intrinsically faulty and that some other way must be resorted to, to bring the tissue of the pelvic organs under the influence of the current, and thus my observations with the electric enema led to the construction of an electrode for the purposes of vaginal electric douches. In exudative inflammations of the pelvis, as well as in the diseases of the vulva and vagina, the principal aim of the gynecologist is to obtain the resolution effects of the current, and by use of the water electrode it is no longer the apparatus, but all the tissues with which it comes in contact, which becomes the electrode and the active pole of the circuit. With the large surface thus brought under its immediate action, one obtains a great enough force of the current to influence the entire pelvic tissues.

In these administrations with an observed E. M. F. of 90 volts, an observed current of 40 milliampères and an observed time of 600 seconds, there was obtained by calculation a resistance of 2,250 ohms; the power (*i.e.*, the rate of expending energy) 3.6 volt-ampères or watts; and the total energy expended, 2,160 volt-ampère-seconds or joules) resulting in severe contractions in the muscular fiber of the uterus which patients have likened to labor pains. That the current density was not under these circumstances sufficient through any given tissue to produce a galvano-caustic action, is the best evidence of the great utility of the method of application.

The electrode which I show here has already been described.⁵ I now use platinum wire, however, instead of a

³ Henoch, Medical News, August 11, 1894.

⁴ London Lancet, Jan. 6, 1894, p. 65.

carbon tube, for the conducting medium. It will readily be seen that there is no point of contact of the conducting material of the electrode with the mucous membrane in either rectal or vaginal applications. The salt water or the medicated solution, whatever its nature, is the electrode. Since the description of this electrode I have substituted a douche pan for the drainage hose. This obviates all danger of wetting the patient's clothing in any given application.

Thus far I have used the vaginal hydro-electric applications in vulvitis, pruritis vulvæ, simple and diabetic, eczema of the vulva, chronic vaginitis, gonorrhœal vaginitis, erosions of the cervix, relaxed and congested condition of the uterus and vaginal walls, in leucorrhœas dependent upon the same, and in displacements associated with these conditions, in pelvic exudates, ovaritis, and supplementary to intra-uterine applications in fibroids, endometritis and salpingitis.

In gonorrhœal vaginitis—a condition which is recognized as extremely difficult to treat—it will be possible by this method to bring not only the os and the cervix uteri, but every interstice of the vagina as well, under the influence of medicated solutions and thus combat the specific condition. The fact that the gonococcus penetrates the submucous structure, makes it very desirable that we should be able to apply our remedies in such a manner as to insure their destruction. By cataphoric medication this is possible, as the medicament not only comes in contact with the mucous membrane, but is caused to penetrate more or less deeply into its structure according to the law of cataphoretic transfer.

In the conditions indicating the use of an alternating current either alone, or as supplementary to an application of the constant current, I frequently apply it by means of the water electrode, with the result of a much more sensible diffusion of the current being felt throughout the pelvic basin by the patient than is experienced from the ordinary mono-polar or bi-polar applications.

In a case of chronic vaginitis and eczema of the vulva, of twenty years' standing, with the most intolerable itching, for which the patient had resorted to various means for relief and obtained none, I have found this electrode of the greatest value. In this case the entire mucous membrane of the inner aspect of the labia was thickened, leathery and fissured. At the ostium urethrale and vaginæ the color was an intense crimson. The same condition extended into the vagina. There was extreme sensitiveness upon digital examination, and the patient was worn and harassed by the continued irritation from which she had not been free in all these years, despite the heroic measures that had been used to insure recovery. After one application of the negative galvanic current in the form of a douche, there was marked relief from the constant irritation and a tendency to heal on the part of the fissures. After four applications had been given, extending over a period of two weeks, the mucous membrane was found to be as sound and whole as that of a child, and the congestion at the mouth of the vagina and urethra had entirely disappeared, the mucous membrane having returned to its normal color and condition. There was complete cessation of the itching which had made the patient's life wellnigh intolerable, and a most marked improvement manifest in her general appearance. She remains under observation.

In making the application, the tendency is for the water to flow out against the shield, and in that way to come in contact with every part of the mucous membrane of the vulva. Patients find this method of applying the current exceedingly tolerable, and in the conditions for which I have used it thus far there has been an invariable expression of relief following its use. In conditions demanding it, the vaginal douche is supplemented by a douche to the external genitals as in eczema, etc.

Since I entered upon an investigation of these methods, I have had the opportunity of treating several cases of bladder trouble and of gonorrhœal infection. The method should be particularly valuable in cystitis, acute, but especially chronic, in gonorrhœal infections of the cyst, in atony and dilatation; in fact, in any condition where the known properties of either continuous or alternating currents would be of value. The applications which I have thus far made have, with low current strength, 5 to 20 milliampères, been without pain or even irritation.

The electrode for these applications is, like the others, constructed of hard rubber and is similar to the ordinary two way catheter used for vesical irrigation, with a third branch for the battery attachment.

The nature of gonorrhœa emphasizes the necessity of re-

⁵ New York Medical Record, August 25, 1894.

sorting to every method which offers a chance for the destruction of the gonococci, ere the opportunity is afforded them of migration and infection of other mucous and serous cavities. The difficulty in the way of doing this is fully recognized. It seems to me that in cataphoresis we have a measure which, from its physical nature, is destined to be of great influence in combating the primary disease. As in four-fifths of the cases the urethra is recognized as the seat of the disease, it is found necessary to direct therapeutic measures to that anatomical site. As it is a fact that the gonococci do not thrive in the bladder, the use of hydro-electric applications as directed to that organ and the vagina can not be depended upon alone to accomplish their destruction. Here, in addition to the use of cupric electrolysis to the urethral canal, the cataphoric douche applied directly to the ostium urethrale itself can not fail to prove helpful. In negative hydro-electric applications with a saline solution, every indication for the washing out of vagina, bladder, and all infected tissues with an alkaline solution is abundantly met, and then by the cataphoric douche the medicament, whether copper sulphate, bichlorid of mercury, zinc sulphate, etc., can be driven directly into the submucous structure of the tissues about the urethra.

In the treatment of atony and dilatation of the bladder the continuous current affords the best results, because structurally we have to deal as in the case of the uterus or intestines with unstriped muscular fiber. The action of the negative electric douche as it impinges on the mucous membrane is necessarily stimulating, inducing muscular contraction, as well as, by its action upon the blood supply, improving the nutrition of the part. The method is unquestionably applicable in every diseased condition of the bladder where electricity is indicated, unless it be a localized lesion, where the galvano-caustic action of the current is desired.

A limited experience with hydro-electric applications to the nose and ear suggests that they may have their value, at least in the conditions where an ordinary douche would be indicated. In diseased conditions of the nasal passages and accessory sinuses, it is rational to expect that we will get the best result wherever there is an atrophic change. Let us glance for a moment, however, at the inflammatory conditions which precede these atrophic changes.⁶ Here we

⁶ I. Braden Kyle. The Etiology, Pathology and Treatment of Ozena, Medical News, May 5, 1891.

have engorged vessels causing intra-vascular pressure, followed by exudation which relieves the intra-vascular pressure, but which in turn brings about extra-vascular pressure or interstitial infiltration. As a result of the organization of the exudative matter, there will be interstitial thickening followed by contraction, and in either case nutrition will be interfered with, causing a certain amount of atrophy with consequent degeneration and alteration dependent upon the extent of nutritive change. In these conditions I should expect by the judicious use of a cataphoric electric douche, simple or medicated, according to indications, to so relieve such an inflammatory condition as to prevent the subsequent exudation. I have had no opportunity of trying it in these acute conditions, but throw out the suggestion. If the passive congestion of the mucosa, which has a tendency when once established to remain, can by this means be overcome, the atrophies and degenerations will be much less liable to occur. The presence of muscular fiber has been demonstrated in the Schneiderian membrane by Herzfeld of Berlin, and corroborated by Kolliker and Zuckerkandl. This fact would indicate the value in all these conditions of an alternating current douche as well, for wherever there is muscular fiber there will be muscular contraction in response to electrical stimulus, with the result of inviting fresh arterial blood to the part, thereby relieving congestion and stimulating the absorbents into healthful activity. The first indication to be met, viz., that of cleansing the mucous membrane with some alkalin solution, can not be more effectually done than by a negative constant current douche (saline solution) where, by the electrolytic action of the current, there is invited to the part the hydrogen and alkalies. With the electric douche there is to be obtained at the same time the physiologic effect of the current stimulating the parts to a healthy nutrition.

In the atrophies and degenerations where a maximum stimulating effect is desired, a cataphoric douche may be administered. Any drug (soluble in water) indicated in these conditions could be used whose electric diffusion is established. The clinical value of cupric electrolysis (with a copper electrode) suggests a solution of Cu_2SO_4 used as a cataphoric douche. I have used this to advantage in atrophic rhinitis.

The value of copious, hot saline douches in the treatment of inflammations of the ethmoidal sinuses suggests the thought that in electric douches, simple or medicated, we may have an agent of still greater value.

In post-nasal applications the stimulating and consequently curative effect of the electric douche would be greater than that of the ordinary washing out or topical administration of medicated solutions, or here again, a cataphoric douche would not only free the passages from accumulated secretions but drive, at the same time, whatever medicament is used into the submucous structures where it would have an opportunity for beneficent action.

In congested and relaxed conditions of the pharyngeal mucous membrane I use the post-nasal electrode attached to the ordinary irrigating bottle or fountain syringe. Here the douche can only be applied momentarily. Even so, the diseased tissue may be brought much more promptly under the influence of drugs by cataphoresis than by means of the ordinary medicated spray.

In the treatment of thickening of the drum, where it is desirable to bring the membrane under the influence of the negative pole, the water electrode is particularly adapted. One can use requisite current strength without any danger of galvanic-caustic action, and whenever it is desired to bring the ear directly under the influence of alternating currents, we have here an extremely painless method of so doing. The indifferent electrode in the treatment of thickening of the drum can be placed at the mouth of the Eustachian tube, thus bringing the diseased tube and drum at the same time within the interpolary influence of the current. In such cases I have used the ordinary copper electrode—nasal—attached to the positive pole at the mouth of the Eustachian tube, and the negative water electrode to the ear. Here, by the electrolytic action at the positive pole, there is obtained an oxychlorid of copper which by the cataphoric property of the current is pushed or conveyed along the course of the tube, while at the same time there is a movement of the hydrogen and salts set free by the electrolytic action, toward and to the thickened membrane, where they act to improve the nutrition of the part. There is also obtained, as well, the characteristic influence of the current upon the circulation, inducing first an anemia followed by a hyperemia and ultimately an equalization of the circulation. As a result of such applications patients have

remarked that there was a *smoother feeling* in the ear and a feeling of *life and warmth* not experienced before.

The electrode which I use for these applications to the ear and anterior nares is made of hard rubber and similar in shape to the usual ear nozzle of a fountain syringe. The shorter arm is for the attachment of the hose of the fountain syringe, while the longer one is for the battery attach-

ment. The conducting medium as I have already indicated is a platinum wire carried to about one-third of an inch from the distal end of the electrode, while a number of small apertures cause the water to flow out in the form of a rose.

(To be continued.)

Heilserum in Diphtheria.—Professor Bokai gives the following opinion before the Royal Society of Physicians in Buda-Pesth as the result obtained from 120 cases of diphtheria treated in the Stephanie Hospital, Buda-Pesth, Sept. 10 to Dec. 31, 1894. All cases were examined bacteriologically and Löffler's bacillus was found in all but five: 1, serum from a reputable source has a specific and beneficial effect; 2, the serum is superior to all other means of combating the disease, and no untoward effects have been observed, except urticaria in 10 per cent. of cases; 3, in severe laryngeal stenosis threatening death by suffocation, an operation, (intubation, tracheotomy) is a necessary addition to the serum-therapy; 4, in those cases in which the disease assumes a distinctly septic character from the beginning, the value of the serum is doubtful. Heart weakness due to organic changes and leading to paralysis, the serum can not relieve; 5, the question of prophylactic injections, from his lack of experience, is not decided for him, but from his results he believes that protective inoculations will be no less approved than the curative. The statistics of this hospital show that in 1891, of 135 cases of diphtheria 40 per cent. recovered; in 1892, of 92 cases 46½ per cent. recovered; in 1893, 32½ per cent., while in 1894, of 120 cases 74½ per cent. recovered. In the discussion following, Gerloczy referred to his use of serum in fifty-five cases and maintained that the serum offered no sure relief, yet he believed that by its general use the mortality is lessened about 10 per cent. and since he had observed no ill effects he regarded it as his duty to use the serum.—*Wiener klinische Rundschau*, May 5, 1895.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 86 Fifth Avenue, Chicago.

SATURDAY, JULY 6, 1895.

THE PRACTICE OF MEDICINE IN CITIES.

The rush of young men, not well prepared, into the practice of medicine is likely to be checked and headed off for a time. The State examinations for license to practice will raise the standard and drive out the incompetents and quacks. In some of the large eastern cities new questions of professional peril are coming into prominence. Teachers and specialists in every city have depended very largely on consultation practice. The strain to secure a position in a medical college was, in most instances, to enlarge their acquaintance and consultation practice. This has grown to such an extent that vacancies for teaching are bought and sold, not always for so much money, but for influence and prospective power to help the college and its teachers.

The time came when the would-be medical teachers far exceeded the demand, and the polyclinics were organized. This appeared to be a most fortunate opening for many, and the rush for places and professorships was the same as in the colleges. Free services were offered, and large assessments were made to cover expenses and buildings, all freely paid. The inland practitioner who came to improve and enlarge his knowledge was cultivated as one who would yield large returns in future consultations. Elaborate and exhaustive studies in clinical surgery and medicine, by large, eminent faculties, are served up with earnest skill. Classes of very enthusiastic physicians go away with hearty praise to the faculty and thankfulness. These physicians return to work with not only greater skill and practical knowledge, but a degree of confidence to do all their own surgery, and be their own consultants. They recog-

nize the practical significance of saving the large consultant fees, and doing the work and keeping the case in their own hands. They open hospital rooms and gather round them appliances and nurses for doing the work that large hospitals have concentrated in the cities. Nearly all the large operations in surgery, occurring in persons who are able to pay, are retained and treated by the polyclinic students and graduates. Hundreds of cases from the villages and towns, that were formerly sent to the large cities, are now treated at home.

Physicians who wish to become expert in some line of surgery, take special courses at these schools and then return and treat all these different cases, while the poor, hard-worked professor finds his dream of increasing consultation vanishing into thin air.

The only class of cases that come in from the country are indigents, and the professor's skill and technical knowledge is assumed by graduates in every town of the land. The poor professor is teaching and paying assessments to keep up the school and educating a class of stirring practical men to do the very work he depends on for a living. This is theoretically most commendable, but, practically, to poor men in large cities it is destructive. All medical teachers in eastern medical centers, who have not an income outside of their medical work, suffer and find the strain of practice growing greater every year. A reversion is going on. The country and village practitioner, who attends the polyclinic every year or more, and becomes familiar with the best methods of practice, is the peer of the city professor. He can command and control his cases and collect his fees while living in most comfortable, easy surroundings. His brother in the city must keep up a style of wealth and prosperity, even although grim want may hang round the kitchen door. If he is a teacher his time and money must be spent freely, although nothing tangible come back. His love of science and willingness for sacrifice must rise above every other consideration.

The polyclinics, while increasing the labors and strain of practice in large cities, are great blessings to the profession, especially to the army of isolated inland physicians, who are anxious to keep well up to the frontiers of science.

They are equally valuable to those who realize their failures in early studies and preparation for work. The present popularity of these schools will decline as better educated men come into the ranks of the profession. In the meantime the frantic efforts to attract patients to the cities by free dispensaries and hospitals, where the foolish teachers give away their time and services for nothing must die away.

At present, the hospital dispensary and much of the private practice of medicine in large cities is conducted on the most idiotic and childish principles.

Some surgeon will charge \$500 for an operation which he may have done a dozen times in the hospital within a month free, on persons able to pay.

Bids are made for cases to come to large hospitals where the operations are free, only some nominal price of board is charged. This has become an abuse which has produced much bitterness in many circles. Free medical services, and a craze to teach medicine for nothing, and the increasing strain to secure patients to illustrate the service, and to furnish an income to subsist on, are grave perils to physicians in large cities. It is a question which is the greater abuse, letting in an array of half-trained men to practice or to sacrifice the members who are in, by demands for free services and free labor, and placing them in positions which require the greatest skill and struggle to even make a living.

Now that the first abuse is to be corrected, is it not wise to agitate the next question, How is the practice in large cities to be regulated so that medical men can receive a rational and substantial recognition for their services? How is this foolish competition to become teachers, both cheapening the dignity and quality of the work, to be abandoned? Evidently some radical reforms are necessary, and this subject needs agitation.

THE ANTI-STREPTOCOCCIC SERUM.

Among the more recent applications of serotherapy is that of treating infections of the streptococci with the serum of animals immunized against the microbe which—as comprehensively summarized by a French contemporary¹—causes phlegmon, erysipelas and puerperal fever; which induces suppuration in cellular tissue, as in serous cavities; which is always present in the mouth and pharynx; which may, in short, give rise to a series of affections ranging from simple angina to peritonitis and which, moreover, complicates nearly all infectious diseases, both acute and chronic. To successfully combat this terrible adversary would be to give aid of extraordinary power to the physician, the surgeon and the accoucheur. It is this aid which various observers, especially ROGER and CHARRIN, MARMOREK and CHANTEMESSE hope to have discovered in anti-streptococcic serum. MIRONOFF first and then CHARRIN and ROGER began by immunizing animals against the streptococci and, by injecting five or six cubic centimeters of serum from one of these immunized animals, prevented the development of the erysipelas microbe in the rabbit—one of the most susceptible animals. Recently the last two observers immunized a mule by injecting, in eight séances, 240 cc. of a toxin prepared by evaporating and sterilizing 2,400 cc. of a bouillon culture of streptococcus. With serum from this mule they cured in a few days two women suffering with grave puerperal infection, by injections amounting in

one case to 50, and in the other to 96 cc. The daily dose varied from 8 to 25 grams, according to the gravity of the symptoms; recovery occurred in three to four days and complete convalescence in five to six days. In a weak new-born child, with erysipelas they succeeded in jugulating the affection with 5 cc. of the serum. Finally, in a pseudo-membranous angina, accompanied by serious depression with cardiac complications, temperature 106.2, pulse 148, a cure was obtained in three days by the daily injection of 30 cc. of serum.

At the same time MARMOREK, at the Pasteur Institute, succeeded in immunizing the horse, ass and sheep, either by injecting weak cultures and then more and more virulent, or by increasing doses of a toxin prepared by simply filtering cultures in bouillon through porcelain.

It is important to obtain as active a toxin as possible, and MARMOREK, by passing a series through rabbits, obtained a culture which killed them in thirty hours in the dose of one one-hundred thousandth of a centimeter. The animals were immunized with this very energetic toxin, though this required several months and several hundred rabbits to obtain the required potency.

Erysipelas was also treated by MARMOREK and CHANTEMESSE. Of eighty-six cases, forty appeared benign and were treated by ordinary methods; forty-six were grave and received serotherapy; all recovered save one old woman, who died of pneumonia ten hours after admission. They injected 5 to 20 cc. of the serum. The general condition was ameliorated; the temperature was lowered in a very short time, and where there was albumin in the urine this disappeared very rapidly under the treatment.

These authors claim that albuminuria accompanying erysipelas is cured by serotherapy. This claim is important, for some observers claim that the antidiphtheritic serum has an injurious effect on the parenchymatous organs and especially on the kidneys. Some patients recovered in spite of an unfavorable prognosis given by the authors; none of the cases were followed by phlegmon or by abscess as is the rule in grave cases of erysipelas. According to the authors this result is due to the activity of the toxin employed to immunize the animals—the larger the dose of the active toxin the greater their degree of immunity. This immunization is a long and delicate process, for the animals react with extraordinary violence to even the smallest dose of the toxin. These results are encouraging but demand confirmation, for nothing is more variable than the gravity of erysipelas and the prognosis is always difficult.

As to the other varieties of streptococcus infection, the cases are too few to form any reliable opinion, though MARMOREK is still engaged in researches and promises some further observations shortly.

¹ Jour. des Sciences Med. de Lille. No. 17, 1895.

ANTIVENIN, THE LATEST CONTRIBUTION TO
SERUM-THERAPY.

According to the *Press and Circular*, June 12, Dr. THOMAS R. FRASER, professor of materia medica in the University of Edinburgh, has made a very significant announcement regarding his original work with serpent poisons. Early in the month of June Dr. FRASER read a paper before the Royal Society, showing that animals may be immunized against the venom of the cobra as well as other serpents. He also showed that antidotal properties inhere in the blood serum of such immunized animals. Dr. FRASER opened his paper with a historical account of the beliefs and traditions of the Hindoos and others, that poisonous serpents are self-immunized by some result of the absorption of their venom.

Since the year 1889, Dr. FRASER has been in receipt, from different parts of the globe, of supplies of snake poison, especially of the Indian cobra, and with this had performed many experiments on animals in the hope of producing immunity. The results he obtained passed his most sanguine expectations.

Continuing its abstract of Dr. FRASER's paper, the *Press and Circular* says:

"Experimenting on rabbits, among other animals, he first satisfied himself as to the amount of the poison which constituted the minimum lethal dose. He then proceeded to inject quantities below this amount, and found that he could gradually increase them to *fifty* times the dose originally fatal. But not only that, for a buck rabbit, which he exhibited, and which was then in about the one hundred and fiftieth day of treatment, had gained enormously in weight, from 2,000 grams to 3,000 grams, and had increased greatly in strength, and especially in virile power. Again, he found that the mixture of 1-240 cc. of serum obtained from a rabbit immunized to thirty times the minimum lethal dose with cobra venom averted a fatal result on injection, while the injection of a similar serum half an hour after the injection of a venom which otherwise proved fatal in one hour, promptly stopped the symptoms which had already commenced, and saved the life of the animal. He called this protective serum by the name of 'Antivenin.' He also mentioned as an interesting fact that the rabbit above referred to had received during the months of treatment *enough cobra poison to kill two horses*, or about two hundred and eighty rabbits if unprotected. Not only are Dr. FRASER's results of the greatest value for the treatment of snake bite in India and other tropical countries, but, as he himself remarked, they possess a deeper significance in accentuating, as they do, the wonderful progress made in serum-therapy during the last few years, and are an earnest of still more wonderful discoveries yet to be made in the same direction. It appears also that immunizing an animal with the venom of one kind of serpent *protects it from the poison of other species.*"

In conclusion, it may be said that Dr. FRASER is well known for his original investigations concerning calabar bean and the other ordeal poisons of

West Africa. We may confidently predict that his findings will be confirmed.

AN INTERNATIONAL CONVENTION OF BACTERIOLOGISTS.

The bacteriologists of the country held a convention, June 21 and 22, in the New York Academy of Medicine, under the presidency of Dr. WILLIAM H. WELCH, of the Johns Hopkins University. On the first day of the conference, papers were read by Drs. FULLER, WELCH, SURGEON-GENERAL STERNBERG and Drs. SEDGWICK and CHEESMAN.

The most important work of the convention was the appointment of a committee to investigate the bacterial field as applied chiefly to the water supplies of cities, and to decide as to the standard types, methods of cultivation, and the interpretation of results.

The following delegates were appointed upon this committee: Prof. J. S. ADAMS of McGill University, Montreal, Chairman; Prof. W. F. SEDGWICK, Biologist of the Massachusetts State Board of Health; Dr. G. W. FULLER, Biologist in charge of the Lawrence Experiment Station of the Massachusetts State Board of Health; Dr. CHARLES SMART, U.S.A., Chairman of the Committee on Water Supply of the American Public Health Association; Dr. T. M. CHEESMAN of the College of Physicians and Surgeons, THEOBALD SMITH of the Massachusetts State Board of Health, Dr. A. C. ABBOTT of the University of Pennsylvania, and Prof. W. H. WELCH.

A LONDON "REFUSE DESTRUCTOR" PLANT ON A
LARGE SCALE.

In one of the parochial districts of London, St. Pancras, the problem of disposing of municipal refuse at the lowest cost is being solved. And more than that, this refuse is made of practical value in connection with the parochial electric-lighting works. The city refuse, or "dust," to use the English word, is consumed in specially constructed furnaces, and the heat thus generated used to produce power to run the electric plant.

These new buildings cover an area of two acres and a half, facing King's Road, and the most noticeable feature of the plant is the huge chimney that rises to a height of 231 feet, and that cost over \$15,000 to erect. The total cost of the plant has been \$500,000.

The "dust" is collected throughout the district by carts and carried to a rear entrance, weighed and tipped into enormous tanks on each side of the main shed. To these tanks are attached hoppers, which convey the refuse to furnaces of new design, and considered to be of the best type now existing.

A novel feature of the whole scheme is its general automatic working, which requires the least possible outlay of manual labor. For instance, the furnace

is fitted with an ingenious appliance of alternating bars, moving up and down with an eccentric forward motion, carrying the refuse continually toward the center of the fire.

There are eighteen furnaces, capable of consuming 1,260 tons of dust per week. There is but a small amount of "clinker" left behind, and this is withdrawn every six hours. This can be used to form an exceptionally tenacious mortar, and its sale, (together with certain reduce expenses) will yield a probable gain to the parish of \$25,000 per annum.

The fiery gases from the burning material pass through long flues to the engine room of the electric works, pass around and in front of the boilers into an "economizer," and so into the chimney. The destructors are said to produce 12,000 degrees of heat, and supply from 300 to 400 horse-power to the boilers. Efficiency with economy is proved possible in this scheme. For instance, the water needed is procured by saving the waste steam, passing it through a condenser and a water softening apparatus, pumping it to the top of the building to a cooler, whence it returns to a tank of 115,000 gallons capacity.

There will be a saving in cartage of refuse, a saving in coal at the electric station, and a saving to the taxpayers who will have cheaper and better street lighting, and a valuable asset.

The *Lloyd's Newspaper*, from which the above description is taken, remarks: "The possibilities of the use of city refuse as fuel may be followed by as interesting results as was the discovery of the value of the despised coal-tar, and also of refuse petroleum."

ASSOCIATION NEWS.

Section on Surgery and Anatomy.—*Minutes of Meeting of 1895.*

The Section was called to order on Tuesday May 7, 1895, at 3 o'clock P.M. by the chairmen Dr. Jos. Ransohoff of Cincinnati, Ohio, who delivered his inaugural address, dwelling in it on the diagnosis and treatment of stone in the kidney and presenting four specimens of kidney stones which he had removed.

The following papers were then read: "Cystoscopy, Catheterization of the Ureters and Catheterization of the Kidneys in the Female," by Howard A. Kelly, Baltimore, Md.; "Acro-Urethroscopy with the Exhibition of a new Instrument," by W. K. Otis, New York, N. Y.; "The Value of Urethroscopy in Chronic Urethritis with demonstration of the Nitze-Oberlaender, Casperand Posner Urethroscopes and other Urethral Instruments," by Ferd. C. Valentine, New York, N. Y., and were discussed by Drs. Otis of New York, Deaver of Pennsylvania, Valentine of New York.

Dr. Valentine also asked leave to present in behalf of Professor Posner of Berlin, Germany, a paper on "Cryptogenic Cystitis and Pyelitis" which was received and read by title. A paper on "Movable Kidney" was then read by Homer Gage of Massachusetts, and discussed by Dr. Wyman, of Michigan; De Forrest Willard, of Pennsylvania; Weeks of Maine; Ferguson, New York; J. B. Roberts, of Pennsylvania; Fenger of Illinois and Davis of Alabama.

A paper on the same subject by Dr. E. B. Davis, of Birmingham, Ala., was read by title.

A paper on the "Radical Cure of Hydrocele" was read by D. C. Hawley, Vermont, and discussed by Drs. McLean, Michigan; Gaston, Georgia; Vance, Kentucky and Rodman of Kentucky.

A paper on "Erosion, Excision and Amputation in Joint Diseases" was read by De Forest Willard of Philadelphia, Pa. The chairman appointed as a nominating committee Drs. De Forest Willard, Pennsylvania, J. B. Murphy Illinois, Weeks of Maine. Adjourned.

The Section was called to order at 9 o'clock A.M. Wednesday, May 8, and a paper entitled "A Note on the Surgical Cure of Hernia" was read by W. B. De Garma, New York.

The subject of "Appendicitis" was then treated by John B. Deaver, Philadelphia, Pa., and discussed by Drs. Weeks, Maine; McMonigle, California; Wyman, Michigan; Quimby, New Jersey; Murphy, Illinois; Marcy, Massachusetts; Hawley, Vermont; Herrick, Ohio; Willard, Pennsylvania; Bishop, Pennsylvania, and closed by Dr. Deaver.

The Secretary then showed for Dr. J. C. Schepps of Brooklyn, N. Y., an improved elastic tourniquet.

"Thoracic Troubles from a Surgical Standpoint" was the title of a paper by J. McFadden Gaston, Georgia, which was discussed by Drs. Wenz, Pennsylvania; Willets, California; Risley, Pennsylvania, and the Section then adjourned until afternoon.

The Section was called to order at 3 o'clock P.M. Wednesday, May 8, and a paper on "The Treatment of Malignant Tumors by the Toxins of the Streptococcus of Erysipelas," read by Nicholas Senn, Chicago, Ill. Discussed by Drs. W. B. Coley, New York; Sayre New York; Rocky, Oregon; Wyeth, New York; Herrick, Ohio; and Kern, Pennsylvania.

The following papers were discussed together: "Tumors of the Mammary Gland," by W. L. Rodman, Louisville, Ky.; "Is Total Extirpation of the Rectum ever Justified" by J. M. Mathews, Louisville, Ky.; "Colotomy vs. Extirpation in Cases of Cancer of the Rectum," by L. H. Adler, Philadelphia, Pa. Discussed by Drs. Tiffany, Maryland; Keene, Pennsylvania; Fenger, Illinois; Jacobson; Rocky, Oregon; Marcy, Massachusetts; Davis, Missouri, and closed by the readers of the papers.

The Nominating Committee reported the names of Drs. C. A. Wheaton, St. Paul, Minn., for chairman, and Dr. W. L. Estes, South Bethlehem, Pa., for Secretary for the ensuing year. On motion, the secretary was directed to cast the vote of the Section for these gentlemen who were thereupon declared elected.

A paper on "Bronchiogenous Carcinoma," by Charles A. Powers, Denver, Colo., was then read by title.

The following papers were read: "An Original Osteoplastic Operation for the Removal of large Vascular Tumors Growing in the Vault of the Naso-Pharynx, Antrum of Highmore, Spheno-Maxillary, and Pterygo-Maxillary Fissures," by John A. Wyeth, New York, N. Y.; "Electrolysis in the Treatment of Sacculated Aneurysm, through Introduced Wire, with Report of a Successful Case," by D. D. Stewart, and J. J. Sallinger, Philadelphia, Pa.

The Section then adjourned until the following morning.

The Section was called to order at 9 o'clock A.M. Thursday, May 9, and a paper on "Some Points in Asepsis in Private Dwellings with the demonstration of some new Aseptic Appliances," was read by Carl Beck, of New York, N. Y., followed by papers on "Ileus," by J. B. Murphy, Chicago, Ill.; "Scientific Uses of the Surgical Flap," George Wiley Broome, St. Louis, Mo.; "The Surgical Technique of Aseptic Wounds," by Henry O. Marcy, Boston, Mass.; "Flat-Foot—Supramalleolar Osteotomy with Report of a Case, Photographs and Specimens of Feet of Man, Orang, Baboon, Chimpanzee and Gorilla," B. Merrill Ricketts, Cincinnati, Ohio.

The Section then adjourned until the afternoon.

The Section was called to order at 3 P.M., and the Secretary having been called away, Dr. J. C. Oliver, of Cincinnati, was elected Secretary *pro tem*.

Dr. Murphy's paper on "Ileus" was discussed and the following papers were read: "Gall Stones in the Common Duct and their Surgical Treatment, with remarks on the ball-valve action of floating Choleliths Stones," by Christian Fenger, Chicago, Ill.; "Skin grafting after the Method of Thiersch," by J. C. Oliver, Cincinnati, Ohio; "Excision of the Knee-Joint, with Report of a Case of complete Dislocation of the Knee, of nine years standing, and with especial Reference to Methods of Fixation," by S. F. Forbes, Toledo, Ohio.

In connection with this paper, Dr. Marcy, of Boston, Mass., showed a case of hip-joint resection done by Dr. L. A. Sayre in 1876. The head and neck of the femur had necroses and the femur was sawed through just below the trochanter minor.

He had excellent motion in the joint and made the difference in the length of his legs, which amounted to six inches, hardly noticeable by means of an "extension shoe," which was laced to his foot, and which allowed the use of an ordinary pair of shoes, the patient walking with the toe pointed instead of at right angles to the leg.

Dr. Marey also exhibited a series of double tubes made by George Tiemann & Co., of New York, after patterns devised by him many years since and for a long time now in general use. The larger ones are designed for the washing out of the stomach, rectal irrigation, etc. The smaller are catheters in various sizes, both male and female. The efferent tube is twice the size of the direct, in order to prevent over-distension. They are made in the same finish as the rubber catheters. The value of these soft rubber tubes for the purpose of irrigation has somewhat recently been emphasized at the Johns Hopkins Hospital, from which they have been offered to the profession as a recent invention of one of the members of the medical staff. It is on this account that they are presented to the Section.

The following papers were then read: "The New Surgical Splinting—Report of Cases Exemplifying it," by E. A. Tracy, Boston, Mass.; "A Simple Method of Dressing Fractures of the Extremities auxiliary to the Bandage," by John E. Link, Terre Haute, Ind.

The Section then adjourned till Friday morning, when it reconvened at 9 A.M., and the following paper was read: "Deformities following Fractures of the Shafts of Bones," by Thomas H. Manley, New York, N. Y.

The Section then adjourned for the year.

REGINALD H. SAYRE, Secretary.

CORRESPONDENCE.

The Michigan Practice of Medicine Act.

CHARLOTTE, MICH., July 1, 1895.

To the Editor:—In the JOURNAL of June 15, in the editorial columns, I notice the report of the Michigan Medical Society for its recent meeting. I wish to call your attention to this paragraph which I herewith quote: "Michigan, still, by deliberate act of its Legislature, remains the dumping ground for the world's incompetent and dishonest doctors."

The Legislature of Michigan in its last session passed the bill to regulate the practice of medicine and to prevent that which you deplore, as well as all honest and intelligent people. It would have become a law, but for the veto of the Governor, who only exercised that prerogative after the Legislature had adjourned, and could not pass it over the veto for that reason.

Hoping you will correct the misstatement, and do justice to at least a portion of Michigan's unfortunates,

I remain yours, G. B. ALLEN, M.D.

Member of the Legislature and Representative 2d District, Eaton County.

ANSWER. "For all sad words of tongue or pen
The saddest are these: 'It might have been.'"

PUBLIC HEALTH.

Yellow Fever.—Press dispatches announce the existence of yellow fever at Tampa, Fla., July 4.

Added Duties in the New York Board of Health.—The Health Board of New York City, along with the fire, excise and building departments, since the recent annexation of a territory covering about 20,000 acres of land, with a population of 17,000, must now extend its lines. This recent addition which more than doubles the city's territory north of the Harlem River, adds more than a third to New York's domain. Many a problem of drainage, grading and water supply remains to be solved, with the inevitable conflict between taxpayers and sanitarians.

A Navy-Yard Garbage Destructor.—At the Brooklyn navy yard, a small garbage destructor has been put into operation. The crematory is a structure about 25 x 30. The framework is steel, and the outer walls are made of corrugated iron.

Within this is the oven or crematory proper. This latter is composed of brick, stone and iron. There are six doors or openings to the crematory. One of them is used for making the fire, another for removing the wood ashes, and the other four are the openings through which the cremated garbage is drawn. The garbage is introduced at the top of furnace, the garbage wagon taking its loads there by means of an inclined plane and platform. The fuel used is largely the waste wood which is collected from the work-shops of the yard. The capacity of this destructor is said to be ten tons daily.

"Malta Fever."—In a brief paper contributed to the London *Lancet*, W. Hill Climo, a retired brigade surgeon, points out that the history of the so-called "Malta fever" is strangely similar to what obtained a few years ago in reference to the increasing prevalence of, and mortality from enteric fever in India. From time to time various explanations were hazarded to account for the phenomena connected with it; but they had to be discarded, and now the disease is admitted to be in every respect identical with the typhoid fever of European countries, being specific in origin, and traceable to a sewage-polluted soil affecting the water supply. It is believed that in the near future a like view will be taken of Malta fever and its specific character recognized, the disease originating in local insanitary conditions and the action of climate in its production being chiefly manifested by its influence on these conditions, and not directly on the constitutions of individuals in the first instance. That such grave sanitary defects as Surgeon Climo describes should be allowed to exist unheeded in a military possession of the country which has done so much for military hygiene is quite as singular as the failure hitherto to recognize the specific filth character of the disease these defects have produced.

Death Rates in Foreign Cities.—The following statistics of foreign cities have been collected and collated, by the Paris *Herald*, for the year 1894: "Among the highest death rates are those of Moscow, 34.1 deaths per 1,000 of population; St. Petersburg, 31.4; Rouen, 31.3; Havre, 29.8; Naples, 27.7, and Milan, 25. Dublin had a mortality of 24.7 per 1,000; Munich, 23.7; Cologne, 23.1; Prague, 22.1, and Bordeaux, 21.3. Among the lowest death rates are those of London, Liege and Berlin, respectively 17.7, 17.6 and 17.2. Still lower are the figures for The Hague, 16.9; for Frankfurt, 16.5, and for Bristol, 15.4. In cities where the population fluctuates rapidly, these figures may be slightly too large or too small. But it is very noticeable that in some of the large towns and cities of Europe the actual death rate has been immensely reduced by modern sanitation. The mortality of London in 1870 was 24.3 per 1,000, and in 1881, 21.6. The death rate in Paris in 1881 was 25.5, but it is now only 20.2. As late as 1873 Berlin's death rate was 28, and in 1878 Professor Virchow showed it was increasing. It is, therefore, apparently a great triumph of sanitary science that in 1894 it should be so low."

Infectious Disease Hospital on Wheels.—In a rural section of Scotland there is in use an ambulatory hospital for infectious cases, that has been devised with no small degree of care. The following is a portion of a description thereof in the *Medical Press and Circular*, May 22: "The county authorities of the eastern part of East Lothian have determined to provide their district with three hospital caravans for the purpose of treating infectious disease. The first one was inspected the other day in Leith and gave great satisfaction. The caravan, which will be drawn by two horses, measures, internally, 19 x 10 x 8, giving an air space of 1,520 cubic feet. It contains two beds, curtained off. It has a double lining of wood and an end is made so that the panelling can be removed and the caravan placed against another caravan in corridor fashion. It is well ventilated by means of Tobin's tubes and has another ventilator on the roof. The total cost of

each will be £100. The advantage of such a movable hospital in a rural district is manifest, and even if there is a considerable epidemic in one part, several caravans can be collected together there. The difficulty, we should suppose will be, in such districts, to procure proper accommodation for the nurse required, and also about the efficient and sanitary disposal of excreta and infected clothing. The caravan itself is so made that it can be thoroughly disinfected when necessary."

Double Role of the Staphylococcus Albus.—The white staphylococcus, *S. pyogenes albus*, found in pus and hitherto associated, as the name implies, with pus formation, has been found according to M. Charrin, in considerable numbers in the breast milk of women apparently in the rudest health and whose nurslings thrive on their milk. This discovery, which was proclaimed at a recent meeting of the Biological Society of Paris, would seem, according to Dr. Dolan,¹ to strike a severe blow against the modern germ theory of disease. In which connection Dr. Dolan cites the observation of a writer in *L' Union Medicale*, who says that in reality, as regards the breast as well as the bronchi, intestines, etc., if the pathogenic agent frequently makes its entry from without, it also at times preëxists within the system, awaiting some occasional cause such as traumatism, a febrile affection, or other exciting agent in order to make its presence manifest by swarming. Dr. Dolan asks: "What is the nature of this occasional cause? Calling it traumatism, etc., does not help toward the elucidation of the knotty point. The staphylococci at one moment are beneficial and wholesome toward their human host; at another they become virulently noxious. What is the real cause of this change of front? It is not too much to say that we know nothing whatever about it."

To Reduce Infant Mortality.—"The Sterilized Milk Charity" in New York City will be continued during the summer of 1895. The fourth of the sterilized milk booths for which Mr. Nathan Straus has the permission of the Park Department to erect, is to be situated in City Hall Park and will probably be completed before this item is published. Three others are already in operation, and the fifth will soon be built in Central Park. The price is one cent per glass. One of the newspapers remarks: "Fewer calls upon the doctor is one of the advantages." Although the enterprise was begun in 1894, as late as July, and many of the booths were in operation barely two months, a total of 600,000 glasses of milk were sold. With the earlier start this year and the increased popular knowledge regarding the plan, the total is likely to be doubled. The scheme has heavy expenses aside from the cost of the milk. There is a pay-roll of those engaged solely in this work which foots up \$300 a week now, and is likely to be materially increased during the height of the season. To begin with, twenty-two young women are employed as clerks in the eleven booths and depots. Then eight men and two boys are needed upon the trucks which are constantly busy carrying the milk from the railway terminals to the central distributing point, and thence to the booths and depots. Tons of ice are consumed daily in keeping the milk cool, and the cost of construction of booths and rent of depots is a considerable item in the expense total.

A Health Commissioner Resigns.—A change has taken place in the New York City Board of Health. Dr. George B. Fowler becomes Commissioner, *vice* Dr. Cyrus Edson, resigning by request of Mayor Strong. Dr. Edson has sustained a good reputation in his public life, but he has the unfortunate handicap to bear of being too closely linked with the malign influences that grew out of Tammanyism. Dr. Edson's father is an ex-Mayor of the variety that sits now

under public condemnation; so that the "Tammany tiger cubs," as the New York *Herald* remarks, are not always judged according to their merits. However, Dr. Edson (unless the reporters have been misled) is reported as paying himself the following delicate tribute: "I have given the best portion of my life to the service of the Board of Health, beginning on the lowest rung of the ladder. I have held nearly every subordinate position to which a physician is eligible. Through all these offices I have been promoted without a backward step. I have served through several epidemics and have had the good fortune to direct my subordinates to such effect as to repeatedly stamp out contagious disease when it seriously threatened the people of the city. I believe that the Board of Health was never so efficient as at the present time." When asked about alleged charges that he had been too free in the use of his official signature in mercantile ways, he is reported as replying: "I have several lawsuits against firms who have used my name to advertise themselves." He said he was not sorry to give up the position, and that he could make more money by his private practice.

"State Care" of the Insane of New York.—Although many strenuous efforts have been made to secure the passage and signature of an act to compel the county authorities of New York to transfer their pauper insane to the State Lunacy Commission, the result has been a failure in 1895. Mayor Strong declined to approve of the law, and the Governor could not sign it without that approval. The New York *Herald* now appeals to the State Commissioners to proceed by urgent measures, through orders of the Supreme Court, to compel the county commissioners to amend existing abuses. It demands that no delay be allowed in the matter of improving the maintenance of "the unfortunate creatures immured in the island madhouses and at Central Islip." The writer further argues the necessity for action by the Lunacy Commission as follows:

"No one, better than the State Commissioners in Lunacy, realizes the shocking state of affairs in the New York city asylums. They knew much before of the evil and neglect, the underfeeding, the wretched food and housing of the inmates, the insufficient number of attendants and the brutal nature of some of the men employed. They knew of the filthy bedding and the filthy bathing. They have made reports upon these features and have made recommendations which have been ignored. It is time for them to act in the premises. The law gives them ample power. They have already resorted to extremities in Kings County, where they compelled the local authorities under an order from Judge Cullen, of the Supreme Court, to amend abuses. Will they act now in the case of New York, or will they permit to exist the abuses of which they complained to Mayor Grant, to Mayor Gilroy and to Governor Morton? The Commissioners, alone, now have the power to terminate the inhumanity that disgraces New York, and which through failure to correct, bears upon the administration of Mayor Strong."

Mayor Swift of Chicago has appointed ex-Alderman Kerr to be Commissioner of Health of that city. Much criticism has been evoked because the appointee is a non-medical man, but it is understood that a new Health Department will be created, on a sound basis, and on a scale equal to the needs of the city, as soon as the ordinance can be prepared, which it is expected will be ready on the reassembling of the City Council after the summer vacation. Dr. John B. Hamilton, the editor of this JOURNAL, has, pending re-organization, been requested by the Mayor to act as consulting hygienist to the Health Department and in that capacity will prepare the plan for the new department. In the meantime, Dr. Frank W. Reilly, the Assistant Commissioner of Health, formerly Secretary of the Illinois State Board of Health, will continue in his present position, to give necessary advice to the new Commissioner in the performance of his daily sanitary duties.

¹ Provincial Medical Journal, No. 160, 1895.

Health Reports.—The following health reports have been received by the Supervising Surgeon-General, Marine-Hospital Service:

SMALLPOX—FOREIGN.

London: June 8 to 15, 1 death.
 Dublin: June 8 to 15, 13 cases, 2 deaths.
 Alexandria: May 14 to 20, 1 death.
 Cairo: May 14 to 20, 3 deaths.
 Bologna: June 8 to 15, 1 case.
 Calcutta: May 11 to 18, 67 deaths.
 Havana: June 13 to 20, 8 deaths.
 Liverpool: June 8 to 15, 1 case.
 Madrid: May 26 to June 9, 5 deaths.
 Moscow: May 25 to June 1, 3 cases.
 Odessa: June 1 to 8, 6 cases.
 Prague: June 1 to 8, 9 cases.
 Rheims: June 8 to 15, 1 case.
 Rio de Janeiro: May 18 to 25, 4 deaths.
 Rotterdam: June 8 to 15, 1 case, 1 death.

SMALLPOX—UNITED STATES.

Tennessee: Memphis, June 15 to 29, 6 cases.
 Pennsylvania: Philadelphia, June 15 to 22, 1 case, 1 death.
 Missouri: St. Louis, June 15 to 22, 1 case.
 Michigan: June 15 to 22, smallpox reported at Detroit and Olivet.
 Indiana: Evansville, June 19 to 26, 1 case.

CHOLERA.

Bombay: May 14 to 21, 2 deaths.
 Calcutta: May 11 to 18, 48 deaths.
 Niogo: May 27 to June 3, 8 cases, 7 deaths.

YELLOW FEVER.

Havana: June 13 to 20, 10 cases, 5 deaths.
 Santiago de Cuba: June 8 to 22, 19 deaths.
 Maracaibo: June 8 to 15, 1 case, 1 death.
 Rio de Janeiro: May 18 to 25, 23 deaths.
 Vera Cruz: June 13 to 20, 8 deaths.

NECROLOGY.

LOUIS A. HOFFMAN, M.D., died June 1 at his home on Ferry Street, Newark, New Jersey. He was a native of the United States and in his fortieth year. He had been sick about five weeks with an attack of dysentery, complicated with meningitis. He had been a resident of Newark about four years and had served as one of the district inspectors of the Board of Health. A widow and one son survive him.

DR. LEWIS D. HARLOW, M.D., died June 23, of heart disease at his home in Philadelphia. He was in his usual health and attended to his practice up to the day before he died. Dr. Harlow was born June 16, 1818, in Vermont and was graduated in medicine by the University of Pennsylvania, in 1845. After spending a few years in country practice, he came to Philadelphia and was elected to a Chair in the Philadelphia College of Medicine and afterward to a Chair in the Pennsylvania College. He was one of the founders of the Philadelphia Obstetrical Society, and its President in 1878. He was a member of the Academy of Medicine, Fellow of the College of Physicians and other societies. He was a delegate to the AMERICAN MEDICAL ASSOCIATION meeting at Philadelphia in 1872.

ALEXANDER BARNETT POPE, M.D., of New York City, died suddenly June 12, aged 35 years. Dr. Pope was a native of Washington, Georgia, and was educated at the University of Virginia. His medical degree was obtained at the New York College of Physicians and Surgeons, class of 1884. In 1886, he was, for a time on the medical staff of Bellevue Hospital. For some time past he had been connected with the Polyclinic, the Vanderbilt Clinic and St. John Guild. The position held by him at the clinic above named, from 1888, was in the department of diseases of children. Among the other appointments held by him, was that of an attending physician at the Bellevue Hospital Dispensary, chair of general medicine from 1886 to 1888; in the Demilt Dispensary from 1888, in the department of the heart and lungs; which

latter subjects were those of his polyclinic service. The press notices refer to the fact that Dr. Pope was possessed of considerable inherited property in Georgia, and he was the nephew of Prof. Bolling A. Pope, M.D., of Dallas, Texas. It is also stated that several years ago, while treating children, he contracted diphtheria and scarlet fever, and had a long siege of illness which left him with a weak heart.

MISCELLANY.

Dr. A. C. Cotton of Chicago, has been appointed as City Physician to succeed Dr. Todd.

Requests to New York Institutions.—Under the will of the late Percy R. Pyne, who died at Rome, Italy, in February, certain charitable objects are remembered. The testator leaves the sum of \$20,000 each to the Young Men's Christian Association in this city, St. Luke's Hospital and the American Museum of Natural History.

Conflagration at the New York Quarantine.—On June 18, the Staten Island Station of the Health Officer at the Port of New York was destroyed by fire. The building was a commodious frame structure, built in 1894, at a cost of \$10,000. Dr. Doty's residence, standing on a bluff, just above the station, was spared, although for a time in serious danger. Many valuable records were destroyed in the burning building. The cause of the fire was not discovered.

Selection of Skilled Surgeons Discharges every Obligation.—The Supreme Court of Tennessee puts itself in line with the few courts which have before it passed upon the same question, by holding, in the case of Quinn v. Kansas City, M. & B. R. Co., May 2, 1895, that, having selected surgeons skilled and competent in their profession, a railway corporation discharges every duty that humanity or sound morals impose, and that it is in no way liable for the mistakes they may subsequently commit.

On the Roll of Honor.—There are fifty-three names on the Roll of Honor, inscribed on the dome of the new House of Representatives in the State House at Boston, Mass. Each of these names is chosen as a representative of some great or worthy deed, or the opening of some new epoch. Among these names appears that of Dr. Thomas T. G. Morton as one of the founders of modern surgical anesthesia, chiefly because he made a definite series of experiments with sulphuric ether, in order to test the efficacy of that agent in the production of unconsciousness.

Entitled to Compensation for Making Post-mortem Examination.—Following its decision in the case of Flinn v. Prairie County, reported in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, June 22, 1895, page 991, the Supreme Court of Arkansas holds, in Clark County v. Kerstan, decided May 4, 1895, that a physician who makes a post-mortem examination at the request of the coroner is entitled to a reasonable compensation for so doing, but is not entitled to additional compensation for disclosing as a witness the results of the investigation and giving an opinion by reason of that knowledge and skill acquired by devotion to his particular profession, beyond the regular witness fees.

Requisites to Collection of Compensation for Medical Services.—The Indiana statutes make it unlawful for any person to practice medicine, surgery or obstetrics in that State without first having obtained a license to do so, and provide further that no action shall lie in favor of any person for services as physician, surgeon or obstetrician unless he shall have been so licensed prior to the rendering of the services. Under such a law, the Appellate Court of the State holds, in the case of Cooper v. Griffin, decided May 14, 1895, that it is not necessary, in filing a claim against an

estate for such services, for the claimant to allege that he was a regularly licensed physician at the time the services were rendered; but that, in an action to recover for such services, no *prima facie* case is made out without making proof of the issuing of the required license.

A Botanical Garden for New York City.—The New York Legislature in 1893 passed a law making it mandatory upon the city to provide a tract of park land not less than 250 acres in extent and to appropriate \$500,000 for the purposes of a garden, provided that within three years one-half that named sum should be contributed by the citizens for the same object. The requisite subscriptions were raised a short time before the three years' limit was reached, so that it now devolves upon the city authorities to issue bonds and proceed to the erection of the necessary buildings. The gardens will be located in the center of Bronx Park, with the river of that name flowing through the middle of the reservation. The gardens will be patterned after the celebrated Kew Gardens, near London. It is said that in all North America there is only one botanical garden worthy of the name, the one developed by the late Mr. Shawe, of St. Louis, Mo. Apart from the European gardens, admirable collections are to be seen in Mexico, Brazil, Sumatra, Ceylon and Borneo, the excellence of which New York may not hope to rival for many a long year. Still, a good beginning is not to be despised.

A "Pedic Society" Formed.—The union of the chiropodists of the country in an organization has been effected under the laws of the State of New York. A newly passed law gives "protection" to the citizens and to those already in the business by giving the society power to appoint a Board of Examiners, three in number. This board will license applicants that are found competent to practice as chiropodists. All persons now practicing as such in the State shall receive a diploma without examination if they apply to the examining board within sixty days. Persons who have been practicing for not less than ten years without having obtained the certificate for qualification from the State Pedic Society must register by January 1 next, with the clerk of the county in which they reside. Every person on receiving the certificate of qualification to practice shall pay into the treasury of the society the sum of \$15.

The Will of a Salem Physician.—The will of the late Dr. William Mack, filed for probate at Salem, Mass., contains the following bequests: American Unitarian Association, \$35,000, to be added to an equal sum given by his sister, Elizabeth, and considered as the legacy of Harriet O. Mack; Massachusetts Medical Benevolent Society, \$1,000, and to the city of Salem Lodge Hill, in North Salem, for park purposes. The residue of the estate is left in trust, the income, after payment of a few private bequests, to be divided between the Essex Institute and the Salem Fraternity. Upon the death of the persons receiving annuities, \$20,000 of this residue is to be paid to the Salem Fraternity for the establishment of coffee rooms, the balance to be divided equally between the Salem Fraternity and the Essex Institute. Dr. Mack was a graduate of Harvard Medical School in the year 1833.

The "Gold Cure" is not quite Dead in England.—The *Medical Press and Circular* of London has been an outspoken enemy of Keeley of the "gold cure" notoriety. In a late issue that journal returns to the charge, for the purpose of showing up the schemes of the present "promoters" in that city. The following note appears in its issue of May 22: "Not content with past failures to induce the profession to take up his so-called 'Cure for Inebriety,' another attempt is now being made to promote the venture on a commercial basis, and the public are asked to subscribe the sum of £25,000 for

the privilege. A Dr. Wolf is the promoter, and he modestly claims £10,000 of this in cash and £15,000 in fully paid shares. Doubtless, relying on the gullibility of the British public, 'he wishes he may get it,' but he has to reckon with the press, and as the writ Dr. Keeley served on us on a previous occasion did not frighten us, so we shall do our duty to the profession and the public now when the occasion arises."

A Case of Baelz's Disease.—In 1890 Unna described an ulceration of the glands of the labial mucous membrane, to which Professor Baelz, of Tokio, had called attention and to which he gave the name of Baelz's disease. No more cases have been seen until recently, when Van Dort describes one in an unmarried woman of 30, affected with an ulcer of the lips for the previous two months. The affection began with a small painless papule, rather thick, which after a few days began to ulcerate, extending slowly in periphery and depth. The ulcer was localized in the middle of the left half of the upper lip. Its form was oval, the edges red, rather sharp, but little tumefied and covered with crusts in some places. The bottom of the ulcer was covered with yellowish matter, adhering rather closely; the parts surrounding the ulcer were infiltrated. There was no pain, either spontaneously or on pressure; no engagement of the maxillary glands. The patient had frequently had attacks of tonsillitis, but no other antecedents. By application of tincture of iodine recovery ensued in four weeks.¹

St. Luke's Hospital, New York City.—This institution is to receive a legacy of about \$200,000 by the will of the late Rufus Waterhouse, manufacturer of men's furnishing goods. This is in the interest of consumptive sewing women or consumptives dependent upon sewing women. Mr. Waterhouse's wife, whose name the ward will bear, died of the disease, and he saw many of the young women he employed in his business stricken with it, and unable to support themselves. He died a widower and childless, and save for four legacies of \$1,000 each to his brother Samuel, his sisters, Mary E. Dognio and Eliza Hatch and Nancy S. Waterhouse, the widow of a deceased brother, left all his estate to St. Luke's Hospital for the ward. Four trust funds of \$10,000 each, in favor of those named were also created, they to receive the incomes, and the principals to revert to the hospital at their deaths. The beginning of the end of the present St. Luke's Hospital, at Fifth Avenue and Fifty-fourth Street, was inaugurated June 20, when the authorities of that time-honored institution declined to receive private patients, in order to adapt themselves to the restricted accommodations which will obtain until the hospital takes possession of its new home on Morningside Heights in the fall. The capacity of the old institution will be reduced from 225 beds to about half that number. These will be contained in the east half of the institution, until the time comes for a removal to the new site.

Modifications of the Skin in Tuberculous Patients.—Schtangueieff has observed two cases of marked dermal changes in the tuberculose. The first was that of a man 30 years old, suffering with acute pulmonary and laryngeal tuberculosis with aphonia, much emaciated, in a semi-typhoid state and with a temperature of 104 degrees. Suddenly there developed confluent ulcerations of the throat, palate and inside of the cheeks; the surfaces were covered with a whitish coat, like thrush. At the same time there was an intense erythema of the neck, resembling erysipelas or scarlatina, which rapidly extended to the subspinous fossa behind. This eruption lasted for about fifteen days, until the death of the patient. The other case had, for some weeks before death, an erythema of the left foot, with edematous swelling and a sensation of heat. There was at the same time a constant

¹ Rev. de Derm. et Syph., May, 1895.

hyperemia of the cheek and ear on this side, on which also the pulmonary lesion was located. The maximum redness and swelling of the foot coincided with the maximum of the fever. Since observing these cases the author has often observed—especially in the acute stages two or three weeks before death—besides pityriasis and ordinary miliaria, ephemeral spots on the skin, analogous to those seen in diphtheria and measles. The marbled state of the skin is still more frequent.¹

Cæsarean Section: 1887-1895.—At a recent meeting of the Obstetrical Society of France, Dœmelin read a paper on the statistics of Cæsarean section compared with those of Porro's operation. The author has collected 164 cases of the section with a mortality of 22 per cent. for the mothers and 2 per cent. for the children; on the other hand, 55 of Porro's operation gave 25 per cent. mortality for the mothers and 50 per cent. for the children. These are the gross figures. The prognosis grows better each year. Taking only those cases since 1893, the maternal death rate is 16 per cent. for the section and 10 per cent. for the operation. The fetal prognosis is also improving, but is much higher in the Porro operation, being nearly 2 to 1. Speaking generally, it may be said that the general cause of death in the latter is septic infection. The best time to operate is just before or just after the commencement of labor, and if the membranes have not ruptured it is especially favorable. Nevertheless, it is not rare to see successes when the operation has been delayed for several hours or even days after the beginning of labor and rupture of the membranes (Van der Mey, Braun, Galabin, Godson, Gray, Schwartz). Rapidity in operation is of the greatest importance and Kelly, among others, has especially insisted on this. The time consumed should not exceed half or three-quarters of an hour. Comparing the section with the utero-ovarian amputation, it is seen that the tendency, save in special cases, is to return to the simple hysterotomy which may be repeated and, moreover, preserves the child-bearing faculty. The Porro operation is to be preferred when the patient has been in labor a long time and the uterus is already infected, or when serious and rebellious hemorrhage follows the extraction of the child, or in the presence of specified complications. The reasons for operative interference in the collated cases were: 1, contracted pelvis, ninety-four cases; 2, uterine fibromas, nineteen cases; 3, cancer of the cervix, eleven cases; 4, pelvic tumors, nine cases; 5, ovarian tumors, three cases; 6, eclampsia thirteen cases; 7, various causes of dystocia, such as stenosis of the vagina, cancer of the rectum, edematous elongation of cervix, etc.; there were also four cases of post-mortem Cæsarean section. As regards the children, in the operation by section, many are extracted apparently dead and a certain per cent. soon die. During the first year the mortality for these children is 40 per cent. against 18 per cent. for those born naturally.²

Society Notes.

BROOKLYN MEDICAL SOCIETY.—A new organization, named as above, received articles of incorporation on June 12. A board of nine trustees will serve during 1895-96, as follows: Albert H. Brundage, H. Fred. Adams, John T. Gibbons, Stanley G. Clarke, Herman L. Armstrong, William A. Myers, Benjamin F. M. Blake, John H. Droge and Christopher D. Kevin.—The ninth annual meeting of the American Orthopedic Association will be held in Chicago, September 17, 18 and 19. The officers of the association are: President, John Ridlon; First Vice-President, Bernard Barstow; Second Vice-President Louis A. Weigel; Treasurer, E. G. Brackett; Secretary, Royal Whitman.

Louisville Notes.

CHANDLER.—Dr. W. T. Chandler, of Campbellsville, met with an accident while bicycling near his home which will confine him to bed for some time. While coasting down a hill he ran into a drove of hogs, in the road, and was thrown from his wheel.

DENTISTS.—The twenty-fifth annual meeting of the Kentucky Dental Association was held in Lexington, Ky., during the past week. The Secretary's report showed 104 registered dentists in the State. Twenty stood the examination under the new law recently and seven passed.

CHANGE OF ADDRESS.—Dr. Wm. L. Rodman has moved to the house formerly occupied by the late Dr. Hewett, at 821 Third Avenue.

G. A. R.—Dr. W. P. White, Medical Director has furnished the following names as officers for the coming encampment: Director, Dr. W. P. White; Secretary, Dr. Henry E. Tuley; Assistants, Dr. Thos. S. Bullock and Dr. C. T. Pope; Ambulance Corps, Dr. E. L. Pearce; Chairman Ladies' Medical Department, Dr. Julia Ingram; Secretary, Dr. Anna Lawrence.

Chairmen of various wards: First Ward, Dr. Peter Gunterman; Second, Dr. Robt. Fallis; Third, Dr. J. M. Krim; Fourth, Dr. F. C. Leber; Fifth; Dr. T. P. Satterwhite; Sixth, Dr. I. N. Bloom; Seventh, Dr. J. M. Mathews; Eighth, Dr. T. L. McDermott; Ninth, Dr. S. H. Garvin; Tenth, Dr. George Simpson; Eleventh, Dr. W. B. Doherty; Twelfth Dr. H. H. Grant. Dr. Chas. P. Cook, New Albany, Chairman. Dr. T. A. Graham, Jeffersonville, Chairman.

Health of the British Army.—The thirty-first annual report of the Army Medical Department for the year 1893, submitted by Director-General Mackinnon to the Secretary of State for War, has just reached this side of the Atlantic. Some of the prominent points in this issue of the familiar yellow-covered series may be of interest to military surgeons and others. Somewhat over 100,000 men served in the United Kingdom during the year, and of these the statistics are said to be favorable. There was a serious outbreak of enteric fever at Aldershot and influenza continued to cause a large amount of sickness; but with these exceptions it is considered by the Director-General that there was no point concerning the health of the troops of the United Kingdom calling for special notice. The admission rate per thousand of strength was 751.6; the constant sick rate 44.10; the average sick time to each soldier 16.10 days, and the average duration of each case of sickness 21.42 days. These cases represent those that in the United States military service would be reported as hospital cases. The trivial cases which are taken on sick report in this country and add so materially to our admission rates, are not reported by British medical officers. The rate of discharge for disability was 15.70. More than one-fifth of this rate was due to diseases of the circulation and of the nervous system, and one-tenth to tubercular disease. The death rate was 5.13. Concerning sickness, some interesting points may be noted: scarlet fever caused a total of 843 admissions and 14 deaths, this relatively extensive prevalence due probably to the extreme youthfulness of so many of the "men." Enteric fever caused 151 admissions and 22 deaths; 49 of the cases with 9 deaths at Aldershot, and 25 with 3 deaths in Dublin where this fever is notoriously prevalent. Besides these enteric fevers there were 459 admissions for other continued fevers. Taking all forms of venereal diseases together the admissions were equal to a rate of 194.6 per thousand of strength and the constantly sick to 16.68. These rates when compared with the average of the past seven years show a slight decrease in the prevalence of these diseases. In the Channel Islands the admission rate for the year was 327.5; in the Home district 291.2. The district showing the lowest rate of prevalence was that of Cork with 92.4. Alcoholism caused a total of 152 admissions and 5 deaths, 7 of the admissions being for delirium tremens. The British soldier on Home service is not specially exposed to injury, the admis-

sion rate for accident and violence having been only 95.1 and the death rate 0.74. There were 24 cases of suicide during the year. This annual number seldom varies much; the average of the past two years was 21. Gunshot was the method adopted in 15 of the cases.

It appears from the recruiting records of the Home stations that of 64,110 candidates for enlistment inspected during the year 37,769 or 589.13 per thousand were found fit for service. Only 55.51 per thousand were rejected for defective vision. The acuteness of vision required for acceptance is only one-fourth of that called for by the U. S. Regulations. On the other hand, as so many undeveloped boys present themselves before the British recruiting officers, 281.89 per thousand examined were rejected as deficient in height, weight or chest measurement. Excluding boys under 17 years of age, the average age of the recruits finally approved during the year was 19.4 years, the average height 5 feet, 5.8 inches, the average weight 125.1 pounds and the chest measurement 33.6 inches. Of every thousand 75 were well educated, 877 were able to read and write, 16 able to read only and 32 unable to read.

Of the colonies, Canada and Bermuda, each with a strength of about 1,400 men, had the best health records; an admission rate of less than 600 per thousand of strength and a constant sick rate of about 31, although enteric fever was rather prevalent in the latter, increasing its death rate to 10.10 as compared with 4.91 in Canada. There were 43 cases with 9 deaths. The disease was attributed to defective sewerage and the existence of cesspits near and even under the walls of buildings. Cyprus, Malta and Gibraltar had rates which differ but little from those of the United Kingdom, with the understanding, however, that a certain number of cases were sent home as invalids, thus lessening the number of sick present with these commands. At Cyprus, with an average strength of 550 men, venereal affections were the prominent diseases, constituting 165.5 admissions per thousand and 15.65 constantly sick. At Malta, with an average strength of 7,161, there was an outbreak of enteric fever, 101 cases, of which 32 were fatal, and 938 cases of other continued fevers of which 5 were fatal. A committee appointed to investigate this outbreak attributed it to infection in the milk supply and to impure water in the tanks. The fever appeared within fifteen days after heavy rainfalls had filled the tanks, at a time when polluting matter was most likely to gain entrance with the rainfall. At Gibraltar, strength 4,743, the sick rate was higher than in previous years, owing to the prevalence of simple continued fever and to the increased prevalence of venereal diseases. The medical officer in charge of the station hospital considered that many of the febrile attacks were due to chill and that the heading "febricula" would represent their characteristics with greater fitness than simple continued fever. The admission rate for venereal disease was 205.1 and the rate of constant sickness 18.32.

The Mauritius had the largest admission rate. With a strength of 551 its rate was 1,547.7 per thousand; 74.75 of constant sickness; a death rate of 17.30 and 58.78 sent home or discharged. Malarial fevers of a severe and fatal type prevailed on the island during the greater part of the year, many of the cases being called "malignant" by the local practitioners. Observation shows that prolonged residence in Mauritius increases the liability to these fevers and that there is no such thing as acclimatization as regards pure-blooded Europeans; residence in this colony, even when attacks of malarial fever are escaped, induces a general deterioration of the health. In the fatal cases during the year, the blood appeared to be quite disorganized, as evidenced by petechial eruptions, lividity of the skin, by the presence of blood in the vomited matter, urine and stools during life, and by a black fluid condition of the blood after death and very rapid decomposition of the body.

Egypt, with a garrison of 5,073 had the highest death rate 23.25, with 72.29 constantly sick and 94.19 discharged or sent home per thousand. The chief causes of non-efficiency were venereal affections, nearly one-third of the admissions being due to these diseases. India, with a strength of 69,865 men gave the highest rate of constant sickness 76.22 with an admission rate of 1,448.3 and a death rate of 15.21. Enteric fever was not so frequent as usual and cholera was rare; but venereal diseases were largely prevalent and some of the cases of a most virulent type. In the Bengal command the rate of constant sickness from venereal affections was 29.90 and in the Madras command 37.60. The total admissions for enteric fever in Bengal numbered 1,076 and the deaths 276. With seven exceptions the disease was present in every station of the command, 64 in number. Rawalpindi had the

largest number, 94 with 29 deaths. These occurred mostly in young soldiers of less than one year's service. At Umballa 78 cases with 23 deaths; at Lucknow 73 cases with 11 deaths and so on.

The disease is generally believed to be contracted in bazars and villages or by drinking contaminated water from pools and ditches out of cantonments. Mr. Hanken, biologist of the Northwestern Provinces government, found the bacillus of typhoid in several of the surface waters near Lucknow. One medical officer, however, reiterates his belief, expressed in previous reports that a fever of a prolonged nature, having as its pathognomonic sign, ulceration of the ileum, can be caused without a specific excitant; that, in fact, youth, indiscretion, undigested food, undue exposure to heat and to fatigue are factors enough in themselves to produce in many people a fever, the nature of which is such that 25 per cent. of the patients die. Several other observers mention that the cases which have occurred in their practice "have not been produced by specific poison."

The first of the appended papers consists as usual of a report on the progress of hygiene during the year, but there is little in it that is not already familiar to readers of the JOURNAL. The report on the International Congress of Budapest is stale reading, but Prof. J. Lane Notter of the Army Medical School prefaces it with an interesting account of the water and sewerage systems of certain continental cities inspected while en route to the meeting. Surgeon Lieutenant W. S. Pratt reports on the eighth congress of the Association Francaise de Chirurgie. Surgeon-Major H. E. L. James gives a full and valuable report on the plague at Hong Kong. The remainder of the appended papers are mostly reports of surgical cases occurring in army practice.

THE PUBLIC SERVICES.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from June 22, 1895, to June 28, 1895.

Capt. ALFRED E. BRADLEY, Asst. Surgeon, will be relieved from duty at Ft. Custer, Mont., upon the arrival there of Major WILLIAM C. SWANSON, Surgeon, and will report at Ft. Yellowstone, Wyo., for duty at that post, relieving Capt. CHARLES M. GANDY, Asst. Surgeon. Capt. GANDY, on being thus relieved, will report for duty at Washington Bks., D. C.

ORIGINAL ARTICLES.

MOVABLE KIDNEY.

Read in the Section on Surgery and Anatomy at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, May 7-10, 1895.

BY HOMER GAGE, A.M., M.D.

WORCESTER, MASS.

Uncomplicated movable kidney was first described by Riolan in 1649 and was even then characterized as *non sine vitæ detrimento*. But very little attention was paid to the subject, however, until the beginning of the present century, and even as late as 1859 Fritz could find records of but thirty-five cases. Since then a special literature has been created on the subject by the monographs of Rollet, Landau, Linder and Newman, and by a multitude of important contributions to medical periodicals, and the number of reported cases has become too large to be easily followed. There is, however, even now a very wide divergence of opinion with regard to the pathologic importance of movable kidney, and also with regard to its appropriate treatment. I think it is fair to say that very many medical and surgical authorities still hesitate, as does Mr. Tait, to attribute to the mobility of the kidney the varied train of symptoms with which it is so frequently associated; and in the matter of treatment, one may choose between the extreme views of Keppler, who advises immediate removal through the abdomen as soon as movable kidney causes any disturbance in the system, and of Newman and Drummond, who believe that in almost all cases an efficient external support will afford entire relief; or one may follow the vast majority of recent writers in accepting nephrorrhaphy as the simplest, safest and surest remedy. In view of the still unsettled opinion which prevails with regard to these questions, I have ventured to introduce the subject for your consideration by reporting as briefly as I can, two of the six cases of movable kidney which have come under my own observation; both present histories that seem to me of rather unusual surgical interest, and a sufficient time has now elapsed to enable us to judge something of the permanency of the results:

Case 1.—Mrs. K., 29 years old, was admitted to the Worcester City Hospital Nov. 5, 1891. Until within seven months, she had always been well and strong; had been married five years, but had never been pregnant. For seven months past had had pain in the right side of the abdomen, and in the region of the umbilicus, severe enough to prevent her from doing any but the very lightest housework. The pain had increased gradually but steadily, and, what was especially interesting, had been worse when in a recumbent position. She was a stout, healthy-looking woman, who had evidently been accustomed to hard work. Examination of right side over painful area revealed an oval tumor, hard, freely movable, as large as the closed fist. It could be moved easily into the median line, down to the level of the umbilicus and would, if depressed, disappear up under the ribs. Pressure occasioned a peculiar sickening

feeling, with nausea and faintness. The urine had a specific gravity of 1008, the twenty-four hour amount was forty-seven ounces and there was no albumin. Diagnosis: right movable kidney. On the 23d, I did nephrorrhaphy through an incision three inches long, extending from the top of the twelfth rib downward and forward. The surface of the kidney was scarified and three stout chromicized catgut sutures were passed through the edges of the wound and through the capsule or cortex of the kidney, one-fourth of an inch from its outer border. The wound was closed around a rubber drainage tube, which was removed the third day. At the end of two weeks, she was entirely free from pain in her right side, and at the time of her discharge, four weeks later, there had been no recurrence. She did, however, during these last four weeks, have very severe and unaccountable pains in her left side. Two months later she presented herself at my office, saying that she felt perfectly well, so far as her right side was concerned, but continued to have more and pain in the left side, and had discovered a bunch similar to the one which had existed on the right. She further said that just before the first operation, while lifting a stove, she had felt something give way in her left side and had had considerable pain for several days. Nothing, however, was said about this at the time, nor during her convalescence. The left kidney could be distinctly felt, dropping downward and forward nearly to the umbilicus. The right seemed firmly fixed. I advised her to wear a firm abdominal support, and did not see her again until April. Her own testimony, and her mother's, showed plainly that she had been much better since the first operation. She had gained ten pounds in weight and had been able to do much more work about the house. Still if on her feet very long, or if she tried to walk much, she suffered from pain referred chiefly to the region of the umbilicus. She could not turn over in bed, or make any quick motion, whether lying down or standing, on account of pain in the left side which she described as sharp, hard, and very like the pain in the right side before the operation. For two or three weeks past had noticed some pain in region of right kidney. The left kidney could be easily felt and was rather more movable than at previous examination. The right one was just palpable beneath and below the margin of the ribs and could be made to slip back against the posterior wall. No relief having been obtained from the abdominal supporter, I sutured the left kidney on April 10, 1892, through an incision similar to that made use of before. I found it even more movable than the right had been and could push it easily down to the brim of the pelvis. Three sutures of silk, instead of catgut, were passed exactly as in the first operation, a drainage tube inserted, and the wound closed. I allowed the tube to remain a week and the sutures a week longer. She remained in bed four weeks, and although having some dragging pain on the right side, was entirely free from pain on the left.

I heard from her nearly two years after the second operation. There had been no recurrence of pain on the left side nor about the umbilicus. She had occasionally some dragging uncomfortable sensations in the right loin, but considered herself entirely well, had gained much in weight, and was doing all her own housework.

Case 2.—Unsuccessful nephrorrhaphy followed by nephrectomy. Mrs. R., 41 years old, was referred to me by Dr. E. M. Frissell of Webster. Dec. 2, 1891. She had two children aged 18 and 14 years, had had one miscarriage thirteen years ago, and a second one, one year ago. She was always frail, had had more or less dyspepsia for twenty-five years, and about the time that her dyspepsia began, she had several hysterical seizures which lasted from three to five hours each and made her almost insane. For two years she had felt a drag-

ging pain in the right side with severe paroxysms of short duration; excited especially by any sudden movement of the body. She was soon rendered incapable of attending to her own work and was obliged to lie down most of the time. In June, 1890, a diagnosis of movable kidney was made at the Massachusetts General Hospital, and a support applied which afforded only a very temporary relief. Her condition became steadily worse and at the time when she was sent to me she had not been out of the house for many months and could walk but very little, was nervous and hysterical and constantly dependent upon morphin and stimulants. There was upon the right side a movable tumor of renal outline, somewhat larger than a normal kidney. It would slip back under the rib, but could be easily brought within reach by firm pressure over the lower part of the thorax and on coming forward superficially against the abdominal wall could be carried down to the umbilicus. Firm pressure elicited the same sickening feeling with pain, nausea and faintness observed in the previous case. On Dec. 5, 1891, I operated through the usual oblique lumbar incision, using six carbolized catgut sutures. I tried to place them so superficially as to include only the capsule, and I am sure that I did not obtain a firm hold upon the kidney. She was able to be up in a wheel chair at the end of two weeks, and on December 29 returned home. She remained perfectly well and free from pain and from dyspeptic symptoms until the following April, had gained nine pounds in weight and been about among her friends more than for years. In April, however, she began to lose flesh and strength and to suffer so much from pain that she was again confined to the house, and most of the time to her bed or couch. She had severe paroxysms of sharp cutting character, beginning in the right lumbar region and shooting down into the right hip. Morphin and stimulants were again freely used, and she had some trouble with her stomach, though not so much as formerly. During the summer she began to feel the same old lump, and in December, 1892, came to me for a second operation. At that time, the kidney could be felt exactly as before. I operated on December 11, this time through a vertical incision from the tip of the twelfth rib. There were some old adhesions between the kidney and the lumbar muscles, but they were so long as to permit of free mobility in all directions. I followed this time the method of Edebohls, splitting the capsule along the outer border of the kidney and folding back a strip about one-fourth of an inch wide on each side. Five silkworm gut sutures were then passed through the deep fascia on the outer side of the wound, through the double layer of the capsule, the renal substance, out through the double layer of the capsule on the posterior surface of the kidney and up through the deep fascia again on the inner side of the wound. These closed the deep wound and brought the inner surface of the capsule and the denuded surface of the kidney firmly against the deep fascia. The superficial wound was then closed and no drainage used.

Convalescence was even easier than from the first operation, although the patient was kept in bed for several weeks, in the hope of favoring stronger adhesions. So fearful was she of dislodging the kidney again, that although free from pain except a dragging sensation in the right side, she could not be persuaded to move about except in her chair, and it was two or three months before she would even walk across the room. She continued very nervous and apprehensive until June, when pains returned again as severe as ever and she felt sure that the kidney was again movable. Severe paroxysms of intense nervousness began to appear more and more frequently with other hysterical manifestations, and she again resorted to morphin and stimulants in still larger quantities. So deplorable had her condition become that I was besought by her friends and by herself to remove the kidney altogether, and in December, 1893, she reëntered the hospital for that purpose. Her general appearance was better than at the time of either of the previous operations. The kidney could be readily felt through the abdominal wall and seemed to be movable, though within a much smaller area than before. It was removed through a vertical incision, without difficulty, the vessels ligatured separately, and as a whole, and the wound closed. Upon exposing the kidney, deep in the wound were found the old buried silkworm gut sutures still intact, and there were intimate fibrous adhesions holding it firmly against the transversalis fascia. Its apparent mobility was due simply to the relaxed flabby condition of all the tissues. A sinus persisted for some weeks after the operation, from which were afterward removed the silk ligatures and several of the old silkworm gut sutures. The wound healed immediately afterward and she returned to her home in January, 1894. She

has since then remained almost perfectly well, free from all hysterical manifestations, stronger, able to do more work and to be about more among her friends than she had been for years before.

Case 1 is interesting, in the first place, as one of double nephrorrhaphy, of which, as will be seen by the accompanying Table A, I can find but five instances. It is also interesting because of the absence of all those vague and troublesome symptoms which often accompany movable kidney, such as the gastrointestinal disorders and the manifold symptoms of neurasthenia. The disability was in this case purely the result of pain, and pain referred to regions of the kidneys alone, and apparently dependent entirely upon their mobility. To the absence of these other indefinite and very troublesome symptoms, as well as to the absence of the more commonly recognized causes of movable kidney, such as rapid emaciation, repeated pregnancies, relaxed abdominal walls and ruptured perineum; to the absence of all these is due the very satisfactory and permanent result of the operations. The trouble on the left side seemed clearly the result of overstrain. That on the right could be attributed only to hard work, but whatever the cause, the important feature is, I think, that the symptoms on both sides were purely local, and I am very sure that the more these local symptoms are complicated by, or result from, other general or constitutional conditions, especially disorders of the nervous system, by just so much the greater will be the probability of failure from the operation.

This, it seems to me, was exactly the trouble with the second case. The failure of the first operation was due to a faulty technique. I used plain carbolized catgut for my sutures and tried to place them in the fibrous capsule of the kidney, to avoid as much as possible passing them into the substance of the kidney itself. Chromicized gut would have been better, but even that is decidedly inferior to silk, kangaroo tendon or silkworm gut, and the sutures should be passed directly through the substance of the kidney. Whether splitting and reflecting the capsule as proposed by Edebohls and practiced in the second operation, is necessary or not, I do not know. In a thin subject it is easily done but in a stout one it presents many difficulties, and its added efficiency is at least doubtful. The failure of the second operation is, I think, exceedingly interesting and instructive. Upon reopening the wound one year later, the kidney was found firmly fixed to the muscles of the back in a position but little lower than that which it would normally occupy. The silkworm gut sutures were found after the lapse of the year just where they had been placed relatively to each other, but no longer passing into the renal tissue. I could displace the kidney only so much as I could move the deep muscles and fascia, but so thin had the patient become that I could easily feel it from the front, and could push it up into considerable prominence. Strictly speaking, however, there was no independent mobility of the kidney. Still, after a lapse of several months, all her symptoms had returned, if possible more aggravated than before, and this was as true of the local symptoms referred to the kidney itself as it was of the more general and more serious manifestations, dependent upon a disturbed nervous and mental organization. After the first failure, I think she had come to look upon the kidney as her natural enemy and was encouraged by the advice of friends to believe that its removal was the only

DOUBLE NEPHRORRHAPHY.

Case.	Authority.	Sex.	Age.	Symptoms and History.	Operation.	Results.
1	Lindner. Ueber die Wandernere der Franen, Berlin, 87, II, p. 507.	F.	35	Five years ago fell on ice. Severe abdominal pain, especially in region of kidneys, and associated with much emaciation. Both kidneys easily palpated.	Simultaneous operation on both sides.	Patient up in four weeks; same troubles returned a few weeks after operation, and patient died one year later of melancholia and insanity.
2	T. M. Rotch. Boston Med. and Sur. Jour. 1892, cxxvi, p. 522.	F.	27	Severe headaches with occasional nausea and vomiting for ten years. For two years abdominal pain, relieved by lying down, referred to coccyx, both inguinal regions and back. Occasional palpitation, constipation, dyspnea, dizziness and frequent micturition.	Left kidney sutured Sept. 23, 1891, and right Nov. 7, 1891.	Feb. 21, 1892. Patient still complained of various nervous aches and pains, but the nausea, sense of weight in the abdomen and headaches were relieved.
3	Tillmann. Deutsch. Ztschr. f. Chir., xxxiv. Festschr. c. Thiersch., Leipzig, 1892, p. 634.	F.	40	Vide case No. 3 in table No. 2.
4	Edebohis. New York Jour. of Gyn. and Obst., 93, III, 588.	F.	39	Suffered for ten years; frequent painful micturition, occasional complete suppression. Right kidney movable 12 cm., left 10 cm.; both normal in shape and size.	Simultaneous operation on both sides.	The symptoms, nervous, gastrointestinal, genital, vesical and urinary, which had existed so long, had almost entirely disappeared after the operation.
5	The same.	F.	26	Dysmenorrhoea, pain in left ovarian region, general pelvic distress, intolerable bearing down sensations, no hysteria. Right kidney displaced downward 15 cm.; left 13 cm.	Simultaneous operation on both sides.	Uneventful recovery, too early to determine permanent results.

NEPHRECTOMY AFTER UNSUCCESSFUL NEPHRORRHAPHY.

Case.	Authority.	Sex.	Age.	Symptoms and History.	Operation.	Results.
1	Kummel. Deutsch. Med. Woch., 1887, No. 4, p. 963.	F.	60	Acute pains for one year, occasioned by movable kidney; was much emaciated; slept little; had acquired opium habit.	Nephrorrhaphy by suture through renal substance—pains returned in one month. The kidney still in place and fixed. Nephrectomy June 26, 1877.	Pains all ceased after four days. No subsequent report.
2	Agnew. Philadelphia Med. News, Jan. 29, 1887.	M.	32	In 1878 felt something give way while working; since had severe pains in lower region, paroxysmal, intensified by work. Some albuminuria, no casts. L. Kidney easily felt and moved.	Nephrorrhaphy with stitches through capsule, old symptoms returned in less than a year, much worse; kidney again worse. Nephrectomy by lumbar route, April 23, 1885.	"Remains well up to present time," i.e., 1887.
3	Tillmann's Deutsch. Ztschr. f. Chir., xxxiv—Festschr. a. Thiersch., Leipzig, 1892, p. 634.	F.	49	Wandering kidney on both sides; in bed for twenty-five years; walking or standing caused severe abdominal pain. Had a laparotomy for supposed ovarian tumor then formed, then ventral hernia and later floating kidneys.	R. Nephrorrhaphy May 19, 1889. L. Nephrorrhaphy Sept. 11, 1889. Six months later left kidney again worse; lumbar nephrectomy in May, 1890.	Remained hysterical and died 2½ years later from inter-current affection.
4	M. Juinne. Bull. et F. Mem. Soc. de Chir. de Paris, 1891, n. s. xviii, p. 533.	F.	25	Violent, painful convulsions and frequent desire to urinate, and diminished urine. Origin in the lumbar region. Convulsions last intermittently three or four days and recurred several times a month, with vomiting and fever.	Nephrorrhaphy; for one month no convulsion, pains returned and pus in urine; nephrectomy three months later, kidney firmly fixed and normal.	Temperature became normal and pus disappeared. No late result.
5	L. H. Dunning. Am. Jour. of Obstetrics, Dec., 1894, p. 891.	F.		Pain, vomiting. Bedridden for four years.	Nephrorrhaphy; pains and vomiting unrelieved; then lumbar nephrectomy.	Pain entirely relieved. Vomiting persisted several months, then gradually disappeared. Now, at end of eight years, in comparatively good health.

chance of permanent relief. She was continually feeling for it and trying to find it, and when at last she did find it, even though it was not movable, the whole train of symptoms naturally followed. The presence of this neurasthenic or hysterical condition is the most important point of contrast between these two cases, and it is just this that, in my opinion, made the difference in the results. I must confess that I did the nephrectomy with very great reluctance, and that I felt very skeptical of its result. I have, however, been happily disappointed and have been pleased to learn, as I shall hope to show you a little later, that the operation has in other hands succeeded where nephrorrhaphy has failed, and that under such circumstances it has a legitimate place, offering a reasonable prospect of final success. In the present case, this relief has continued long enough, I think, to warrant the prediction that until some

other local disorder shall destroy her nervous balance it will remain permanent and complete.

It has always seemed very strange to me that the literature of movable kidney contained so little reference to the association with it of a strongly neurasthenic habit or temperament. Morris, Newman, and the recent systems of surgery hardly mention it. Nowhere, so far as I can discover, has there been any satisfactory study of the relations of the movable kidney to its accompanying neuroses. Four of the six cases which I have observed have certainly presented two very different groups of symptoms; one group consisting of pain, tenderness with dragging sensations, with sense of weight and fullness in the hypochondrium, all symptoms directly referable to the kidney itself; and a second group made up of loss of flesh and strength, palpitation, various gastric and intestinal disturbances, ovarian and uterine

neuralgia, dysmenorrhea, and other evidences of permanent neurasthenia, accompanied in one case by a condition of mental depression amounting at times almost to insanity. Whether this second group of symptoms is a cause or a result of movable kidney, I am not able to determine. I feel very sure that it is more than a coincidence. Of the thirty-one cases reported by Drummond, he says, "twenty-two were exceedingly nervous and might very properly be described as decided neurotics, and it is noteworthy that these were the cases in which the dyspeptic symptoms were most marked. . . . So often is a marked nervous habit to be met with in cases of movable kidney with symptoms, that I have been led to ask myself the question, Would the symptoms arise were it not for the neurotic tendency even with a pronounced degree of ectopia? It must, I think, be admitted that in the great majority of cases they would not. But that the kidney condition determines the region and distribution of the disturbance, there can no doubt, and further, it would seem that in some cases at least it is the cause of the neurotic temperament." These functional neuroses accompanying movable kidney seem to me to be identical with those so commonly observed in cases of ovarian neuralgia where the ovaries seem perfectly healthy, and also identical with the neuroses so often associated with coccydynia. Surgically, they are of the utmost importance in determining the prognosis and treatment. Whenever they are absent, as in the first of the cases I have just reported, I think nephrorrhaphy may be undertaken with very positive assurances of success. When present, they lessen very much the probability of securing permanent relief. In the event of failure, nephrectomy, as is illustrated by our second case, still offers some hope of a favorable result, but even that, like the removal of the ovary and the coccyx is often unsatisfactory.

Since the introduction of nephrorrhaphy, nephrectomy for the relief of uncomplicated movable kidney has met with but little favor. Suture of the kidney not only is easier and very much safer, being attended by a mortality that is almost *nil*, but it seems to meet more perfectly the indications for surgical interference. No one now credits the dictum of Keppler, that a movable kidney is in itself a menace to its possessor's life, and should be immediately removed. On the contrary, the prevailing surgical opinion is rather that of Landau and Mr. Knowsley Thornton, who regard the "removal of a kidney simply because it floats or is mobile, as quite unjustifiable." In fact, I think most surgeons would go a step further than Mr. Thornton, and say that no operation should be undertaken on a healthy kidney simply "because it floats or is mobile." It is only when by its mobility it occasions symptoms that interfere with one's ordinary occupation or habit of living that any operation is indicated. Nephrorrhaphy is then certainly the operation of choice, but in the event of its failure, nephrectomy is, I think, not only a justifiable but a reasonable procedure as is illustrated by the second case here reported. I have further collected five other cases, as will be seen by the accompanying table, in which the failure of future has been followed by the successful removal of the kidney. One of them in which the nervous symptoms were especially prominent is reported as having remained hysterical until the time

of her death, two and one-half years later from some intercurrent affection. Agnew's case remained well nearly two years after the removal of the kidney, and Dunning's was in comparatively good health eight years after operation, while the remaining two cases were immediately relieved of their symptoms, but were reported too early to give permanent results. These cases are too few and the records too meager to enable us to draw any positive conclusions. They are more than sufficient, however, I think, to justify us in attempting a radical operation when the simpler alternatives have failed.

In calling your attention to this subject by reporting these two cases, I have been actuated by the desire to emphasize more particularly two factors in the consideration of movable kidney, which are, it seems to me of very great importance, and which do not often receive the attention they deserve. They are: 1, the frequency with which movable kidney is associated with a marked and very distressing neurotic habit and under these circumstances nephrorrhaphy is often unsuccessful; and 2, the possibility of securing permanent relief by nephrectomy when nephrorrhaphy has failed.

APPENDICITIS.

Read in the Section on Surgery and Anatomy, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY JOHN B. DEEVER, M.D.

PHILADELPHIA, PA.

From my experience in appendiceal work, and particularly during the past year, I feel that I have a right to make a further contribution upon this much debated subject. Notwithstanding the vast amount of literature which has appeared, and the numerous discussions which have occurred upon this subject in the past twelve months, I regret to say that there are still too many skeptics, first as to the prevalence of the affection, and second, as to the importance of the only curative treatment, namely, operation. I had hoped that the nomenclature of this subject had been definitely settled and that appendicitis was the accepted term for inflammation in the right iliac fossa, which we now know invariably originates within the appendix, but a recent article by Frederick Treves in the *British Medical Journal* describes appendicitis under the headings, typhilitis and perityphlitis, terms no longer accepted by American surgeons.

As I have before remarked, the diagnosis of appendicitis is not a difficult one to make. I must confess I have been astounded when attacked by a few prominent clinicians on making the above statement. The history of onset in the great majority of cases of acute appendicitis, as well as in acute attacks supervening upon an already chronically inflamed organ presents a picture, the outlines of which are so striking that if once seen it must be everlasting.

The initial pain, the gastric disturbance, the point where the tenderness to touch is most intense, the torpid bowel, all these following closely upon either the ingestion of indigestible substances or the ingestion of digestible substances, if the integrity of the lining membrane of the digestive tract has been disturbed, as by sudden exposure to cold, fright, grief, etc., these symptoms, I say, form the background of such a picture.

The rigidity of the abdominal walls of the lower

right quadrant of the abdomen, nausea if not vomiting, the disposition to flex the thighs upon the abdomen, the limited abdominal respiration, the increased pulse rate, the elevation of temperature, the intense thirst, the pain referred to the back, the abdominal distension, complete the picture in detail. There is now left the finishing touch, which is true in both senses of the word, that of locating the inflamed organ by palpation. While the tenderness early in the attack is diffuse, yet the point of greatest tenderness can, by careful examination, be most clearly defined over the position held by the appendix.

The etiology and pathology of appendicitis being intimately associated, I have thought it best to describe them together.

From my experience in the past year I have no reason to change the views expressed in former articles regarding the etiology of this affection. I still believe that there is a certain proportion of cases of appendicitis in which foreign bodies are an active factor in its production, when a catarrhal condition of the mucous membrane already exists and, especially when associated with it is the bacterium *commune coli*. Foreign bodies may, however, remain and cause little or no disturbance until some indiscretion in diet or exposure to cold or dampness excites a catarrhal condition, when their presence adds to the irritation thus produced and prevents drainage of the organ by occluding its lumen. They are the important factors which favor ulceration of the walls of the appendix and perforation or even gangrene of the entire organ.

Occlusion of the lumen of the appendix may also result from one of the following conditions: a very long meso-appendix, a shortened meso-appendix, a meso-appendix due to infiltration, containing an excess of fat, adhesions, thickening of the mucous and sub-mucous coats or displacement of adjacent viscera.

All inflammations of the appendix are septic; consequently, drainage is essential for a spontaneous recovery from an attack. The mucous membrane of an appendix beyond the point of obstruction undergoes structural changes which render otherwise innocuous materials (bacteria, etc.,) actively malignant and thus favor migration.

In cases of chronic appendicitis, a catarrhal condition of the mucous membrane of the appendix primarily renders it predisposed to slight irritation and though macroscopically and microscopically the mucous membrane of such an appendix would show but little evidence of disease, this is clinically disproved. I have seen cases of recurrent appendicitis where all the symptoms disappeared after the removal of the appendix, which showed but slight disease of the mucous membrane.

I recall one case in particular, where the patient had been an invalid for seventeen years. The removal of the appendix which was small, and the mucous membrane which showed but slight pathologic changes, was followed by a prompt disappearance of the symptoms. This patient is to-day perfectly well and leading a comfortable and happy life.

Many of the cases of chronic intestinal indigestion of both the catarrhal and the nervous type, also cases of chronic enterocolitis and colitis, I maintain are due to structural changes found in the appendix, which I have removed for the relief of one or more of these various conditions.

The appendix is a highly organized structure, as much so as is any portion of the alimentary canal. It possesses the same number of coats, has its individual mesentery and is equally as well supplied with blood vessels, nerves and lymphatics as are the intestines. The point of essential difference, however, is that it has but one opening and this is the reason that inflammations of this organ are of so destructive a character and hold a place second to no other intra-abdominal inflammation.

Catarrhal inflammations of the appendix are very common, but heretofore have not been recognized as attacks of appendicitis. When the inflammation is more marked there are other factors which enter into the case. If the *bacillus coli communis* is present in a virulent form or is associated with the *staphylococcus* we have an infective appendicitis which is of the virulent type; when this condition is associated with a fecal concretion or other foreign body causing pressure, necrosis occurs and we have perforation. In infective appendicitis we frequently find minute points of suppuration in the mucosa; these foci start in the glands which are infected and then suppurate. The virulent bacilli can and do migrate through the walls of the inflamed appendix and cause suppuration around the organ without perforation.

The termination of an attack of the infective variety of appendicitis depends upon the direction which the bacilli take. If they pass into an appendix whose lumen is not encroached upon, the attack may terminate favorably. If the migration is through the walls into the right iliac fossa, suppuration about the organ occurs and we have a peri-appendiceal abscess, or a general infective peritonitis. This is the awful uncertainty, and places upon the physician a terrible responsibility. In support of my position, I will simply refer you to the statistics of the early operative treatment and to those of the so-called conservative or expectant treatment.

This is the view I have held, and when the opportunity has presented itself acted upon, and I have yet to record the first death where the appendix was removed in the early stage of the acute attack.

The personal equation in the resistance to septic absorption is a matter of the greatest importance and one which figures conspicuously in appendicitis. Two cases, in which there is, as nearly as it is possible to demonstrate pathologically, a parallel condition of affairs, may show very different degrees of infection; one patient will be profoundly septic while the other will show but slight evidences of poisoning. This fact must be understood and borne in mind by the physician in attendance upon a case of appendicitis; otherwise he will be less likely to appreciate the responsibility of his position.

The symptoms of appendicitis present such a vivid picture clinically that I can not conceive how, ordinarily, they could be misinterpreted. The cramp-like pain in the epigastric or umbilical region, which ushers in the initial symptoms of this affection, is severe and usually constant, although it may be intermittent, and is associated with nausea, vomiting and extreme restlessness. The pain may be referred to these regions for a period ranging from one to twenty-four hours, but later is confined to the iliac fossa where it manifests itself in wave-like paroxysms. With the advent of general peritonitis the pain becomes diffused. The nausea and vomiting

usually cease in favorable cases after the pain is referred to the region of the appendix. In unfavorable cases it becomes regurgitant and persists until the end.

Rigidity of the abdominal walls which in the majority of cases is most marked on the right side, occurs before the pain localizes itself in the right iliac fossa. There is usually constipation but occasionally diarrhea. Where constipation persists it is due to one of two causes, either an intestinal paresis of septic origin or the use of opium.

Tenderness is the most important symptom of appendiceal inflammation. Deep palpation over a normal appendix will not elicit tenderness. There is only one condition which renders difficult or impossible the palpation of an appendix, viz., marked tympanites. Tenderness may also be elicited through the rectum in the male, and the vagina and rectum in the female, when the appendix is directed into the pelvis. The point of greatest intensity of tenderness is over the inflamed appendix. Excruciating tenderness indicates pus, and in some cases is elicited only by vaginal or rectal examination.

Temperature and pulse rate in moderately severe cases bear no relation to the amount of disease going on within. I have seen cases with abscess and even perforation in which the pulse rate and temperature were normal. These are explained by the various pathologic conditions found in the peritoneal cavity in appendicitis. A sudden fall of temperature in acute cases should be looked upon with suspicion, as this only too often indicates perforation of the appendix.

The ordinary form of appendicitis is readily diagnosed, but I have met with some variations which have been misleading and puzzling; cases in which the pain has been referred to the left side, to the spleen, to the bladder and to the testicle.

The history of attacks is at times indistinct, one being frequently only able to get a story of a chain of vague symptoms which patients refer to as an attack of cholera morbus. Again, I have seen cases in which a persistent colitis or entero-colitis, were the only clues to the real cause of the trouble. There is one symptom, however, which is constant and that is tenderness; this, in the majority of cases is accompanied by a palpably enlarged appendix. If one palpates the right abdomen of patients who suffer from dyspepsia, entero-colitis, or colitis with or without histories of attacks of appendicitis, the number of tender, enlarged vermiform appendices he discovers will astonish him. The following case will illustrate: Miss W., age 16; no history of an attack of acute appendicitis; had been suffering for some time from a severe colitis. Her appendix was tender and was easily palpable. I advised its removal. We found the appendix constricted and indurated at its extreme tip, bound by adhesions to the surrounding bowel, and the omentum adherent to the outer wall of the cecum. The appendix contained pus. I have come to the conclusion, after a varied experience in appendiceal work, of accepting the histories of attacks of cholera morbus as those of acute attacks of appendicitis and have yet to see the first operative case presenting such a history which did not substantiate this belief.

The diagnosis of appendicitis can be made early, and when made, should be followed by operation for the removal of the inflamed organ. A case of *bona*

fide appendicitis should not be allowed to go to the point of suppuration. A point upon which all authorities on this much debated question agree is that there is no sign or symptom, class of individuals, age, or time of disease which foretells perforation, gangrene and pus. No man can tell how the case may proceed from hour to hour and therefore the only logical conclusion at which one of experience can arrive is immediate early operation.

The prognosis depends not only upon the character of the attack and the complications which may supervene, but especially upon whether or not an early operation is done. In other words, the earlier the operation is performed the better the prognosis.

When the collection of pus is circumscribed and the general peritoneal cavity walled off, the prognosis is generally favorable. If the general peritoneal cavity be infected the prognosis is grave, although if operation is at once resorted to there is a possible chance of recovery; while if the infection be late or operation deferred, a fatal termination is invariably the rule. When a circumscribed appendiceal abscess ruptures and evacuates its contents into the bowel, recovery from the attack usually follows, while evacuation into the bladder is fatal in about 50 per cent. of the cases. The age of the patient is a decided factor in the prognosis, as the disease is more fatal in the very young, on account of the slighter powers of resistance.

Appendicitis is a surgical affection and should be so treated. The first question which arises after the diagnosis has been established is the character of the attack and what will be the probable outcome? It is here that we come up against the stone wall of fact, backed up with logical conclusion based upon experience. We can not say positively which case or class of cases will recover from an attack and which will go on to suppuration, gangrene and perforation. The question is, Shall we guess, and run the risk at the patient's expense? or shall we accept the only other alternative and remove the organ at the incipency of its inflammation? The operation has been performed so often by skilled surgeons with a mortality of 1 to 2 per cent. and in many instances without a death, that there is absolutely no ground for attacking the procedure upon the score of fatality. Hernia is not a frequent sequence of abdominal section and is not the bugbear it is thought to be by the opponents of the knife. We can not accept objections to scientific procedure, upon the score of prejudice or on general principles, but must meet facts with facts.

A record of 100 appendisectomies with one death and no hernias speaks for itself. The records of McBurney, Richardson, Fowler, Murphy and others stand out like the "handwriting on the wall," to substantiate the scientific wisdom of early operation, and to stamp delay as dangerous and unscientific.

Early operation is a conservative and not a radical procedure. We are not governed by the same reasons that influence us to perform the radical operation for the cure of a simple hernia, or for the removal of the uterine appendages for a fibroid. But we see before us the probable consequences of allowing suppuration, gangrene and perforation to occur in the peritoneal cavity which may or may not be protected by nature's kindly action.

The proportion of cases of appendicitis which have one attack, then become perfectly well and are

cured of the disease, is so infinitely small, compared to those which have repeated attacks with an interval of invalidism, that I do not believe the rare exception should interfere with the rule.

One of my recent cases had had three attacks, with the interval filled in with gastro-intestinal uneasiness and tenderness over the appendix, increased by the slightest dietary indiscretion. He decided he would be operated upon as he considered the risk of another attack far greater than that of operation. On the day of operation he remarked that the tenderness was less pronounced than at any time for three months previous.

The appendix which lay behind the cecum and colon, first observed a northerly and then a southerly direction, making an acute flexion; it was firmly bound down by strong adhesions. The omentum was adherent to the base of the organ as well as to the cecum. An interesting feature in the case was the presence of a neighboring knuckle of small bowel which was anchored to the base of the appendix by an adhesive band, causing an acute flexion. This condition would have been capable of producing an attack of acute mechanical intestinal obstruction upon the slightest provocation. The appendix was thickened and contained pus. It is now four weeks since the operation, and he says he has no dyspeptic trouble and feels the first relief since his initial attack nine months ago.

The early operation is, as a rule, a comparatively simple abdominal procedure. The operation at the end of an attack or during the interval between attacks is usually more difficult than when done very early in the attack before adhesions are formed. After pus has formed, an operation for the removal of the appendix calls for the best judgment and skill, along with experience in this particular line of work. One meets with pus which has originated in an appendiceal inflammation, in every conceivable part of the peritoneal cavity, and only too frequently the entire cavity is invaded.

The appendix holds a northerly position in so large a percentage of cases that it is common to meet with many cases of acute appendicitis in which the purulent collection is post-cecal or post-cecal and post-colic. In this class of cases I invariably remove the appendix. With the proper abdominal technique, an important part of which is the disposition of the sterile gauze by which the greater peritoneal cavity is temporarily sealed off, the risk of infecting this membrane is reduced to a minimum. To one whose experience in this class of cases has not made him expert, I would strongly urge that having opened the peritoneum in cases of this character, and recognizing the position of the swelling, that it is far safer for him to immediately close the abdominal wound and complete the operation by draining the collection through the loin space. This is not only feasible, but at the same time safer than to take chances on exposing the peritoneum to contact with pus, of the character which is generated in connection with appendicitis. In those cases where the abscess points anteriorly, one of two procedures is to be followed out; evacuation without any attempt to remove the appendix, or, first carrying an incision through the abdominal walls to the inner side of the collection, in this wise opening the general peritoneal cavity, which is to be protected with sterile gauze, to be followed by a second incision down over the most

prominent part of the swelling. The pus is evacuated, the cavity then washed out thoroughly, and the appendix removed. This latter plan of operation should only be practiced by a surgeon who is an adept in this line of work.

When the general peritoneal cavity has been protected in the manner referred to, the appendix removed and the wound cleansed, the first packing of gauze is to be withdrawn and replaced by a fresh piece which is allowed to remain *in situ* for two or three days, the time depending upon circumstances. By a strict observance of this step in the technique, the peritoneum can be left permanently sealed off. This anticipates nature's means of closing off the abscess cavity by adhesive inflammation. When the permanent gauze packing has been removed, the wound is closed by sutures introduced at the time of the operation.

I do not consider the evacuation of an appendiceal abscess without removal of the appendix in any way curative. On the contrary, experience has taught me that these cases are equally liable to recurrent attacks. I have operated for removal of the appendix upon too many cases, with such a history, to regard the simple evacuation of the pus other than merely palliative. Cases in which the abscess has ruptured into the colon and the rectum, suffer from subsequent attacks and for these during the quiescent period I have removed the appendix. In only a small percentage of the appendices removed under these circumstances do we find evidence of a previous perforation. From our knowledge of the pathology of this subject we know that perforation is not necessary for pus formation.

I take this opportunity of adding a remonstrance against the median incision in the operation of appendicitis. The number of cases are limited where this route offers any advantage. In the majority of cases, therefore, and from this we must reason, it is contra-indicated, first, on anatomic grounds, second, on the ground that the peritoneal cavity can not be so well protected against infection. Granting that what I have said is true, the median operation is unsurgical. A knowledge of the topographical relations of the appendix, must impress one's mind with the fallacy of the median operation.

In suppurative cases it is impossible to open and drain an abscess in the right iliac fossa through a median incision, no matter how large, without infecting the peritoneal cavity. A large incision is always to be avoided in abdominal work. Where the appendix lies to the outer side of the cecum or behind the cecum or colon the difficulties of this route would be increased. To gain access to the retro-colic space by way of the median incision would probably call for division of the internal layer of the ascending meso-colon, always to be avoided as it is preferable to go through the outer layer of the meso-colon on account of the relation the blood vessels hold to the former.

The two incisions to be considered are through or immediately to the inner side of the linea semilunaris (not cutting the rectus but pushing it inward), or through the abdominal walls after the manner proposed by McBurney.

The McBurney operation which offers a better safeguard against ventral hernia, is especially adapted to chronic cases. In favor of this operation is the direction of the deep incisions which do not entail

cutting the nerves of the abdominal walls. Some of the nervous phenomena which have been said to follow the operation of removal of the appendix through the semilunar line, I believe have been due to the section of the nerves which must follow opening the abdomen by this route. With McBurney, I would not recommend it to one who has not had a considerable experience in appendiceal work, as it is more difficult to perform than is the operation through the semilunar line. In either operation the incision should be small. In the McBurney operation the incision through the internal oblique, the transversalis muscle, the transversalis fascia and the peritoneum is of necessity small. Ordinarily, in cases of chronic appendicitis, the incision in the peritoneum need not be more than an inch in length, just sufficient to admit the index finger to pick up the cecum, the landmark in finding the appendix.

The medical clinician carefully views and studies the exterior of the abdomen, and upon the information thus gathered bases his conclusions as to what may be going on within. The surgeon sees the process and, if he has had a large experience, sees so much of the destructive possibilities of the disease that he naturally comes to the conclusion that an inflamed appendix is better in the laboratory.

THORACIC TROUBLES FROM A SURGICAL STANDPOINT.

Read in the Section on Surgery and Anatomy at the Forty-sixth Annual Meeting of the American Medical Association at Baltimore, Md., May 7-10, 1895.

BY J. McFADDEN GASTON, M.D.

ATLANTA, GA.

In this notice of some of the phases of thoracic surgery there has been nothing of an exhaustive nature undertaken, but only an attempt to bring to the attention of surgeons the great landmarks which should prompt to further investigations in this very important branch of surgery. While many have explored every nook and corner of the abdomen, and have brought forth rich fruits of their labors, comparatively few have turned their attention to the contents of the chest.

It is true, that a few individuals have devoted their energies zealously and successfully to the investigation of the surgical disorders of the chest; but the data for studying the results of traumatism or diseases of this part of the organization are scattered throughout current literature, so as to render it difficult to arrive at satisfactory conclusions. With a firm conviction that these *dissecta membra* may be collected and systematized in a manner to prove instructive and profitable to the medical profession, this contribution is now presented.

There are such conflicting views in regard to the various practical measures which have been adopted in thoracic troubles, that any one who seeks for authority in the treatment of the injuries to the walls of the chest and to the viscera within, or for the diseases of the thoracic cavity, is involved in doubt and uncertainty.

The more extended such investigation may be, the greater is the confusion from direct antagonism in the practice of those whose names are prominent in the department, and there is a pressing demand for methodic rules in the management of this class of cases.

No greater boon could be conferred upon the profession than a thorough analysis of all the details available in connection with the pathology and treatment of surgical disorders of the chest, and a work which may afford a rational and comprehensive grouping of the therapeutic agencies indicated in the different troubles of the thorax ought to prove a most acceptable offering to the surgeon.

The conical space within the chest, having its apex upward, is occupied on each side by the lungs, and between them lies the heart with its investing pericardium and the arch of the aorta with the descending aorta. The pleural serous covering of the viscera is reflected over the inner walls of the thorax and the two membranes being approximated form an antero-posterior partition constituting the mediastinum. The different spaces included between the folds of the pleura are designated as the anterior, posterior, middle and superior mediastina, and play a prominent part in the rôle of thoracic troubles, amenable to surgery.

In different divisions of the mediastinum, we find the trunk of the pulmonary artery, the ascending vena cava, the innominate veins, the phrenic nerves, the vagus nerve, the esophagus, the thoracic duct, the bronchial lymphatic glands, the cardiac lymphatic glands and the posterior mediastinal gland, with other highly organized structures. This fruitful field for investigation has only recently awakened the interest of original workers and it is expected that it will be explored more fully in future.

If a patient is so unfortunate as to suffer from a surgical disorder, he does not always require the use of the knife, and I appeal to my intelligent colleagues to disabuse the minds of people as to surgeons being mere operators.

It may be that the critical reader shall expect some explanation of the term surgical disorders, employed for generalization of chest troubles. All departures from the healthy or normal condition of the tissues, involving any material modification of structure, either in size or density, may be included under the designation of surgical disorders. As has been intimated already, this does not imply a necessity for the employment of the knife or any other surgical instrument, but may be appropriately submitted to medication as a part of the surgical treatment.

In illustration of the transition of cases from the domain of medicine to that of surgery, an instructive and interesting report of Christian Simpson, giving four cases in which he had successfully used a new method of bleeding in pulmonary congestion, with a trocar, may be presented. This is an extension of Harley's method of performing hepatic phlebotomy, which was laid before the profession in 1886. There is, however, an improvement upon that process, which meets the sanction of Harley. After the withdrawal of twelve ounces of blood from the lung, the canula was kept in position with the fingers over the end to allow of a clot forming, and then it was slowly withdrawn. The patients were immediately relieved. A modification in the mode of procedure is proposed by Harley that makes the plugging of the wound by the coagulation more secure and effective, while it obviates its detachment. His proposal is that the trocar being thrust some distance into the tissues of the organ from which it is desired to extract blood, before placing the point of the finger on the mouth of the canula with the view of arresting the blood flow,

it should be slightly withdrawn—say, about half an inch or more—in order to leave an empty passage wherein a sufficiently large blood clot may form and fill the channel. In this case, the surrounding tissues of the organ will, in contracting upon the clot, hold it so firmly by their own resilience that, on the withdrawal of the canula it will break off from the end of the much larger mass, which remains as an effective plug in the wound. This mode of relieving sanguineous engorgement of the lung is worthy of further trial.

There seem to be very few points definitely settled in regard to the appliances specially adapted to the surgical disorders of the chest.

There is a marked discrepancy in the views of different observers touching the efficacy of aspiration simply, or the continued drainage aspiration upon the siphon principle in purulent pleurisy.

The discussion has been kept up in regard to medicated injections into the pleural cavity after operations, for the purpose of correcting septic processes, and as to the employment of irrigation for the entire removal of purulent collections from the thorax. The apprehension which heretofore existed in respect to the entrance of air into the chest, upon the withdrawal of a purulent collection has undergone some change from further experience as to its effects, and less concern is manifested as to it in making single or double incisions for the purpose of drainage.

The difficulty of locating foreign bodies in the bronchial tubes, either by exploration through the trachea, or by physical signs from without through auscultation and percussion, has heretofore proved a serious barrier to accurate diagnosis of the location of such bodies, but the accidents involving the bronchi from the entrance of solid matters into the air passages have generally led to operative measures for their removal. There has, however, existed considerable skepticism as to the propriety of undertaking any operation for the removal of foreign bodies from the bronchial ramifications, and Kocher consigns operative measures in those cases to the domain of experiment. A few fortunate results have been reported from time to time in the extraction of articles of different forms from the bronchi, affording encouragement to further diligence in this department of exploratory work.

There has been notable progress latterly, in the management of abscess of the lung and gangrene of the parenchymatous structure of the lung. Resections of a greater or less portion of the pulmonary tissue have clearly demonstrated the fact that thorough decarbonization and oxygenation of the blood may be effected by one lung.

The preparatory treatment of a case for an operation, and the subsequent management, often demand a resort to the use of medicinal agents by the surgeon, and the old distinction of external and internal treatment belongs to an exploded régime. It sometimes occurs that a surgical case escapes recognition by the attending physician until it has reached a point that does not any longer admit of relief by an operation, though clearly indicated at an earlier period.

Again, there are instances in which the efforts of nature may be assisted so as to overcome complications, by means which are not regarded as strictly surgical, yet all such resources pertain to the surgeon. He should avail himself of all agencies calculated to relieve his patient without an operation, and it is

more creditable to heal a diseased part by conservative measures than to mutilate or excise an organ. We should not, therefore, ignore therapeutics in surgical treatment.

All concur in removing large accumulations of fluid, after various modes of internal treatment have failed to give relief; yet the conditions for this procedure, in the view of many having ample experience, indicate an apprehension of consequences which may be averted by energetic measures of treatment by medication at the outset.

The development of pneumo-thorax, either spontaneously or from traumatism, has been met by two distinct processes; one being by aspiration of the chest, so as to take away the superfluous air, and the other by the introduction of an innocent solution of boric acid or chlorid of sodium by a canula, while another alongside of it allows the air to escape from the thoracic cavity. Thus the space previously occupied with air will be filled with the fluid to be removed by siphonage, or which in due course of time is absorbed. Of course, perforations of the lung will be reduced in size by the partial collapse from the outside pressure of the fluid.

The mode of treating wounds of the parietes of the chest has given rise to much discussion. While the weight of authority is favorable to closing incised or gunshot wounds of the walls of the thorax, there are advocates for laying open freely all the parietal structures in traumatic injuries of the chest walls and lungs which are accompanied with internal hemorrhage.

It would appear from the favorable view taken by some surgeons in regard to the practice of laying open the chest, in cases of considerable hemorrhage into the pleural cavity, that this procedure was the recognized treatment. On the contrary, this practice is in opposition to the best established principles which govern the treatment of penetrating wounds of the thorax. The course adopted generally by those surgeons having the largest experience in the treatment of thoracic wounds has been to allow of the escape of all the blood which may flow out of the wound when placed in a dependent position, and afterward to close the opening by suture so as to shut off the pleural cavity from the external air.

It is recognized that all penetrating wounds of the thorax may be closed hermetically, by suture or otherwise, after allowing the discharge of fluid blood from the opening. It is also allowed by the best authority, that of experience, that foreign bodies lodged in the bronchi may be reached through an incision of the trachea at the lowest available point. Experiments for reaching the bronchi through the chest wall afford little encouragement for operation upon the human subject. Medication as a preventive and curative agency in pleuritic effusion is worthy of trial before having recourse to aspiration. Aspiration is indicated where there are large serous accumulations in the chest and likewise in pneumothorax, but can not be relied upon for the relief of purulent collections. Partial resection of ribs is attended with better results in some cases of empyema than the complete removal of the segments of several ribs. The excision of a small portion of one rib with the introduction of drainage tubes has been generally attended with good results,

A few years ago it was thought that a most desirable consummation had been reached by Estlander's

operation in empyema, but to-day serious misgivings are entertained by the conservative surgeons in America and in Europe as to its applicability, except in extremely rebellious fistulous openings of the thorax.

Quenu recommends for opening the posterior mediastinum (*University Medical Magazine* for July, 1892), to make a vertical incision 15 centimeters long over the angles of the ribs, between the spinal border of the scapula and the vertebral column about four fingers breadth from the spine, the middle of the incision corresponding to the spine of the scapula. By retracting the inferior border of the trapezium upward and inward, three ribs may be divided and resected for 2 centimeters and this permits the hand to penetrate by stripping off the pleura. This opening in the thoracic wall extends from the inferior border of the second rib to the superior border of the sixth, and drawing back the ribs enables one to explore the hilum of the lung, the aorta and that portion of the esophagus which extends from the root of the bronchus to the diaphragm. If, instead of stripping off the pleura, it is incised, the upper lobe of the lung and even the summit of the thoracic cavity are easily accessible and more readily than by resection of the ribs in front below the clavicle. It is asserted that this opens the way for relief in abscesses and other affections of the mediastinum.

A point of much importance in connection with the restoration of the respiratory function to the disabled lung without risk of injury to its structure, in aspiration and valve drainage, when no air enters to replace the fluid, is the gradual and partial evacuation of the purulent contents. An enfeebled and contracted lung can not expand suddenly to fill up the space occupied by an extensive collection of pus, and to avoid an injury to its tissues the discharge should not be completed at one time but in two or more evacuations. Levasheff has recommended the withdrawal of a certain amount of the intra-pleural exudation and replacing it at once with an equal quantity of a solution of chlorid of sodium. He says that after this operation has been repeated from two to six times, the pleural cavity would contain nothing but an indifferent salt solution which would be rapidly absorbed. While those with a limited sphere of work in the graver classes of chest trouble have claimed satisfactory results in treating empyema by thorough drainage without the resection of ribs, others have found that after these measures have failed, a resort to extensive removal of several ribs has succeeded; when the lung has become materially diminished in size or totally unfitted for the function of respiration by contraction and adhesion, it is evident that the walls of the thorax on the corresponding side should be proportionately reduced, and the only practicable mode of effecting this is to excise portions of the ribs.

Yet the growing conviction of those who have had the largest field of observation seems to be adverse to Estlander's operation except in extreme cases.

Quenu, at the suggestion of Estlander, first executed section of the ribs without resecting them, while Delorme improved upon this idea of a trap-door to reach the contents of the chest; and Jennings, Richelet, Morreau and others have done it

The following thoraco-plastic operation done by Mr. Subbotin, a Russian surgeon, some five years ago, offers many advantages over other modes of lessen-

ing the space around the collapsed lung; a segment from two to three inches long is first resected from the seventh rib and the pleural cavity is opened and washed out. This opening is then plugged with gauze. Then a vertical incision about two inches long is made along the outer border of the pectoralis major muscle. Through this the sixth, fifth and fourth ribs are exposed without being denuded of periosteum, and from each of these a little wedge is removed by means of Liston's bone scissors so that the rib is made movable. A similar vertical incision is then made in the posterior axillary line, serving for the exposure and division of the same ribs in this situation. These two incisions not opening into the pleural cavity are sutured without drainage. The portion of ribs lying between the two points of section are thus enabled to sink in and when healing has taken place they protect the thoracic cavity and support the vertebral column.

While there may be cases of pulmonary abscess with adhesion, relieved by simple incision and washing out the cavity, the procedure of Runeburg in excising a large piece of rib directly over the abscess and making a free opening directly into the pleural sac, with a smaller opening into the pulmonary tissue, is often indicated.

It is held that abscess of the lung presents signs and symptoms which admit of a positive diagnosis and that operation is often demanded. Perier, of Paris, reports the case of a man 58 years old, in which an incision was made in the left second intercostal space and the lung tissue, covered by pleura, was seized with a pair of forceps. The pleura and the lung were incised and about two fluid ounces of pus were discharged, when two long drainage tubes were secured in the cavity which had been washed with camphorated naphthol. The operation gave an entirely satisfactory result.

A case of pulmonary gangrene is reported by Delageniere, of Mans, in which resection of lung gave a favorable result. He infers from this and nineteen other recorded cases of pneumotomy for pulmonary gangrene, that the operation has hitherto failed to give the desired result, because surgeons have been content merely to drain the gangrenous focus instead of extirpating it as completely as possible.

It seems to be demonstrated beyond a doubt that interference in all cases of abscess of the lungs which have not opened into the bronchi is attended with success, and that gangrene of the lung is completely amenable to surgical interference.

The operation of thoracotomy for abscess and gangrene of the lung should be accompanied with antiseptic applications and gauze tamponage. The great importance attached to the operation of pneumonec-tomy is demonstrated by the extensive notice in medical journals in different countries, of the excision of the apex of lung for tubercular disease in March, 1892, by Tuffier. The first pneumonec-tomy ever reported was performed by Milton Anthony, of Augusta, Ga., in March, 1821, for an injury inflicted originally by a fall from a horse. A rib was fractured, empyema resulted, and four years afterward Anthony found the lung tissue in a disorganized condition, when he removed portions of the fifth and sixth ribs and detached all the diseased parts of the lung with his fingers.

A personal examination of twelve dead subjects by

Eugene Rochard, of Paris, for the determination of the average tract of the interlobular fissures of the lungs, will doubtless be of service in surgical treatment of abscess and gangrene of the lung by transcostal openings. This is ascertained to occupy a zone containing the fifth and sixth ribs, which are the ones therefore to be taken out by the surgeon. The fifth intercostal space in front and on the side is the one most commonly in communication with the oblique fissure. It will be observed that this corresponds very nearly to the free spot of Marshall which is near the attachment of the costal cartilage of the fifth rib, which has been indicated as the most favorable point for entering the thoracic cavity.

Two cases are described by J. H. Cox, one being aspirated with good effect, and the other from neglect of this procedure, terminated in pointing and spontaneous discharge through the chest wall about the seventh interspace. There was an average discharge of one quart a day for eight months, of thick creamy pus; but in a year afterward this had entirely ceased. This case affords an illustration of the unaided power of nature.

Those who have kept abreast of the advances in surgical resources for chest troubles will fully appreciate the aggressive work in this department. But, unfortunately, there are comparatively few of the medical profession who have taken the trouble to ascertain the facts in regard to the various measures which have been adopted in wounds of the thoracic walls, or in the modification of the pleural contents from diseases. The aggressive spirit manifested by the operative measures of those who have been reaching out for relief in treating the disorders of the chest has been checked to some extent by the difficulties met with in some departments of original work.

There has been exhibited also by a few prominent investigators, a tendency to masterly inactivity in certain fields of exploration, which is now held to be conservative surgery. But a retrospect of the result indicates decided advancement.

A NOTE ON THE ADVANCE IN THE SURGICAL CURE OF HERNIA.

Read in the Section on Surgery and Anatomy at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY W. B. DEGARMO, M.D.

PROFESSOR OF SPECIAL SURGERY (HERNIA) IN THE NEW YORK POST-GRADUATE HOSPITAL AND MEDICAL SCHOOL, NEW YORK.

In order to bring into marked contrast the operations now being extensively done for the cure of hernia, with those of the past which have failed, we must devote a few moments to the review of the latter.

It would be a waste of time to go back farther than the past twenty years, and it would be impossible to even name *all* of the various procedures that have been advocated during this period.

In 1876, Czerny gave to the profession the operation bearing his name, which, with various modifications, and under the names of their authors held the field for ten years. The neck of the sac at the external ring was tied off, but its removal was seldom attempted. The pillars of the external ring were then brought together as tightly as could be done without constricting the cord. The suture ma-

terial was usually catgut. In 1886, the MacEwen operation spread rapidly over the surgical world. MacEwen dissected out the hernial sac, folding it upon itself into a bunch or "boss" which, after being pushed up through the canal, was stitched to the abdominal wall at the internal ring, where it was expected to act as a barrier to the re-descent of the hernia. In certain very favorable cases this hope was realized, but in a large percentage of the very class of cases which were in the greatest need of surgical aid, nothing but disappointment was in store for the surgeon and his patient.

Then came the method bearing the name of our eminent countryman, McBurney, which rapidly took the lead of all others in this country. This operation, while it did not prove a success as regards permanence of cure, was a long step in advance, in that it opened the canal to the internal ring and removed all foreign substances. The error in its technique was in closing the wound by cicatricial tissue which did not prove stable in character.

Next in line, and in importance, came the almost simultaneous publications of Halsted and Bassini, in 1890, of methods in many respects similar, but with the evidence in favor of Bassini in that he had been using his operation since 1884, and was able with his first publication to give a report of over two hundred cases. Not only was this a larger number of cases than the author of any previous operation had ever reported, but the results as presented were such as had never been secured by any other method and his death rate so light as to remove it from the list of dangerous operations.

This operation has now been under trial in this country for the past four years, with results fully equalling those presented by its author, and, personally, I can say far in excess of my most sanguine expectations. I had for some time used the operation of Barker, of London, with fairly good results, but have now not only abandoned it, but have become an enthusiastic advocate of the method of Bassini.

The operation needs little description at this late date. Its details are within the reach of all, and quite familiar to most of my hearers. The canal is, in every instance, opened to the internal ring. The sac is separated from the cord, ligated, and cut off flush with the peritoneal surface. The cord is elevated and the original canal for its transmission obliterated. The divided structures are brought into apposition and held by a suture material which is not quickly absorbed, and which does not act as an irritant to adjacent tissues. While Bassini uses silk for this purpose, most operators in this country are using kangaroo tendon, and are quite willing to confess their obligations to our former President, Dr. Marcy, for this valuable material.

Without further detail, let us consider *why* this operation, and Halsted's, as well, is liable to cure where former methods have failed. The secret, if there be any, is soon discovered by those who adopt it, and it is this—that the canal is cleared of all foreign substance—then the repairs begin at the internal ring, and the structures are restored to as nearly a normal condition as is possible.

In my operations I have found in the canal in various cases, since doing the Bassini operation, the following substances which, if they had not been removed, would have furnished strong predisposing causes for the recurrence of the hernia:

1. Tough and thickened sacs, a persistent tube with serous lining.
2. Good sized bunches of soft fatty tissue connected with the cord.
3. Lipomatous growths—extra-peritoneal.
4. Enlarged veins connected with cord.
5. Masses of adherent omentum inside of sac and in vicinity of internal ring.

In former methods none of these complications were found, but as I have had opportunity to demonstrate upon some of my own patients, they have been the cause of recurrence. The opening of the canal throughout its entire length has therefore been, it is believed, the most important advance in the surgical cure of these cases.

Twenty years ago to remove a portion of the omentum was deemed a hazardous undertaking and for this reason, large and hypertrophied masses were returned to the abdominal cavity. These have not infrequently acted as a foreign body producing peritonitis. If the patient was fortunate, and escaped this accident, the hardened plug of fat remained at or near the internal ring, ready to act as a wedge for re-dilating the canal. Later, several eminent operators were unfortunate enough to have sepsis or secondary hemorrhage following its removal. At present, this is all changed, and the speaker has now operated upon forty-five cases, in patients of all ages, from 13 to 70 years, where pieces of omentum of various sizes have been removed, and without an accident of any kind. There have been enormous masses, requiring the ligation of numerous large vessels in some instances. Formerly, operators were in the habit of surrounding large masses of this tissue by a single ligature, and that usually of catgut, cutting it off and dropping the stump back into the abdomen. Under pressure the fatty tissue was rapidly absorbed, the ligature slipped off and hemorrhage occurred. I regret to say that this method is still followed by some surgeons, to the very great risk of their patients. In a recent report of these cases before the Surgical Section of the New York Academy of Medicine, which will be published shortly in the *Annals of Surgery* (June 2, 1895, p. 658) I have demonstrated a method which seems to insure the greatest amount of safety. This is to use silk as the ligature, to tie every vessel that is large enough to be seen, without including any fat. I have applied over twenty silk ligatures to a single omentum. I have used silk in all of my cases, and have seen no bad effects from leaving it in the cavity of the abdomen.

The method of tying off omentum, which is suggested, has also another advantage. When the omentum returns to the abdomen its edge is free to spread out naturally, instead of being held in a mass in the vicinity of the canal.

I regret to see that two of our countrymen have recently advocated operations, each different in character, where attempts are made to utilize the hernial sac, to fortify the parts against a return of the hernia. The word regret, is used because I am convinced that the sooner we recognize the hernial sac as a foreign body, the sooner will we come to a definite understanding as to just how much we can promise our patients who suffer from hernia. It is surely a step backward.

In closing, we can put the facts of our advanced position in the surgical cure of hernia in a few brief sentences:

1. Asepsis has so far removed the dangers that we are justified in doing a truly "radical" operation.
2. Any method that fails to remove all abnormal tissue, or that uses suture material quickly absorbed, invites failure.
3. Mortality has been reduced from 8 per cent. to a small fraction of 1 per cent.
4. The time of confinement to bed has been reduced from three or more weeks to eight or ten days.

We can not at this time speak with absolute certainty, but we have the best reasons in the world to believe that the number of permanent cures have been advanced from 40 or 50 per cent. to at least 90 per cent.

REPORTS ON TYPHOID FEVER CONTINUED.

NO. VIII.

Read before the Ohio State Medical Society, Columbus, Ohio,
May 17, 1895.

BY JOHN ELIOT WOODBRIDGE, M.D.

YOUNGSTOWN, OHIO.

A few days since I overheard a physician say: "There is no physician in the world so learned and possessed of such perfect integrity as to have been able to convince me by any statement that the uniform results I have seen Dr. Woodbridge secure in the treatment of typhoid fever were possible."

When asked by his interlocutor what he regarded as the strongest evidence of the truth of a declaration "that typhoid fever can be aborted," he answered: "Seeing it done. After that, the charts and reports of the cases of other physicians who have treated typhoid fever by Dr. Woodbridge's method and thus have succeeded in saving the life of every patient and greatly shortening the duration of the disease." His remarks prompted me to amend the report which I had prepared, of cases of typhoid fever which I had treated during the past year, by embodying in it some accounts of the failures and successes of other physicians who have essayed the abortive treatment of the disease; relying on the directions which I had given in papers (written only to prove that the disease could be aborted); on hastily written letters; on instructions given orally or on bedside consultations. Many of them have shown their enthusiasm over the results of their trials and tests of this method of treatment by sending me clinical charts of the cases; and gratefully acknowledging their indebtedness to me for their marvelous success; a most laudable example of true courage and heroism, to thus report results (the very possibility of which had been so strenuously denied) which it is devoutly to be hoped may be largely followed.

As the object of this paper is to place the Ohio State Medical Society in a position to reach a just conclusion of the veracity of the affirmation "that typhoid fever can be aborted," I shall draw from all these sources. Many of the original charts (copies of which I hand you) and the letters from which extracts are made are here for your inspection.

Those of you who were present at the last meeting of this society, when I read my paper on "Typhoid Fever," will remember that a member arose in his place and said: "Being from Dr. Woodbridge's town and society, I wish to say that we have had several 'fights' on this subject, and we have been watching

his cases for several years to see if he could make his pledges good; but so far we have been unable to discover that he has made any failures, or had a death from typhoid fever." . . . "And we intend to continue to watch him in the future and if he have a death we will report it." The fact that no such publication has been made, may be accepted as conclusive testimony that for thirteen years I have had no death from the disease and have aborted every case of typhoid fever which has come under my care at a reasonably early stage of the disease.

During the past year I have treated alone or in consultation, 58 cases of typhoid fever; during the same period, there have been treated by 117 other physicians, acting under my advice; by consultation at the bedside; in conversations in which I have given very complete and precise counsels in regard to the guidance of the patient throughout the illness—more than eight hundred cases.

I have seen in consultation during the past twelve months two fatal cases.¹

Case 1.—Mr. H. C. O., of Sewickley, Pa. This patient had been feeling sick and miserable, and, under the impression that he had la grippe had been taking quinin for several days. Yielding to the inevitable, he finally went to bed and sent for his physician who found that he had pneumonia. Later, he had an alarming hemorrhage of the lungs. No pathognomonic symptoms of typhoid fever were observed until the night of December 1, during which he had numerous profuse intestinal hemorrhages. I was called the next day and found him in a condition bordering on collapse, bleeding from both the lungs and bowels, and he died before the hemorrhages could be arrested.

The only other fatal case which I have seen in consultation, occurred in the practice of Dr. M. V. Cunningham; whose experience in the Cook County, Ill., Hospital and at the Emergency Hospital, during the World's Columbian Exposition, had served to render him an unusually accurate diagnostician, and taught him to appreciate the value of antiseptic medicine. Conservative to a degree—educated to believe that there was no power in medicine to abort typhoid fever—he had watched my cases with the eye of an unfriendly critic, until forced by the logic of my repeated successes, he called me in consultation several times, and consequently was able to produce such brilliant results in a number of instances that I had the most implicit confidence in his ability to treat typhoid fever in a perfectly scientific manner.

Case 2.—James K., aged 24 years. (See chart marked "Dr. Cunningham, No. 3.") This patient was very sick on March 13. On April 1 he sent for a physician, who (according to the statements of the family) made a diagnosis of la grippe and called again the next day. The patient growing worse, Dr. Cunningham, who a few weeks earlier had treated a small niece of the patient through a very severe attack of typhoid fever by the method I had advised, with unusual success; (see chart marked "Dr. Cunningham, Case No. 1, Ella G.") was called on April 6, and he called me in consultation on April 7. I found that the patient had been so sick nine days before I saw him as to lead to the obvious conclusion that he had been sick even longer; a conclusion fully justified by his condition, his temperature having been the previous day 105 degrees; his bowels excessively tender and tympanitic; nervous symptoms exceedingly bad; his tongue very dry and brown, also tremulous. He had persistent hic-cough and was delirious. The next morning Dr. Cunningham came to my office to say his patient was so wildly delirious that his father who was taking care of him was unable to give him medicine and could with difficulty keep him in bed; and consequently wished to send him to the hospital—a desire which met my heartiest concurrence. This, unfortunately, was abandoned on account of expense.

I did not hear from the patient again till April 10, when

Dr. Cunningham invited me to see him, remarking in a pleased way: "I would like you to visit him once more before he is well; and you must hurry or you will be too late, for his temperature was 101 this morning, and at the rate it is dropping it will be normal in a day or two." Visiting him about 10 A.M., we found his temperature 100 6-10 degrees; his tongue moist and less coated; his head clear; his abdomen quite flat and entirely free from tenderness; tympanitis very slight; nervous symptoms greatly improved; and sleeping naturally. He had taken no antipyretics or stimulants. His condition having improved so rapidly since my last visit, I told the Doctor that I believed his patient would be well in less than ten days; and according to reports, he continued to improve till the following evening, when his symptoms were all better and his temperature was 99 6-10. Up to this time the disease had run the usual course expected under antiseptic treatment, and, save that it had been instituted too late to prevent necrosis and ulceration of Peyer's glands which needs must have time to heal by granulation, the patient was nearly well.

Dr. Cunningham's case. James K.; 24 years; date of admission April 6, 1895.

Consequently I was greatly surprised, when Dr. Cunningham telephoned me the next day that the patient had had two convulsions during the early morning and was very restless, delirious and seemed to be suffering great pain, apparently abdominal, as indicated by the manner in which he rubbed and tugged at this region.

Examination revealed a doughy mass, filling up the abdominal cavity, most solid on the right side. He continued to have convulsions; his mouth and tongue became dry and parched; his temperature became subnormal; he grew more restless; his delirium became more profound; and he died of shock, two days after the accident.

The autopsy revealed an intussusception, the obvious cause of death by shock to the nervous system, already exhausted by the long and exceedingly severe delirium and under great strain on account of the septic condition due to the enormous pyogenic surface; the whole of the small intestine being inflamed, and all of the agminated glands of Peyer, in the more

¹ Since this paper was written, a third case, which I saw only once on the twenty-ninth day of the disease died.

than six feet of intestine examined—ulcerated. The stomach and intestine above the intussusception were full and distended—below it, empty and collapsed.

This case presents the strongest possible confirmation of the correctness of my diagnoses—because there is not, among all the cases I have reported as typhoid fever, a single case which offers fewer pathognomonic symptoms of the disease than this one. It positively confirms my declaration that “typhoid fever can be aborted;” for severe as it was, and despite the fact that treatment was so long deferred that necrosis of Peyer’s gland was unavoidable; it yet pursued the ordinary course toward recovery, and before the unfortunate accident occurred which caused the death he was practically cured.

It presents the most convincing and irrefutable evidence of the validity of my assumptions as a whole; and it seems to me that it should overwhelm with shame and confusion the arrogant and impudent critics who, forgetful of my nineteen years of clinical experience, with a method of treatment to which they have not given the slightest attention, presume to say that because the clinical chart does not present the so-called typical “typhoid fever curve”—*ipso facto*—it ceases to be a typhoid fever chart.

If any one of the gentlemen are present who in former years have criticized my charts (and in doing so have positively asserted that a chart showing a steplike decline in the temperature, which touches normal in eight or ten days, could not be one of a case of typhoid fever) will scrutinize well the chart marked “Dr. Cunningham’s Case No. 3., James K.,” and examine also that book of charts—in it he will find that there are not three charts which depart further from the so-called typical “typhoid fever curve than the thermic line,” on the chart of this man, whose small intestine presented the most extensive series of ulcerated Peyer’s glands that I have ever seen.

Had the physician who was called to attend this man on April 1, made a correct diagnosis or, failing to do so, had he called in consultation a physician who, if unable to make a positive diagnosis, would at least have given the patient the benefit of the doubt, and immediately instituted proper antiseptic treatment; the misfortune of an intussusception may still have befallen the patient, and he may have died; but he would have been spared those days of burning fever; those sleepless nights of wild delirium; the necrosis of Peyer’s glands and their consequent dangers.

I have known all these years that these were the clinical charts of cases of true typhoid fever; known that some of them were charts of cases of the disease in which necrosis and even ulceration of Peyer’s glands had already supervened; and I have also been aware that there were among them the charts of patients who, but for the treatment I had advised, would have been sleeping beneath the sod.

In nearly every medical society before which I have presented dissertations on typhoid fever, certain members have wisely delivered themselves of one or more of the following sage citations, either literally or with a very slight re-arrangement of words as, for instance: “We all know that typhoid fever is a specific infection which must run its course of four, five, six or ten weeks or longer;” or it may be that one will sapiently remark: “If there is one fact in medicine that is well established, it is that the course of the disease in typhoid fever can not be shortened by

a single day;” and these erudite persons seem to deem these parrot-like assertions as incontrovertible testimony, amply sufficient to confute totally and instantaneously the whole of the accumulated evidence of my clinical experience; quite sufficient, too, to disprove the statements of all the proficient physicians who have corroborated my diagnoses and results. But it should be remembered that unwarrantable assumption is not valid reasoning and the plausible arguments that have been adduced in confutation of my claims are not more convincing than have been opposed to every step in the progress of medicine.

In the Cleveland Medical Society where, without malice toward any member of the medical profession of that city or county; but for the two-fold purpose of emphasizing my confidence in the potency of antiseptic medicine; and also of letting the profession abroad, comprehend and realize that I had attained the unattainable—that I had, in defiance of all known laws of pathology, “achieved a victory” over diseases of a microbic origin, which, when accepted by the medical profession, would add perceptibly to the average duration of human life, by greatly reducing the mortality from this class of diseases—I told what I had accomplished; described my method of procedure; stated in strong language the responsibility which I believed devolved upon those members of the profession who, knowing or having the means of learning how to save the lives of all cases of typhoid fever and who failed to give their patients the benefit of the knowledge; thus nettling the members of this, as well as of my own local society, to such an extent that had my house been made of glass, it would have been about my ears—for my expressions were harshly criticised and in the heat of debate many broad and preposterous arguments were advanced.

The ubiquitous professor, already in possession of all of this world’s knowledge that is worthy of his attention, was ridiculously conspicuous in a way that would have been laughable had not the subject been so serious; and exposed his ignorance, not only of antiseptic medicine, but of the true character and pathology of typhoid fever. Thus, one savant added superciliously and blusteringly to his remarks: “He claims that the temperature has gone to normal in four or five days after intestinal hemorrhage. Absurd! What could he do for the ulceration of the bowels?” As if the ulceration of Peyer’s glands were the cause of the elevation of the temperature. Absurd! And as a climax and a final adjustment of the subject said, sententiously: “Talk of aborting typhoid fever. Impossible!”

To me, and to those who have with ease, confidence and tranquillity aborted the disease, these infelicitous comments are “absurd,” indeed.

A latter-day Sydenham, gifted with peculiar perspicacity, selected three charts as looking very much like the record of the temperature in cases of malarial fever. The fact of the matter is, that his extraordinary clear-sightedness availed him nothing for he had, unluckily for himself, chosen the charts of three cases of typhoid fever which occurred during two epidemics. The patients had been examined and the diagnosis verified by no less than six different physicians at the bedside; and no doubt was expressed, at the time, as to the character of the disease. It is hardly conceivable how so grievous a

mishap could have befallen the critic, for unfortunately, the lines on the charts did not delineate the rise and fall of the temperature of malarial fever—a blunder most inexcusable even in the most inexperienced medical man. The arguments thus adduced by notable professors whose reputation for scholarship beyond measure has heretofore been undisputed have been puerile indeed—unworthy alike of the speaker, his auditors and the topic under discussion. It is hard to understand, too, how a philosopher so penetrating, so profound, could be so willfully blind as not to have observed that at least fifty of these were the clinical charts of typhoid fever patients each one of whom had been examined by from two to six physicians, the diagnoses and results of treatment attested to, and all of these facts written on the face of the original charts, which were signed by physicians whose integrity and experience in diagnosis can not be questioned.

But when these charts were criticised, and when the fact that the temperature touched normal in

Dr. Justice's case. Lorenzo C.; date of admission Feb. 9, 1895.

seven or eight days was said to be proof that these patients did not have typhoid fever, I knew that if the opportunity should ever present itself, I would be able to demonstrate on the cadaver the truth of my statements. I little expected, however, that I would live to see a case of *aborted typhoid fever* in the dead-house.

But here I present to you a temperature chart kept at the bedside of the patient by the attending physician, Dr. M. V. Cunningham (Case No. 3—James K.) in which the temperature touched normal on the seventh day of treatment; the thirteenth day of the disease. And here I present to you, both dried and moist specimens of the intestine of the same patient, showing the characteristic and extensive ulceration of Peyer's glands. Here is the intussusception which caused the death. Please open the bottles and investigate to your entire satisfaction. The history and the pathologic specimens prove conclusively that one case of typhoid fever was aborted. "*Ab uno disce omnes.*" Thus, this obscure colored man—dying—

has rendered a greater service to the world, than can her most distinguished citizen—living.

It is interesting to note that every adverse criticism of my theories; my management of disease or of my conclusions, have come from those having no practical and, I fancy, very little theoretical knowledge of the subject; while those who have tested my methods have favored me with more valuable reports and kindly expressions of approval than I have been able to transcribe or properly answer.

I append a few of them here. I presented others in my papers read before the Sections on Pediatrics and Practice of the AMERICAN MEDICAL ASSOCIATION.

Dr. John McCurdy, one of the most distinguished physicians in the State of Ohio; many times President of his County Medical Society; ex-President of the Ohio State Medical Society; during the war, Regimental, Brigade and Division Surgeon; Assistant Medical Director, and Acting Medical Inspector of the 14th Army Corps, has had 320 cases of typhoid fever under his care at one time. A firm believer in the idea that any limitation of the course of the disease in typhoid fever was impossible; in the County Medical Society in 1880 he spoke eloquently against the acceptance of my theories, and in 1893, in the

Dr. I. F. Reed's case, No. 1. Clarence F.; age 24 years; residence, Massillon, Ohio; date of admission Sept. 6, 1894. After the 21st temperature remained normal, pulse 76. Treatment "Woodbridge" formulas for aborting typhoid fever.

same Society in which he had spoken thirteen years before, said: "Dr. Woodbridge has made the greatest discovery that has been made in medicine for a hundred years. I have treated typhoid fever by his method for several years, and have aborted a large number of the sixty-five or seventy cases treated since 1890, although I have not been able to abort every case and have had two or three deaths; these occurred, however, in cases that came under my care at the end of the second week of the disease or later. I know that this treatment has power to destroy the specific poison of typhoid fever and if begun early will abort the disease. It is the best treatment I have ever seen advised."

At a public banquet given to the Chamber of Commerce, at which there were probably three hundred guests present, Dr. McCurdy, in responding to the toast, "The Medical Profession," said: "We claim that one of our number here is the discoverer of a treatment for that universal and justly dreaded disease, typhoid fever which, as a rational and scientific plan of waging battle with that life destroyer, is far

in advance of any treatment yet practiced. This treatment has stood the crucial test of years, in hundreds of cases, and the theory is fully sustained by the long list of victories achieved."

Dr. C. R. Justice, the very able Health Officer of Poland, Ohio, and ex-Member of the Pension Board, with whom I have had seventeen bedside consultations over cases of typhoid fever during the past year, had for years condemned my theories and denounced my position as "absolutely untenable;" until I had learned to regard him as a devotee at the shrine of the "expectant method," who would go on to the end of his professional career treating the disease symptomatically; accepting the long weeks of sickness of his patients as something entirely beyond his control, and the deaths as visitations of Providence for which he was in no way responsible. I was greatly surprised, therefore, to learn that he had been investigating the subject for months. That he has continued his investigations to good purpose is proved by the success he has secured in treating some very severe cases of typhoid fever (a few of the charts of which are submitted for your inspection), and by the fact that I was able to write to one of his brother practitioners of his town, advising him to call Dr. Justice in consultation, as he had treated so many cases by my method that I felt perfectly safe in saying to the friends of the patient that if they called him early enough they need never fear that he would have a death from typhoid fever, or that any of his patients would be severely ill.

Your attention is especially invited to the clinical chart of Case—(Dr. Justice, Lorenzo C.) who had been under the care of two other physicians at a neighboring town. He had been sent home with the statement that he had a severe attack of typhoid fever and would necessarily be sick a long time. He arrived, wildly delirious, with a temperature of 106 degrees and all other symptoms characteristic of the disease. His temperature touched normal on the eleventh day and in a few days he was out driving, feeling perfectly well.

Dr. Justice has treated during the year, by my method, twenty-three cases without a death; although some of them have been complicated by grave pre-existing or concurrent affections and some of them came under his care at late stages of the disease. In speaking of the treatment, Dr. Justice said: "Looking back over the past, I can see where I could have saved many lives had I understood this method of managing typhoid fever as I now do; and I think I would be committing a crime were I to treat a case of the disease in any other way than that advised by Dr. Woodbridge."

Dr. J. A. Dickson, of Youngstown, Ohio, a gentleman of the highest integrity, a physician whose reputation as a general practitioner is happily not marred by his success as a laparotomist, sends me the following report:

"YOUNGSTOWN, OHIO, April 29, 1895.

"I have treated several cases of typhoid fever with Dr. Woodbridge's treatment, and find that it will invariably cut the fever short, if begun early enough in the disease; the illness lasting often but a few days; the temperature soon dropping to normal and remaining there. I have tried also the mixed treatment; that is, using the tablets as directed and also, perhaps, some turpentine emulsion, quinin, etc., but find that it pays better to 'hew to the line.' I have recently been treating a case of typhoid fever, which came to me from another physician who was ill. It had not been treated by Dr. Woodbridge's method, and when I first saw

the case I found the temperature 104 degrees, the pulse 100. I immediately began with the tablets, giving one every fifteen minutes for the first day, one every half-hour during the second day, and one every hour during the third day, etc. During the second day the temperature came down to 101.8, upon the third day it was 101.4, fourth day 101.4, fifth day, 101.2, sixth day 98.6. After this the temperature remained normal for four days, when the patient came down with pneumonia, with the characteristic râles, egophony, hepatization and expectoration—from which he is now recovering. The temperature upon the onset of the pneumonia trouble went up from normal to 101.8 the first day, and gradually to 103 degrees, but the tongue was moist and there were no symptoms of typhoid fever.

"If I were stricken with typhoid fever, or one of my family were taken down with the dread disease, I think I would feel like sending for Dr. Woodbridge from the Atlantic Coast to the Golden Gate. J. A. Dickson."

There must be royal blood coursing through the veins of Dr. Reed of Massillon, Ohio, for of such material as he is made, made they the kings and rulers of the earth in olden times. In one of the darkest hours of my existence he wrote me as follows:

"MASSILLON, OHIO, Nov. 14, 1894.

"J. E. Woodbridge, M.D.,

"Dear Doctor:—I wish to add a word of encouragement to you against the many denunciations of your treatment of ty-

Dr. Reed's case, No. 2. Wm. G.; age 16 years; admitted Dec. 7, 1894. Delirium, some cough and lungs filled with mucus; three weeks before was treated by Dr. Waldron, of New Berlin, for malarial fever. Was moved, and for a week nothing was noticed until the night of December 6, when his parents found him hunting water and delirious. On the third day mucus râles in both lungs; sixth day became slightly hepatized in both apices; ninth day apex and base of both lungs hepatized, leaving an area of about six inches for breathing capacity; tenth day hepatization not so great; fifteenth day both lungs clear. Patient worked at a place where there were three cases of typhoid fever, and made a visit before he was taken sick. Treatment: I used no treatment for lung trouble except that which I used for the treatment of fever; and for that only the "Woodbridge treatment." Result most satisfactory, as shown by chart. Patient is up and doing well to-day, Jan. 18, 1895. Family history: Mother had two sisters, father and mother, who died of pulmonary phthisis.

typhoid fever. I wrote for your formula some time ago, and you referred me to the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, from which was obtained the required knowledge. My father, Dr. T. J. Reed, has also used it; we have met with very good success, and can offer only words of praise in its favor. We have been giving about 30 grains of quinin per day (this being a great malarial district), for four days, and if at the end of that time we found the temperature high and the symptoms the same or aggravated, we put them on the treatment prepared under your formula, and although we have not aborted the disease in every case inside of ten days, we have done so, with the exception of two cases, inside of fourteen days, and seldom see them after the sixteenth day. I have kept diligently the charts of the cases I have had and have taken

pleasure in showing them to other physicians who laughed at my daring to use the treatment. They take a different view of it now, though. Had I but known a few hours earlier of your intention to speak in Cleveland, I should have gone there and let my voice help to defend you; or if not allowed that, at least it might have been some satisfaction to you to have seen the few charts (ten in all) we have been able to prepare. Hoping that you may meet with greater encouragement at the hands of the profession, and that I may be able to meet you personally at some future time, I remain

Yours truly,
T. F. REED."

A few days later Dr. Reed kindly sent me the charts to which his letter refers, with the accompanying letter:

"J. E. Woodbridge, M.D.,

"Dear Doctor:—I send you by this mail, a few of my charts that were unmistakably typhoid fever cases and some of them were the last cases of from two to four in the family who had similar attacks, but of which I regret to say no records were kept. We have had, in all, about twenty-five cases, and these charts are examples of them. We are well pleased with the results we have had, and can positively say that it is due to the form of treatment. I hope the charts will be of use to you, and anything I have or may get is at your disposal.

"I should like to have the charts returned, as I have no duplicates and want to keep them for future use. The temperature marked was taken at the height of fever. Wishing you better success, and acceptance of your theories,

I remain very truly yours,
"T. F. REED."

(To be continued.)

CONSERVATIVE SURGERY ON THE BATTLE-FIELD AND FIRST AID TO THE WOUNDED.

BY N. SENN, M.D., PH.D., LL.D.

COLONEL AND SURGEON-GENERAL OF THE ILLINOIS NATIONAL GUARD;
PRESIDENT OF ASSOCIATION OF MILITARY SURGEONS OF ILLINOIS; EX-PRESIDENT OF THE ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES.
CHICAGO.

(Concluded from page 14.)

Autotransfusion.—In threatening danger to life from hemorrhage much can be gained from autotransfusion. The exclusion from the general circulation of unessential parts of the body will often secure for the vital organs an adequate blood supply. Autotransfusion for this purpose is secured promptly and efficiently by elastic constriction of one or more extremities at their base. This can be accomplished by Esmarch's constrictor, suspenders, or in the absence of elastic material, by the use of the Spanish windlass. According to the urgency of the symptoms presented, the base of one or more extremities is constricted after rendering the limb comparatively bloodless by elevation. By exclusion of the circulation from one or more extremities, intravascular pressure compatible with essential functions is restored and life is bridged over for a sufficient length of time for the employment of remedies of more lasting value.

Shock.—Next to hemorrhage, shock should receive the surgeon's attention. It is often difficult to differentiate between the symptoms produced by shock and hemorrhage. The non-professional assistant should be made to understand that the maximum symptoms of shock are developed almost immediately after the receipt of the injury, while in hemorrhage the intensity of the symptoms increases progressively. Even in a complete transverse tear of an

artery the size of the common carotid, it requires at least five minutes to produce death from hemorrhage in intense shock, symptoms pointing to a fatal issue appear almost immediately upon the receipt of injury. Shock is the result of a reflex vasomotor paresis and, consequently, if severe, calls for the most energetic and prompt treatment. A patient suffering from shock should be kept in the dorsal recumbent position and treated by active stimulation. Inhalations of nitrite of amyl and hypodermatic injections of strychnia in doses of from one-fifteenth to one-twentieth of a grain, repeated every half hour, until reaction takes place, constitute the most successful treatment. The administration of alcoholic stimulants, camphor and ammonia is also indicated, as well as the external application of dry heat. In the transportation of patients suffering from shock, the greatest care should be exercised not to subject them to any unnecessary movements, and it is of special importance that the recumbent position should be maintained until reaction is established. No operation of any considerable importance should be performed until the patient reacts from the immediate effects of the injury.

Primary Dressing of Wound.—Perfect aseptic surgery upon the battle-field is a happy dream which will probably never be realized. The bullets, as recent experiments have shown, are frequently contaminated with pathogenic microbes, and often carry with them infectious fragments of clothing and

FIG. 12.—Cartridge belt with package sewn on inner surface.

other foreign substances, as well as microbes from the surface of the injured part. Again, in large battles the number of wounded is so great and the number of those to whom their treatment is intrusted so small, that the necessary antiseptic precautions to obtain an antiseptic condition of the wound can not always be carried out. The duty of the surgeon upon the battle-field in rendering the first aid to the wounded, after having given proper attention to the treatment of shock and hemostasis, will be to prevent subsequent contamination of the wound by protecting it with an antiseptic occlusion dressing. Shaving and disinfection of the surface in the vicinity of the wound will be out of the question under such circumstances. Search for bullets and efforts to secure their removal must be postponed until the patient reaches the field hospital, where these procedures are facilitated and the attending danger of causing infection diminished by a more complete instrumentarium and more efficient means to secure asepticity of the wound and its vicinity.

Behind the fighting line, and at the first dressing station, the primary dressing of the wound should consist of the antiseptic package which every soldier should carry with him. The best place where this package should be kept has not been determined. Esmarch suggests that it should be sewed in some part of the uniform. It appears to me that no part of the clothing of the soldier would be a sufficiently

NOTE.—The "denunciations" to which Dr. Reed refers, are those of physicians who denounce the abortive treatment of typhoid fever without trial or investigation, as they would denounce anything which did not chance to fall within their intellectual horizon.

safe place for this most important outfit when in active service. In the heat of battle the soldier often relieves himself of a part of his clothing, his knapsack, but there are two things which he will not part with willingly, and these are the cartridge belt and gun. It appears to me that this package could always

safety-pin, two compresses of salt sublimate mull, 10 cm. wide and 100 cm. long, each wrapped in impermeable paper, one salt sublimate cambric bandage, 10 ctm. broad and 2 m. long. All these articles are wrapped in gutta-percha paper. This package is too cumbersome and contains articles which can be dispensed with in the dressing of wounds upon the battle-field. In the majority of cases the first dressing is only a temporary one and is replaced later when the wound is subjected to thorough examination and treatment by a more efficient one. The package should be as small and compact as possible and should contain only such articles as are absolutely necessary to protect the wound against infection during the interval between the receipt of the injury and the arrival of the patient at the field hospital. Cotton is the most compressible hygroscopic dressing material and the most efficient filter in preventing the access of microbes to the wound. Two

FIG. 13.

FIG. 14.

be found upon the wounded soldier if it were sewed upon the inner surface of the cartridge belt. The package should be thin and correspond in width with the cartridge belt. Esmarch's package used in the German Army contains: one triangular bandage, one

FIGS. 13, 14, 15.—Showing primary dressings of the head, upper and lower extremities.

drachms or half an ounce of compressed salicylated cotton will furnish the necessary material for a primary occlusion dressing. This can be held in place in almost any part of the body by a triangular gauze bandage, assisted, if circumstances make it necessary, by the cartridge belt, gunstrap, or articles of the patient's clothing. A safe and efficient antiseptic powder which does not easily deteriorate should invariably constitute a part of the package. A combination of boric and salicylic acid is the one I should propose for this purpose. Two grams of boric acid and half a gram salicylic acid, thoroughly triturated, should be incorporated in the center of the compressed cotton, the cotton surrounded by the triangular gauze bandage and with the addition of a safety pin wrapped in gutta-percha tissue.

In applying the dressing, the compressed cotton is loosened, the wound freely dusted with the powder

contained in the center of the package, the wound well covered with the cotton which should overlap its margins, and the dressing held in place by the triangular bandage and such additional extemporized means of retention as may be necessary.

For the purpose of preventing rapid decomposition of the blood which will soon saturate the primary dressing, and with a view of guarding against infection of the wound from this source, it is absolutely necessary to incorporate with the dressing material and bring in contact with the wound a safe and efficient antiseptic which, in this package, consists of a combination of boric and salicylic acid.

Immobilization of Injured Joints and Fractured Limbs.—In the case of fractures and joint injuries, the affected limb should be properly immobilized to prevent additional injury and pain during the transportation of the patient to the field hospital. As it

FIG. 16.—Immobilization of arm and forearm by fastening the sleeve to the coat near the wrist and elbow joints with safety pins and inserting hand underneath coat on opposite side between two buttons.

is impossible for the surgeons and Hospital Corps to carry with them upon the battle-field, material for splints in sufficient quantity, they must depend upon articles which can always be found upon the battle-field, in securing for the limb a proper mechanical support. A few of such extemporaneous dressings will be shown in the following figures:

The splint should be well padded with the blanket, or articles of wearing apparel. In compound fractures and penetrating wounds of joints, perfect immobilization by a plaster-of-Paris splint should be secured as soon as possible, but as this can not be done behind the fighting line, for obvious reasons, the temporary improvised dressing should be replaced by the permanent fixation dressing at the field hos-

pital. Antiseptic precautions and perfect immobilization will be the most important elements in the conservative treatment of compound fractures and penetrating injuries of large joints.

Transportation of Sick and Wounded.—Increased and improved facilities for rapid transportation of the wounded from the fighting line to a place of safety, will be an essential requirement in securing the greatest amount of benefit from conservative surgery upon future battle-fields. The general introduction of the new infantry weapon will make it necessary to establish the field hospital farther in the rear of the line of battle than formerly. Unless a natural protection by a hill or deep ravine is available, it will be necessary to locate the field hospital at least 3,000 meters from the line of action. This will necessitate an improved ambulance service. The

FIG. 17.—Mitella by fastening lapel of coat on injured side with two safety pins in such a position as to support the forearm in a flexed position.

latter will be resorted to in transporting the severely wounded from the point where the first aid is rendered to the first dressing station.

A well-trained Hospital Corps, and the use of improved litters and ambulances will be instrumental in securing prompt and easy conveyance of the wounded from the line of duty to their destination. An efficient bicycle litter is a much needed desideratum in the transportation of the wounded from the fighting line to the first dressing station and field hospital.

The Surgeon's Work at the Field Hospital.—The conservative work begun on the battle-field is continued at the field hospital, which offers additional facilities for the practice of ideal conservative surgery.

It is here that efficient measures can be employed to correct the injurious effects of profuse hemorrhage and to overcome the symptoms of prolonged shock. It is here that every serious wound will be thoroughly examined and under strict antiseptic precautions will be subjected to the necessary treatment. It is here where permanent hemostasis will be substituted for temporary measures. It is here that the abdomen and cranial cavities will be opened for penetrating wounds requiring such intervention for the arrest of hemorrhage, the removal of foreign infected

the different parts of the body, regardless of the resistance offered by the osseous structures at a distance intended for shooting to kill. In the presence of a wound of entrance and exit, the use of the probe should be dispensed with, as an exploration of this kind would yield no indications of diagnostic value and might become a source of infection or a cause of renewal of hemorrhage. The jacketed bullet is less liable to undergo deformation in striking a hard object such as bone, and is also less likely to become deflected than the leaden bullet. Additional modifi-

FIG. 18.—Saber splint for leg and thigh.

FIG. 18 a.—Gunsplint.

FIG. 19.—Stick and blanket splint.

bodies and the direct treatment of visceral wounds. It is here that permanent plaster-of-Paris splints will be substituted for the temporary fixation dressings, in cases of compound fractures and penetrating wounds of joints.

Indications for Probing and Extraction of Bullet.—The modern small caliber bullet will render a resort to the bullet probe much less frequent than was the case in the wars of the past. Owing to its greater velocity and power of penetration it will pass through

indications of the character of the bullet wounds will render the use of the probe less frequent in the future than the past. Search for the bullet under antiseptic precautions is justifiable in gunshot fractures, penetrating wounds of the cranium and joints. It is absolutely contra-indicated in penetrating wounds of the chest and abdomen. In bullet wounds of the soft parts, an attempt in this direction is warranted when the surgeon has reason to believe that the bullet is located

FIG. 20.—Bark splint for forearm and wire splint for arm.

in a place accessible to its safe removal. Probing for bullets, on the whole, has done more harm than good in the past, and the limits of the indications for this procedure will be greatly narrowed in the future. If the bullet can not be removed without performing a formidable operation it is much better to permit it to remain and wait for additional indications than subject the patient to additional risks incident to the operation. The modern bullet in an antiseptic wound will become encysted like the leaden

bullet and, in the majority of cases, will remain permanently in the tissues as a harmless foreign substance. If the nature of the injury makes the search for and an attempt at its removal necessary, the exploration should be made systematically and under the strictest antiseptic precautions.

The metal jacket of the modern bullet detracts from the value of the famous Nélaton probe, and has made the equally famous American bullet forceps obsolete as an instrument of extraction. The porcelain bulb of Nélaton's probe will, however, answer a useful purpose in following the track made by the bullet and in demonstrating the presence of a foreign substance in the soft tissues. The porcelain bulb of the ordinary Nélaton's bullet probe is too small, especially in searching for bullets of large caliber. It is much easier to follow the tubular wound made by a bullet with a probe, the porcelain bulb of which approximately corresponds in size with that of the bullet. As in instrumentation of the urethra, a false passage is more likely to be made with a small than a large instrument. I have had a bullet probe made which is supplied at both ends with a porcelain bulb, one of which corresponds in size with a 22 caliber bullet, the other with that of a 38 caliber.

The porcelain bulb of the ordinary probe is very liable to become detached in exploring deep wounds, and may be lost in the wound, as happened in one of my cases. To prevent such an accident, the bulbs of my probe are drilled through, the ends of the silver probe pass through, and are clinched in a depression on the surface of the bulb. In searching for bullets it is of the greatest importance to bring the parts and tissues of the body as nearly as possible in the exact position they occupied when the injury was received. That no more force should be employed in using the bullet probe than in passing a catheter is simply to repeat a cardinal rule to which there should be no exceptions. Skill in the delicate manipulation

FIG. 21.—Litter transportation.

of the instrument, patience and perseverance will accomplish more than force in these cases. Bullets which can be felt under the skin opposite the wound of entrance are extracted without exploration of the wound canal. If the bullet occupies a locality where its presence would be incompatible with a good functional result, as the cavity of a large joint, it becomes usually necessary to enlarge the wound with the knife, chisel and mallet to follow the course of the bullet and to effect its extraction. In one case I removed a 22 caliber bullet from the center of the knee joint by such a procedure, in a boy 14 years of age, who recovered with nearly perfect use of the limb. A similar case is reported by Volkmann. The metal jacket of the modern bullet will make it necessary to construct bullet forceps with great grasping power to facilitate its extraction. In pene-

course of the bullet at a point opposite the wound of entrance, for the purpose of establishing thorough drainage and to facilitate the removal of the bullet.

Laparotomy.—In my address at the last annual meeting, I discussed the advisability and feasibility of laparotomy upon the battle-field in cases of penetrating bullet and stab wounds of the abdomen, and I shall not occupy your time on this occasion by further remarks on this subject.

Amputation.—The object of conservative surgery upon the battle-field, as well as in civil practice is to obviate, whenever possible, the necessity of mutilating operations. Prompt and careful hemostasis, antiseptic precautions, immobilization of compound fractures and injured joints, and early and careful transportation of the wounded from the field to the temporary hospital are the most fruitful resources

FIG. 22.—Manner of transferring patient from litter to ambulance.

FIG. 23.—Senn's bullet probe.

trating gunshot wounds of the skull, Flührer's aluminum probe and his technique in removing a bullet from the cranial cavity merit the earnest attention of every military surgeon.

Craniectomy.—Operative interference is indicated in every case of penetrating gunshot or stab wound of the cranium. The object of such operation is to secure asepticity of the wound and its environment, removal of loose spicula of bone and infected foreign substances, arrest of hemorrhage by torsion, ligation or tamponade and, if feasible, removal of the bullet.

The wound of entrance is enlarged with chisel or rongeur forceps sufficiently to enable the surgeon to meet the indications for the operation. If the bullet is lodged in the interior of the skull, it may become necessary to make a circular craniectomy in the

of the modern military surgeon in the prevention of complications that so often necessitated intermediate and secondary amputations in the wars of the past. A primary amputation for gunshot wound of the extremities is only justifiable by extensive injuries of soft parts and fractures and joint wounds complicated by injury of large vessels and nerves. In other words, the indications for a primary amputation will be studied and sought for, more by the character and extent of the injury of the soft tissues than the extent of the bone or joint lesion. In doubtful cases the patient will be given the benefit of the doubt, as under antiseptic precautions the risk to life is greatly diminished in the attempt to save a limb by conservative treatment. The conditions which will demand an intermediate or secondary amputation in cases

thus treated will prove less perilous to life than in the past, an additional inducement to practice conservatism in doubtful cases.

Resection.—Primary resection for gunshot wounds of joints for obvious reasons has become an obsolete operation in modern military surgery. The most brilliant results have already been obtained by conservative treatment of such cases. The military surgeon will make it his duty in such instances to resort to such measures as will prevent complications necessitating secondary resection and amputation. Thorough disinfection of the wound, removal of loose fragments of bone and infected foreign substances including the extraction of the bullet, if this is found within or in the immediate vicinity of the injured joint, gauze drainage and immobilization of the limb in a circular plaster-of-Paris splint are the most effective measures in accomplishing this end.

I have briefly sketched in this paper the essential topics which will engage the attention of the military surgeon in the future in keeping pace with the rapid advances of modern surgery, and which will enable him to extend the blessings of conservative surgery to the wounded upon the battle-field of the future. The members of this Association should regard it as their duty to so perfect themselves in the principles and details upon which rests ideal conservative surgery, as to apply it in practice should they be called upon to serve their country upon the battle-field.

PERITONEAL SUPPORTS—(LIGAMENTUM PERITONEI.)

BY BYRON ROBINSON, M.D.

PROFESSOR OF GYNECOLOGY POST-GRADUATE SCHOOL,
CHICAGO.

(Continued from page 637, Vol. XXIV.)

Development of the great omentum did not seem to give anatomists any amount of trouble before the digestive canal was carefully followed in all its fetal stages. Is it true? From the old descriptions of anatomists some modifications, it seems to me, must be introduced. The two blades of the peritoneum which extend from the greater curvature of the stomach to the transverse colon are recognized by all as correct. But it is the relation which the transverse colon sustains to this fold that needs modification. I will proceed with a few simple diagrams to make myself better understood. The first, (Fig. 11) will represent the adult stage with the relations of the transverse mesocolon. The mesogaster extends from the mid-dorsal line to the stomach as a double fold of peritoneum. It grows or expands toward the left in the form of a pendulous bag. When the stomach has assumed the adult position, the mesogaster becomes the great omentum and hangs down from the great curvature of the stomach in front of the small intestines. The object of the diagrams is now to show how the transverse colon gets between the blades of the great omentum, and then it will fit the old descriptions of anatomists who knew not embryology. Figure 12 shows how the fold of peritoneum (*d*) passes back to the spine. I wish to show that the peritoneal fold (*d*) is dragged out from between the stomach and colon. I wish especially to show that it does not coalesce. In the early embryo the cecum remains in the center of the body in proximity to the navel, so that there is at first only a descending colon existing which has a mesentery.

By the rotation of the great umbilical loop and growth of the colon, there finally exists a transverse and ascending colon. Until the great intestinal loop rotates, the whole of its colon is fixed to the mid-dorsal line by its mesentery. This mesentery extends as high as the lower end of the mesogaster. By a glance at Fig. 2 it will be readily seen how Haller, Müller and Meckel come by their views. With them the lower blade of the great omentum and the upper blade of the mesocolon coalesced, *i. e.*, the loop or fold of peritoneum represented by (*d*) becomes adherent; it is cemented together and has lost its epithelial surface and that would produce Fig. 1 again. Now, the view held in this work and gained by embryologic and adult animal investigation is that the fold of peritoneum (*d*), is drawn out as far as the transverse colon (*c*), and is readjusted, displaced. Haller, Müller, Meckel and many older anatomists asserted in order to sustain their theory, that the transverse mesocolon consists of four layers. It seems to the author more reasonable to accept the theory of displacement or re-adjustment, since coalescence is not a general rule in tissue life, especially when it has been once differentiated into organs. Toldt claims that the theory of coalescence is reason-

Fig. 11.

Fig. 12.

Fig. 11—*s*, stomach; *m c*, meso-colon; *o*, great omentum; *m*, mesentery of small intestine; *c*, colon; *p*, parietal peritoneum; *i*, small intestine; *g h*, gastro-hepatic omentum. This figure represents the adult condition of the peritoneum and in the next figure I wish to show how the peritoneum develops from the fetal to the adult condition. Fig. 12 shows the fold of peritoneum, *d*, against the dorsal wall; *s*, stomach; *c*, colon; *i*, small intestine. The object of the diagram is to illustrate how the fold *d*, descends to allow the transverse colon to finally lie between the meso-colon as in Fig. 16.

able, and as proof offers the white line existing along the left side of the descending colon. I have examined such white lines, but they seem to be situated distant from the colon. It might be pertinently asked, Why does coalescence, especially, associate itself with the transverse colon and omentum? The assertion of old and even modern anatomists to the effect that the two ascending layers of the omentum can be stripped off the upper transverse blade of the mesocolon, in fetuses, I do not believe to be true; at least in no fetus of any age could I separate the ascending layers of omentum from the transverse mesocolon. The view that makes the two ascending layers of the omentum pass to the vertebral column and then return (or at least one blade return) over the transverse mesocolon and at the same time coalesce, I do not believe will be sustained by careful investigation in embryologic and adult mammalian life.

The following statements I can make from human embryologic work: take an embryo of about an inch long and the colon will consist of a transverse

and ascending part which has, so far, no connection with the great omentum. Now, the ascending layers of the great omentum pass directly back to the spinal column, but do not touch the colon to be fixed to it as in Fig. 13. Again, the under blade of the omentum passes downward to become continuous with the upper blade of the transverse mesocolon as in Fig. 13 at *d*. The whole interest, now, lies in the peritoneal fossa at *d*. The final disposition of the fossa, *d*, will determine the theory of coalescence or displacement, Fig. 14. If the fold of serous membrane, *d*, is dragged out displacement triumphs, but if the fold at *d* adheres, coalescence carries the day. Now, take embryos of about one and one-half to two inches and we find distinctly that the transverse colon is beginning to assume relations with the great omentum. But significantly it begins on the right end—a very important matter. The reason is the close relation that the right end of the transverse colon bears to the duodenum and consequently the mesogaster. The mesoduodenum is really a part of the great omentum. As a matter of fact, the great omentum assumes relations with the transverse colon gradually from right to left. This, in my opinion proves that this new relation of the omentum and transverse colon comes about by displacement (from right to left) rather than coalescence, *i. e.*, the fold,

embrace the transverse mesocolon and again converge to form the transverse mesocolon. It may be asked, What are the forces which tend to displace the fold, *d*, *i. e.*, what drags the fold of peritoneum, *d*, from between the omentum and mesocolon. The rapid increase in the size of the stomach and its being forced downward by the liver may be factors. But it is more likely to be the rapid increase of the transverse mesocolon. It also fills with meconium and will drag on its mesentery. The increase in size and dragging from meconium contents are no doubt the essential factors. A curious feature of embryos under one and one-half inches or up to two inches, is that the colon is the smallest part of the digestive tube and the colon has no bands, no appendicæ epiploicæ and no sacculations. But in fetuses of some three inches an extraordinary rapid growth occurs in the colon, and meconium begins to accumulate which no doubt accounts for many new changes in the relation of the colon and the blades of the great omentum. Hence, from considerable personal observations on embryos, both human and animal, and investigations on adult man and mammals, I am of opinion that the transverse colon assumes its relations with the layers of the great omentum by displacement and not coalescence.

Dr. Lockwood has written an excellent article on

Fig. 13.

Fig. 14.

Fig. 13 shows the fold of peritoneum, *d*, gradually being drawn out from between the layer of omentum and mesocolon; *s*, stomach; *c*, colon; *z*, intestine. The fold, *d*, is being gradually displaced and not coalescing with its adjacent layers.

Fig. 14 illustrates further progress in displacing or dragging out of the fold *d*.

d, is gradually displaced from right to left and the relation of the great omentum and colon assumes adult relations. (Fig. 15.) As the relations of the omentum and colon gradually arise, we can not trace the two ascending layers of the great omentum back to the spine, because the transverse colon has gained access to the space between the lower blades of the omentum as seen in Fig. 1. Beside, I never could discover any positive evidence of adhesions or coalescence between the lower blade of the omentum and the upper blade of the transverse mesocolon. The fold, *d*, becomes gradually drawn out from between the lower blade of the great omentum and upper blade of the transverse mesocolon as is represented in Figs. 12, 13, 14, 15, and 16 until the adult condition, Fig. 11 and 16 is reached.

Fig. 15 shows the last stage of the displacement of the fold, *d*. The dog, in my opinion, gives the best base to work on. In the dog, one can easily observe how the process proceeds. In Fig. 1, it can return on itself, so that the two ascending layers of the omentum, as they pass back to the spine diverge to

Fig. 15.

Fig. 16.

Fig. 15 shows the fold, *d*, almost entirely drawn out or displaced. It is the stage just preceding the one where the transverse colon lies in the mesocolon through displacement or readjustment and not coalescence.

Fig. 16 represents the final adult condition of the omentum, *i. e.*, the transverse colon, *c*, now lies between the blades of the mesocolon, or, in other words, between the layers of the secondary mesogastric. The peritoneal folds and pocket connected with *d*, have disappeared.

the development of the great omentum, to which the reader is referred. Dr. Lockwood makes the significant remark that coalescence is not a common occurrence. The size of the great omentum is a very variable matter. In man it normally reaches in the pelvis. In the dog it reaches well in the pelvis. In the pig, so far as I have examined, it is not quite so liberal. The great omentum is not so liberal in the horse or ox as in man and animals. There is no rule or principle in comparative anatomy, known to me, whereby one can estimate in any animal the amount of great omentum. It is reported present in all mammalia, but least developed in cetaceous animals, hence the difficulty of comparing it in animal species. In about three hundred bodies examined, living and dead, I found the omentum in various conditions as regards size. In quite a number of humans, both living and dead, I have found the omentum so large that it covered nearly every abdominal viscus out of sight. In one autopsy, performed by Dr. Waite and myself, the omentum was so large that scarcely a point of the liver was visible, after opening the ab-

domen as wide as possible with a crucial incision. In some parts the omentum was about an inch thick, so that such a body would possess at least six square feet of great omentum. A dog is much more liberally supplied with great omentum than man. In short, so far as I can observe by peritoneal examination, man has relatively less peritoneum than any other animal. The great omentum may spread over all the abdominal viscera, except a portion of the liver and stomach. I have seen it cover almost the whole of the abdominal viscera and become tucked in around the edges like a bedquilt, forming a wonderful protection against infectious invasion and also a wonderful protection against the distribution of pus. In general, children have not large omenta. The omentum increases especially from the sixth fetal month until birth. It then grows rapidly in the first and second years of life. It must be remembered that the omentum exists distinctly in fetal life from the second month on, and I think I have found it at the end of the first month. So, for large sized omenta we must look at extra-uterine life, just beyond the age of childhood, in the early stages of adolescence.

The omentum is variously supplied with fat. One can observe it as transparent as glass in subjects dying of long and continuous wasting diseases. I have observed the human omentum loaded with fat an inch thick. When the fat first begins to accumulate in the omentum it assumes the paths of the blood vessels and in various animals it appears in streaks of elegant figures. In most animals with a large omentum the accumulation of fat is at first quite ornamental, as it figures the highways of nourishment. The color of the fat varies from a white marble color to that of a pronounced yellow. The fat is inclosed in the meshes of the connective tissue, especially in the mesenterii membrana propria. The omentum is inclined to fat accumulations in all animals which I have examined (or noted in comparative anatomy works). The fat seems to be in indirect amount to the size and number of the blood vessels, hence the greatest accumulation of fat is at the roots of the omentum, along the greater stomach curvature or along the colon transversum. So far as I have been able to observe, the fat in the omentum is in direct proportion to the fat in other portions of the body. When the fat is abundant one can observe that it molds itself to the various chinks and depressions existing between the adjacent viscera. It tucks itself down in the crevices between intestinal coils and clefts of organs. After a certain amount of fat accumulations in the omentum one can not determine the course of vessels.

The position of the omentum I have observed in some animals and in over one hundred humans. It may reach into the floor of the pelvis or it may be rolled up behind the transverse colon until it will not be visible on opening and turning outward the abdominal walls. The first and most generally applicable statement in regard to the position of the omentum is that it tends to the left in nearly every case. This seems to be on account of the relation of the omentum to the spleen and ligamentum phrenico-colicum. Also because the last relation of the transverse colon and omentum is assumed at the left end of the transverse colon, *i. e.*, in the ligamentum phrenico-colicum. The acquired relations of the left lower border of the great omentum with the

ligamentum phrenico-colicum arises in fetal life—in the fifth month and more completely later. The left-sided tendency of the great omentum is also induced by the greater curvature of the stomach being well disposed to the left of the median line.

(To be continued.)

SOCIETY PROCEEDINGS.

American Electro-Therapeutic Association.

Fourth Annual Meeting held in New York Academy of Medicine
New York, Sept. 25, 26, and 27, 1894.

WILLIAM J. HERDMAN, M.D., President.

(Continued from page 32.)

Mr. F. B. N., age 28. Presented himself for treatment, June 5, 1894. Impairment of general health. Has had catarrhal trouble for many years. For four years tinnitus aurium, at first in both ears, never bad in right ear and disappeared after a month. Trouble in left ear persistent. Once in a while has a roaring, never without the hissing noise. Post-nasal dropping, formerly profuse discharge from anterior nares, but now dry with scabs and crusts. No odor. Has been under the care of specialists for past four years.

Physical examination: tonsils enlarged, swollen, intensely red. Uvula swollen, elongated, tipped with string of mucous and deflected to the side. General relaxed condition of pharyngeal mucous membrane with marked congestion and hypersecretion. Left Eustachian tube thickened and not free to Politzer's test. Hypertrophy of middle turbinated, left nares. Has been treated for thickening of left Eustachian tube and drum of left ear. Passage of left nares obstructed by enlarged turbinated bone, middle.

Diagnosis: atrophic rhinitis, with thickening of left Eustachian tube and drum.

Treatment: in all thirteen hydro-electric applications, negative, water slightly saline, one quart, have been administered to ear at intervals of four and five days, current strength 4 to 6 milliampères. Occasionally, not oftener than once in eight days before beginning the nasal douches, the indifferent electrode was the copper sound at the mouth of the Eustachian tube; at other times, the ordinary electrodes (area fifteen square inches) at the nape of the neck. After first negative douche there was complete cessation of the hissing sound and it remained in almost complete abeyance for an hour; much modified during the day. It has continued to gradually grow less and from a sibilant hiss has become a sound of a similar nature reduced at least a half. Hearing distance—test by means of watch—has increased two inches. At one time tinnitus disappeared for one hour and a half immediately after treatment.

For the atrophic rhinitis seven applications of the Cu_2SO_4 cataphoric douches were given at intervals of seven and eight days, 3 gr. to 1 qt., sp. gr. 1002, percentage strength 0.02057. Indifferent electrode, fifteen square inches in area, placed at nape of neck, current strength 3 to 10 milliampères.

After first nasal douche there was a good deal of smarting and burning through nasal passages and in frontal sinuses, with suffusion of eyes and coryza, also a headache which lasted during the entire day. Subsequently there was a very free watery discharge from anterior nares. Three days later the tonsils, uvula and entire pharyngeal mucous membrane were found markedly less swollen and congested, with very much diminished secretion. The watery discharge from anterior nares continued in gradually diminishing quantity during the week and was slightly increased at each subsequent treatment but not to the same extent as after the first application. Nasal respiration became freer; scabbing ceased, also post-nasal dropping; tonsils and uvula returned to normal size and color. Two cupric punctures of 11 milliampères each to the hypertrophied, middle turbinated, left nares, resulted in a marked diminution in its size. These were not made until the establishment of relief by means of the electric douche. General health very much improved.

In administering the intra-nasal douche, the left nares, narrowed by the hypertrophied turbinated, was preferably utilized for the inflow so as to secure perfect drainage.

Left Eustachian tube free. Patient continues under care. Other cases of atrophic rhinitis have been treated in the same manner with the same clinical results.

THE STOMACH.

For some time electricity has been used within the cavity of the stomach by means of a specially devised electrode in the hands of Dr. Max Einhorn of New York. His method is to have the patient drink a requisite amount of water and then to swallow the electrode, which is subsequently attached by means of its conducting cord to the battery terminal and the pole indicated. Possibly, in general conditions, there is no better method of applying the electrical current.

My experience with hydro-electric applications to other cavities suggest the value of the electric douche, simple or cataphoric, in diseases of the stomach. If judiciously applied, and by an expert, one can not fail to see its possible value in many conditions, among which may be mentioned, atony, hyperesthesia, subacute gastritis and dilatation.

Since beginning this paper, I find that Rosenheim⁷ suggests the use of a stomach douche non-electrically applied, and while advising the use of electricity in nervous dyspepsia, in chronic gastric catarrh and in severe affections of the sensory and secretive apparatus of the stomach as in gastralgia and hypersecretion, he does not, so far as I can ascertain, combine the use of the douche and the electric current.

I simply suggest the use of an electric douche in these conditions of the stomach and have arranged to have an electrode constructed for that purpose. If an electric douche applied to the surface of the body has a more stimulating action upon the skin than to be immersed in the constant current bath, may we not expect better results from the use of the douche to the stomach than by permitting the patient to swallow the water and then dropping in an electrode. The action of the douche heightens the sensibility of either skin or mucous membrane, quickens motor excitability and can not fail to influence nutrition and absorption by its control over the distribution and circulation of the blood current. The function of the current in either event is to establish artificially the local electro-motive forces which stimulate metabolism. Would it not be possible in this way to bring reflexes under the effects of the stimulation much more readily than by any other method?

Electrode for external use.

I have also used hydro-electric applications of the constant current 3 to 10 milliamperes to the face in acne, comedones and the general mal-nutrition of the skin, which exists in these conditions with success, and present an electrode here for such applications.

The same electrode I have found useful in localizing the electric douche, simply or medicated, upon patches of eczema and other diseased conditions of the skin.

Cataphoresis.—The amount of cataphoretic transfer depends upon the quantity of electricity, the coulombs transferred through the partition, the resistivity of the solution and upon the nature of the porous septum. It is independent of the area or thickness of the septum.⁸

A solution of sulphate of copper of requisite strength can be used to advantage in gonorrhoeal cases. In the later stages of gonorrhoea, in conditions of pelvic congestion, uterine catarrh and in some leucorrhoeas, hydrastin thus diffused would be of much greater efficacy than in its ordinary administration by the mouth, or by means of vaginal injections. Bichlorid of mercury in solution can also be used according to the indications and in strength of 1 to 1,000. In all such instances we are enabled to avail ourselves, not only of the electric diffusion of the drugs, but the physiologic action as well. That drugs thus used enter the local and ultimately the general circulation, no longer admits of doubt. This diffusion takes place, as a rule, from the positive to the negative pole, but in some instances from the negative to the positive.

Appropriate tests will at any time determine the drugs thus used in the urine, demonstrating beyond cavil that it is not a mere topical application, but that there is a systemic influence.

In the treatment of syphilis, Gartner⁹ and Ehrmann obtained not only the specific action of bichlorid of mercury

upon the disease, but ascertained its presence in the urine as well after from fifteen to twenty minutes' treatment with the galvanic bath, containing from 4 to 6 grams of the drug. The positive pole was used and a current strength of 100 milliamperes. These experiments have been corroborated by Kronfeld in Professor Lang's clinic in Vienna. In the treatment of gouty joints with bromid of lithium cataphoresis, lithium has also been found in the urine.

Labatut,¹⁰ who asks in general, what are the laws of quantity and quality which govern the transportation of material into the tissues, has chosen lithium for experiments and in the center of a rectangular glass case he put a piece of horse muscle and a solution of chlorid of lithium. Electrolysis was carried on for an hour with 0.08 of an ampere, then the muscle was cut into equal parts and the lithium extracted. Six-tenths of the amount used was found. First there is a transport of lithium into the dead tissues and second, the first effects of this means of introduction is local, the several effects becoming manifest after diffusion into the circulation. Lithium has also been found in the urine by spectral analysis in a patient treated four days.

I have used in these hydro-electric douches a variety of medicaments, among them copper sulphate, zinc sulphate, bichlorid of mercury, iodid of potassium and hydrastinin.

The strength of the copper sulphate as well as zinc sulphate has varied from three to nine grains to the quart. As yet I have not seen fit to use solutions of greater strength, but doubtless shall.

The specific gravity of these solutions is low and their resistivity is high. The amount of transfer I hope to approximately determine, for instance, in the case of a vaginal application by the change in the specific gravity of the solution which has been used cataphorically.

A solution of Cu_2SO_4 , grs. iij to Oij has a specific gravity at a temperature of 59 degrees F. of 1.002, a percentage strength of 0.020507 and a resistance of 500 ohms.

Even with a high E. M. F., say 90 volts, a cataphoric douche, vesical, vaginal, rectal or nasal, will only give from 3 to 10 milliamperes.

Case 1.—July 14, 1894. Eczema of vulva, six months' dura-

tion, intolerable itching and intense burning. Mucous membrane of vulva intensely reddened and irritated. Dilatation of capillaries about meatus urinarius. Same redness extending into vagina. Characteristic vesicular eruptions extending from vulva to thighs and up to abdomen. Treatment: hydro-electric douche, vaginal, negative, 25 milliamperes, two and one-half quarts, also to vulva and all irritated parts, one pint, 5 milliamperes. Immediate relief. Hyperemia immediately diminished.

July 16, 1894. Reports great relief. Treatment: hydro-electric douche, vaginal, negative, (salt water always used with the douche for negative applications) 30 milliamperes, three quarts. Afterward douche to external genitals Cu_2SO_4 , gr. vj to a quart, positive, localized also to a protruding hemorrhoid, size of a hazel nut.

Resistance immensely increased and current strength small, with solution of Cu_2SO_4 . Hemorrhoid quickly became anemic and diminished in size one-third.

July 18. Marked improvement, practically well.

July 21. No symptoms, all eruptions had disappeared. Hemorrhoidal mass shriveling as before with treatment.

July 23. No itching, no symptoms of any sort.

July 27. Same treatment. Discharged. Improved.

Case 2.—Mrs. C. Ovaritis, right, exudates, right side, and fibroid tumor, interstitial, developed in right and anterior walls of uterus. Pain, soreness, sensitiveness to pressure, cruralgia, constipation, premature and profuse menstruation, impaired health, etc. Here hydro-electric douches only were given, negative, 20 to 50 and 75 milliamperes. Result, complete relief of all symptoms, disappearance of exudates with return of uterine mobility, regular bowels, regular and normal menstruation, relief of crural pain and establish-

¹⁰ Labatut (in Revue d'Electrotherapie, January, 1894, page 185.

NOTE.—I have been obliged to give up determining even approximately, the amount of transfer by the change in the specific gravity, as the secretions present in the drainage and the difficulty of maintaining an absolute temperature of the solutions interfere with the accuracy of such an observation.

⁷ Berlin Klinik, May, 1894.

⁸ Prof. A. E. Kennelly.

⁹ Lewandoski Electro-diagnostik and Therapeutik. Wieu and Liepzig, 1892.

ment of general health. Fibroid mass firmer, harder and more defined. No increase in size, nor diminution, but utter cessation of symptomatic evidence of disease. Here current traversed tissues of least resistance and expended energy on ovary and exudative mass.

Case 5.—M. M., single, age 31. Vulvitis. Presented herself May, 1894. Mucous membrane of the vulva swollen, red, sensitive and bathed in profuse glairy discharge. General congestion and relaxation of vaginal walls and uterus. Uterus sensitive, cervix slightly eroded. Lower bowel filled with fecal matter. General health markedly impaired, patient excessively nervous. Treatment: electrical douche, vaginal, negative, 30 milliampères, two quarts.

In administering treatment, a certain amount of overflow was purposely allowed, bringing thereby the vulvar mucous membrane much more completely under the influence of the water electrode. Patient left the office feeling very much relieved from the distressing local sensations.

June 2, 1894. Patient reports that she is very much better, local sensations and consciousness markedly diminished. Has lost her anxious face. Looks brighter and more hopeful.

Physical examination: diminished swelling and redness, with no appreciable discharge. Very little sensitiveness. Repeated treatment.

Case 4.—K. I. H., age 28. Intestinal catarrh, began in 1884. During acute attacks, four or five passages a day, at other times one or two. For past seven months, notices at times "pipe-stem" substances, whiter than feces. Occasional pain after stool. Passes a great deal of gas from bowel. Patient easily tired, complains of frontal headache, almost constant for the past three weeks. Patient feels weak, flushes and pales easily, appetite fair, sleeps well.

Sept. 13, 1894. Treatment: hydro-electric rectal douche (two quarts saline solution), 20 to 30 milliampères. Electrode introduced as high as sigmoid flexure. This treatment repeated daily for six days. Steady improvement each day as regards bowels and general health. At present, Sept. 25, 1894, patient has only one movement a day, well formed, gas almost gone, followed by no discomfort.¹¹

Case 5.—A. T., age 20, seamstress. July 14, 1894. Atony of the intestine; constipated for past two years, constantly under medical care, much medicine, high injections for four months prior to coming under care, in a kneeling position, followed by movement, but impossible to get a movement without them. Medicine without effect. Gaseous eructations; stools hard, round balls, dark brown color. Face covered with acne. Suffers from much bloating and distension of the bowels. Headache, dizziness, impaired circulation and unhealthy appearance. Four rectal douches were given with saturated saline (rock salt) solution, the electrode carried as far as the sigmoid flexure, with an Apostoli pad, thirty-six inches area over the abdomen. The last three were given consecutively. Two quarts of water were used at each sitting, and from 20 to 30 milliampères of current. The first and second treatments were followed by a free action of the bowels. At the third treatment the stool was much more natural and very free, while after the fourth application there was a perfectly free and formed movement. The patient was very much better, felt well, and looked a different person than when she first came to the office. The headache was relieved as well as the distressing symptoms from which she suffered. She was given to take, after the action had been established, cascara mixture consisting of:

Fluid extract cascara sagrada	4 dr.
Dilute nitro-muriatic acid	3 dr.
Tinct. nuc vomica	4 dr.
Elixir calisaya bark	to 4oz.

One teaspoonful three times daily in wine-glass of water. Patient did not return for further treatment.

Case 6.—K. E., age 38, married. July 20, 1894. Pruritus vulvæ—diabetic—referred by her physician for local treatment only. Sugar present. Polyuria. Violent itching and irritation, for relief of which patient resorts to most extreme measures. All parts of the skin and mucous membrane about vulva thickened and reddened. Small papules scattered over the mucous membrane. Discrete vesicles scattered about the nates and inner aspect of thighs. Treatment: electric douche, vaginal, negative, salt water, three quarts, C. S., 40 milliampères. During progress of treatment patient complained of pain which she likened to labor pain, showing the intense action of the current on the muscular fiber of the

uterus administered in this way. Pain ceased with the cessation of the treatment. The electric douche applied to entire external genitals, with douche-pan under patient. From the time of treatment on July 20, up to the morning of July 23, when the patient reported through another person, there had been no return of the symptoms, save a slight irritation that morning. Establishment of menstruation prevented patient's return for treatment July 23, and the day following I left the city for my vacation. Case not followed up.

Case 7.—M. H., age 26, single. July 13, 1894. Referred to me by physician at the Florence Mission. Two years since laparotomy. Removal of right ovary and tube. Now gonorrhæal vaginitis and urethritis. Opportunity for infection three months ago. Since, micturition frequent with stinging and burning pain; itching and burning about vulva. Characteristic creamy discharge oozing from vagina and meatus urinarius; extreme redness about vulva; localized redness and discharge at meatus urinarius. Vagina reddened and bathed in creamy discharge. Slight granular erosion of cervix uteri. No sensitiveness of left tube or ovary. Normal in size. Treatment: electric douche, cataphoric, 3 gr. Cu_2SO_4 to quart of water, two quarts. Four applications in all were made, extending over a period of ten days. Current strength from 5 to 20 milliampères. After first application there was no return of the burning, stinging pain upon micturition, no itching, nor smarting of external genitals, and micturition was only of normal frequency. At time of second visit, examination was made three hours after patient had bathed the parts, and there was absolutely no discharge. At time of third visit, slight milky discharge about mouth of urethra, localized. Electric douche, cataphoric, Cu_2SO_4 , 3 gr. to the quart, three pints; 6 to 10 milliampères of current was administered at this visit to the bladder by means of the two way vesical electrode. The douche was also applied to the mucous membrane about the mouth of the urethra. No pain nor discomfort. Patient discharged July 23, 1894, without symptoms and without any local evidence of disease, the parts only moist as in health.

Case 8.—M. B., age 42, widow. Referred with diagnosis of rectal stricture. Extremely constipated for two years. Subject to violent attacks of pain; colicky; cramping; preceded by inability to empty bowels. Pain relieved by movement consisting of tiny tape-like stools covered with mucus, pale in color. Present condition the same. Daily movement obtained under influence of drugs. Character of stools as for past two years. Appetite fair. Sense of distension after eating, gastric and abdominal, gaseous eructations. Circulation poor, extremities cold. Headache, sense of vertical pressure, dizziness, sense of oppression in chest, easily fatigued, locomotion difficult, sleep broken.

Physical examination: abdomen covered with fat, pendulous, marked distension of cavity. Percussion note extremely dull over transverse and descending colon; resonance poor, entire surface; some tympanites. Rectal examination: sphincter ani normal. Hemorrhoidal veins distended. Digital examination: rectum free in middle and lower thirds. At proximal end of upper third, encountered numerous folds of mucous membrane similar to invagination with sensation communicated to finger as of a doughy mass beyond.

Diagnosis: impacted colon, with fecal tumor at sigmoid flexure. Treatment: rectal electrode carried to sigmoid flexure, negative, Apostoli pad over abdomen, forty-two square inches, positive, two quarts salt water, lukewarm, 15 milliampères for five minutes.

The desire to empty bowels urgent. Resulted in profuse, ill-smelling movement, with large hardened fecal masses, followed by a second movement and a period of extreme exhaustion with chilliness. A half pint of warm water was given by the mouth which, with rest, soon restored patient to her usual condition. In all some six applications were given, 15 to 20 milliampères, for from five to ten minutes, resulting in daily movements. Subsequently Franklinization, with long percussive sparks, was employed, resulting in improved muscular tone. No evidences of a stricture found. Under care two months. Recovered.

DISCUSSION.

DR. WALKER asked the strength of the saline solution for use in the intestinal treatment?

DR. CLEAVES replied that she had used it under and to the point of saturation, usually the former. Quite an important part of the paper was the use of drugs cataphorically in the vagina and bowels, and in nasal applications. So far, she had used sulphate of copper and zinc more than anything else in gonorrhæal vaginitis, nasal catarrh, etc.

¹¹ Patient remains perfectly well and has had no return of her intestinal trouble. The Franklinic current, positive insulation, with long percussive sparks was given to further metabolic processes and encourage nutritional gain.

DR. MASSEY said he had tried the negative electrical treatment of the bowel with some satisfaction in cases of membranous enteritis. He also thought it had a general solvent action on pelvic exudates.

(To be continued.)

Colorado State Medical Society.

Abstract of the Proceedings of the Twenty-fifth Annual Meeting, held at Denver, June 18 and 19, 1895.

[Special correspondence of the JOURNAL.]

(Continued from page 28.)

WEDNESDAY, JUNE 19.

ENLARGED PROSTATE AND ITS SURGICAL TREATMENT

was the subject of a paper by DR. WILLIAM P. MUNN, of Denver. The enlargement of the prostate which frequently causes trouble after 60 years of age is not due to hypertrophy of the gland but to fibroid growths within it. The resulting relaxation of the sphincter causes inability to retain the urine in the bladder, the encroachment of the enlarged gland upon the urethra in front causes retention, and the decomposition of the retained urine renders it acrid, causing pain. He presented some special forms of prostatic catheter. They retained the elevated beak, which he thought the one valuable feature of the ordinary instrument, but were furnished with a longer, flatter, slightly irregular prostatic curve. He thought that so long as the urine could be kept clear, retained from three to four hours, and passed without pain, palliative treatment was to be relied on. But when in spite of the best care the urine became cloudy, could not be retained more than an hour or two, and suffering was impairing the patient's general health, that operative measures should be promptly resorted to, before the general condition became such as to render improbable a favorable result. He would first resort to prostatotomy, perineal or suprapubic according to the case; and would reserve castration as a last resort. He reported six cases operated on, with two deaths and two complete recoveries, one of the latter only after castration.

IS BICYCLE RIDING A CAUSE OF IMPOTENCY?

DR. JOHN T. DAVIDSON, of Denver, thought that as bicycle riding became more general the number of cases of impotency would be found to be on the increase. He had not found any riders who admitted such an influence on the part of the wheel, and did not think it a necessary result from proper riding. But stimulation of the perineum would in time render it less sensitive to other stimuli; and traumatism, especially from riding on an improperly fitted saddle, was likely to aggravate or excite other troubles that are recognized as causes of impotency.

"Alopecia Prematura" was the subject of a paper by DR. J. M. BLAINE, of Denver, who attributed it chiefly to two causes—the custom of using water on the hair at too frequent intervals; and frequent shaving, which by a counter stimulation of the face tended to lessen the nutritive supply of the hair follicles of the scalp. The share of this latter factor was indicated by the fact that among races that plucked the beard, or had little beard to start with, idiopathic alopecia was unknown. Of predisposing causes, he regarded heredity as more common than disease of the scalp during childhood.

DR. P. R. THOMBS, of Pueblo, read a paper on "Epilepsy, Its Causes and Treatment." Definitions as to what constitutes epilepsy vary considerably, and its pathology is uncertain; but the neuropathic tendency seems to be the one constant essential condition. The term idiopathic, applied to epilepsy does not mean that it is without cause, but that the cause has not been discovered. A sharp distinction is to be made between reflex and traumatic cases; the prognosis for the latter being more favorable. He believed that few chronic troubles are so much helped by treatment, but that the treatment must be carefully adjusted to the particular case. A considerable proportion of cases are related to the uric acid diathesis, which can best be controlled by regulation of the diet.

"A Case of Myxedema" was reported by DR. W. J. ROTHWELL, of Denver. A man of middle age had typhoid fever four years previously, had since been losing strength and gaining weight, and presented a typical case of this affection. Under the use of thyroid extract he lost thirty pounds in weight and got quite well. The dose first given, 5 grains three times a day, had caused tachycardia and diarrhea, and had to be reduced to 3 grains. After his recovery the rem-

edy was continued in the dose of 1 grain three times a day, as the thyroid gland seemed to be entirely atrophied.

DR. E. R. AXTELL, of Denver, reported a case of "Toxic Paraplegia." The patient was a man of 23 years, who had begun to drink liquor at 8, and had frequent sprees before he was 12, had smoked cigarettes since he was 9, and had for three and a half years worked at painting. He had probably suffered from multiple neuritis and meningio-myelitis.

"A Case of Pseudo-hypertrophic Muscular Paralysis" was reported and exhibited by DR. J. W. HIGGINS, of Denver. The patient was a boy of 15, of healthy Italian parentage. He had been noticed to stumble easily at 1 year, and at 5 years the enlargement of the calves was perceptible. The hypertrophy was marked in the lower extremities, but in the thorax and back, atrophy predominated.

THE DIAGNOSIS OF CHRONIC CEREBRAL ABSCESS.

DR. J. T. ESKRIDGE, of Denver, presented an elaborate paper on this subject. The differentiation of acute abscess of the brain may present great difficulties, but chronic abscess taxes the resources and skill of the most experienced clinician. Etiology may fail to aid because the manifest cause is only one of several causes that have to act together to produce the result. The same cause, too, may produce in different cases very different effects. A patient with otorrhea of sixteen years standing, and who had received a blow on the head, died of brain tumor. The autopsy in the case of a boy with otorrhea, psoas abscess and a head injury showed a small tumor. On the other hand, the autopsy in the case of a man of 70, suddenly seized with symptoms of apoplexy, with no cause for suppuration, showed chronic cerebral abscess.

The symptoms of chronic abscess are common to other forms of organic disease of the brain. Conclusions from accurate histories may lead astray, but usually will indicate the truth. The cause may have been forgotten but may be brought out by careful questioning. Headache is usually pronounced, especially in the terminal period. The typical temperature is normal or subnormal. Optic neuritis is a valuable sign when present, and it is more frequently present than absent. He concluded that the diagnosis of chronic cerebral abscess was often most difficult, and sometimes impossible; that resort to operation should not be limited to cases in which the diagnosis was certain; that the physician who never recommends an exploratory operation in a probable case of abscess cares more for his own reputation than for the good of his patient.

"Opium Poisoning" was the subject of a paper by DR. CARL JOHNSON, of Denver. It was based on fifty-five cases, of which eight were fatal. In all but two, the drug had been taken by the mouth. In thirty-five cases the stomach tube was required; the others were treated by emetics. As an emetic he preferred apomorphia, one-tenth of a grain given hypodermically, but it should never be resorted to after unconsciousness, as it was then useless, and tended especially to cause cardiac depression. As to stimulants, he regarded strychnia as the most valuable. Atropia was of little value. Potassium permanganate was of value to destroy the portion of the drug remaining in the stomach; but his experience with its hypodermic use to neutralize the poison in the circulation had been very unfavorable, the injections causing great rise of temperature and aggravation of the symptoms, beside local trouble if the patient recovered. In discussion, several physicians expressed confidence in the value of atropia.

CASTRATION THE REMEDY FOR CRIME.

DR. B. A. ARBOCAST, of Breckenridge, read a paper on this subject. The rational solution for the problem of crime was to be sought in the restoration to normal condition of those capable of such restoration, and the speedy extinction of those not capable of it. The physician is the proper one to suggest the remedy. For the rapist and other sexual criminals the appropriateness of castration would scarcely be questioned. It was the province of the Government to provide such treatment as was necessary to enable these defective individuals to become good citizens; and to effect the extermination of the criminal classes.

DR. E. STUYER, of Rawlins, Wyo., read a strong plea for "Asexualization for the Limitation of Disease and the Prevention and Punishment of Crime." Self-preservation is the first motive of action, and next to it comes the sexual instinct. The conditions of city life are such as favor the development of certain forms of vice and crime; and the great charitable institutions of the day assist, by preventing the extinction of the vicious and the criminal, that otherwise would naturally occur. It was time for the medical

profession to turn its attention to the prevention of venereal disease, the scourge of our civilization. There is a widespread tendency to do away with harsh punishments, that formerly had a tendency to check the propagation of the criminal classes. The frequency of lynching shows a prevalent lack of faith in the present penal provisions. There are three indications to be met: punishment for the criminal act, the restoration of the criminal to usefulness in society, and the prevention of future crime. Asexualization meets these indications better than any other remedy. The deterrent effect on others would be most powerful, and it would often convert the most dangerous criminal and disseminator of disease into a useful citizen.

THE RESTRICTION OF TUBERCULOSIS.

Upon this topic the society was addressed by Dr. VICTOR C. VAUGHAN, of Ann Arbor, Mich. He said that with the observance of certain rules, now fairly understood, the healthy and the tuberculous might mingle with impunity. The place in which one is most safe from infection is the properly kept surgical operating room; and so with the observance of the proper precautions the place where the tuberculous congregate may be kept free from danger as regards tubercular infection. But no climate is so salubrious but that local conditions can vitiate its value, and a place that may be good for the infected to live in, might become very bad for the healthy to visit. He believed that, primarily, tuberculosis was usually an unmixed infection, and as such was rarely fatal. Secondly it becomes a mixed infection, and tends toward a fatal termination.

To restrict tuberculosis, the sale of tuberculous milk and meat must be prevented. Cattle should be submitted to the tuberculin test, in which he had great confidence. Sputa must be efficiently taken care of and disinfected. To accomplish the object mere verbal instructions are not sufficient; the rules printed and circulated by boards of health, and the directions given by physicians do good, but they are not enough. Details and practical processes must be taught by personal instruction. He advocated the establishment of schools for the instruction of consumptives in the care of themselves and the disinfection of sputa. Such institutions should be State hospitals. They would ameliorate the condition of the patient, and prevent the spread of the disease. Such a plan would be expensive; but how great is the loss now sustained through the 150,000 annual deaths from this disease. We have a parallel for the undertaking in the eradication of leprosy from Europe by the segregation of the lepers. It would not be necessary that chronic cases of tuberculosis should remain permanently in such institutions. After they had learned to take proper care of themselves and their sputa they could live in their own families without danger.

Dr. E. R. AXTELL showed a case of "Chronic Internal Hydrocephalus with Spina Bifida." The child was a year old; hydrocephalus had been noticed at three weeks of age. There had been no convulsions. The connection between the fontanelle and the spinal tumor, and their reciprocal relaxations as regards pressure was very noticeable.

"The Germ Theory" was the theme of an elaborate adverse criticism by Dr. E. L. WOOD, of Pueblo. He pointed out that many theories generally held in the past have been found wholly false. The presence of the microbe in disease merely proves that the disease furnishes the conditions necessary for its growth. Of no disease known to man is it proved that it depends on a microbe.

THE EXTINCTION OF COMMUNICABLE DISEASES.

This was the general title of a series of brief papers and addresses. In some introductory remarks Dr. MUNN said, that experience with a century of vaccination, and recent experience with cholera in this country and in Europe seem to justify the discussion of this subject. Respecting the general bacteriologic status of the subject, Dr. CROUCH said: It must always be remembered that the germ is not the disease. In every case there is the question of the seed and the soil. It may be as necessary to strengthen the defense as to avoid the attack. We must still consider the possibility of specific diseases originating *de novo*, that is by the variation of non-pathogenic into pathogenic bacteria. For instance, the possibility that the tubercle bacillus may exist in a non-parasitic form.

Dr. HENRY SEWALL spoke on "Tuberculosis Contracted in Colorado." It is very difficult to say where any case of tuberculosis is contracted, but practically we may assume that cases beginning here were contracted here. In other health resorts, tuberculosis has become more common. The climate of immunity is a myth. The propagation of the dis-

ease among new races was directly in proportion to their contact with the race harboring the disease. In four years twenty-one cases of the disease contracted in Colorado had been observed. Of these fifteen had been pulmonary, and thirteen had died. In eleven the sputa had been examined, and in five autopsies had been made. Eighteen of the patients had been in the State from two to twenty-three years, fourteen for over five years. In the last two years 100 deaths had been reported in Denver from tuberculosis contracted within the State, about 12 per cent. of all such deaths in that period. He concluded that tuberculosis contracted in Colorado was not infrequent; and that when so contracted it was extremely dangerous.

"Is Diphtheria Doomed," was the topic assigned to Dr. F. E. WAXHAM, of Denver. He thought that while the weight of testimony was in favor of the use of antitoxin, the claim that by it diphtheria was doomed was not sustained. Smallpox has never been stamped out by vaccination, and the immunity afforded by antitoxin was only temporary. He believed it the best remedy we possess for diphtheria, but it had its limitations. It should not be used in the mild cases that were sure to recover without it. Among nineteen cases treated with it in Denver, in all of which the diagnosis was confirmed by bacteriologic examination, but three had died.

"On Scarlet Fever and the Public Schools," Dr. C. F. SHOLENBERGER, of Denver, said: An important factor in the spread of the disease is that light cases sometimes attend school throughout their course. Others are not diagnosed so that other children from the family continue to attend. When it is ascertained that a child with the disease has been in attendance, the school should be closed until thoroughly disinfected. Children known to have been exposed should be excluded. It should be a duty of scholars and school officers to report all cases to the board of health. It might aid to have some school officer a member *ex-officio* of the local health board. Boarding schools should also be under the supervision of the health authorities. The spread of such a disease is favored by the lack of accommodations for the outer clothing of the scholars, which is therefore piled promiscuously together; and through library books.

"Typhoid Fever and the Agencies that Contribute to It," were discussed by Dr. S. A. FISK, of Denver. It was chiefly spread through drinking water and milk. In a few cases nurses take it by contagion. It is very difficult to entirely control a water supply, and failing this we must resort to boiling. Freezing does not protect. Attention must be paid to each individual case, especially to disinfection of the stools. If the medical profession would take the trouble, the disease could be, if not eradicated, at least controlled.

"On Surgical Infective Diseases" Dr. LEONARD FREEMAN, of Denver, said: We hear too little of dangerous doctors; the doctrines of surgical cleanliness are still too little preached. The needs of surgical cleanliness are bringing the mass of surgical work to specially trained surgeons in well-equipped hospitals. As to infective venereal diseases, inspection has utterly failed to limit their spread. The most potent influence at our command for this purpose is education. False and dangerous modesty should be cast aside. Gonorrhoea is more difficult to deal with than syphilis, because it is not so much feared, and it shows no tendency to lessened virulence.

THURSDAY, JUNE 20.

THE LOCOWEED (ASTRAGALUS MOLLISSINUS).

A chemico-toxicologic study was reported by Dr. CARL REUNI, of Denver. The symptoms produced by it, especially in the sheep, closely resemble those of cerebro-spinal meningitis. But the temperature is depressed, or not elevated except by intercurrent pneumonia. The most striking post-mortem appearance was the extreme anemia of the brain. The active principle is difficult to isolate, and seems not to be a glucoside but an associated acid.

Dr. H. B. WHITNEY, of Denver, reported two cases of "Abscess of the Liver" and a third case of hepatic disease, not abscess but with hectic and other symptoms closely resembling that condition; with some general observations on the diagnosis of such conditions.

"Mal-assimilation Due to Chronic Gastro-duodenal Catarrh" was the subject of a paper by Dr. W. L. DORLAND, of Pueblo. He compared it to the conditions produced by chronic poisoning by lead and arsenic, and called attention to the importance of auto-infection, and the sterilization of the alimentary canal as an essential part of the treatment.

"Dilatation of the Stomach" was discussed by Dr. H. C. CROUCH, of Denver. The important fact is not so much

dilatation as stagnation. The clinical meaning of the term is, a condition in which the contents do not pass from the stomach at the proper time, as when it is not empty in the morning after an ordinary meal the night before. He believed that in the treatment of this condition washing out of the stomach was not so often necessary as the practice of some would indicate. For cases not relieved by medical treatment he urged recourse to surgical interference. Gastro-enterostomy was a comparatively simple and safe procedure, and gave brilliant results.

The Committee upon Sanitation and Preventive Medicine reported upon the need of prophylaxis against phthisis in Colorado. Of 812 cases terminating in death within the last two years in Denver, 549 were known to have originated outside of the State; in 163 the place of origin was not known, and in 100 it was Colorado.

Dr. H. W. McLAUTHLIN, of Denver, reported a case of Addison's disease lasting five years. The autopsy showed atrophy of the suprarenal bodies and tubercular disease of the lungs.

The American Neurological Society was invited to hold its annual meeting for 1897 in Denver.

"Vomiting of Pregnancy and its Treatment" was the subject of a paper by Dr. P. J. McHUGH, of Fort Collins. He regarded it as a reflex nervous disturbance, but had found that in the severe cases there had been some pre-existing stomach trouble to which treatment should be directed. He recommended resort to the use of the stomach tube for purposes of diagnosis, and if needed for treatment.

Dr. T. M. BURNS, of Denver, described his plan of "Abdominoscopy in Obstetrics." He pointed out that in vertex presentations, on account of the flexion of the head, the forehead was more prominent than the vertex, and was the part to be sought for.

"The Management of Retained Placenta," in the hands of Dr. G. H. STOVEA, of Eaton, was: If after ten or fifteen minutes the Crèdè method did not bring it away, to insert the hand and break up the adhesions which, in his experience, were always present in such cases.

Dr. T. E. TAYLOR, of Denver, reported a "Case of Symphyiotomy." The woman was aged 33; four previous deliveries had been by craniotomy, and she had been in labor several hours, the membranes having ruptured ten hours before the operation. The conjugate diameter was two and five-eighths inches. The bones separated to two and one-half inches as the head passed. The child was healthy; the mother left the hospital on the ninth day and was about her work after three weeks; there remained no movement of the pubic bones, and her gait was normal.

"Disease of the Uterine Appendages." Dr. SOL. G. KAHN, of Leadville, said that inflammation of these organs was due to gonorrhœa and septic trouble after abortion. Every case of metritis will extend to the tubes if neglected, but if metritis be properly treated we will have few cases of salpingitis. He urged the currying of the uterus, and local treatment, including ichthyol tampons, and applications of aluminum acetate to the cervix.

Dr. T. A. STODDARD, of Pueblo, believed that disease of the appendages occurred through extension of uterine disease, first to the tubes and from them into the abdominal cavity. All cases of peritonitis were due to the escape of some irritant into the peritoneal cavity. It should be remembered that fourteen women die of peritonitis to one man. We should not permit a woman to carry around pus tubes, and call it conservative surgery. As to the talk of unsexing a woman, it should be remembered that the sexual life of woman is threefold, as woman, wife and mother; and that in two of these respects she was already unsexed when we come to consider the removal of diseased appendages.

Dr. W. A. JAYNE, of Denver, read a paper on the "Management of Pelvic Suppuration in Women." He pointed out that in many cases extirpation of the uterine adnexa had not given relief. Lately, removal of the uterus also had been tried, either by the abdominal or vaginal method, and this seems now to give better ultimate results; but it is still too soon to judge. That prompt removal is the only proper treatment for purulent inflammation is at variance with the accepted principles for the treatment of all other organs except the vermiform appendix; and it, being functionally useless and prone to degeneration, did not offer a parallel case. More careful study of these cases may show that a considerable part of them can be cured by evacuation of pus through natural channels, or artificially through the vagina, with or without the aid of celiotomy. He reported two cases in which treatment on this plan had secured recovery.

Dr. I. B. PERKINS, of Denver, reported a series of cases of "Hysterectomy for Fibroid Disease." In one case the growth was of five years' standing, the uterus measured thirteen inches, was as large as at full term, and weighed fifteen pounds.

Meeting of the American Public Health Association at Denver. Dr. HENRY SEWALL called attention to the meeting of this Association to be held at Denver October 1 to 4, and urged the special interest that Colorado had in the success of the meeting.

THE PRESIDENT'S ADDRESS.

In the Annual Address Dr. WORK said, that of the sixteen who met to organize the Society in 1871, but five remained upon its rolls. Since that time medicine had undergone a revolution. There had been division and subdivision until the danger now was from excessive specialism. The need of the day was the diagnostician; and there was danger of his being supplanted by the exploratory incision, and the post-mortem section. The work lying nearest to this Society was the scientific study of tuberculosis. Its opportunities for the scientific investigation of climatic influences were unequalled, and free facilities for bacteriologic diagnosis were offered to every physician in the State. He urged the establishment of national sanatoria for the treatment of consumption, and suggested the appointment of a committee to confer with the coming meeting of the American Public Health Association, and memorialize Congress upon the subject. His suggestion was adopted.

After the final reports of committees, the election of members and officers, and the installation of the newly elected President, Dr. I. B. PERKINS, of Denver, the Society adjourned.

The social features of the meeting included a *conversazione* the first evening, a theatrical entertainment the second, and a banquet to the visiting members by the profession of Denver the third evening, who contributed their share to the success of the meeting.

Proceedings of the Convention of Bacteriologists.

Academy of Medicine, New York, June 21 and 22, 1895.

The Bacteriological Convention called by the Water Committee of the American Public Health Association met in the Academy of Medicine, New York, at 10 A.M., June 21, 1895. Over forty bacteriologists, representing prominent colleges and boards of health, were present when the meeting was opened by Major Charles Smart, U. S. A., Chairman of the Committee, who briefly explained the object in view as being the full discussion of certain points, the settlement of which was needful to enable the Water Committee to perfect a scheme of laboratory methods for adoption in a coöperative investigation into the bacteriology of water supplies. Dr. Smart then invited Professor Welch of Johns Hopkins University to take the chair and proceed with the special work of the Convention.

It was evident from the program, Professor Welch said, that the subjects for consideration related almost exclusively to certain technical matters which must be settled before any coöperative investigation could be undertaken. He suggested a strict adherence in discussion to the questions submitted, and called upon Mr. Geo. W. Fuller, of the Lawrence Experiment Station, to contribute his views on the first question: What method shall be followed in neutralizing all media and what standard degrees of reaction shall be adopted? Mr. Fuller presented an able and interesting paper full of important results of original laboratory experiments. He commented on the fact that although bacteriologists generally acknowledge the importance of the reaction of their culture media, no special study has been given to the subject which remains now in practically the same condition as when first described by Koch fourteen years ago. He then cited numerous instances of the sensitiveness of pathogenic bacteria to the reaction of media and of alterations in pigmentation, phosphorescence and morphology due to change in the degree of alkalinity. He recommended phenolphthalein as an indicator with sodium hydroxide to effect neutralization; and for convenience and accuracy in expressing the acidity or alkalinity of a medium he approved of the chemio method of giving the number of cubic centimeters of a normal acid or alkali needful to effect neutralization per liter of the medium. He had ex-

perimented also with various other indicators and had found that the neutral point of meat infusions, etc., as established by litmus is many cubic centimeters on the acid side of the same point as established by phenolphthalein. Thus, so-called neutral solutions may in reality be very different, varying as much as 25 c.c. normal acid or alkali per liter in some instances. Mr. Fuller's experiments showed that the best culture results are obtained when the medium is 18 c.c. per liter on the acid side of the phenolphthalein neutral point. It will be observed that this solution is several cubic centimeters on the alkaline side of the litmus neutral point. His directions to secure a standard alkalinity of medium are to determine in a small quantity of the liquid the number of cubic centimeters of normal caustic soda to be added to the stock to make it neutral to phenolphthalein and having added this to it then add normal hydrochloric acid in the proportion of 18 c.c. per liter. The paper was discussed by Professor Welch and Drs. Kinyoun and Theobald Smith, the general tenor being in accord with the views expressed by Mr. Fuller as the result of his investigations.

Discussion on the second question was opened by Professor Sedgwick, of the Massachusetts State Board of Health: What effects on species differentiation are produced by the ordinary differences in composition of peptone, meat juice, gelatin, etc.? In the discussion that followed was embodied Mr. Fuller's presentation of the third question: What media shall be used for all species differentiation and how shall they uniformly be prepared? The relative advantages of meat infusion and beef extracts, agar and gelatin were considered. Distilled water was generally accepted as desirable in making the media. Dr. Abbott was in favor of meat extracts in place of infusions, because the extract is taken in large quantities of all sorts and kinds of meat and comes nearer to representing a mean than any single sample of meat; moreover it is very convenient. Dr. Kinyoun objected to extracts, particularly to Liebig's on account of its varying proportions of salt; he preferred veal infusion. Dr. Welch had never met with this difficulty and liked the extracts for routine work. Mr. Fuller and Drs. Moore, Cheesman and Johnston coincided with Dr. Kinyoun in his preference of meat to extracts; and Dr. Welch considered that the sense of the meeting was in favor of the infusions, for while instances of failure to grow in extracts had been brought forward, no one had instanced a failure in the meat infusions. Dr. Theobald Smith discussed the propriety of adding glucose and Dr. Welch the quality of peptones and the character of the gelatins. The jellies made from the latter varied much in acidity and the solidifying point was extremely variable. Dr. Sedgwick preferred hide gelatin because it was a better nutrient and clearer, although it liquefies at a lower temperature. Dr. Johnston, in reply to a question said it was impossible to get anything profitable from Iceland moss. As to the relative value of gelatin and agar, the former gave as much in two days as the latter in four. There was some difficulty in getting the proper degree of alkalinity, on account of changes taking place after it was put in the sterilizer; but he explained how this could be overcome. Mr. Fuller and Dr. Sedgwick detailed their practice at Lawrence with agar and claimed better results than with gelatin. The question of sterilization was then considered by Drs. Abbott, Cheesman, Kinyoun, Welch, Mr. Fuller and others. The potato as a medium was objected to by Mr. Fuller as inconstant in its results. Drs. Abbott and Welch sustained the cause of the potato. The gas production is an important point and the presence or absence of discoloration. Milk was considered of limited value as a medium by Mr. Fuller, but many others believed that it would be a loss to give up its use; its coagulation and the development of acidity were valuable for differentiation. The use of sterilized asbestos wool as a filtering medium was eulogized by one speaker. The discussion ended by a consideration of the subject of preparing large quantities of medium at one time and of making these available for use when required.

The discussion of the second and third questions was unfinished when the morning session was ended by an adjournment until 3 p.m. It was resumed when the convention met again at the hour named.

Professor Jordan, of the University of Chicago, who was on the program to open discussion on the fourth question: What shall be the medium for and the conditions of the stock culture from which all media are seeded? was unavoidably absent; but Mr. Fuller explained his views. The keeping of stock cultures in an ice box also came in for consideration.

Professor Sedgwick opened discussion on the fifth question: What shall be the systematic detailed method to be

followed in observing the results of cultures and the manner of recording them? If we take the results of any good bacteriologist and see how he describes his species fully and carefully, with obvious attempt to be accurate in observation and full in report, we may learn how to do this. Dr. Cheesman thought it would be a good thing to have some kind of chart or a table on which the record could be made. As pertaining to this branch of the subject, the paper of Prof. E. B. Shuttleworth, of University of Trinity College, Toronto, on the nomenclature of colors for bacteria, was presented. This paper was an effort to get as near to precision as possible, in view of the different appreciation of color tints, shades and hues by different individuals. The various primary and common colors were tabulated with their modifications, the qualifying words, pale, light or medial and dark being used to denote gradations of the same hue.

Dr. Cheesman then submitted his paper on the sixth question: What method shall be adopted by which full benefit may be derived from morphologic characteristics? He reviewed the main groups of cocci, bacilli and spirilla as subdivided by morphologic characters, shape, structure, size, formation of spores, flagella and capsule. The greatest benefit may be derived from these characters only by having them fully developed and plainly visible. For their development it may suffice to carry each species through a single routine method of cultivation on a standard medium, or perhaps two, or even three, routine methods. Various methods of staining must be used. The adoption of a systematic uniform plan to be followed in all examinations will lead to better results than have been obtained in the past. The discussion on the subject was very animated and dealt with a standard medium for morphologic characters or many different media to exhaust all possibilities of development.

The seventh question: What tests shall be used for separating bacteria into clearly marked groups? was answered by Dr. Wyatt Johnston, of the Provincial Board of Health of Quebec. He referred briefly to twenty tests in common use and to various modifications of these. He concluded that there was a certain want of individuality about the water bacteria as described by their discoverers which prevented the average amount of intelligence which he had at his disposal from grasping the subject in a way that would make a fellow feel that he had mastered it; and this was the result of the complication of these tests of bacteriologic classification. He proposed a system of cataloguing and cross-indexing by which the labor of studying and looking into the affinities of species might be lessened. This was favorably regarded by the convention, and he was requested to submit a practical outline of his system. In connection with this subject, a paper by Prof. H. L. Russell, of the University of Wisconsin, was submitted. This paper was special in its character, and related to the peculiar method of branching in the genus *Cladotrix*, found in stagnant waters. The *C. dichotoma* and the *C. intricata* were described and figured. These, although filamentous in their growth, are essentially bacilli. The meeting then adjourned until 10 a.m. the following day.

The convention was called to order at 10 a.m., June 22, when Surgeon-General Sternberg's paper was read by Dr. Smart in the absence of its author. This was on the eighth question: What shall be the method followed in determining the relation of bacteria to temperature? General Sternberg discussed first the most favorable temperature for development; secondly, the extreme limits within which development occurs and lastly, the thermal death point. The first and second are to be determined by culture experiments made at gradually increasing fixed temperatures until the desired information is obtained. In ascertaining the thermal death point the temperature or the time of exposure should be fixed. We may ascertain how long an exposure is required at a given temperature or how high a temperature is required in a given time. He recommended an exposure of ten minutes to fixed temperatures, rising 2 degrees Cent. in each experiment until the death point was reached. This is determined by culture experiments showing the sterilization of the medium containing the bacteria operated on. The cultures should be incubated for seven days before the result is recorded. In applying heat to determine the death point the water bath was recommended, with the tube containing the bacteria and the thermometer on a glass stand at mid-depth of the water. The thermometer should be accurate and the temperature of the bath properly regulated. When not otherwise specified the death point should be understood to refer to the temperature which in ten minutes' time destroys the vitality of all the cells in a liquid medium. The spores of bacilli have a far greater resisting power to heat than the vegetative cells and the question of their

thermal death point must be determined separately. With spores which resist the boiling temperature it is best to state the time required for their destruction by a temperature of 100 degrees Cent. The thermal death point depends to some extent on the age of the culture. For bacteria which grow in our standard neutral flesh peptone solutions the use of a culture kept at 37 degrees Cent. for forty-eight hours was advised; and to secure uniform conditions 3 ccs of the culture should be added to 5 c.c. of distilled water for the purposes of the experiment. In his own practice, capillary tubes containing a small quantity of culture, not diluted, were used; but he considered that for general use it would be best to recommend the test tubes of hard German glass which are always on hand in bacteriologic laboratories, specifying the diameter of the tube and the quantity of fluid, 5 c.c., which it should contain. This subject was discussed by many of the members, the views of Dr. Sternberg being generally accepted; but a strong tendency was manifested toward the acceptance of the capillary pipette instead of the test tube. The importance of immediately cooling the tube as soon as removed from the bath was also insisted upon. The recommendation was made to thrust it at once into the water so that the high temperature should cease to act upon it.

The ninth question: What special methods are of value in the isolation of pathogenic bacteria in water? was submitted for discussion by Professor Abbott of the University of Pennsylvania. As to special methods of development, he held that there has been no general work done, nothing that would be of use to the working bacteriologist. There are scattered observations relating to the typhoid bacillus and its isolation. The degree of reaction is important and the method of injection into animals. Mechanical separation, artificial filtration, fermentation and precipitation by coagulants were also discussed. While on this subject, Dr. Kinyoun described a standard dye method with fuchsin by which differentiation may be effected. Commenting on this, Professor Welch considered it one of the most encouraging things that we had at last an elected method for the isolation of the cholera spirillum; but on the other hand it is a source of regret that we have no similar mode of procedure for the typhoid bacillus. Dr. Abbott stated his results with this bacillus to have been most inconstant. The general feeling now, said Professor Welch, in regard to this matter is one of uncertainty as to whether any one has ever isolated the typhoid bacillus from drinking water. Professor Sedgwick referred to an epidemic of typhoid fever at Providence, R. I., where filters were sent to Professor Prudden. This brought the latter gentleman to his feet with a smiling remark to the effect that we can not know what is going to happen in science during the next ten years; and that had he known that this convention would meet here to-day he might not perhaps at that time have considered typhoid as emanating from the invisible growth on potatoes. Professor Welch referred to an impression existing, especially among boards of health, that bacteriologists are expected to report whether or not the typhoid bacillus is really present. Dr. Hewitt of Minnesota, referred to the positive diagnosis of typhoid bacilli that had been given to boards of health by bacteriologists and considered that the preceding remarks were somewhat discouraging. Dr. Sedgwick acknowledged that so far as pathogenic bacteria in water are concerned we are unable to make the positive diagnosis which Dr. Hewitt desired. It seemed to him, however, that if this were the only thing that boards of health in their history had to take back water on it would be well to discourse largely on it; but there are various things boards of health have had occasion to regret that they have done and he did not see that this was any greater than the others. He knew Dr. Hewitt had been misled by not keeping on tap in his office a good bacteriologist. Dr. Benjamin Lee of Pennsylvania, thought on the whole that it was a good thing that we are tending toward the solution of the broad problem of the various drinking waters rather than of one particular pathogenic organism; and this brought the convention back to its special work.

Professor Welch then presented his views on the tenth question: What shall be the mode of procedure in determining the pathogenesis of bacteria found in water? He spoke of the propagation of cholera, typhoid fever, dysentery, etc., by water. There is no satisfactory evidence of the spread of malaria by drinking water although there are those who believe in this infection. The pathogenic properties of water should be tested as a routine procedure. He preferred bouillon cultures of forty-eight hours, .1 c.c. injected by means of an ordinary hypodermic syringe into the peritoneal cavity of a mouse. The probability of a negative result

is great; and if the mouse does not succumb the chances are that a larger animal would not. All biologists should insist on a more careful pathologic study of lesions as they are often of the greatest interest. Bacteriologists are apt to consider an organism as pathogenic only when it kills; yet animals are frequently made very ill from certain species of bacteria and yet recover. Sharp distinction should be made between infection and intoxication. The discussion was general. At its conclusion Drs. Sedgwick and Welch referred to the need for care in the language used in reporting experiments on animals. The latter cited the expression of a writer: "I now see that these experiments were of no use and really appear to me absurd," which was caught up by the Humane Association and used for a violent attack on pathologists in a pamphlet recently issued.

The paper of Professor Adami of McGill University, treated the eleventh question: How is variability of species to be regarded? The difficulty of the subject of differentiation was clearly stated. Experimentally in the test tube it is a matter of comparative ease to so vary the properties of bacteria that were one to be given the modified forms, without any information as to the previous treatment undergone by them or their predecessors, it would be impossible by the ordinary methods employed for the differentiation of species, to arrive at any other conclusion than that we were dealing with a form of microbe totally distinct from the parent species, in fact, with a totally distinct species. If this be true of experimental modifications, how are we to become assured that many of the closely allied forms which we encounter in the bacteriologic study of water, air, soil and cases of disease are truly distinct species? How can we protect ourselves against a multiplication of described species, as unwise and depressing as it is scientifically false? We know from experiment that comparatively slight changes in environment acting over a long period impress modifications on bacteria quite as surely and strongly as do great alterations acting for a short time. We know that time after time in the study of the bacteria of water, as in those of disease, we encounter forms which while in general harmonizing, depart in some particulars from the classical description of well-recognized species. We are becoming hardened to the departure from type of some of the pathogenic species, so much so that the tendency among those dealing with the bacteriology of disease is to regard closely allied forms possessing pathogenic properties of like nature, not as separate species but as races and varieties of a common stock. This may not in itself be scientifically accurate for in most cases no attempt is made to demonstrate the relationship. Nevertheless, to take the opposite view and regard each form that departs in any particular from the text-book description as constituting a separate species is to drop into a bacteriologic Babel of confusion.

Professor Adami then referred to the varieties of domestic animals and plants and to their tendency, if permitted to return to a state of nature, either to die out or in the course of a few generations to regain largely or entirely the characters of the original stock. With bacteria the same is to a great extent true, and he suggested as a means of discrimination, the method of keeping doubtful forms under observation for some months upon standard media. If allied forms be grown on ordinary media which have not been prepared with a view to accentuate differences, the effects of the continuance of a common environment will eventually remove those characteristics which are temporary impressions due to previous modified environment, and in the course of a few weeks or months, forms that are varieties will revert to type. He recommended that each describer of a new species be expected to report its condition at the end of a year, and whether it has reverted to type or has continued to present characteristic differences.

Dr. J. J. MacKenzie of the Board of Health of Ontario opened discussion on the last question: What new methods can be suggested for the separation of bacteria into groups and for the identification of species? He referred to the advantages to be derived from the use of synthesized media. He pointed out the variability and the unknown chemico composition of the media now in use. Beef broth is an unknown quantity; and the composition of peptone is variable. Practically, the bulk of the material of the commercial peptones consists of albumoses of various kinds. Witte's peptone which Kühne found to be the most satisfactory is almost entirely made up of albumoses. Gelatin and agar also are variable, but as solidifying agents we can not do without them. Dr. MacKenzie then sketched the history of the effort to obtain synthesized media, giving the methods of preparing many of them and the results obtained from

them. He then detailed his own experiments in this line, particularly in plate cultures of water bacteria. He touched also on the advantage that might be taken of Beyerinck's respiration figures and of the formation of nitrites and hydrogen sulphid in the study of water bacteria. He concluded that in the study of all these physiologic chemico reactions of bacterial cultures the necessity of exact chemico composition is absolute, otherwise it is impossible to make comparisons. With a chemically pure medium, synthetically formed, we can speak with definiteness of the formation of nitrites, ammonia, hydrogen sulphid or any of the other products of bacterial life.

In connection with this, Dr. V. A. Moore, of the Bureau of Animal Industry, submitted a paper on the nature of the flagella and their value in the systematic classification of bacteria. The author dwelt first on the difficulty of obtaining constant and uniform results by any of the methods heretofore devised for demonstrating the filaments, and then on the impossibility of making a classification by the filaments agree with our present natural grouping. The *Monotricha*, for instance, or those having one flagellum at the pole of the bacillus, would include bacilli, spirilla and at least one micrococcus. Certain of his experiments have demonstrated that in the grouping of pathogenic organisms the flagella have little or no significance. Differences in the motile filaments of the same species of bacteria are quite as great as those found to exist in preparations of various species; thus the flagella of the hog cholera bacillus differ in different preparations, and often in different fields of the same preparation, quite as much as they differ from the flagella of the typhoid or colon bacilli. Until the nature of the flagella-producing substance is better understood, the only significance which can be given to these appendages in classifying bacteria is to determine their number on the individual organism, their length, general appearance and peculiarities, and include such data in the morphologic description of the bacilli.

In the course of the proceedings of the previous day it had been decided that no vote would be taken on any of the questions, but that the whole series would be referred to a committee of five, the chairman to be one of the members. After the discussion of the twelfth question, Dr. Prudden moved that the committee be increased in membership to eight. As the success of the convention will depend on the decisions of this committee, he considered that it would be better to have more members on it. This was agreed to, and the Chair appointed Drs. Abbott, Adami, Cheesman, Fuller, Sedgwick, Smart, Smith and, at the request of the convention, Welch, the committee to report to the Water Committee of the American Public Health Association, which will endeavor to secure the publication of the proceedings of the convention and of the future report of its committee by the Association.

After some discussion on the advisability of forming an Association of Bacteriologists to insure a recurrence of meetings like the present, Dr. Welch stated that he considered the meeting a success. The interest shown in it by the large attendance and the presence of so many members from a distance have been most encouraging and clearly point to the formation of some society in the future which will bring together the men of mind and ability and which will be the means of continuing this work. He offered a vote of thanks to Drs. Smart, Adami, Fuller and Johnston, who were responsible for the inception of the meeting. Dr. Prudden, on behalf of the convention, expressed indebtedness to the chairman for his skill and kindness in conducting the meeting. Dr. Smart, on behalf of the Water Committee of the American Public Health Association, rendered acknowledgments to the Academy of Medicine for the pleasant quarters afforded the convention, to Dr. Cheesman, of the College of Physicians and Surgeons, and Dr. Ferguson, of the New York Hospital, for having acted as a local committee of arrangements and made things easy for the management; to Dr. Welch for the able manner in which he had conducted the special work of the convention; and lastly, to the members for their earnestness and interest in the business of the meeting.

The convention adjourned *sine die*.

SELECTIONS.

Carcinoma of the Uterus.—(*Charité Annalen*) 557 cases were treated at the Charité from 1883 to 1893. The majority were from the fourth and fifth decades of life (30.5 and 39.3 per

cent.) while Winckel finds the larger number between the ages of 50 to 55 years (22.3 per cent); the statistics of the Charité divide the most in about equal proportion between the three periods of five years from 35 to 50, and also transfer them from the climacteric back into the period of maturity. As an explanation of this, it is noted that the cases are derived from the poorest classes of the population. Total extirpation in 89 cases 15.4 per cent., and 48 in women under 41 years, 54 were still menstruating, 21 in the beginning of the climacteric 10 in menopause which on the average began at 47.9 years. Of 528 cases furnishing trustworthy information 28 had never borne children; of the remaining 500, 106 (21.2 per cent.) had borne 1 child, 227 (45.4 per cent.) 2 to 5 children, 167 (33.4 per cent. 6 to 16 children; while among Winckel's 130 cases of carcinoma, only 10 per cent. had borne 1 child, 40.8 per cent. 2 to 5 children, and 49.2 per cent. 6 to 16 children. In 46 cases the disease started just after a delivery, or during pregnancy, and in 12 of these the disease was more or less directly the cause of abortion, while all took a rapid course, and 10 were inoperable.—*Centralblatt für Gynäkologie*, No. vi, Feb. 9, 1895.

A Case of Gunshot Wound by the New Swiss Ordnance.—Fr. Brunner (*Korrespondenzblatt für schweizer Ärzte*, 1894, No. vii.) reports a case of gunshot wound by the new small caliber weapon, model of 1889; distance 20 m. The shot first penetrated and tore in pieces the cover fitting firmly over the barrel. It then pierced the front of the coat, vest and shirt, making a round hole through these pieces of clothing, as if by a punch, penetrated the body 3 cm. below the left clavicle in Mohrenheim's (infra clavicular) fossa, left the body below the spine of the scapula and produced three radiating rents in the clothing on the back. Wound of entrance circular as if struck with a punch of the diameter of the missile. Wound of exit circular with sharp edges, 10 mm. in diameter, surrounded with a livid, swollen area. Lung uninjured. The course grazing the tip of the coracoid process, passed close over the collection of nerves and vessels into the scapula, which was pierced $2\frac{1}{2}$ cm. below the spine. Wound healed kindly, although not aseptic. No subsequent hemorrhage. This case shows typically the result of small caliber shot. Although the projectile in boring through the gun-cover certainly lost considerable in energy, it was able to penetrate the body in a confined course without causing further harm by the way, without injuring nerves and large vessels though in close proximity and without splintering the scapula.—*Centralblatt für Chirurgie*, No. iii, Jan. 19, 1895.

Pathologico-anatomic Researches on the Method of Extension of Cancer of the Uterus.—(Seelig, Inaug. Diss., Strassburg, July, 1894). This work contains painstaking macroscopic and microscopic investigations. The conclusion of most practical importance is, that one must no longer be satisfied with supra-vaginal amputation, but he must always perform total extirpation if the disease has only started in the cervix, for even at that time the body of the uterus may be affected. The writer distinguishes carcinoma of the cervix and of the body; carcinoma of the cervix extends by the lymph channels, by preference those accompanying the blood vessels, and in those situated in the outer muscular layer and on the boundary of the peripheral and middle layers. There is a connection between the lymphatics of the cervix and the body, which lies within the wall of the organ and is represented by the lymph channels accompanying the large blood vessels of the middle and external muscular layer. These channels have a relatively large caliber. In the body of the uterus the lymphatics of the inner and of the larger part of the middle layer are very small, those of the outer of larger caliber. Carcinoma of the cervix does not remain limited to the lower portion of the uterus. It passes the internal os, not usually in the mucous membrane, but in the external muscular layer. Therefore it is hardly tenable strictly to retain the term, carcinoma of the cervix. 2. carcinoma of the body grows relatively slowly, and is marked by a centrifugal increase. Participation of the lymph vessels is first evident between the middle and outer

muscular layers. The cervix is affected only after a longer existence of the disease in the body. Its wall is destroyed from within out; the outer layer remains long intact, also the vaginal mucosa.—*Centralblatt für Gynäkologie*, No. VI, Feb. 9, 1895.

Pathology of Rickets.—(Jahrbuch für Kinderheilkunde Bd. xxxvii, Hft. 2). The writer assumes with Kassowitz that even the slightest elasticity or yielding of the bones of the skull or along the sutures is to be regarded as the surest and most undoubted sign of an active rachitis. His observations on 338 healthy children during the first two years of life show:

1. The average size of the anterior fontanelle during the first three months is 2.71 qcm. (42 sq. in.) and it decreases constantly in the succeeding months. The rate of diminution becomes much faster in the second year.

2. The largest anterior fontanelles, met with in children without rachitic changes in the skeleton during the first year, measured 3qcm. (465 sq. in.) This was rarely found. Quite probably such cases are to be looked upon as the starting point of rachitic affections. At least, fontanelles of this dimension are found far more frequently in connection with evidences of craniotabes the rickety rosary, etc., than under normal conditions.

3. The complete closure of the fontanelles rarely occurs before the tenth to the twelfth month, and usually in normal children in the course of the second year, though it was found in 20 per cent. in the thirteenth to fifteenth month and in 75 per cent. in the nineteenth to twenty-first. The variations in the size of the anterior fontanelles, in perfectly normal children of the same age, are in the opinion of the writer, merely natural differences in the growth of the skull. Fontanelle measurements in 786 rachitic children showed: 1, the anterior fontanelle was decidedly larger than in normal children (up to 14.8 qcm. 2.294 sq. in.); 2, it does not diminish constantly from birth, but increases gradually up to the ninth month, becomes smaller in the three succeeding months, yet does not reach its original size, and only after the beginning of the second year is a constant diminution to be observed. Yet even in the second and third years anterior fontanelles are found, measuring 25 qcm. (3.875 sq. in.); 3, the closure of the anterior fontanelle is delayed until well into the third year. All details may be obtained from the original.—*Centralblatt für Gynäkologie*, No. 6, Feb. 9, 1895.

NECROLOGY.

ALBERT C. GORGAS, M.D., Medical Director of the United States Navy, died of heart disease at his home in Germantown, a suburb of Philadelphia, June 29. He was a native of Philadelphia and was graduated from the Jefferson Medical College in March, 1856. He entered the United States service, August 30 of the same year, as Assistant Surgeon, being assigned to the sloop-of-war *Germantown*. He served on the East India Station, from 1857 to 1860, and was then transferred to the receiving ship *North Carolina*, at New York. In 1861 he was commissioned Surgeon and was attached to the *Vandalia* of the South Atlantic squadron until 1863. After serving a year at the Norfolk Naval Hospital, in 1864, he joined the *Juniata* of the South Atlantic blockading fleet. He was present at the bombardment and taking of Fort Pulaski and the assault on Fort Fisher. In 1867, Dr. Gorgas sailed on the *Brooklyn* as Fleet Surgeon of the Brazil squadron. Shortly afterward, he was assigned to the Portsmouth Navy Yard. From 1870 to 1873, he was stationed on the *Wabash*, as Fleet Surgeon to the European squadron. He was on duty at the Naval Hospital, Annapolis from 1873 to 1877 and went to sea for the last cruise in 1879, as Fleet Surgeon of the South Atlantic squadron on the flag-ship *Hartford*. He was stationed at the Naval Academy in 1880;

at the Chelsea Naval Hospital, 1882 to 1885; President of the Examining Board, 1885 to 1889; Naval Hospital, Philadelphia, 1889 to 1893; National Museum of Hygiene, Washington, from 1893 until recently. He was commissioned Medical Inspector Oct. 6, 1873, and Medical Director March 4, 1884. He leaves a wife, a daughter and two sons, the latter being Miles Gorgas, who holds a prominent position in the United States Navy, and the Rev. Henry Gorgas, who is assistant rector at a New York Protestant Episcopal church.

JOSHUA GREEN WILBUR, M.D., of Brooklyn, died at his summer home in Montclair, N. J., on June 25. He was born in Massachusetts on Sept. 25, 1825, the son of Hervey B. and Anne Tappan Wilbur. Two of his brothers, as well as himself, followed the profession of medicine. His eldest brother the late Dr. Hervey Wilbur of Syracuse, was the first man to adopt a practical system of education for the feeble-minded children and for years had charge of the State asylum for those unfortunates. Another brother, Dr. Charles T. Wilbur, devoted years of study to the same affliction and is now superintendent of the Michigan State Asylum for the feeble-minded at Kalamazoo. He was graduated from the Harvard Medical College in 1862. Soon after the breaking out of the war he went to the front as a surgeon with a Massachusetts regiment. Throughout the struggle Dr. Wilbur attended to the wounded on the fields and in the Union hospitals. At the close of hostilities he settled in Brooklyn and engaged in general practice for about five years. Then he decided to make a specialty of life insurance examinations. For about twenty-five years he was engaged, chiefly in New York City, as the medical examiner for such companies as the Mutual Benefit, Washington Life, Berkshire Life, New England, Aetna, Mercantile Benefit and Penn Mutual Life Insurance companies and medical director of the New York Jewelers' league. He was reputed to have examined more applicants for life insurance policies than any other physician in America and, perhaps, in the world. The cause of his death was paralysis, from which he had been failing for about three months.

EDWARD SPALDING, M.D., of Nashua, N. H., who died June 24, in his eighty-first year, was better known as a capitalist and cotton-spinner than as a medical man. He was, however, a graduate of the Harvard Medical School in 1837. He was a graduate in arts at Dartmouth College and afterward for a time one of the board of trustees.

GEORGE TAYLOR ROBINSON, M.D., of Camden, N. J., died June 28. He was a graduate of the University of Pennsylvania in the class of 1882 and a member of the staff of the Cooper Hospital of Camden, and is reported to have given special attention to the application of the spectroscope to clinical medicine.

ALEXANDER I. ARONSON, M.D., of New York City, died suddenly June 25, from apoplexy. He was a native of Germany, and a graduate from the University of Jena in 1879. About a year later he settled in New York and soon became known as one of the most popular physicians of the East Side. He leaves a widow and three children. He was a member of the German Medical Society of that city.

GEORGE GARMANY LARCOMBE, M.D., died June 28, at Savannah, Ga., aged 34 years. He graduated from Princeton College in 1882, and from Bellevue Hospital Medical College three years later. He was ambulance surgeon at Bellevue Hospital in 1885 and on the surgical interne staff, Third Surgical Division, in 1887. He thence went to the University of Vienna, but in 1888 enrolled himself at the King's College School in London and in the same year took the degree of M.R.C.S.E. When he returned to this country he took up his residence at Savannah, engaging in general practice.

E. R. PALMER, M.D., of Louisville, July 6, aged 53.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 86 FIFTH AVENUE, CHICAGO, ILLINOIS.
W. H. LOWDERMILK & CO., WASHINGTON AGENT.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 86 Fifth Avenue, Chicago.

SATURDAY, JULY 13, 1895.

THE SURGERY OF PIERRE FRANCO.

The learned NICAISE, who through the press of FELIX ALCAN enriched modern surgical literature by translating the great surgery of GUY DE CHAULIAC, and the surgery of HENRI DE MONDEVILLE, has recently brought out the surgery of PIERRE FRANCO. Thanks to NICAISE, we can now view French surgery continuously from DE MONDEVILLE down to modern times. It is true DE MONDEVILLE and DE CHAULIAC were under the impress of THEODORIC and the Arabian school, but in many directions they were original, and without doubt these were the real founders of the French didactic school, and with the later labors of FRANCO and PARÉ its distinctive character was completed. That PARÉ distanced FRANCO in the race for recognition by immediate posterity was due quite as much to the political changes of the time, and accidental circumstances, as to any intellectual supremacy.

The intolerance of the period of FRANCO is well illustrated by the story told by NICAISE of BRISSOT, a young doctor of the Paris faculty who, in 1514, proposed to practice bleeding on the same side in which the pain was located, and cited GALEN as his authority. Although BRISSOT was sustained by the Paris School, his doctrine was struck by the anathema of the School of Salamanca, which decided that it would not permit a patient to be bled for a pleurisy on the side in which the pain existed. The practice was denounced as impious, and its adherents were branded as the "Lutherans of Medicine." CHARLES THE FIFTH issued a decree which defended the old-fashioned bleeders—that is to say, those who bled on the opposite side of the disease. "Nevertheless,"

says NICAISE, "GALEN triumphed, but in the end bleeding was practiced indifferently on one or the other side." FRANCO adopted the doctrine of BRISSOT and always counseled that the operation be performed on the side of the disease.

FRANCO used the incandescent knife in amputations, but like all those of his time ignored the dictum of DE MONDEVILLE that "suppuration of wounds was a pathological accident and not a necessary condition." FRANCO was born at Turriers in Provence about the year 1500 and died about the year 1561. His operations on hernia, and on stone in the bladder were his most distinctive ones.

THE DEATH OF HUXLEY.

THOMAS HENRY HUXLEY, the eminent English naturalist, died June 29, aged 70 years. He was in his twenty-first year when he took his M. B. degree at the University of London, after having studied three years at the Charing Cross Hospital Medical School; he took second honor in anatomy and physiology. In 1846 he joined the medical branch of the Royal Navy, serving first at the Haslar Hospital, and afterward as assistant surgeon on H. M. S., *Rattlesnake*, during its four years' voyage to the South Pacific. In 1853 he resigned from the Navy, to become the professor of natural history in the Royal School of Mines. From that point in his life, when not quite 30 years of age, his course as a scientific investigator and teacher, especially in the field of zoölogy, became fixed.

The papers that he wrote from the *Rattlesnake*, embodying the results of his studies, remained unpublished for some time, because the Admiralty refused to contribute anything toward the expense, and his pay as assistant surgeon was but seven-and-sixpence a day. So it was not until 1859 that the essays saw print. They were published then by the Royal Society.

After the first struggle, HUXLEY's rise to eminence was steady and rapid, until he became one of the foremost scientific men of the century. He had returned to England in 1850. In the following year he was made a Fellow of the Royal Society, and the next year he received one of the two medals that the society awards annually.

HUXLEY and TYNDALL, before they became famous, applied for the chairs of natural history and natural philosophy in an American university, where they hoped to work together, but other men, supposed to promise better work, were chosen.

As an estimate of the status of PROFESSOR HUXLEY in the scientific world, the following editorial from one of our daily cotemporaries may be set down as just and fair:

"By the death of PROFESSOR HUXLEY at Eastbourne England has lost one of her greatest scientific inquirers. HUXLEY's name will stand with those of TYN-

DALL, DARWIN and SPENCER at the head of English science of our generation. His views on the relation of science to religion and his attacks on revealed religion caused endless controversy, which has been oftentimes renewed during the publication of his collected works. But his true fame was based on his work as a scientist, pure and simple, and as such he will be honored in the annals of scientific research and literature."

"MEDICINE AND CRICKET."

A medical man in England has achieved fame by his mastery of the national game of cricket and the *London Daily Telegraph* recently started a shilling subscription to provide "a great national testimonial" to his success. Among the subscribers we find the following in a recent issue of the *British Medical Journal*:

Mr. Ernest Hart	100 shillings
Dr. Bridgewater	20 "
Dr. Isambard Owen	20 "
Dr. Dawson Williams	20 "
Mr. Francis Fowke	20 "
Mr. Burr	20 "
Sir T. Spencer Wells	20 "
Dr. R. Temple Wright	5 "
W. E. Soffe	5 "
Mr. H. Langley Brown	21 "
Dr. R. Shingleton Smith	21 "
"Nemo"	10 "
Compositors of the <i>British Med. Journal</i> , 14	"
Clerks at the <i>British Med. Jour.</i> office	10 "

Our valued contemporary, the *Medical News*, makes this GRACE testimonial fund the occasion for a timely and telling exposition of "Professional Indifference to Professional Enemies" in this country, and compares the subscriptions to the cricketer in England, with those received to pay the expenses and to publish the report of a trial—"the economic, social and professional importance of which is simply incalculable." "Besides the illustration cited," says our contemporary, "none could be more striking than the present professional disregard of the splendid work so modestly, bravely and effectively carried to a successful issue by DR. JAMES E. REEVES in his fight with the Amick Company. A large number of State and national societies have met since DR. REEVES' noteworthy victory, and not one of them by any public action has so much as alluded to it. As we write the advance sheets of the report of the trial are before us. We have read them with delight, and wish once again to arouse in the minds of the medical men of the United States a sense of their obligation to the good men engaged in this trial—the defendant, the attorney, the judge and the jury. It even yet seems marvelous, in our quack-ridden land, that such a result should have been brought about. Every physician should read the interesting story as related in the report, in the satirical letter of DR. REEVES, the charge of the judge, the arguments and declarations and, especially, in the specious logic of the plaintiffs' attorney, so redolent of popular error and demagogism. We regret

that we can not republish the entire pamphlet in the *Medical News*, but we regret far more the inertia of professional sentiment that is shown in the subscription of but fourteen men, amounting in all to the magnificent sum of \$141."

Following is the list of the fourteen subscribers, which we produce to contrast with the similar list above given:

Dr. George M. Gould	\$10 00
Dr. D. L. Page	1 00
Dr. N. P. Dandridge	10 00
Dr. P. S. Conner	10 00
Dr. F. Forchheimer	15 00
Dr. John A. Murphy	5 00
Dr. A. B. Richardson	5 00
Dr. J. F. Baldwin	5 00
Dr. J. H. Kellogg	5 00
Dr. A. Vander Veer	35 00
Messrs. William Wood & Co	25 00
Drs. Davis & Davis	5 00
Dr. John B. Hamilton	5 00
Dr. R. J. Trippe	5 00

The total thus subscribed for the REEVES fund is, as already stated, \$141; that for the English cricket-player is nearly \$10,000. The *JOURNAL* heartily indorses the sentiments of the *Medical News*, and urges every member of the AMERICAN MEDICAL ASSOCIATION to send his subscription of at least 50 cents to DR. REEVES for a copy of this report.

In relation to the Amick "Cure" it is interesting to note that MR. S. G. SEA, whose certificate of having been cured of consumption by this nostrum and who was at one time business manager, or advertising manager, or something which placed him in official relations with the Amick Company, recently died of consumption, from which he had suffered for several years. His was a case of fibroid phthisis, with the usual history of improvement and relapses running through five or six years, and several times during that period, before he fell in with this concern, he supposed himself cured of the disease. Indeed, at the time he began to take their treatment he asserted that he felt well, but the physical signs caused his physicians in Chicago to recommend him to change climate. A short time after this recommendation, his circular letter claiming to be cured began to be sent broadcast over the country.

MICRO-ORGANISMS IN THE HEALTHY NOSE.

Among the interesting facts we owe to bacteriology is the discovery that so-called healthy persons are the lodging places of myriads of bacteria, powdering their skins, dwelling in the cavities and orifices of the body, mouth, nose, throat, intestines, etc. Taking the nose, we should expect to find a large number of microorganisms in its cavities, both from its anatomic construction and its function. It is calculated that 500 litres of air, bearing on a low average 1,500 bacteria, are inspired every hour.¹ These microbes of the healthy nose have been investigated by HAJEK,

¹ *Lancet*, June 1, 1895.

LÖWENBERG, FRANKEL, VON BESSER, PAULSEN, ST. CLAIR, THOMSON and HEWLETT, among others.

A great diversity of opinions are arrived at by these observers; the first two, as also THOMSON and HEWLETT, found a scarcity of bacteria in the nose, while the others all found a greater or lesser number. Some found a number of pathogenic organisms such as the erysipelas coccus—one in every five healthy individuals) and FRANKEL'S coccus—one in every four cases. WEIBEL has cultivated a comma bacillus from the nose. WELCH² points out that capsulated bacilli are among the interesting features of nasal bacteriology. The ozena bacillus of ABEL closely resembles FRIEDLANDER'S bacillus, but it is not certain yet whether it is found in the healthy nose. PAULSEN made sixty-four cultures from the noses of twenty-seven healthy persons; eleven of these were sterile, the rest, fifty-three, furnished colonies; cocci were more frequent than bacilli; pathogenic bacteria were only observed in one normal case, and in this the streptococcus pyogenes was found.

A recent paper by THOMSON and HEWLETT³ seems to account for these diverse results. These authors examined thirteen healthy cases and examined the vestibule of the nose and the mucous membrane separately. From the former, twenty-seven cultures and thirty-four cover-glass preparations, and from the mucous membrane seventy-six cultures and thirty-four cover-glass preparations, were made. No attempt was made to differentiate the organisms; it was only sought to determine the presence or absence of bacteria. The authors arrive at the following conclusions: 1, the vestibule is lined with skin furnished with hairs and with sudoriferous and sebaceous glands, and is not part of the nose cavity proper—only leading to it; hence, in bacteriologic examinations of the nasal fossæ a distinction must be made between the vestibule and the mucous cavity proper; 2, contamination from the lining of the vestibule is difficult to avoid, even when this source of error is realized; 3, in the dust and crusts of mucus among the vibrissæ of healthy subjects microorganisms are never absent—as a rule they are abundant; 4, on the Schneiderian membrane the reverse is the case, since in over 80 per cent. of the cases no organisms whatever were found and the mucus was completely sterile; 5, the occurrence of pathogenic organisms on the Schneiderian membrane is quite exceptional.

While the number of individual cases in these researches is hardly large enough to be conclusive, still, if they are corroborated, it would seem that nearly all the microbes of inspired air are arrested either by the moist surface and the vibrissæ of the vestibule, or that, as has been already claimed by WURTZ and LERMOYEZ, the nasal mucus is germicidal.

THE PHYSIOLOGY OF SLEEP.

The suggestions from the later discoveries in the minute anatomy of the nervous system seem inexhaustible. Not only has the conception of the neuron modified all our ideas of nervous physiology and pathology, but we now have the protoplasmic neuroglia extensions also bearing a part in the newer theories of the mechanism of the nerve centers. Not long since, M. DUVAL offered a theory of sleep, according to which the nerve cells drew in their processes during slumber, as some flowers do their petals, basing himself in this, on the observation of certain lower organisms, in which he thought he had discovered amœboid movements of the nerve cells. His priority in this theory has been contested by LEPINE (of Lyons) but inasmuch as no one has yet seen these amœboid movements in the nerve cells of higher animals, it can only pass as an ingenious hypothesis.

At a recent meeting, however, of the Anthropological Society of Paris, M. AZANLAY called attention to some suggestions in this direction by RAMON Y CAJAL, one of the investigators to whom we owe the most in the striking discoveries in neural anatomy. He remarks that no matter how we kill an animal, whether by shock, strangulation, or anesthesia, we never find evidence of any amœboid movements of the prolongations of the nerve cells. His attention, however, was attracted by the phenomena presented by the neuroglia cells under the same conditions. These have numerous prolongations, some of them have very fine hairlike ones, and his theory is that these, endowed with amœboid movements, contract in the waking state, and extend themselves during sleep. In the former condition they permit the prolongations of the nerve cells proper, to come in contact with the end brushes of the neuron and to thus permit the conduction of the nervous influence. In the extended state, on the other hand, they isolate the nerve cells and thus interfere with conduction.

Around the capillaries and vessels we find a great number of these cells, and when they contract the vessels are enabled to dilate, the blood circulates freely and the nerve cells are excited to activity. In this way we can explain the effects of attention or concentration of the mind on a subject, as well as account for the phenomena of sleep.

As M. AZANLAY says, this theory, however much it may seem probable or take the fancy, is only as yet an undemonstrated hypothesis. The physiology of sleep is a very complicated subject, and any theory that has yet been advanced is open to many objections, some of them hard to meet. The same is true even to a still greater extent as regards the phenomena of attention and mental activity, and every attempt at explanation only opens up new questions that still remain for solution. This theory of RAMON

² Dennis' System of Surgery, 1, 262.

³ Lancet, June 1, 1895.

Y CAJAL has the advantage of appearing an almost ultimate mechanical explanation, which would still remain to be given with any chemical or other theory, and it has also the prestige of having been offered by one who is, as yet, one of the most successful investigators and discoverers in the finer anatomy of the nervous system.

GLADSTONE'S VIEWS REGARDING MEDICINE.

The great ex-Premier of Great Britain has frequently expressed his high appreciation of medical men and their honorable walk in life, but he has seldom said anything more memorable than in the sentiments given below. The article from which we quote, purports to be a sketch of a great physician—the late SIR ANDREW CLARK—who was for nearly a quarter-century the family physician of the author. It is such a loving tribute as the worthy statesman is well capable of making, but it is something more and higher. It is a philosophical statement of the social rise and progress of medicine. The antiquity of the profession is admitted and it is placed farther back in the vistas of time than our own writers commonly aver, and the progressive exaltation of medicine among the avocations of life is both outlined as to the past and predicted for the future. Is it true—can it be true—that medicine is destined to outstrip in the social race those haughty competitors, law and theology? It may be, and if GLADSTONE'S philosophical insight is correct this will be its future position—the peer if not the superior of the other two.

The concluding paragraphs of MR. GLADSTONE'S sketch, which we quote from the *Youth's Companion*, June 27, are as follow:

"It was a common but it is probably now a vanishing practice, to speak of medicine, the law, and the church, meaning the sacred ministry, as the three learned professions. The three are probably of equal antiquity, but not of equal antiquity with anything like equal eminence. The primitive physician probably survives in the herbalist. He pursued his profession, as it were, underground, while the priest and the judge were originally to be found in the sovereign, or a little later perhaps in prominent and weighty members of society.

"Though there are isolated names of distinction associated with medicine, the doctor as such was the object of ridicule as well as, perhaps not less than, of confidence.

"It is needless to say that the state of things which made ridicule possible has passed away as completely as have the ecclesiastical conditions described in the opening verses of Hudibras, and the period

*'When pulpit, drum ecclesiastick
Was beat with fist, instead of a stick.'*

"The physician has still this note separate from those of the lawyer and the clergyman. They are, at least in the country where I write, both of them largely endowed by the nation; whereas the physician or surgeon receives little public money, and that by the piece, or with a strict reference to work done; a circumstance which has not prevented a rise in their professional emoluments and in connection with all but the poorer classes of society, within the last hundred years or little more, greater, I apprehend, than has accrued in either of the other cases.

"It is not, however, emolument, but something higher and subtler by far, that I have now in view, namely, influence. The immense advance of knowledge and care in the training of medical men has of itself operated largely in opening to them the interior of families, and an access to personal confidences. But also time has been upon their side. When gold was first discovered, says HORACE,

*'males et nova febrium,
Terris incubuit cohors.'*

"In this simple utterance there is a broad and comprehensive meaning. The increase of wealth signifies the multiplication of enjoyments without any corresponding advance in conscientious motive, or in prudential restraint.

"Other causes coöperate with those I have already named—such as the change in communication between man and man, from slow to rapid, and from rapid in many cases to instantaneous. All I have said seems to imply new sensitiveness and complex developments of the nervous system, answering to a condition in which we live so fast, and even while making life more and more luxurious, we abridge the first and most innocent of all luxuries, and deny nature her repose.

"The physician had always to use his eyes; and now he has to use them more largely, more sharply than ever. But in our day he has, and in the coming day yet more will he have, to use also his ears. He becomes, and he must become increasingly, the recipient of the confidences of the family and the individual. He has a kind of priesthood to exercise as he grows in acquaintance with the secrets of the heart.

"He must, whether he will or not, in the higher circles of his profession, find himself invested with a sacred guardianship of purity and integrity for the soul, as well as with purveyance of health for the body, as the connection and interaction of the two come to be more intricate. If he declines this guardianship, the alternative is that he will aid relaxation, and will abet corruption."

GEORGETOWN MEDICAL COLLEGE, WASHINGTON, D. C.

It is with pleasure we note that this college has had the courage to break away from the custom which has heretofore prevailed at the National Capital, of having night sessions. The Georgetown Medical College will hereafter be a day school, and there can be no question but the change will not only meet with the approbation of the clientelage of the school, but the friends of higher medical education everywhere, who have always noticed with regret that the medical colleges in the capital of our country were simply night schools, for the most part dependent upon Department clerks, necessarily otherwise engaged during office hours. That many good men have been graduated at these schools everybody knows, but their success has been achieved in spite of the handicap.

CORRESPONDENCE.

Prophylaxis of Paludism.

NEW CASTLE, COLO., July 1, 1895.

To the Editor:—Under this caption, in the last number of the JOURNAL, is a quotation from Noel: Any prophylaxis with the oft applied agent, quinin, belongs rather to the field of practical medicine than hygiene. Those who adopt the old-time theory of malaria-swamp poison, or the more recent one of micrococci-malaria, until they have arrested the beneficent action of the sun rays that carry the waters of the ocean to the "dry and thirsty land," or destroyed the microscopic entities that abound in all paludal regions will probably find in medication with anti-periodics their chief prophylaxis.

Wherever evaporation is abundant there will be hot days and cool nights, with the enervating and chilling influences of dampness. During the chill of night there will be contraction of the capillaries of the periphera and consequent hyperemia, with engorgement and congestion of central or-

gans, followed, soon or late, by more or less pronounced chill, febrile reaction and diaphoresis, the physiologic and pathologic expressions of thermometric and hygrometric environment. A simple and rational prophylaxis will readily suggest itself to those who are not wedded to the old ruts, and who do not go "round Robin Hood's barn," to find causation. If, instead of wooing the cool and chilling air of night in the garb of fashion, or going to sleep in the damp clothes worn during the day, and half covered, those living in such localities would pay due regard to ordinary hygienic laws, and take a friction bath, damp or dry, as night approaches, put on dry warm clothing, and sleep between flannel blankets, they may laugh to scorn both the marsh poison and pathogenic germs of even the lagoons of Hindostan, or the swamps of Louisiana.

W. L. SCHENCK, M.D.

"Audi Tertiam Partem."

SAN FRANCISCO, CAL., July 4, 1895.

To the Editor:—In the June 29 issue of the JOURNAL, on page 1021, under the head of "A Question of Translation," Dr. G. A. Aschman, of Wheeling, W. Va., takes the liberty to so construe the latter part of my communication of June 15, (appearing under the heading of "Audi Alteram Partem,") as to make it appear that I have been guilty of incorrectly translating the German term "entgiften" which is the opposite of the German term "vergiften"—to poison—and which has no equivalent in the English language—except "disem-poison" perhaps.

The Doctor, after pretending to be familiar with the expressions of Binz—and after stating that I have no reason to take issue with Binz on his doctrine, sums up his article by stating that it is sometimes dangerous to make a translation when not perfectly familiar with the respective languages. In this I fully agree with the Doctor, and he will, no doubt, agree with me after reading this article, that it is still more dangerous to criticize that which one does not fully understand.

When I penned the words, "to poison the organism as it were," I knew full well that unless the readers thereof were familiar with the subject upon which Binz expressed himself, they would construe these words in a translatory sense, when, in fact they were penned in a definitory sense—as will be seen hereafter.

That slight incidents will furnish the key to great truths is fully illustrated in the present case—as the incidental error on my part in substituting "Buda-Pesth" for "Weisbaden," the place where Binz expressed himself, as quoted by me, goes to show that Dr. Aschman was not familiar with the expressions of Binz until I caused them to appear in print on June 15, as he would hardly have overlooked this error on my part, hence I am not surprised that the Doctor failed in comprehending the sense in which I penned the words, "to poison the organism as it were."

As "sero-therapy" is the outgrowth of just such expressions as those made by Binz at Weisbaden in 1883, and as the adoption or rejection of said therapeutic method in this country must depend upon a full understanding of the cardinal principles underlying it—I will take this opportunity to expose these principles more fully, for the benefit of those who are not familiar with the German language.

The subject upon which Binz expressed himself at Weisbaden was "Antagonism between Microbes and Toxins." He expressed himself in a bacteriologic sense—on the assumption that infectious diseases are due to specific microbes and their toxins, capable of antagonizing or chemically neutralizing one another in the blood—when he said: "Our future therapeutic efforts in infectious diseases must be toward 'den lebenden organismus zu entgiften,' in contra-distinction to our past therapeutic efforts which have been toward 'den lebenden organismus zu entgiften,' by eliminating the contagium at the bedside by such physiologic processes as emesis, catharsis, diaphoresis, diuresis," etc.

That a therapeutic method having for its object chemie neutralization of one toxin by another, or destruction of one microbe by another in the blood—phagocytosis as it were—differs radically from a therapeutic method having for its object physiologic elimination of the contagium, can hardly be gainsaid, hence I have good reason to be at issue with Binz, Dr. Aschman's opinion to the contrary notwithstanding. And inasmuch as I have shown that there exist no reliable scientific data that would justify us in assuming (see my papers, the "Status Presens of Antitoxic Blood

Serum," and the "Status Presens of Inherited Tuberculosis," read before the State Medical Society of California, April 16, 1895) that infectious diseases are caused by specific micro-organisms or their toxins, the majority of the American medical profession will no doubt agree with me that I made no "serious mistake" when I defined the "serum method," based upon the expressions of Binz and others, "to poison the organism as it were," especially so, when I have shown by reliable scientific data that the serum causes chemie decomposition of the blood and has increased the mortality from diphtheria in Berlin over 25 per cent.

Concluding, I will say, that while I would regard chemie neutralization of the etiologic factor concerning infectious diseases as the "ideal" therapeutic method in such diseases, still, until such results shall be demonstrated beyond a reasonable doubt, I, and I believe the majority of the profession in this country, will continue in the future, as they have done in the past, to eliminate the poison, "ad via naturam," physiologically as it were.

Respectfully submitted,

CHAS. G. KUHLMAN, M.D.

Dr. Robert L. Annan.

To the Editor:—In your issue of June 8, on page 909, under the caption, "An Example to be Followed" it is stated that "Dr. Andrew Auvan of Emmitsburg, Md., who was 90 years old on April 27, has contributed \$50 to the Rush Monument Fund."

In a communication written immediately on reading this paragraph, but which has evidently failed to reach you, I begged you to state that the worthy physician whose example I hoped would be followed was Dr. Andrew Annan, of Emmitsburg, Md., whose father, Dr. Robert Landales Annan, was a student of Dr. Rush, and whose certificate of qualification for the practice of medicine, bearing this great man's signature, is now in the possession of the latter's grandson, Dr. Robert L. Annan, of Emmitsburg.

In asking you to make this correction, I beg also to remind the members of the ASSOCIATION that at its last meeting it was made their individual duty "to collect funds for the Rush Monument from their fellow-practitioners and transfer the amounts to the Treasurer of the Committee on Rush Monument at as early a day as possible"—and I hope that every delegate and member present at that meeting will promptly follow the example which our esteemed and venerable colleague, Dr. Annan, has set, by transmitting the funds he may collect to George H. Rohé, M.D., Secretary, Catonsville, Md.

Very respectfully,

ALBERT L. GIBSON, M.D.,
Chairman Rush Monument Committee.

Woman's Medical College of Pennsylvania.

PHILADELPHIA, PA., July 6, 1895.

To the Editor:—In a recent issue, you reprint the greater part of an editorial appearing in the *Medical Press and Circular*, concerning the status of American diplomates and, while noting some errors, fail to point out that the "Female Medical College" to which allusion is made in the editorial, is a non-existent institution and has been so for over twenty-five years. The unfavorable light in which the college is placed, may be easily transferred by some persons to the only institution existing in Philadelphia for the instruction of women in medicine, namely, the Woman's Medical College of Pennsylvania. This institution is a member of the Association of American Medical Colleges, has been represented at all its recent meetings and conforms to its requirements. I presume it is hardly necessary to state that the college is in good standing in the medical profession of the United States.

Yours,

HENRY LEFFMANN.

Illinois State Board of Health.

To the Editor:—Enclosed please find copy of a set of resolutions unanimously adopted by the Illinois State Board of Health, at its recent meeting held in Chicago June 25, 1895. Will you kindly give the same publication in the next issue of your JOURNAL? and greatly oblige,

J. W. SCOTT, M.D., Sec'y.

WHEREAS, The Faculty of the Northwestern University

Woman's Medical College adopted a set of resolutions, criticizing the Illinois State Board of Health for having issued to three non-graduate students of said College, the State certificate entitling them to practice medicine, whom they claim were not entitled to receive them, and charging the Board with having adopted a lax policy in numerous other instances, thereby seriously detracting from the usefulness of the Board; and

WHEREAS, Although the resolutions were "ordered to be placed before the Illinois State Board of Health," they were furnished to the various medical publications of the country simultaneously with their presentation to the Board, and before the Board had opportunity to make any defense; and

WHEREAS, The said College has not made any investigation of the methods or policy of the Board, and could not be in possession of information upon which to found such serious charges; and

WHEREAS, The Secretary of the Faculty admitted to the Secretary of the Board that the resolutions were adopted without due consideration, and were not so applicable to the present Board; and

WHEREAS, In the past two years no certificate has been granted to any applicant upon an average rating of less than 80 per cent. on all branches, and the questions and examination papers, and a tabulated record of all examinations are preserved, and are matters of record in the office; and

WHEREAS, It is not in the province of the Board to adopt any policy regarding the admission to its examinations of non-graduates, the law prescribing that "non-graduates shall submit themselves for examinations," and further prescribing that "the examinations shall be of an elementary and practical character;" therefore, be it

Resolved, That justice demands that the Faculty of the Northwestern University Woman's Medical College, and all others interested, inform themselves as to the methods and policy of the Illinois State Board of Health in conducting its examinations, with a view to the establishment of the charges made, or of making such withdrawal, alteration or explanation of the charges as the facts may warrant; and further, that the Faculty inquire as to whether any individual interest or personal animosity prompted the drafting and circulating of the resolutions.

(Signed) B. M. GRIFFITH, M.D.,
SARAH HACKETT STEVENSON, M.D.

It was J. Marion Sims.

PHILADELPHIA, July 7, 1895.

To the Editor:—In an article by Dr. R. H. Dalton, published in the JOURNAL, Dec. 23, 1893, I find Dr. Marion Sims called Francis Marion Sims, "named after General Francis Marion of the Revolution." Now in the "Physicians and Surgeons of the United States," page 48, you will find the name is J. Marion Sims, and as the data for this sketch came to me from Dr. Sims and was revised by him, it undoubtedly is correct. This may be a trifle, but for the sake of future history it is better to make the correction.

Yours truly, W. B. ATKINSON, M.D.

PUBLIC HEALTH.

The Proposed Reorganization of the Health Department of Chicago.

The following is self-explanatory:

86 FIFTH AVENUE, CHICAGO, June 26, 1895.

Hon. Geo. B. Swift, Mayor, Chicago.

Dear Sir:—It has been apparent for some time to those familiar with the workings of the Health Department of Chicago, that it needed reorganization. The ordinances on which it is based do not show any harmonious plan but, on the contrary, they are the result of the changes which have taken place in the growth of this city from a village to a metropolis. The time, therefore, seems ripe for the establishment of a Health Department which may not only serve for the purposes of the city of to-day, but one capable of indefinite expansion, according to the future growth and needs of the city, with an increase of subordinate officers from time to time. I have therefore prepared and drafted an ordinance which, in my judgment, meets the necessities of the case,

and as it does not increase the general expenditure voted for the Health Department, I sincerely hope you may see your way clear to transmit it to the Council for early passage.

This plan involves future codification of all the laws and ordinances bearing upon the public health and the allotment and definition of the duties of all classes of public employes as related thereto. It provides also for the adoption of such regulations as concern the division of the city into sanitary districts, to be increased from time to time as the growth of the city requires; in other words, it is an elastic plan which will not require changes in the immediate future. I have omitted the compensation to be attached to each office and submit in another inclosure a proposed schedule of the same for the information of the Finance Committee. In the preparation of this schedule, I have been assisted by the Assistant Commissioner, Dr. Frank W. Reilly, who has had access to the records showing amounts at present paid by the department.

I will now take the bill up by sections for the purpose of explanation. Sections 1, 2 and 3 are, in my opinion, necessary to secure the perfect working of the officers and employes of the department. Indeed, it will be found impossible to secure the appointment of proper persons unless the tenure of office be made more secure than has been the case under previous ordinances. Moreover, it is such as to bring the department in line with the civil service laws of the State and of the United States. I had charge of a Bureau of the Treasury Department when the present civil service law was enacted, and I am entirely familiar with its operations. Some passages in this ordinance will be recognized as quoted directly from that law.

Sections 4, 5, 6 and 7, are self-explanatory, and relate to the different classes of officers, and especially to the qualifications and appointments of the Sanitary Director and Assistant Sanitary Director.

Section 8, relating to the City Physician, after giving the qualifications, makes specific mention of his duties. There is some conflict in the present ordinances as to his exact relations with the Health Department, and this section makes it entirely clear.

Section 9, relating to the Commissioner, sets forth his duties, and, as I understand it, is well calculated to carry out your views in regard to placing the business portion of the Health Department under the direction of a skilled business man, and as will be seen, there are duties of this nature quite sufficient to occupy the time of a man of this character.

Section 10, providing for a Sanitary Captain, is self-explanatory. It must be obvious that some one must be had to account for the property owned by the Department, to have charge of the same, and to superintend and to direct the outdoor work. I have nowhere seen in the ordinances or regulations of the Department any provision looking to an accounting for the property, as is provided for in this section, which is not only calculated to protect the interests of the city, but to prevent misuse or misapplication of any property or appliance belonging to the Department.

Sections 11 and 12 relate to the appointment of a City Chemist and a Medical Inspector, which are self-explanatory, except that definite qualifications are, for the first time, provided for. The system of examination of medical inspectors, as preliminary to appointment, as proposed in this ordinance, should by all means be adopted at the earliest possible moment, as the appointment of persons through motives of friendship or political association fails to secure that standard of professional qualifications that a great city should always be able to command.

The Sanitary Corps, provided for by Section 14, simply defines the status of the existing affairs, with this exception, that it does not provide that physicians shall be employed as fumigators, who are practically skilled laborers, as there is no need to pay such high prices for work of this character. It appears on investigation that the designations laid down by present ordinances do not by any means define the work actually accomplished by the persons being designated as fumigators, who are employed in the Vaccination Department and elsewhere, and it seems that no particular regard has been paid to ordinances in the matter of nature of employment of persons as designated by the ordinances. These irregularities, perhaps impracticable to be avoided under existing conditions or circumstances, will be done away with if the new ordinance shall be passed.

Section 16 provides for the employment of an interpreter, an office not at present borne on any roll, but which is extremely necessary for the issuance of circulars in the different languages which are necessary in order to reach a polyglot population such as exists in Chicago, and his ser-

vices will be required whenever personal investigations are undertaken in certain districts, not only by the Sanitary Director or by the Medical Inspectors.

The enactment of this ordinance will necessarily require the re-appointment of all officers and employes mentioned in the act, except the City Physician and Commissioner of Health.

Respectfully submitted,

JOHN B. HAMILTON.

AN ORDINANCE TO REORGANIZE THE DEPARTMENT OF HEALTH.

Be it ordained by the City Council of the City of Chicago: There is hereby established in the municipal government of the city of Chicago an executive department to be known as the Department of Health.

Appointments—General Provision.

§ 1.—No person shall be appointed to any office or position in the said Department, until proper inquiry shall be made by examination, or otherwise, into the ability and fitness of such person to perform the duty that may be required of him, should he be appointed.

Removals—General Provision.

§ 2.—No officer or employe of this Department shall be removed except for cause and no person shall be appointed, promoted or removed for any political reason. Any officer or employe may be removed for crime, malfeasance, habitual neglect of duty, willful misconduct, insubordination, disobedience of orders, incompetence, or insanity, and for no other cause.

Officers and Employes shall not accept Gifts or Bribes.

§ 3.—Any officer, inspector or member of the Sanitary or Ambulance Corps who shall accept any gift of money or other valuable thing for reporting or not reporting the existence of any nuisance or case of contagious or infectious disease, shall upon proof thereof be dismissed by the Sanitary Director and shall in addition be subject to such other penalty as the ordinance may prescribe.

Enumeration of Officers and Employes.

§ 4.—The Department of Health shall hereafter consist of the following officers and employes to-wit: a Sanitary Director; an Assistant Sanitary Director; the City Physician; the Commissioner; a Sanitary Captain; the City Chemist; Medical Inspectors; the Sanitary Corps; Clerks and Interpreter.

Sanitary Director—General Qualifications.

§ 5.—The Sanitary Director shall be a physician of not less than ten years' practice and shall be skilled in sanitary science. He shall be appointed by the Mayor, by and with the advice and consent of the Council. He shall hold his office until his successor shall have been appointed and qualified.

Duties of Sanitary Director.

§ 6.—The Sanitary Director shall supervise all matters connected with the sanitary interests of the city, and shall perform such specific duties as may be defined in this ordinance, or designated in former ordinances to be performed by the Commissioner of Health except such duties as are prescribed for said Commissioner in this ordinance, and he shall have authority over all officers and employes in said Department. And when at any time it shall become necessary to establish lake or land quarantine, he shall have command of such quarantine. He shall according to circumstances and season, issue such circulars of popular instruction as shall lead to the preservation of the public health.

Assistant Sanitary Director—Qualifications.

§ 7.—The Assistant Sanitary Director shall be a physician of not less than ten years' practice, and shall be skilled in sanitary science. He shall upon recommendation of the Sanitary Director, be appointed by the Mayor, by and with the advice and consent of the Council, and shall hold the office until his successor shall have been qualified and confirmed.

Duties.

He shall perform such duties as may be assigned him by the Sanitary Director. In case of the sickness, disability or prolonged absence of the Sanitary Director, he shall by direction of the Mayor, act in the stead and perform the duties of the Sanitary Director.

City Physician—Qualifications.

§ 8.—The City Physician shall be a physician of not less than ten years' practice in the State of Illinois, of which not less than five shall have been in the City of Chicago. He shall be appointed by the Mayor, by and with the advice and consent of the Council.

Duties.

He shall supervise the administration of the hospitals established by the city, including hospitals for contagious diseases, excepting quarantine hospitals. He shall prepare regulations for the government of police surgeons, ambulance physicians, resident physicians and superintendents of the city hospitals, in the performance of their duties and shall have immediate supervision of the city ambulance service, when established. He shall attend or cause an assistant to attend the sick in the city workhouse, calaboose, watchhouse, police stations or houses of correction, and shall attend such meetings as may be held by the Department of Health, and in case of epidemic, he shall render such assistance and coöperation, and perform such duties in connection therewith as the Sanitary Director may require.

Commissioner.

§ 9.—The Commissioner of the Health Department shall be skilled in business affairs and shall be appointed by the Mayor, by and with the advice and consent of the Council.

Duties.

He shall have supervision over all clerks of the Department except as hereinafter provided; and shall have charge of all accounts. He shall keep an accurate record of all receipts and expenditures and shall be responsible for all fees received. He shall keep the records of births, marriages and deaths, and issue burial permits under regulations to be made by the Sanitary Director. He shall disburse all monies, pay all officers and employes, make all purchases of supplies, and execute all contracts, but he shall make no purchase of sanitary or special appliances without the approval of the Sanitary Director.

Sanitary Captain.

§ 10.—The Sanitary Captain shall be a person accustomed to superintendence of workmen, and qualified to keep records. He shall be appointed by the Mayor on the recommendation of the Commissioner, and shall have the rank and pay of a Captain of Police.

Duties.

He shall be the custodian, and have charge of the storehouse of the Department with all property belonging thereto, including horses, wagons, carts, ambulances, fumigating apparatus and sanitary appliances of every kind belonging to the Department, and shall make a semi-annual return thereof to the Commissioner. The return shall show from whom the property was purchased or received, to whom issued, and the present condition thereof. No property of any kind shall be issued to any person except upon requisition duly approved by the Sanitary Director, Assistant Sanitary Director, City Physician, Commissioner or Chemist. He shall have charge of the Sanitary Corps and under the Department regulations, supervise their work.

Chemist—Qualifications.

§ 11.—The Chemist shall be a graduate in medicine, skilled in chemistry, pharmacy and bacteriology. He shall be appointed by the Mayor on the recommendation of the Sanitary Director.

Duties.

His duties shall be to have charge of the laboratory, and to conduct such chemic and bacteriologic investigations as he may from time to time be instructed to make by the Sanitary Director, to make test investigations of food products, milk, water, ice, beverages and drugs, and to make report thereof to the Sanitary Director.

Medical Inspectors.

§ 12. The Medical Inspectors shall be appointed by the Mayor on the recommendation of the Sanitary Director, but no person will be appointed Medical Inspector until after such examination as shall satisfy the Sanitary Director that the applicant is fully informed in the principles of sanitary science.

Qualifications.

Physicians holding the collegiate degree of Doctor in State Medicine, or its equivalent, will not be required to pass such examination.

Chief Inspector.

One of the said Medical Inspectors shall be specially skilled in the diagnosis of the exanthematous and contagious diseases, and shall be designated as Chief Medical Inspector.

§ 13. Medical inspectors, except the Chief Medical Inspector, will perform such service as may be required of them from time to time, and they shall be paid according to the service actually performed, on a schedule of pay to be prepared by the Sanitary Director and approved by the Mayor.

Sanitary Corps.

§ 14. The Sanitary Corps will consist of three divisions viz., first, those employed in the division of the City Physician as litter bearers, ambulance drivers and hospital attendants; second, milk, meat, food and other inspectors employed in the chemist's division; third, plumbing inspectors, fumigators, and persons employed in the work of placarding infected premises, and disinfection of the same, acting under the Sanitary Captain.

Uniform to be Worn.

§ 15. All members of the Sanitary Corps shall wear the uniform of their grade, and shall receive such monthly compensation as the Mayor may by order promulgate, as equitable for the services respectively performed by each class.

Clerks and Interpreter.

§ 16. There shall be employed in the Department of Health—clerks who shall be appointed after due examination into their fitness for such position, and they shall be assigned to such duty as the Commissioner may designate, provided, that the Sanitary Director is hereby authorized to employ one person as stenographer and clerk to serve under his immediate direction, and one person as interpreter and translator. No person shall be employed as translator who can not read correctly and converse in five modern languages to be designated by the Sanitary Director.

Repeal Provisions.

§ 17. So much of all previous ordinances as conflict with or in any way impair the operation of this ordinance are hereby repealed, and all provisions of law and ordinances relating to the Department of Health, the Commissioner of Health, the City Physician, the inspection of food, milk, ice and drugs, and miscellaneous ordinances relating to health, in Chapter xxvii, and numbered consecutively from section 1907 to section 2059 inclusive, of the revised laws and ordinances in force April 2, 1890, and the laws and ordinances from April 2, 1890, to July 10, 1894, being Chapter xxvii, numbered consecutively from section 5053 to section 5137 inclusive, shall, so far as they may be applicable, remain of full force and effect.

Health Reports.—The following health reports have been received by the Supervising Surgeon-General, Marine-Hospital Service:

SMALLPOX—FOREIGN.

Antwerp: June 1 to 8, 1 case, 1 death.
Batoum: June 4 to 18, 8 cases, 4 deaths.
Buda-Pesth: June 3 to 17, 1 case, 2 deaths.
Cairo: May 20 to 27, 6 deaths.
Calcutta: May 18 to 25, 56 deaths.
Dublin: June 16 to 23, 4 deaths.
Edinburgh: June 16 to 23, 2 deaths.
Havana: June 20 to 27, 3 deaths.
Liverpool: June 15 to 22, 1 death.
Leith: June 16 to 23, 3 deaths.
London: June 8 to 15, 19 cases, 1 death.
Manchester: June 8 to 15, 2 cases.
Montevideo: May 10 to June 1, 3 cases.
Odessa: June 8 to 15, 1 case, 3 deaths.
Paris: June 1 to 8, 1 death.
Rio de Janeiro: May 25 to June 8, 18 deaths.
Rotterdam: June 15 to 22, 4 cases.
St. Petersburg: June 8 to 15, 6 cases, 2 deaths.
Triste: June 8 to 15, 1 case.

SMALLPOX—UNITED STATES.

Ohio: Cincinnati, June 28 to July 5, 1 case.
New Jersey: Hoboken, June 22 to 29, 1 case (varioid.)
Tennessee: Memphis, June 30 to July 6, 2 cases.
Missouri: St. Louis, June 22 to 29, 3 cases.

CHOLERA.

Calcutta: May 18 to 25, 47 deaths.
Hiogo: June 8 to 15, 13 cases, 7 deaths.

YELLOW FEVER.

Cienfuegos: June 23 to 30, 1 death.
Havana: June 20 to 27, 10 cases, 5 deaths.
Rio de Janeiro: May 25 to June 8, 30 deaths.
Santos: May 24, to 30, 33 cases, 18 deaths.
Vera Cruz: June 20 to 27, 5 deaths.

The following letters have been received from Dr. R. Cleary, Sanitary Inspector Marine-Hospital Service at Rio de Janeiro, Brazil:

CONSULATE-GENERAL OF THE UNITED STATES OF AMERICA.

RIO DE JANEIRO, June 4, 1895.

Sir:—I have the honor to transmit report for week ended June 1, 1895.

There were 8 deaths from *accessio pernicioso*, a decrease of 6; 9 from yellow fever, a decrease of 14; 6 from smallpox, an increase of 2; 6 from enteric fever, the same as in the foregoing week; 2 from beriberi, none in the former week; 2 from measles and one from whooping cough, the same as in the previous week; 1 from influenza; 2 from choleraform diarrhea, an increase of 1, and none from other choleraic diseases.

The total number of deaths from all causes was 279, a decrease of 64 from the foregoing week.

I am happy to say that the above shows a decided improvement in the sanitary condition of the town and port.

Cholera.—I hear nothing more of this disease, though occasionally a death from some choleraic form of disease is reported, which I do not think means much.

Yellow Fever.—The few sporadic cases of this disease are steadily declining in number, so that there is nothing here now more than usual for the time of year.

RIO DE JANEIRO, June 11, 1895.

Sir:—I have the honor to inclose report for week ended June 8, 1895.

There were 9 deaths from *accessio pernicioso*, an increase of 1 over the foregoing week; 21 from yellow fever, an increase of 12; 12 from smallpox, an increase of 6; 4 from beriberi, an increase of 2; 3 from enteric fever, a decrease of 3; 2 from measles and one from whooping cough, the same as in the foregoing week; 1 from choleraform diarrhea, a decrease of 1; 1 from diphtheria and 1 from leprosy. From all causes there were 350 deaths, an increase of 71 over the previous week.

The increase in the number of deaths is great, and I do not know what to attribute it to, unless to the damp weather.

Yellow Fever.—The number of deaths from this cause more than doubled in this week, but it is not unusual at this time of the year to have rises and falls in the number of deaths until the end of June, when the disease becomes almost extinct, as a rule, but it is never entirely so in this town. There is no fear of an epidemic at this time of the year.

Cholera.—No more cases of this disease have appeared, either in the interior or in the town. The one case of choleraform diarrhea reported may or may not have been cholera. I doubt it.

Smallpox.—There is always an increase in the so-called winter season, which is now beginning, and the total of 12 deaths from this cause is not excessive, as they occurred at scattered points, and the disease does not appear to be extending epidemically.

Leprosy.—It is well known that there are many lepers in the interior of the State of San Paulo, and this case may have come from that part of the country.

Measles and Diphtheria.—As for these diseases they are not epidemic here, and have not been since I knew the place, but sporadic cases do appear, usually brought from outside.

MISCELLANY.

Dr. Ernest Laplace, LL.D.—At the last annual Commencement of Georgetown University, Washington, D.C., the degree of LL.D. was conferred on Dr. Ernest Laplace, Professor of Surgery in the Medico-Chirurgical College of Philadelphia.

Dr. Bransford Lewis, of St. Louis, having resigned his position with the Missouri Medical College, has been elected Professor of Genito-Urinary Surgery at the College of Physicians and Surgeons; and Genito-Urinary Surgeon to the Baptist Hospital.

A Corporation with a Soul.—The Metropolitan Telephone Company of New York has published the following humane regulation, adopted Dec. 31, 1894: "Any person may be granted free service at any public pay station of this company for the purpose of securing an ambulance or medical assistance necessitated by some accident in the immediate vicinity of such station. A statement of the circumstances, signed by the pay station agent will be accepted as a basis for remitting the charge. Pay station agents should secure, if possible, the signature of the person using the instrument for such purpose." It would be well if all other companies would make their service "as free as air," as an assistance to the emergency or ambulance work of our cities.

Correct Addresses Wanted.—Will some one please give the correct addresses of the following: Dr. George Baine, Washington, D. C.; Dr. Geo. Bensen, Philadelphia, Pa.; Dr. B. J. Byrne, Baltimore, Md.; Dr. W. Balgroun, Baltimore, Md.; Dr. W. J. Craigen, Baltimore, Md.; Dr. W. F. Hines, Baltimore, Md.; Dr. G. M. Kober, Baltimore, Md.; Dr. S. W. Lotto, Philadelphia, Pa.; Dr. F. Meyer, Baltimore, Md.; Dr. W. L. Nosbeen, St. Louis, Mo.; Dr. J. R. Thomas, Baltimore, Md. These names were added to the mailing list as new members of the Association, but their JOURNALS have been returned by the postmaster, requesting better directions for the delivery of same. All JOURNALS, especially those sent to the larger cities, would reach their destination more promptly if the street and number were added, and we respectfully request members to furnish us with these in cases where they are omitted.

"Tuckahoe," or the American Truffle.—The scientific writer for the New York *Independent* has collated the following facts regarding the so-called "Indian bread," or "Indian loaf:" "Attention is being called in some of our scientific serials to certain species of cryptogamic plants, which grow wholly beneath the surface, and which might perhaps be popularly called underground puffballs. Like all the puffball family they are nutritious, and if they could be produced in large numbers would be valuable commercial articles of human food. The best known American species is found southward, and is known as 'Indian bread' from its nutritious properties, and by the Indians called 'tuckahoe.' The average size is about that of one's fist, but often much larger. They are believed to be somewhat abundant, if one only knew how to locate them; but it is only now and then that specimens can be seen outside of museums. In the Old World the best known of this class is the truffle. But a difficulty was found in locating them until a race of dogs were trained to indicate by scent where the truffle lay buried, when the truffle-gatherer would dig up the little delicacy. These dogs are the chief stock in trade of the collectors, and they rarely part with the animals. The truffles seem to grow the most naturally under oak trees, or in oak forests. For all the large number annually collected the product does not diminish, though, so far as known, the collectors take no special care to extend the growth by artificial methods. There have been statements of the truffle being found in America, but it has not been clearly shown. It is thought that the tuckahoe may be more abundant than it seems to be, or would be made more abundant if the roots it best loved to feed on could be definitely ascertained, and such trees in the region where the fungus is known to grow could be in some measure protected. When assured of an abundant annual product, there might be no difficulty in training 'tuckahoe dogs' as well as 'truffle dogs' to aid in harvesting the crop."

Emergency Rations for the Army.—The Subsistence Department of the Army has received reports from two of the boards convened to determine the best form of an emergency ration. A board consisting of three line officers, one medical and one subsistence officer, was convened in each of the military departments to consider and experiment on this subject. According to the *Army and Navy Journal*, the Commissary General of Subsistence declines to give out the reports of the boards for publication at the present time. It is his desire to have the findings on this important question remain secret until all the organizations have submitted their views. It is said that the two reports received show great research and make many valuable recommendations. What will be done in the matter will be to take from each report any recommendation it may contain which General Morgan may consider worthy of adoption. It is understood that the New York board is receiving a large number of samples of condensed foods from manufacturers and others interested in their adoption in the service. Returns from other boards indicate similar activity on the part of dealers. It is expected that all the reports will be received before September next and that then the matter will be decided. The Adjutant-General has received a long report on the subject of the emergency ration from Capt. J. H. Dorst, 4th Cavalry, military attaché to our Legation at Vienna. He has forwarded samples of the Austrian war rations, viz., cans containing a beef stew; tablets of concentrated soups;

one of parched flour, another of peas. Other articles sent are meat and other sausages, with a mixture of vegetables intended for making soup; also compressed tablets of roasted and ground coffee prepared with the proper percentage of sugar. The war rations are of several classes: the full ration, the supplemental "nachshub" ration, the reserve ration for the period during and immediately following mobilization, the reserve ration for field operations, and a railroad ration. All war rations are issued in kind and the full ration is always issued when practicable. The nations of Europe are apparently a long way ahead of us in this matter, but the present activity of our Subsistence Department will demonstrate the faults of our ration as a war ration and enable us to adopt improved methods of subsistence for the future.

A Great Work on Hippocrates.—The London *Lancet* notes with gratification that both French and German scholars are at work upon a Hippocratic revival. Dr. Michel Sourlangas, for the French, has given a study of the ideas of Hippocrates regarding infection and the antiseptic treatment. The author gives the following among the conclusions reached by him in his monograph: first, that Hippocrates made medicine a science, and that on this ground he merits the title rather of Legislator than of Father of the Healing Art; second, that most of the infectious diseases were known to him—the rôle he attributes in their production to the air and the water constituting in fact a scientific study in etiology; and third, that he availed himself in treatment of substances whose virtues as microbicides are undeniable.

But of the great German work the *Lancet* writes as follows: "But more important than these incidental excursions into the fascinating field of ancient medicine is the new German translation of the entire Hippocratic collection by Dr. Robert Fuchs, of which the first volume is now before us. In this the reader will readily discern that Dr. Fuchs is a more learned scholar than his predecessors, and that he has also the advantage of belonging to a sounder, more scientific medical school. The language in which he re-clothes the Greek author is that of modern medicine, and the interpretation he gives is such as was possible only to one who has profited by the vast accessions to our knowledge of antiquity by the archaeologist, the epigraphist, and the special investigator of antique life and culture. His familiarity with such monographs as the well-known 'Die Botanik Homers' and such monumental treatises as that of Berendes on the 'History of Pharmacy' will illustrate our meaning. The undoubted advantage he possesses over Littré, Adams and Ermerins is also manifest in the notes, which from their richness in expository matter contribute to make this book an encyclopedia of Greek medicine. The first volume comprises the introductory writings of Hippocrates, then the general treatises, then that on dietetics, and, finally, the general pathology and the prognostics. The second volume will include the special pathology and therapeutics, and will be ready next summer. The third, completing the work, will appear in September or October, and will deal with therapeutics (second part), surgery, ophthalmic medicine, gynecology, treatment of infancy, and the Hippocratic correspondence. The entire publication will indicate the high-water mark attained by European research and scholarship in the 'mare magnum' of Greek medicine, and our only regret in calling attention to it is that, since Francis Adams published his translation some fifty years ago for the Sydenham Society, British learning has done so little for a subject in which it has in past centuries shown its ability to excel."

Diagnosis Tags for Use on the Battle-field.—During the past year much attention has been given by Army surgeons to the perfection of a diagnosis tag for field service. Drs. Havard, Woodhull, Hoff, Worthington and Forwood have each presented models. The tag, model of 1895, issued from the Surgeon-General's office is of tough cloth paper and bears more resemblance to the Forwood tag than to the others. It is five inches long by two and three-quarter inches wide, with a bright red border, three-sixteenths inch deep, on one side, and a dark blue border of the same depth on the other, each of which can readily be torn off along a line of perforations. The tags are put up in booklets of twenty-five with a few additional slips of white paper on which the word "urgent" in large blue capitals is printed. Each tag is provided with a slender copper wire by which it may be attached to the clothing. On the inside of the

covers are printed "Directions" and "Remarks" as follows: "Directions: 1, the diagnosis tag is to be attached as soon as practicable to every sick or wounded man on the battle-field. The diagnosis must, as a rule, be entered by a medical officer. 2, the red border is left on and the blue torn off when from shock, severe injury or other cause the soldier is at the time unable to endure transportation. 3, the blue border is left on and the red torn off when the soldier requires transportation and can be moved. 4, both borders are torn off when the soldier's disability is slight or such that he can walk to the dressing station or hospital. 5, under 'diagnosis' the medical officer will give a brief and intelligible description of the seat and character of the injuries or the nature of the disease and sign it. 6, under 'Treatment' is to be recorded what is given, especially anodynes and stimulants, and what is done from time to time by medical officers or attendants, and, when proper, it may be indicated what further is needed and the urgency of the case. If necessary for brevity the following characters may be used to save time and space: X, temporary dressing applied; =, permanent dressing applied; O, operation needed (amp., liga., etc.); OO, operation urgently needed; X within O, operation done and temporary dressing applied; = within O, operation done and permanent dressing applied; XO, temporary dressing applied and operation needed; XOO, temporary dressing applied and operation urgently needed. Remarks: The urgency tag is to be used in addition to the usual diagnosis tag as a conspicuous mark to call attention to some case requiring immediate assistance. The date is important and should never be omitted. When narcotics or stimulants are administered the quantity given and the time should always be stated. If practicable the name, rank, company and regiment of the sick or wounded man should be entered upon the diagnosis tag." The diagnosis tag is an elaboration in time of peace for war service which will probably be thrown aside when the war time comes, except in special cases. A wounded man who is able to walk to hospital and to tell the surgeons there all about himself will not wait in the arena of danger for a medical officer to write all this information on a tag for him; and in the cases of men who are badly wounded and unable to give an account of themselves the Hospital Corps men who carry them to the hospitals may be intrusted with the needful instructions. If the tag should come into use in the field as at present intended, it seems an unnecessary loss of time for the medical officer to enter the name, company, rank and regiment of each wounded man; in fact, if the man is unconscious, difficulty may be found in obtaining this information. To permit of the identification of wounded soldiers at the hospital each man in time of war, as recommended by Dr. Forwood, and as is customary in the French Army, should have his name and command engraved on a small medal, which should be worn around his neck under his clothes. There would then be no need to enter this information on the tag.

Washington Notes.

HEALTH OF THE DISTRICT.—The report of the Health Officer for the week ended June 22 is as follows: number of deaths (still-births not included): white, 35; colored, 35; total, 70. Death rate per 1,000 per annum, white, 9.91; colored, 20.92; total, 13.45. Death rate per 1,000 per annum for corresponding week last year, 33.93. Still-births: white, 5; colored, 3; total, 8.

DR. S. C. BUSEY.—Dr. Busey, the President of the Medical Society of the District, has entirely recovered from his severe injury and left on the 29th ult., for Narragansett Pier. The profession can well congratulate themselves on the recovery of one who has done so much to advance medical science. The local physicians look forward with pleasure to his return to the "charge" of the Medical Society in the autumn.

MEDICAL SOCIETY OF THE DISTRICT.—The regular meeting of the society was held on 1st inst. Only business matters were discussed, and on motion it was decided to hold the next regular meeting on Wednesday October 2. The regular monthly essayists for the year 1895-1896 were announced by the Committee on Essays.

CENTRAL DISPENSARY AND EMERGENCY HOSPITAL.—The new fire escapes have been completed, the lower basement repainted and the steam elevator replaced by an electric one. The annual report with an official history of the insti-

tution since its foundation, will be ready for distribution in a few days. The term of service of Dr. James H. Church, the resident physician expired June 30, and Dr. Peter M. Smith the first assistant, was promoted to the position of resident physician. Dr. E. D. Shortlidge was promoted to be first assistant, Dr. Francis M. Furlong having passed first in the competitive examinations was appointed second assistant resident physician. Dr. Church will practice medicine in Washington City and carries with him the best wishes and confidence of each member of the hospital board.

THE PUBLIC SERVICES.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from June 27, 1895, to July 5, 1895.

First Lieut. CHAMPE C. McCULLOCH, Asst. Surgeon, is granted leave of absence for one month, to take effect about July 1.

Major BLAIR D. TAYLOR, Surgeon, is granted leave of absence for one month, to take effect between July 1 and 10, with permission to apply for an extension of ten days.

First Lieut. FREDERICK P. REYNOLDS, Asst. Surgeon, now at Ft. Sam Houston, will proceed to Ft. Bliss, Texas, not later than July 1, and report for temporary duty during the absence on leave of Major BLAIR D. TAYLOR, Surgeon.

Capt. CHARLES M. GANDY, Asst. Surgeon, is granted leave of absence for two months, to take effect upon his relief from duty at Ft. Yellowstone, Wyo.

Lieut.-Col. DAVID L. HUNTINGTON, Deputy Surgeon-General, is granted leave of absence for one month, to take effect upon his relief from duty in the Dept. of the Colorado.

Capt. CHARLES B. EWING, Asst. Surgeon, is granted leave of absence for two months.

Marine-Hospital Changes. Official list of changes of stations and duties of medical officers of the U. S. Marine-Hospital Service, for the fifteen days ended June 30, 1895.

Surgeon GEORGE PURVIANCE, to proceed to Delaware Breakwater Quarantine as Inspector, June 19, 1895.

Surgeon JOHN GODFREY, detailed as chairman of board for physical examination of candidates, revenue cutter service, June 17, 1895.

Surgeon FAIRFAX IRWIN, detailed as chairman of board to consider necropsy reports, June 15, 1895.

Surgeon H. R. CARTER, granted leave of absence for fifteen days, June 24, 1895.

P. A. Surgeon C. E. BANKS, detailed as member of board to consider necropsy reports, June 15, 1895. Detailed as member of board for physical examination of candidates, revenue cutter service, June 19, 1895. Detailed as chairman of board for physical examination of officers, revenue cutter service, June 27, 1895.

P. A. Surgeon J. J. KINYOUN, detailed as member of board to consider necropsy reports, June 15, 1895.

P. A. Surgeon G. B. YOUNG, granted leave of absence for thirty days, June 19, 1895.

P. A. Surgeon B. W. BROWN, detailed as recorder of board for physical examination of officers, revenue cutter service, June 27, 1895.

P. A. Surgeon M. J. ROSENAU, detailed as recorder of board to consider necropsy reports, June 19, 1895.

Asst. Surgeon J. A. NYDEGGER, granted leave of absence for five days, June 19, 1895.

Asst. Surgeon W. J. S. STEWART, detailed as recorder of board for physical examination of candidates, revenue cutter service, June 19, 1895.

Asst. Surgeon RUPERT BLUE, detailed as recorder of board for physical examination of candidates, revenue cutter service, June 17, 1895.

Asst. Surgeon EMIL PROCHAZKA, granted leave of absence for twenty-six days, June 27, 1895.

ORIGINAL ARTICLES.

RELATION OF MATTER AND MIND IN HYPNOTISM.

Read before the Indiana State Medical Society, June 6, 1895.

BY JAMES F. HIBBERD, M.D., LL.D.
RICHMOND, IND.

All will concede that the present popular consideration given to hypnosis renders it incumbent on the physician who would creditably fulfill his mission that he be posted with knowledge of its phenomena and nature.

In presenting my views on hypnosis, there is no pretense that I am a scientist detailing my original experimental investigations, but rather a philosopher scanning the field of psychic culture, analyzing the products of the labors of experimentalists in mental science, and deducing conclusions by associating and comparing such products with the results of progress in the broader field of physics.

My contention is that the somatic mind is the product of the functioning of the encephalon, the motor of which is vital energy, an isomeric phase of and directly descended from, the oscillatory motion of atomic matter through molecules, protoplasm and tissue metabolism, and I hold that hypnosis, spiritism, Christian science, hysteria, etc., are cognate forms of correlative neuroses, the subjects of which are not up to the fullest development in mental force and balance, the shortage being due to a congenital imperfection in the encephalon or a defective working of the intellectual apparatus.

To fully present the points illustrative of my contention and rehearse the facts and arguments that to my mind demonstrate their verity would require a volume, while my privilege of recital here is limited to twenty minutes reading. I must therefore content myself with a verbal triangulation of the field outlined, and submit for your consideration such of its more prominent features as in my estimation are most likely to interest you.

In a study of hypnosis our first obligation to ourselves is to acknowledge the reality of its existence, and our duty to our *clientele* demands that we be able to point out to them its nature and significance. A weighty fact that should be kept constantly before us is that only a small fraction of the civilized people of the world are susceptible of hypnotization, and not one of this small fraction can be hypnotized without his consent.

The most facile steps in producing a state of hypnosis are for one or more susceptible persons to take an easy sitting position on the invitation of some one in whom each has confidence, known as a hypnotist, who instructs them to fix their gaze and attention on some distinct thing, generally a bit of bright metal, held in front of, and a little above, the

eyes and close enough to require a slightly convergent vision to see it clearly, and maintain this position until a sense of drowsiness creeps over them to which they yield and fall asleep, or into a state simulating sleep wherein they are oblivious to everything except the suggestions of the hypnotist. This hypnotist is no particular person but may be any one who by agreeable appearance and bearing wins the confidence of the subjects, nor is there a special virtue in this bit of bright metal; anything, bright or otherwise, which can hold the attention of the subject without exciting his curiosity or other inquisitive sense will answer the purpose. The subject who thus becomes hypnotized I will call a hypnotic.

Suggestion by the hypnotist may be successfully made by touch, by motion, or by words, but not by will power of the hypnotist, except through some act recognizable by one or more of the hypnotic's normal senses. By these means the hypnotic can be made to believe that the tincture of wormwood is a delicious syrup, that the odor of assafetida is the attar of roses; that the notes of a mandolin are the howl of a wild beast; that potatoes are lumps of gold; that contact with ice will scorch his fingers, and so on through the most irrational vagaries. But this line of suggestion has its limits; it must be kept within the bounds of the natural endowments of the hypnotic and the influence of his education, as also the impression of his immediate environment.

These limiting impressions are known as auto-suggestions and are of the highest importance in understanding the possibilities of hypnosis. Mr. Hudson, an attorney, an investigator and writer of hypnosis, in an article (*New York Medical Journal* Jan. 26, 1895,) on the "Relations of Hypnosis to Medical Jurisprudence," and Dr. Cocke in his recent book on "Hypnotism: How it is done; its Uses and Dangers," Boston, 1894," have treated of auto-suggestion quite fully, from which I epitomize as follows: a hypnotic who is a moral man strongly averse to injuring a fellow mortal has a pasteboard dagger placed in his hand when under the deepest influence of the hypnotizer, who directs him to stab the person nearest him in the breast, which he does instantly and without hesitation; then the hypnotist places a real dagger in the hand of the hypnotic with the same instructions, but the hypnotic hesitates and if the hypnotist insists, the hypnotic comes out of the hypnotic state in great agitation. This is due to the hypnotist's instructions to the hypnotic to commit a crime which in the hypnotic's normal state nothing could induce him to do. Notwithstanding his hypnotic state his conscience readily distinguishes between a pasteboard dagger which could do no harm and a steel dagger which would destroy life.

Again, a hypnotist has a virtuous woman for a subject and when he has her under full control makes improper advances to her which she will promptly

resist, and if he presses his purpose will come instantly to the normal exercise of her mind with a shock, probably followed quickly by a hysterical explosion. Any one who submits to be hypnotized can determine before the séance begins, that if certain things are commanded of him while under the influence of the operator he will not obey, and if the certain things are attempted he refuses and can not be forced.

The environment also has a guiding control in the extent to which the hypnotic can be carried. If the séance be a public exhibition and several subjects are presented, there will be a wide difference in the limits within which they can severally be manipulated. In public presentations most of those who offer themselves as subjects do so with the conviction that they are to contribute to the entertainment, and those of them who place no restraint on their actions before the public, obey the hypnotist in every suggestion, however ludicrous it may be; others will refuse to follow suggestions that infringe on their dignity, while still others will decline further advance if the lead crosses the line of their sense of moral rectitude.

The lesson of this phase of hypnosis is that if the hypnotics in any séance should, at the suggestion of the hypnotist commit murder, prove licentious or make buffoons of themselves, neither hypnotism nor the hypnotist would be the essential cause of the misdeed, but at most would only be amenable to the charge of affording the offender an opportunity, and prompting him, to advertise his real character. In his heart he was a murderer, a lecher or a buffoon before he was a hypnotic.

If this sketch of hypnotism be true, it neutralizes the apprehension many excellent people have entertained, that the public was liable at any moment to be confronted with a hideous felony, brought about by a depraved hypnotist suggesting the crime to an otherwise innocent and conscientious hypnotic.

A fortnight since, I read in a Richmond newspaper a statement to the effect that in an Indiana city a man had recently been convicted of murder and sentenced to the penitentiary for thirteen years, mainly on the testimony of a woman who subsequently confessed that her testimony was false and that she had committed the murder herself. This woman was now in a hospital near to death from consumption, and on May 19 the judge went to the hospital with a hypnotist and authorized him to hypnotize the woman that she might tell which was true, her testimony or her confession. Under hypnosis she declared her testimony true and her confession false, the latter being made under duress.

If the mental condition of this moribund hypnotic was such as set forth in this essay, as the ordinary condition of hypnotics, she would declare touching the truth or falsity of her previous statements just as the hypnotist now suggested or as she had determined for herself before entering the hypnotic state. If seriously made, such use of hypnosis would be misprision of criminal jurisprudence, and a travesty of forensic medicine.

Charcot, "Dictionary of Psychological Medicine," states that a typical case of hypnosis traverses three well-marked stages of development, to-wit: catalepsy, lethargy and somnambulism. Catalepsy is the first step and is secured by withdrawing the bright object at which the subject has been gazing, the moment he loses consciousness. On such withdrawal

the subject with fixed unwinking eyes continues to gaze at the spot from which the object was removed and, if not disturbed, will remain in that exact position until the contractile energy of his involved muscles is exhausted, when his body will adjust itself obedient to the law of gravity.

In this state, the subject is as plastic clay in the hands of the potter; his arm can be raised to any position and will remain there; his head may be placed awry and will continue thus; his whole body may be molded to any form, esthetic or fantastic, consistent with his anatomy.

The lethargic state may be induced by the hypnotist simply closing the staring eyes of the subject, or he may be allowed to continue his gaze at the bright object and his eyelids will soon droop, then close, his lethargy will be complete and profound and he may so remain, if undisturbed perhaps twenty-four hours, with no other apparent objective evidence of vital activity than is manifested in his respiratory and circulatory apparatus.

The lethargic condition is converted into the somnambulistic state by certain manipulations, especially by the operator rubbing the vertex of the subject with the tips of his fingers or the palm of his hand. The effect of this vertex friction is a well-established clinical fact for which no rational explanation has been afforded.

While the foregoing stages are clearly enough marked in typical seizures, in fresh subjects, the manifestations are mixed and irregular in many fresh cases, and in those who have been frequently hypnotized, the distinction is not observable.

Charcot maintains there is a clear relationship between the hysterical diathesis and hypnosis, and the close observer, after sufficient experience, will not hesitate to accept his conclusions. Conceding the relationship between hypnosis and hysteria, as taught by Charcot, it is as far as we can go, for the phenomena characterizing the two have little in harmony and their sequels are widely divergent—hysteria simulating by times almost every idiopathic pathologic condition, frequently ending in permanent invalidism or structural changes of a hopeless character, while hypnosis but repeats its original distorted features with less and less prompting and its only common mischievous sequel is a perverted intellect.

To obtain a rational concept of hypnosis we must keep distinctly before us that the mind is the product of a multiple organ of most complex organization and complicated physiology. So emphatically is this true that to analyze the structure of this organ and comprehend clearly the fruit of its functioning in the adult human by a study of it in such human, is beyond the powers of the acutest observation and the profoundest comparison.

A year ago it was my privilege to read a paper before this society, devoted to a consideration of the origin and development of man's mental powers, wherein I advanced the proposition that since the time of Aristotle, students of mind had substantially confined their investigations to its structure and manifestations in the adult human, in general terms regarding it as a dual thing composed of a natural and a supernatural moiety, with the result of great diversity of conclusions without satisfaction in any of them. Without questioning the dual character of our minds, I further stated that all its opera-

tions, open to our observation, were due to the vital energy as exhibited by or through our nervous organizations, and that the study of mentality involved only the investigation of the nervous apparatus, the fruit of which is known as the somatic mind, and to comprehend this we must abandon the scholastic method of research and, instead, adopt the modern method of scientific interrogation of nature which discards primary inquiry into the complicated and involved nervous system of adult man, descends through the less and less intricate organizations of the long catalogue of inferior animals, and finally reaches the amœba, held to be the simplest living thing presenting the essential characteristics of the animal kingdom. The amœba is a single cell of undifferentiated protoplasm. It has no muscular system, yet moves; it has no organs of special sense, yet selects its food and seizes it; it has no digestive system, yet consumes food and is nourished; it has no organs of generation, yet propagates its kind and continues its species; it has no nerves, yet all vital activities are accomplished with precision and in the utmost harmony. Here, then, the scientist meets his opportunity to begin the study of the nervous system of man, for this simple one-celled animal is the first link in the extended chain of animal existence, whose final link is the wonderfully complicated human organization. And the succession of living things, from amœba to man, is but an unbroken continuance of added cells and differentiated function, man being apparently the acme of the Creator's intent, but not a uniform product of creative power, for excepting the distinctive points that fix man's place in the classified animal kingdom, the differences of both body and mind among the peoples of the earth, due chiefly to environments or other mundane influences, are so patent that it may be fairly claimed that the contrast between the highest and lowest humans is not less than the difference between the lowest human and the highest simian.

Without further attention to man's organization as a whole, let us give brief consideration to his nervous system—not to its anatomy but its physiology. For the present lesson we recognize three grades of nervous energy, functionally distinct in their typical endowments, yet so intimately blended and interdependent as to require constant recurrence to the type of each to avoid confusion in their conjoined service. The first grade has its genesis in the centers that preside over the automatic activities of the body which include digestion, assimilation and the whole diversified metabolism of the organization, and are but little influenced by the other grades and that little by indirection. The second grade has its seat in that part of the encephalon centrally situated that, in the last few years, has been experimentally demonstrated to be constituted of motor centers. To a considerable extent these centers have been shown to have original motor jurisdiction when excited by either external or internal stimulants. The third grade emanates from the anterior and posterior regions of the cerebrum and includes the perceptive, the intellectual, the emotional and the will powers of the mind, and in its entirety dominates all the voluntary activities of the body, which it does through its command of the other grades of the nervous system. This is the grade that gives rise to the phenomena of hypnosis, and the seeming mystery of these phenomena will disappear if we realize

that the mind is not a unit, but is made up of sundry greater departments, sub-departments and minor divisions which may all act in unison, but also under some circumstances one or more of the divisions may function within certain limits quite independently of others and it is here that hypnosis has its genesis.

The actual condition of the mind in hypnosis is the suspension of the will power, except as to the suggestions of the hypnotist which are obeyed implicitly, until obedience involves a violation of the moral sense of the hypnotic as it exists in his normal mental state. This dominant power of the moral sense is a fact of the highest significance, being the witness to a phase of insentient mental operations included by psychists under the terms, unconscious cerebration, mental automatism and reflex action of the brain, that have exceedingly important relations with the entire range of human thought and action.

There is no rationale for the phenomena of hypnosis any more than there is for chemic affinity, gravity or other motorial factor in nature. The fact we need to clearly comprehend and persistently retain is that the full catalogue of vital activities recited, are such, obedient to cosmic law, under which the Creator fashioned the earth and governs all things therein.

Recurring to the amœba, I may recall the fact that it was elaborated protoplasm in which the first vital cell was organized, and that in man there is no elemental matter not found in the world around him, and that of seventy or more elements of the earth only about fifteen enter into the substance composing the human frame. It is the manner of the combination of these fifteen that distinguishes man, and indeed all living things, from other products of the energy of the omniscient and omnipotent Creator. So far as we can now discern, this progress is due solely to the continuous operation of a universal law impressed on elemental matter in the beginning, and as I see it, the status of civilized man and the degree of his enlightenment are measured by the fullness of his recognition of this fundamental law.

It has seemed to me that we shall find the key to all we shall ever know of vital activity, including the expanded intricacies of nervous functioning, by devoting successful study to the dynamics of physics. The striking difference between the variegated movements of advanced animal life and the limited rigid movement of inorganic matter is found in this; in the movements of animal organisms there is witnessed the operation of volition, *i. e.*, the organism, in certain directions, may do things or leave them undone as it elects; even the amœba, the prototype of all the animal kingdom in this behalf, floating in its supporting medium, may simply float as a globular speck of protoplasm or it may project a pseudopod, seize a bit of food and convert it into its own tissue; whereas if atoms of oxygen and hydrogen come into contact under appropriate environment they must unite in definite proportions and form water, and from this destiny there is no escape and no modification, and no atomic matter has other line of action.

Physicists teach us there is but one energy in nature. In our present lesson, reviewing matter in motion, we first meet with this force in the chemic affinity of atoms, and follow it through molecules in increasing number and complexity until they form protoplasm, and in protoplasm still further, until a

cell is organized which presents the characteristics of animal life.

If this review of the progress of matter from the conjugation of atoms to the organization of a living cell has been thorough and true, we will have realized but one energy. The force of chemic affinity in atoms is the same as vital activity in the amœba—nothing added, nothing lost.

It has already been shown that the primal animal cell presented potentially every tangible attribute of man, and that in traversing the wide range of mental force from amœba to man, even by the most enlightened, no new element nor new energy was discovered—simply more cells and higher differentiation of function.

It is the consideration of these patent facts and the logic of affiliated events that enables us rationally to investigate the somatic human mind in its diversified compartments as manifested to us by the countless centers of the brain, and leads us without a peradventure to the conviction that by exciting one set of centers and inhibiting other centers, we may induce hypnosis, and by a parity of reasoning it is easy to convince ourselves that by the same token we have the *open sesame* to the understanding of the whole physiology of the encephalon, and its pathology as well.

TUMORS OF THE MAMMARY GLAND.

Read in the Section on Surgery and Anatomy, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY W. L. RODMAN, A.M., M.D.

PROFESSOR OF SURGERY AND CLINICAL SURGERY IN THE KENTUCKY SCHOOL OF MEDICINE, ETC., LOUISVILLE, KY.

There is no surgical subject the literature of which is less satisfactory, than that of mammary tumors. This is not due to a lack of writers, but rather to their contradictory positions.

In the first place the nomenclature of the subject could not well be in a worse condition. The American, English, German and French schools each has a classification peculiar to itself. The general reader finds himself hopelessly at sea, in endeavoring to reconcile the teachings of standard authors.

The only true classification—one based upon accurate pathology—has not been followed. Growths considered by some as benign, are by others treated as malignant. This confusion, noticeable as it is with malignant neoplasms, is much greater with benign affections. Take, for instance, the most common of benign tumors, and we find it described under the same name by only two recognized authors. It has at least a dozen names. The fibroma of Gross, Labbe and Coyne is the adenoma of Broca, the adeno-fibroma of Billroth, the fibro-adenoma of Cornil and Ranvier, the mammary glandular tumor of Paget, the chronic mammary tumor of Cooper, the pancreatic sarcoma of Abernethy and the lobular imperfect hypertrophy of Birkett. Many of the English writers also call this growth "adenocèle." Could confusion be greater?

Further, villous papillomata which are innocent and never repullulate when properly removed, are by some authors described as tubular or duct cancers. They are admittedly somewhat similar pathologically, yet withal very different, in a most vital feature. The duct is a perfect capsule to the papilloma, beyond which it never extends. The cancer defies the barrier and proliferates beyond its confines.

Therefore one must be somewhat arbitrary and follow the author whose position seems to him best chosen.

Operators are in a large measure responsible for this confusion. The gross or macroscopic appearance of a tumor after removal is of great value, and is at times scarcely secondary in importance to a careful microscopic examination. I have seen many distinguished operators who never touched a tumor after its excision, but felt that their duty was performed when an assistant was told to take a part of it to a microscopist. The latter, however experienced, may get a very incorrect idea of the growth from an isolated portion of it removed at random. The most careful microscopist will often properly refuse an opinion when asked for one under such circumstances. He is entitled to the entire growth, with a full clinical history of the case. The presence or absence of a capsule, secondary degenerations, cystic transformations, whether it was central or peripheral, growing from the upper or lower surface, adherent or not to the surrounding tissues, are all facts rightly his, before a growth is prepared for the microscope. Should one do this in all cases, I am sure he will have less cause to dissent from the final verdict of the microscope, which must be our court of last resort.

According to a recent and excellent authority, Mr. Raymond Johnson, of London, the general opinion that breast tumors originally benign are prone to degenerate into malignancy, is incorrect, and can not be proven. In a series of lectures delivered at the Royal College of Surgeons, of England, in June, 1894, Mr. Johnson devotes considerable time to combating this well-nigh universally accepted view. He asserts that adenoma, which is by most authors supposed to be exceedingly liable to cancerous change, never does so, and says that no one has ever reported a case where an encapsulated tumor as the adenoma, has been seen bursting through its capsule and infiltrating the surrounding tissues. Until he has seen such specimens and examined them macroscopically and microscopically, he can not believe they are of common occurrence, if indeed they exist at all.

ETIOLOGY.

Notwithstanding their frequency, it is surprising how little is known of the causes of mammary neoplasms. S. W. Gross showed very clearly by a most patient and careful analysis of a large number of cases, that many opinions more or less well fixed in the minds of professional men were absolutely untenable. The social condition—hitherto supposed to play such an important rôle in the etiology of breast tumors—is absolutely without influence. Single and married, sterile and fruitful women are equally liable. Trauma plays the same rôle in the production of innocent and malignant growths—11.94 per cent. of the former, 11.70 per cent. of the latter. Disordered menstruation, hysteria, etc., cut no figure whatever. Heredity perhaps has an influence, but it is slight. Gross concludes that heredity can not be shown in non-carcinomatous growths, while it exists in one case out of every nine carcinomas. Eczema and psoriasis of the nipple and areola—usually spoken of as "Paget's disease"—were thought by Gross and others to cause both innocent and malignant growths. Recent investigations by Raymond Johnson, W. Roger Williams and others on villous

or duct cancer, are in line with the teaching of Thin who some years ago stated it as his belief that the so-called Paget's disease instead of being the cause of tumors was simply the result of tubular growths, the discharges from which caused the irritation and angry condition of the areola. This position, I am satisfied, is undeniably correct in the vast majority of instances.

Puerperal mastitis seems to leave lumps in the breast, which are followed by innocent neoplasms in less than 2 per cent. of all cases, while malignant tumors follow such conditions in rather more than 8 per cent. In many instances, however, the neoplasm does not follow for five, ten, twenty or even thirty years—about fifteen on an average. We may, therefore, with propriety doubt that such influence is great.

RACE.

I have not seen it stated in any work on mammary tumors that race exerts any influence. That it does, so far as malignant disease is concerned, I have no doubt. The negro is relatively immune from cancer. In twenty years' experience passed in the South, where the negro population is as 1 to 5, I have encountered malignant disease in the breast of the full-blooded African but once. During ten years of this time I have been constantly on the staff of the Louisville City Hospital, and in charge of the surgical clinic of my college, where our patients are largely negroes. Prof. J. M. Holloway, of Louisville a surgeon of forty years' experience, doing for twenty years a very large business, tells me that after a careful examination of his case-book, he has seen 170 breast cancers, and only 2 were in negroes.

At a recent meeting of a Louisville society I asked the Fellows present to speak upon this subject. Two members, each of whom have been in practice over thirty years, had never encountered malignant disease in the breast of the negro. All agreed that it was rare.

Young, also Livingstone, in his book of travels, and Walshe in his famous work on cancer as geographically distributed, emphasize the relative immunity of the African from malignant disease in general. Billings has recently made the same observation. Therefore, we should not be surprised at the difference we find in the relative frequency of breast tumors in the two races. I believe, however, that the same disproportion will not be found to exist in other regions of the body.

In the white woman, cancer of the breast and the uterus is on a parity, for, according to Herbert Snow, "of 467 cases of cancer at the London Cancer Hospital in one year, 115 suffered from malignant disease of the breast and exactly the same number from that of the uterus." Each organ represents about 25 per cent. of all cancers in women. So that one-half the cases of cancer in females affect the breast and uterus. Other regions of the body furnish the same number of cancers in the male and female; therefore the disease is twice as common in the latter.

Diagnosis.—The superficial situation of the mammary glands, the frequency with which they are affected with neoplasms of a destructive nature, would presuppose a more exact knowledge of their diagnosis than we can truthfully lay claim to. That mistakes in diagnosis are common, more so than with tumors of any other region of the body, few, I think,

will deny. There are, however, trustworthy data, in so far as they go.

The age of the patient is a valuable guide. In general, young subjects have benign growths and sarcoma, whereas middle and advanced life are most obnoxious to cancer. Malignant growths are by far more common than benign, the proportion being rather more than 10 to 1. During the rudimentary state of the gland, benign growths (usually fibroma) may be encountered. Gross in an analysis of 777 cases taken largely from reports of German surgeons, did not find sarcoma under the fourteenth year. I have seen journal reports of cases in children under 10; one in an infant. The average age of patients with benign growths is rather under 30. They constitute less than 10 per cent. of mammary tumors (9.5).

Sarcomas occur from the beginning of menstruation to the seventh decade of life, the average age being 35 years. They constitute less than 9 per cent. of breast neoplasms.

Cancer has been seen at 21, by Henry, though it is rare under 30. The average age for carcinoma has been placed by Gross at 48. It has been seen after 90.

Villous or duct cancers, according to Roger Williams occur at an average at 53½ years. Cancer claims about 82 per cent. of all mammary neoplasms. Undoubtedly the most valuable guide in diagnosis, is the presence or absence of enlarged lymphatic glands.

For convenience of comparison, we may group sarcomas with benign growths, as the former are little if any more liable to cause enlargement of the neighboring lymphatic glands. Non-carcinomatous tumors cause enlargement of the axillary glands in less than 3 per cent. of all cases. The supra-clavicular glands are never enlarged. The enlargement of the axillary glands is largely due to irritation, and not the result of infection. They are soft and not adherent to the peri-glandular tissues. Carcinoma, *per contra*, practically always causes enlargement of the neighboring lymphatic glands, first the axillary, then the supra-clavicular.

It may be noted here that villous cancer caused enlargement of the axillary lymphatic glands in only five out of eighteen cases seen by Roger Williams, due, according to Labbe and Coyne, to a barrier of fibrous tissue between the cancer and the nearest glands.

In 65 per cent. of all cases the axillary glands are enlarged when patients first apply for relief—an important fact to remember when operative measures are undertaken. The glands are hard, manifest a tendency to coalesce, and soon become adherent to adjoining structures.

Of the remaining differential diagnostic points, the location of the tumor and whether it be mobile or not are the most important. Benign affections as a rule are movable, the malignant soon become fixed. Benign growths are usually located in the upper and inner portion of the gland, while malignant disease is more liable to affect the upper and outer quadrant and to be situated behind the areola. The latter circumstance explains the frequency of retraction of the nipple in cancer. Gross found it in 52 per cent. of his cases, a larger proportion than other observers have seen.

Non-carcinomatous tumors cause a displacement of the nipple in less than 6 per cent. of all cases. In the early stage of breast tumors when any diffi-

culty of diagnosis might be expected, such symptoms as pain, enlarged veins, discharge from the nipple, history of trauma and heredity are practically valueless.

To conclude, age, location of the tumor, its mobility, and the condition of the axillary glands are our surest guides. Doubt as to whether or not a growth is solid or cystic will be settled by aspiration. True cysts are rare, making less than 2 per cent. of all cases. Cystoid degeneration of solid growths is common, particularly so in non-carcinomatous tumors. Cystic degeneration of the acinous varieties of cancer rarely occurs, though it is more frequent in the tubular or villous growths.

An aseptic incision into the tumor for diagnostic purposes is proper, and is advised by Bull of New York, Keen of Philadelphia, and others.

Treatment.—Little need be said concerning the treatment of benign tumors, solid and cystic, as all are practically agreed. They should be removed along with their capsule, and in such a way as to leave the nipple when it is practicable. When a tendency to rapid growth is shown, and the patient is past 40, it is far safer to excise the entire gland, for it should always be remembered that mistakes in diagnosis are common, and in patients of this age the chances are 13 to 1 in favor of malignant disease.

How shall we treat malignant disease, and is it curable? Reports from many distinguished sources during the past year especially, leave little room for doubt that one of the brightest chapters in the history of operative treatment for malignant disease is now being written. The day for pessimism has passed. American operators have so far secured the best results, with the Germans a close second. The English, with whom the complete or radical operation as practiced to-day originated have, strange to say, fallen behind. This is, no doubt, due to the fact that some of their best authorities as Butlin, Treves, Sutton and others have thrown all their influence against radical measures. The writings of these gentlemen have evidently to a great extent fashioned professional sentiment throughout Great Britain.

In 1867 Moore, of London, first advocated the complete operation as it is understood at the present time. He advised thorough extirpation of the entire mamma, removal of the pectoral fascia in all instances, supplemented by cleaning out the axilla. His teaching passed unheeded for a time, but was soon taken up by Banks in England, many of the Germans and Austrians, notably Volkmann, Billroth, Langenbeck, Knüster and others. S. W. Gross, of Philadelphia, was quick to see the possibilities of the radical operation, and was its first champion in this country. I was an interne in Jefferson Hospital during the time he was writing his "Monograph on Breast Tumors," and assisted him in many of the complete operations reported in this work. No one who ever heard him lecture, or saw him operate upon breast cancer, can forget his intense earnestness born of deep conviction, at a time when all of his colleagues—his great father included—to draw it mildly, looked upon him as a misguided optimist. In the lecture room, wards of the hospital, and his own private office, I have heard him say a hundred times that no surgeon however experienced, could rightly affirm that the axillary lymphatic glands were not enlarged, until the axilla was opened and inspected from base to apex. This is now accepted of all men. All honor to this brainy, aggressive, prescient surgeon!

Excellent as were Gross' results—12 to 15 per cent. of cures—they have been improved upon by subsequent workers in this line, aided by more modern methods. The present occupant of his chair at Jefferson, Prof. W. W. Keen, is doing work equal to the best. Weir and Dennis, of New York, each report a series of cases, 125 and 33 respectively, the former getting in round numbers 20 per cent., the latter 25 per cent. of cures. By far the most valuable, instructive and encouraging report up to date is that of Bull, of New York, published in the *Medical Record* of August, 1894. No one has followed up cases so methodically as he has done. Only 3 out of 118 cases operated upon between 1880 and 1894 remain unaccounted for; 115 were followed to their death or to Jan. 1, 1894, when their condition is fully set forth. Excluding cases operated upon since 1891, as a three year limit has been generally agreed upon before a cure can be reasonably claimed, there are left seventy-five cases submitted to the complete operation as defined by Moore. Of this number four died from the operation, two from erysipelas, one from sepsis and one from pneumonia; fifty succumbed to recurrences or metastases; two are living with recurrence; four died of intercurrent affections after having passed the limit, and the remaining sixteen are in perfect health. Counting the four dying of intercurrent disease after passing the limit, there are twenty cures or 26.6 per cent., the best showing yet made by any surgeon. Deducting five cases which should not have been included and Bull has nearly 29 per cent. of cures. Of the sixteen still living it may be said that there has been an average of six years since operation—twice the usual limit.

It is also of great interest to note that 40 per cent. of Bull's cured cases had cancerous involvement of the axillary lymph glands, as demonstrated by microscopic examination. Therefore, a complete operation is able to cure, even after lymphatic involvement has occurred.

This series further shows that where no lymphatic glands are involved, 54 per cent. are permanently cured. This sounds strangely enough, I know, to those who remember that such men as Sands of New York, and Agnew of Philadelphia, each said at the close of an illustrious career in surgery that he had seen no successful case of operation for breast cancer.

Results are getting better, year by year, month by month, almost day by day. The trend is in the direction of a still more complete operation, and the value of it is shown by a brilliant series of fifty cases recently reported by Halsted of Johns Hopkins Hospital. In every case he removes the larger portion of both pectoralis major and minor muscles. He also removes the axillary and supra-clavicular glands in all cases. This seems necessary in a certain per cent. of cases to get beyond the invisible zone.

Volkmann's observation, that infiltration of the muscles sometimes occurs, has been verified by Heidenhain after the most careful investigation. For a time, fortunately, the pectoral fascia arrests the march of cancer.

Willy Meyer, of New York, has proposed an operation even more radical than Halsted's, as he removes all of the great and lesser pectoral muscles from origin to insertion. Both Halsted and Meyer assert that such radical measures add nothing to the dan-

ger of the operation and, further, do not leave the patient with an arm materially less useful. Halsted has reported seventy-six such operations without a death, and with only 6 per cent. of local recurrences. It is too soon to estimate his percentage of cures.

If statistics prove one thing, it is that partial operations should no longer be practiced. They do little good and are almost as dangerous as the complete method—where the axilla is invaded and all glands and fat removed—vessels and nerves only being left behind. The space of Mohrenheim—between the upper border of the tendon of the small pectoral muscle and clavicle—is to be systematically inspected and cleared in every case. If the two pectoral muscles are not removed, the space between them must be carefully examined for outlying gland tissue and fat.

What is the mortality of such operations? Taking the reports of six American operators recently given to us and we find that in 630 operations for cancer there have been 6 deaths. In nearly all of these cases the complete operation was practiced. W. W. Keen reports 200 cases with 1 death. Bull 118 with 4 deaths and Dennis 71 with a single death. Weir, Halsted and Powers have reported series of 125, 76 and 50 respectively, without a death. Curtis gives the average mortality of the leading German surgeons as 6 per cent. though many operations done before modern methods were practiced are included.

The English (Butlin, Treves, Williams and others) place the mortality as high as 10 per cent. This can only be reconciled with the rather less than 1 per cent. of six American surgeons, on the score of many operations being included which were done at a time when breast excision was properly ranked as a dangerous measure. Erysipelas, sepsis, secondary hemorrhage, etc., claimed their victims by hundreds. The matchless Billroth years ago admitted a death rate in his own practice of 23 per cent.

We can only contemplate such figures now with feelings akin to horror—as an aseptic operation in skillful hands is to-day practically devoid of danger. We conclude with the following summary:

1. Mammary cancer, submitted to operation before infection of the axillary glands, should promise 50 per cent of cures.
2. Although the axillary glands seem not to be involved, the axilla should be opened in every case and thoroughly cleared of glands and fat.
3. Infected axillary glands are of bad prognostic import, but a radical operation which removes them and at the same time the supra-clavicular glands may cure 11 per cent. of such cases.
4. The complete operation should be practiced in every case of malignant disease.
5. The mortality following the complete method is doubtless somewhat greater than it is in partial operations. The difference in results, however, is so conspicuous when the question of "cure" is considered, that the radical operation is the only one to be countenanced.
6. Statistics gathered many years ago are as valueless as those made use of in estimating the mortality after amputation of the extremities.
7. The mortality will probably be not more than 2 or 3 per cent. with the average operator. We have shown it to be less than 1 per cent. in over 600 cases operated upon by six American surgeons.

EXTIRPATION AND COLOTOMY IN CASES OF CANCER OF THE RECTUM.

Read in the Section on Surgery and Anatomy, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY LEWIS H. ADLER JR., M.D.

PROFESSOR OF DISEASES OF THE RECTUM, PHILADELPHIA POLYCLINIC AND POST-GRADUATE SCHOOL; SURGEON TO THE CHARITY HOSPITAL, AND TO THE OUT-PATIENT DEPARTMENT OF THE EPISCOPAL HOSPITAL, PHILADELPHIA, PA.

Colotomy and extirpation are two recognized procedures for the relief of malignant disease of the rectum. Both operations offer to the patient a chance of prolonging life; and, in addition, extirpation holds out the possibility of effecting a radical cure, in selected cases.

The choice between these two methods is a question of uncertainty only in a relatively small group of cases, and extirpation is not to be considered in the majority of instances, for the reason that the disease is usually an incurable malady, and by virtue of its concealed position within the rectum its presence is not revealed or even suspected until the growth has existed for some time. Furthermore, it is rare for cancer of the rectum in its incipiency, to manifest itself by any symptom pointing to a lesion within the bowel. This is a familiar observation to all surgeons.

It frequently happens that a patient comes to us complaining of some slight diarrhea or other mild rectal trouble, and an examination unexpectedly reveals the fact that cancer is present to such an extent that it is obvious the neoplasm has existed for a considerable period. Consequently, its complete removal is often rendered impossible. Again, the patient's vitality is such that so grave an operation and one requiring the length of time for its performance, as an excision, is contra-indicated.

In arguing thus, I would not convey an impression that I am opposed to extirpation for malignant disease of the rectum in suitable cases; on the contrary, I firmly believe it to be a perfectly justifiable operation when the growth is circumscribed and confined to the lower five or six inches of the bowel; provided, however, that the tumor does not involve all the coats of the intestine, that it has not attacked the viscera which are intimately associated with the anterior wall of the rectum, that it has not invaded the pelvic glands, or, by metastasis any of the other organs of the body, and finally, that its growth be not rapid or have a tendency to spread widely. From these considerations, it naturally follows that the number of patients who can be benefited by excision of the disease is comparatively small.

Colotomy, on the other hand, is indicated in a large number of instances, where it is quite impracticable to attempt an excision. The advantages of the operation lie partly in the relief it affords to symptoms and partly as a means of retarding the growth of the neoplasm.

To indicate the relief afforded such patients by a colotomy, I can not do better than quote the opinion of Kelsey on this subject as, expressed in the fourth edition of his work: "Diseases of the Rectum and Anus."¹

This authority is not only a strong advocate of the operation, but is also in a position to judge of its merits by reason of his large experience. He thus states his views: "As to the benefits arising from the

¹ Pp. 409 and 410.

operation, too much can scarcely be said. That it prolongs life by the relief of pain, the preventing of obstruction, and retarding the growth of cancerous disease is beyond question. That it substitutes in many cases a painless death for one of great agony is indisputable. The idea that it is as well to let a patient die as to subject him to a colotomy has no supporters among surgeons who have had any experience with these cases. Indeed, I think that the practitioner who to-day sat by and allowed a patient to die of obstruction because of any sentiment against this procedure would hardly be held blameless. I can only say that, after trying every other means of treatment and being obliged to admit the fruitlessness of them all, I have come, with most others, to admit the great benefits of colotomy, and *have never performed it in any case in which either the patient or myself has afterward regretted it.*" (Italics mine.)

In another article,² Kelsey mentions even more minutely the advantages of this operation, as follows: "Colotomy, especially inguinal colotomy, relieves pain; does away with the constant tenesmus and discharges from the rectum, which by their exhausting effects are the immediate cause of death; delays the development of the disease by preventing the straining and congestion of defecation; prevents absolutely the complication of intestinal obstruction, which is another cause of death; enables the patient to sleep, eat and gain flesh, and often makes him think himself cured in spite of the plainest prognosis to the contrary. Instead of passing his days and nights upon the commode, wearing out his life in the effort to free the bowel from its irritation, he has one or perhaps two solid fecal evacuations from the groin in twenty-four hours."

In conclusion, I would like to allude to one more topic, to-wit: the choice of sites of opening the colon. I mention this subject with the sole purpose of eliciting the present views of the members of this society. My own belief is that the inguinal region is to be preferred in the majority of cases. Its advantages over the lumbar operation are, to my mind:

1. The smaller incision and lesser depth of the wound requisite to reach the colon, and the minimum amount of disturbance of the structures overlying the seat of operation;
2. The greater facility offered for the exploration of the abdomen, when such a procedure is required;
3. The better position for safe anesthesia, during the operation;
4. The comparative ease with which the colon may be identified in this position, and the little difficulty experienced in fixing the bowel to the skin without undue tension on the stitches;
5. The greater readiness with which a good spur may be formed;
6. The convenience to the patient of the site, for purposes of cleanliness and for the adjustment of pads; and
7. The recent statistics seem to indicate that it is the less dangerous operation.

1610 Arch Street.

Influenza and Life Insurances.—At a meeting of one of the large English insurance companies it was shown that more than six hundred thousand dollars had been paid out for deaths due to influenza. The report of the Secretary showed that this disease has cost the insurance companies more in the last two years than in the previous forty-three years.

IS TOTAL EXTIRPATION OF THE RECTUM EVER JUSTIFIABLE?

Read in the Section on Surgery and Anatomy, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY JOSEPH M. MATHEWS, M.D.

PROFESSOR OF SURGERY KENTUCKY SCHOOL OF MEDICINE, ETC.,
LOUISVILLE, KY.

In giving the above title to my paper the fact is indicated, at least, that such a procedure is advised, and I may add, is strongly recommended by many. With true deference to all such, I shall raise the question as to its justification, and will try to adduce sufficient reasons for putting the question in the attitude of being mooted. It can not be gainsaid that some, if not many surgical operations, are done with but little to recommend them. In this age of progress in surgery, I opine that some of us are led astray into doing operations as much to test the efficacy, methods, etc., of others, and to put ourselves in line, as to accomplish that which should be the surgeon's chief aim, viz., to relieve the patient. It can not be denied either that there is what might be properly called a *rage* in surgical work, and it behooves us as surgeons to occasionally take a breathing spell, and look backward over the field, if not over the dead. I am quite willing to admit that conservatism in surgery may oftentimes mean early and complete operations, but it must be admitted that he is the best surgeon who has studied well his subject from all standpoints and is ready for any emergency.

To operate or not to operate, is often the question, and much responsibility rests on the decision. If the eager, ambitious, aspiring young surgeon could have in his time of need, the advice of his cooler-headed elder brother, who has met with many a danger, what a blessing! We are much given in this country to copying after our European brethren, even to their vagaries, in both medicine and surgery. New instruments, new operations, new books, new everything, is the cry with us, and we don't stop to think whether they are any improvement over the old or not. Oftentimes, too, the *original* operation is far preferable to the so-called modification of the same. With these remarks as a preface, I desire to call your attention to the question propounded in the title of my paper, Is total extirpation of the rectum ever justifiable? Very naturally you will say, Why, I thought that question had been settled, and that most authors recommended such an operation under certain conditions. You might add in truth that Mr. Kraské had designed his operation especially for this purpose. To both propositions I answer, quite true. But in the same breath I would beg to ask, Is the operation justifiable? An operation might be designed which would demonstrate the fact conclusively that the liver could be easily and dextrously removed. There are two propositions that I would submit for argument in reasoning against the advisability of the total extirpation of the rectum for any cause:

1. Is the patient ever cured of the trouble operated for, by said operation?
2. Is the patient ever materially benefited or relieved by the operation?

I beg to take the negative to both propositions.

1. I take it for granted, that the only cause for which it could be said that total extirpation of the rectum should be practiced is malignancy. I use the term here as synonymous with cancer. We note,

then, the characteristic features of malignancy as: the disposition to grow, to ulcerate, to infiltrate and to propagate. It is an aphorism well known in surgery, in cases of cancer, "to operate early if you desire success." All teachers too, know how assiduously they teach the student to do a *thorough* operation, and "cut wide of the mark," whenever dealing with this character of tumor." For instance, when removing malignant growths of the breast, how important it is, we say, to remove the glands in the axilla also. Again, how insidiously does a malignant tumor invade the system, and establish a cachexia. How difficult to tell the dividing line between a local condition and a general infection. Add to this the suspicion always that the tumor has likely propagated.

These questions are difficult of solution, even when the growth is situated in or upon the external parts. How much more difficult when located in an obscure part of the anatomy as is the rectum. Cancers found here are so stealthy in their growth and invasion of tissue that oftentimes the whole rectum is blocked by the mass, when only symptoms of constipation and some reflex pain are complained of. The tissues surrounding this portion of the gut are soft and easy of invasion; the blood circulation is great and the lymphatics are freely distributed. The contiguous parts are vital ones; the bladder, the peritoneum, the prostate gland, the vagina, in the female, are all easy of invasion. By the time that a growth in the rectum has assumed sufficient proportions to be diagnosed as cancer, many of these parts are already invaded by the process of infiltration. To dissect and draw down the rectum in the normal state may be comparatively an easy matter, but to completely dissect out a rectum that is so pathologically changed, as in a cancerous growth, is nearly a physical impossibility. Beside the difficulty of accomplishing its free dissection, it is one of the bloodiest operations that I have ever attempted. Admit that it can be successfully done, I would ask what amount of good accrues to the patient? Infiltration is clearly proved by the amount of adhesion that is witnessed. Can we, now, "cut wide of the mark?" I believe that every surgeon present will concur in the opinion that to make the operation complete, all glands in the inguinal region should be removed. But what about the infiltrated tissue left in and around the rectum? It does not require very much dissection to draw down the natural gut. Sever its connection at the anus, and it can be pulled down. But it requires a long, tedious, and free dissection to remove the cancerous rectum. What, I again say, shall we do with the injunction to "cut wide of the mark?" It can not be done without invading with the knife the vital parts mentioned, nay not then. Then of what use is the operation? A bloody procedure, rectum gone, and infiltrated tissue left. Would any sensible surgeon dissect out a cancer in the breast and cover the wound with infiltrated flaps? Why, then, should a surgeon dissect out a cancer of the rectum and leave infiltrated tissue? How can he prevent it, or how is he to know that infiltration into the adjacent tissues has not taken place?

It is nearly self-evident from the clinical history of all these cases and from the pathologic changes, that such condition does exist. A cancer of the rectum in its incipiency is very difficult to detect, and is rarely seen by the surgeon in this stage. If it invades the anal orifice first, this rule does not hold

good, but no surgeon is likely to remove the entire rectum for a growth at the anus. It must be admitted that it is in the incipient stage of cancer that an operation would be most justifiable. And yet for a nodule along the course of the rectum, any surgeon would hesitate about removing the whole rectum. Then if it is not justifiable to totally extirpate the rectum for a circumscribed or incipient condition of cancer, is it justifiable to remove the same after adhesions, infiltration and a cachexia has been established. When, I would ask, is total extirpation of the rectum justifiable?

All malignant growths affecting the anus first should be removed, if seen at the proper time. If a growth of this kind is situated in the immovable portion of the rectum, and has not extended higher than this, or has not invaded vital structures, the surgeon can remove it, observing the injunction to "cut wide of the mark." But this is a very different thing from removing the entire rectum and that, too, when no promise can be given. I have written this paper after a fair trial of all methods proposed for the total extirpation of the rectum. But as I have usually seen these patients go on from bad to worse, I must confess that some remorse of conscience has overtaken me when the question stared me in the face, why I did so formidable an operation, when in truth there was no good surgical reason for doing it. This is an unfortunate class of patients, the most unfortunate of all, and they do indeed catch at straws. They need our fullest sympathy, and nothing less than a firm conviction that we can either cure, or materially benefit them, should lead the surgeon to do so radical an operation as the total extirpation of the rectum. Can we promise either? I think not.

THE CAPACITY OF MEDICINE.

The Doctorate Address to the Graduating Class of the College of Physicians and Surgeons, Chicago, April 2, 1895.

BY WM. ALLEN PUSEY, A.M., M.D.

PROFESSOR OF DERMATOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO.

The man is fortunate who has a high conception of his life work. In this respect, at least as regards the humanitarian aims of his profession, the doctor is usually fortunate. I believe it is the rule that the doctor has a conscious pride in the high purposes of his profession; I believe it can be said, without exaggeration and without straining the truth, that the doctor usually approaches his work with a realizing sense of his duties and of his heavy responsibilities. Often—oftener I believe than most men—he is animated by lofty ideals and sustained in a career of heavy responsibilities and, perhaps, unrewarded endeavors by the approval of his own conscience for doing, as well as in him lies, the work that comes to his hands. I believe, too, it can be said with truth, that he does not usually have to depend upon the approval of his own conscience for his sole reward. For the world at large is usually ready to applaud him for his good work and to praise him for his charity and his humanity. In fact, excepting here and there a soured pessimist or a fanatical anti-vivisectionist, who would cast upon us all the anathemas of the damned because we sometimes kill dogs and guinea pigs in order to save babies—excepting these, I say, I believe the world in general gives us credit for high purposes and for untiring efforts in behalf

of mankind. Indeed, one sometimes fears that they emphasize the goodness of our intentions and our charity and benevolence, because they feel that in these they have the safest grounds upon which to praise us; just as at times one calls a man a good man, when little else can be said in his favor. For it is undeniable that medicine has to stand a good deal of patronizing and condescension, particularly from people who imagine themselves progressive and from those workers in other departments of science, who, knowing only their own fields, imagine that they possess all there is of scientific merit. Every once in a while some innocent seeker after truth wants to know, "If medicine is a science?" We are reminded of the advancement of other arts and sciences in this century, and are asked in a hopeless sort of way if medicine has anything to offer commensurate with these. We are not allowed to forget that medical opinions have changed from time to time; that the doctrines of one period have given way to different doctrines of another; and that even now doctors disagree; just as if these things were the unique characteristics of the medical profession. And the intimations are not uncommon that medicine, while perhaps advanced in theoretical knowledge, is behind in practical realization; that, to paraphrase Montaigne, it has always known its Galen, but does not yet know its patients; that it has always been full of fruitless promises, but has given to the world little of useful results or of stable truths of practical value.

This mild and perhaps well-meaning skepticism is widespread, and finds expression in various forms. It is not enough to say in reply that the most cursory consideration demonstrates the falsity of such statements; or that scientific medicine is too strong to be affected by the impressions of the half-educated or the judgments of the inexpert. The man, who is in touch with his surroundings, can not be insensitive to such influences, and I question if the doctor is fortunate in his complacency who has not at some time asked himself how much justice there is in these imputations. Indeed, the doctor who starts out with enthusiasm for his profession and with high conceptions of its usefulness will probably, for his own satisfaction, do well to ask himself the questions to which such aspersions give rise. And to ask ourselves these questions now: What, really, is the position of medicine? Can medicine pretend to stand on an equal footing with the other physical sciences? Is it worthy of a place beside chemistry, or physics, or mechanics, as a science, or beside electrical, or mechanical, or civil engineering, or manufacturing chemistry as a technical profession? Or, to put it practically, can medicine show any solid contributions to useful knowledge in the last hundred years comparable to the much vaunted contributions of steam power, of electricity, or of mechanical invention? Has medicine shown in the past, or does it show now, an ability to meet its obligations and to fulfill the demands upon it equal to that of the other arts and sciences? And now on the verge of this twentieth century, can medicine pretend to prospects of usefulness and development as promising as those of any other of the physical sciences?

These questions suggest themselves with more or less distinctness to all of us at times, and it may not, therefore, be unprofitable to consider for a few minutes the position and the capacity of medicine as shown

in its course in the century now drawing to a close.

The nineteenth century, in respect to the progress of the physical sciences and the development of useful knowledge and inventions, is a period marvelous to contemplate. When one reviews in his mind what had been done in these departments of knowledge before 1800, and what has been done since, he finds it difficult to characterize the period without apparently indulging in the grossest hyperbole and exaggeration. The wildest imagination of a hundred years ago could not have faintly conceived the progress which this century would witness. This century has, in fact, reaped the harvest of the Renaissance. Perhaps it would put it more accurately to say that this century represents the entrance of the physical sciences into their period of adult vigor. All that had gone before, since the revival of learning—and practically nothing before the revival of learning is of any consequence in the physical sciences—represented the period of preparation.

At the end of the last century the times were ripe for advancement. Awe of tradition, even respect for the established order of things had vanished. Revolution was in the air. The spirit of unrest and of independence, of rebellion against privileged classes and arbitrary authority that had begun with Luther in religion and Galileo in science, that had driven the Puritan pilgrims to America, and had produced a Cromwell in England, had finally resulted in an American rebellion, and the establishment of a government by the people; and had reached its climax in the awful upheaval of riot and license of the French Revolution. The established order of things had lost its sanctity. Men were ready to prove all things, but to take nothing on faith or on tradition. And that is the true spirit of science. And, moreover, science and art suited the spirit of the times, in that they represented an aristocracy of intellect in contra-distinction to an aristocracy of birth. The times were, in fact, as ripe for a revolution in knowledge as they were for the civil and social revolutions that were occurring.

And yet one at that time, looking for indications of the future, would have found little positive material on which to foretell the advancement of this century. Of the pure physical sciences, astronomy was the only one that had reached a condition of anything like completeness. Of the broad generalizations that are at the same time the glory and the very foundation of physical science none, except Newton's law of gravitation had been worked out. Laplace was just indicating the fascinating but uncertain hypothesis of the nebular origin of the solar system. Dalton had not yet enunciated the atomic theory, upon which modern chemistry has been built. Schwann had not yet demonstrated the cellular structure of vegetable and animal tissues, which is the very basis of modern biology. And more than half the century was to pass before Darwin promulgated the doctrine of natural selection, which has given to the world a new conception of the order of development of living things. Perhaps the most important generalization of physical science, Joule's law of the conservation of energy, which permeates every conception of modern science, was to wait for its enunciation until after the middle of this century. Newton's corpuscular theory of light and the conception of heat as due to a vague "caloric" still prevailed. These facts in their bare statement convey no im-

pression of their momentous importance. Unverifiable hypotheses, as some of them are, they are nevertheless the very foundation of modern science; and the times when they did not exist are times in science that you and I can only realize by a strong effort of the imagination.

And if pure physical science, as we know it to-day, was thus undeveloped the mechanical arts and the practical applications of science to the uses of civilization, which are the peculiar characteristics of our times, were even more so. Watt had but recently made the steam engine into a practical servant of man and its usefulness was not yet established. The first steamboat had not been built; and as for railroads, the memories of men now living take them back to the time when Stephenson's "Rocket" demonstrated the practicability of a steam locomotive. The spinning-jenny, the automatic power-loom, the cotton-gin of Eli Whitney—these three fundamental inventions, which have rendered possible the vast textile industries of modern times—had just been invented; and that other boon of laboring women, the sewing machine, was not to come for fifty years. The electric telegraph had hardly been thought of, and its invention was away in the future; and as for the possibilities of submarine telegraphy, of electric lighting, of photography, or of transmitting the human voice by electricity, who could have dreamed them a hundred years ago?

A hundred years ago men were, in fact, as regards mechanical inventions, much in the same place that they had held from the earliest civilization. They cleaned their cotton and carded their wool; they spun and wove and sewed; they harvested and threshed their grain; they lighted their houses; they sent messages, and traveled by land and sea, in practically the same ways that men had done a thousand or two thousand years before. The list in fact could be indefinitely continued. All the inventions of mechanics; all the applications of physical science to the uses of man, that have made the forces of nature man's servants, that have made intelligence dominant over force, that have welded the civilized world into a sentient whole, with community of interests and community of knowledge; all these, with few exceptions, are the inventions of this century. Could anything be more marvelous than this progress? If medicine had not kept pace with the other departments of physical science in this century would it be a reproach, considering the infinitely delicate and confusing problems which biology and pathology and medicine proper have to solve? But has that happened? Has medicine been outstripped by the other sciences in the nineteenth century? Can medicine, in fact, stand in a free and open comparison of this sort, or must it enter such a contest with excuses and apologies, and with such humility as befits the poor relation of a prosperous family? It requires, perhaps, a reckless degree of temerity to attempt such a question, but let us, as best we can, consider it for a little while.

At the end of the last century, medicine was able to give a good account of itself. The pressing necessity of getting relief from pain and disease had started medicine on a career of usefulness before most of the physical sciences were born. It could point to a history of investigation and of development along the best lines of knowledge of its times, as old as the revival of learning. Beginning with

pioneers in scientific research like Vesalius and Ambrose Paré and Harvey and Sydenham it had come down through a line of great observers to such masters as Petit and Bichat and the Hunters and Percival Pott and Jenner. Through the labors of a long list of such men, medicine could fairly claim—in actual achievement and in positive knowledge—a position among the physical sciences as good as any. Gross anatomy, after infinite work, had been brought to a state of practical completeness. Surgery, at its beginning an appendage of anatomy, had attained a degree of skill in which it could claim to meet the reasonable expectations of its times. Operative surgery was highly developed. The great operations have come later, but the ordinary surgical procedures—amputations, the treatment of fractures, the ligation of arteries, and like surgical operations were carried out with intelligence and technical skill. And better than that, men like John Hunter and Pott and Desault and John Bell, were studying the pathologic processes at the bottom of surgical conditions, and were developing a practice of surgery founded upon principles—were indicating the way to a rational practice of surgery, in which surgical procedures would be carried out in the light of a correct understanding of underlying pathologic conditions. In medicine proper the phenomena of disease had been accurately observed and recorded; systemization and classification on a clinical basis had been well done; and diseases had been studied carefully and philosophically for two centuries. Most of the diseases which we recognize now as clinical entities had been differentiated and well described; and the best lines of their management in the light of existing knowledge had been carefully considered. Pathology had been founded by Morgagni, and physiology had made a correct start under Haller in the middle of the eighteenth century.

But the enumeration can not be carried much further. The science of medicine as we know it now, built upon accurate data obtained with instruments and by methods of scientific precision, did not exist. Without any adequate conception of the functions of the various organs; without knowledge of the microscopic anatomy of diseased tissues; without accurate instruments for the investigation of the various elements of disease, medicine, as we know it now, could not exist. What, for instance, could be known of the composition of body-secretions when Priestly had only just discovered oxygen, and fifty years before Liebig and Wöhler had indicated the possibilities of organic chemistry. There was no adequate knowledge of the functions of any of the organs. Schwann had not yet indicated the ultimate cellular structure of animal tissues. Charles Bell had not demonstrated the difference between motor and sensory nerves. Marshall Hall had not discovered the reflex functions of the cord. And Claude Bernard, who was to discover the vasomotor system of nerves, and demonstrate their enormous importance in the nutrition of the tissues, was not yet born. Bichat had just indicated the possibilities of pathologic and normal histology. His superlative genius had carried the subject probably as far as the appliances at his command would allow—for the microscope when Bichat died in 1802 was little better than a toy—but in spite of such geniuses as Bichat and Morgagni before him, a real science of pathology, a thorough-going investigation into the pathology

factors of any disease, did not exist, could not exist in the very nature of things. As for exact methods of studying disease, there were none. Physical diagnosis had not been discovered. Auenbrugger had discovered percussion as a means of diagnosis fifty years before, but no attention had been paid to it. Laennec had not yet given to the world the method of auscultation or the stethoscope; and as for the other instruments of precision in physical diagnosis, the ophthalmoscope, the laryngoscope, even the duck-bill speculum, and all the minor instruments of diagnosis were as yet unheard of. On the practical side, obstetrics was still in the hands of midwives; and to any one who knows the horrors of ignorant midwifery, could there be a more beneficent example of progress than obstetrics to-day presents? Surgery, in spite of what it had done, was still merely operative; it could only cut off what it could not cure. It was hopelessly handicapped; it could not annul pain during operations, and it could not prevent the ravages of septic infection after operations. In therapeutics all was of necessity dark. The lancet, the purge, and the blister were the main reliances. Excepting opium, all the list of invaluable remedies that soothe the body and relieve pain; all the alkaloids that make exact medication possible are the products of this century. Morphin and chloroform and ether, chloral and the bromides and, of course, all the synthetic anodynes, quinin and the iodids, and salicylic acid, aconite and ergot, corrosive sublimate and carbolic acid are all the products of a later time.

That was the condition of medicine at the end of the last century. It needs no prolonged comment to point out the contrast between medicine then and medicine to-day. In the century that has passed medicine has put itself in such a position that it can attack any question of disease that confronts it with intelligence and with a clear appreciation of the problems that must be solved. All of the fundamental subjects, upon which the existence of rational medicine depends, have been worked out to a condition of nearly satisfactory completeness. The work in none of them is ended, for science is never done, but it can be said, in full view of the facts, that only minor details are to be worked out in the fundamental branches of medicine. Physiology has established with certainty and precision the functions of the body. We have definite and almost complete knowledge of the conditions of the tissues in health and in disease. The processes of pathologic anatomy that underlie diseases have been so thoroughly worked out that only rare and extraordinary conditions remain to be investigated. Physiology, biology, normal and pathologic histology are in a state of practical completeness. The minor problems that they have yet to solve merely indicate the high state of knowledge which these subjects have reached.

Clinical medicine is in a position of definite knowledge. The natural history of disease has been worked out with an accuracy that could not have been foretold. Symptomatology, it may be said without exaggeration, and the differentiation of diseases and groups of diseases have been so sharply and clearly marked out that little more can be expected. But medicine has gone further than this. As is the case in any kind of research the consideration of one set of problems has suggested others; and medicine has solved, and is solving, problems of the most momentous importance to mankind that were beyond the

scope of the imagination a hundred years ago. Medicine is obtaining an insight—and not a speculative insight, but a positive insight based on sensible fact—into the intimate causes of disease that no man could have foreseen even fifty years ago. Medicine has gotten to the point where it can say of many important diseases—and the list is rapidly increasing—“This is the cause of the disease; without it the disease can not exist.” And it can not only affirm that these are the essential causes, but it can take these essential causes and separate them and study them apart from the diseases which they produce; can accurately work out their life-histories; can carry them through generation after generation of pure cultures; and can then complete the demonstration of their essential causal relationship by reproducing the diseases from their pure principles. What a contrast to the times when men were seeking a universal explanation of disease in plethora, or in congestion, or in any other of the indefinite conceptions with which they juggled in the eighteenth century! And medicine is doing even more than this; it is not only demonstrating these positive causes of disease, but it is separating from them the principles which are the source of their pernicious activity. It is studying these elementary causal principles and already, with positive assurance, is indicating the methods by which their effects can be overcome. There is no science that can show more brilliant investigations than these.

These investigations—in themselves purely scientific—have already borne results of almost inconceivably great practical value. The demonstration by Lister that the formation of pus is caused by the presence of microorganisms and that it can be prevented with mathematical certainty by their exclusion—this demonstration, which resulted in the founding by him of antiseptic surgery, has probably done more for suffering humanity in twenty years than all the uncertain charities of twenty centuries. It has made curative surgery practicable; it has shorn child-bed of its greatest danger; it has banished erysipelas and hospital gangrene from surgical wards; it has relieved the wounds of the battle-field of the dangers and tortures of septic infection—that specter of surgery that probably killed more men in our Civil War than all the bullets of that unhappy time. And Lister's application of bacteriology is but one example of what has been done. Cholera and yellow fever visit us no longer. With proper precautions no man need have typhoid fever—and a hundred years ago typhoid fever had not been described. Lockjaw is under our control; and hydrophobia is robbed of its victims. Proceeding along lines not bacteriologic, medicine has overcome myxedema; it can practically call back to health the obtunded victim of that miserable disease. It can even bring the sporadic cretin to a condition of passing intelligence; and certainly there is no object that would seem to be further beyond the possibility of medical skill than the hideous, drooling, idiotic dwarf, who is the victim of congenital myxedema. And we are not confined to these spectacular instances for illustration of what medicine can do. Medicine can claim to-day to take hold of disease with an accurate knowledge of its natural history and of the underlying conditions that produce it; and on a basis of such knowledge, if it can not do the impossible and prevent what has already occurred, it can claim to manage disease with a clear appreciation

of the conditions to be met and of the contingencies to be provided for. Can any science do more? Could any more be expected?

Medicine, indeed, has reached a position of positive achievement, in which it can court comparison with any of the arts or sciences. And it now stands in a position of promises almost realized that offer to suffering humanity benefits almost beyond comprehension. Huxley in 1887, writing upon the advance of science during the Victorian era, in speaking of medicine, said in words that sound now almost prophetic: "One century since, smallpox was almost as great a scourge (as the plague). Science, though working empirically and almost in the dark, has reduced that evil to relative insignificance. At the present time, science working in the light of clear knowledge, has attacked splenic fever and has beaten it; it is attacking hydrophobia with no mean promise of success; sooner or later it will deal in the same way with diphtheria, typhoid and scarlet fever." The spirit of Huxley's prophecy is being fulfilled as regards many diseases. As regards diphtheria, it looks now as though the prophecy was already fulfilled. There is a good deal of reason to believe now that diphtheria has been conquered. And to the man who has seen the ravages of diphtheria, what greater evidence could there be of the advancement and capacity of medicine than the fact that medicine is to-day in a position in which it can seriously hope to produce a specific for that dreadful disease.

Can there be any question of the capacity of a science that has such achievements as these to offer? Has any other department of knowledge done better? Can electricity even, with its marvelous history show results any more startling? It would seem indeed that the branch of knowledge that has produced modern physiology and biology and pathology, that has discovered the essential causes of tuberculosis and leprosy and cholera, that has given to the world such men as Helmholtz and Virchow and Koch and Joseph Lister and Joseph Leidy—it would seem that that branch of knowledge would need no defense against the charge of being unscientific. It would seem, too, that that same science, that began the century with a discovery that has practically banished smallpox from civilized communities, and is ending the century with discoveries that promise to give us control of some of the worst scourges that afflict mankind; that has given the world immunity from pain under surgical operations, and has produced antiseptic and conservative surgery; that has banished from us scurvy and cholera and yellow fever; and that, on a basis of accurate physiology and pathology, furnishes a rational treatment of disease—it would seem that such a science would no more need a defense against the charge of being impracticable and barren of useful results.

Indeed, I believe we may be pardoned for thinking that medicine is not the poor relation of any scientific family.

103 State Street.

The Chicago Department of Health issued, in June, a circular on the care of infants and young children in hot weather, which can be had in quantity by physicians, at that office. It gives directions regarding food and cleanliness that in many instances will be of value and assistance to the physician and is intended for distribution to the laity.—*Chicago Medical Recorder*, July, 1895.

REPORTS ON TYPHOID FEVER CONTINUED.

NO. VIII.

Read before the Ohio State Medical Society, Columbus, Ohio, May 17, 1895.

BY JOHN ELIOT WOODBRIDGE, M.D.
YOUNGSTOWN, OHIO.

(Continued from page 59.)

Dr. E. J. March, of Canton, Ohio, sends me the following letter with the charts, which are marked, "Dr. March's Cases, Harry W., and Sadie J."

"CANTON, OHIO, April 26, 1895.

"Dr. J. E. Woodbridge,

"Dear Doctor:—An apology is due for my long delay in giving you the reports of some of the cases of typhoid fever which I have treated with the medicine you furnished so kindly. I have simply postponed it from time to time, till this P.M., I saw a report of your cases in P. D. & Co.'s 'Therapeutic Notes.' Inclosed find detailed treatment and temperature charts of two cases. The first of them, Mr. W., was to my mind a typical case. The second Miss J., a trained nurse, came from a family all of whom had typical and severe attacks, at which place she contracted the disease. She came back to Canton and asked me to give her the 'Woodbridge treatment,' as she had nursed my first case, and was much taken with the results obtained in it. By-the-way, she

Dr. E. J. March's case. Harry W.; age 25 years; native of United States; occupation, tourist. Diet, milk. Treatment, "Woodbridge's." Result, cured.

had had large experience in the New York hospitals in nursing typhoid. You will see the results as per charts inclosed. I had two other cases as well marked and typical as these two; but both being in non-professional nurses' hands no notes or charts were kept, but they were convalescent in ten days' time. The one, a woman about 30 years old, had come from the bedside of her brother who died of the disease; and she started in with a severe attack. I am sorry I did not keep such a record as I could, myself, so as to add water to your wheel. I have a friend here who has tried the plan of treatment, somewhat modified, and says that the objection he has to it is that whereas he formerly made from \$20 to \$40 out of each case of typhoid, this cuts his bills down to less than \$10 in each case. Doctor, I feel sure that you are on the right track, and if we should have a run of fever in our hospital wards this fall, I will furnish you with some more charts and results. Thanking you again for your courtesy,

"Yours very truly, E. J. MARCH."

I will now present from my own practice a few cases which ran a course similar to that of Dr. Cunningham's Case No. 3, with the exception of the unfortunate accident of the intussusception. These cases represent not only most careful and positive diagnoses from the clinician's standpoint, generally verified by one or more physicians; but every pre-

Dr. E. J. March's case. Sadie J.; age 24 years; occupation, trained nurse; residence, Canton, Ohio; date of admission, October 13, 1894. Diet, liquid. Result, cured.

Case 101.—Miss Ellen H.; age 20 years; date of admission Jan. 30, 1895.

caution has been taken to reduce the errors of diagnosis to a minimum by calling to my aid every known means of excluding mistakes. The diazo-reaction described by Ehrlich, and the microscope were appealed to, and in a large number of cases where malarial fever was suspected or had been diagnosed, careful search was made for Laveran's hematozoa.

Case 106.—Mrs. McC., aged 70 years. Was a feeble woman and one of five typical cases in one house. When I first saw her on February 7 her temperature was 105 degrees, pulse 140. Although she was reported to have been sick only five days she was delirious; her bowels were very tender; there was considerable tympanitic distension; rose-spots were abundant; her tongue was thickly coated, dry and brown. Her temperature, as you will see, had dropped to 99 degrees; her pulse 96 on February 13, after which her temperature was not taken; in a few days she was able to be about, and at the end of a week more she was able to be out of doors.

Case 101.—Lenore S., aged 27 years (daughter of Case 106), residing in the same house with her mother. When I first saw her on January 14, she had a temperature of 103 degrees; pulse 120, and all other symptoms of typhoid fever as characteristic as were those of her mother. A few days later, January 17, her temperature was 100, pulse 100, and the general condition was so much improved that I have no record until January 21, when the temperature had been reduced to 99.8 and the pulse to 96. I saw her the last time on the 26th, and she was out in a week.

Case 101. Lenore S.; 27 years; date of admission Jan. 14, 1895.

Case 108.—Carolyn S., aged 2 years (daughter of Case 101). She was far from well on February 7, when I was called to see her grandmother, and on February 9 had a temperature of 105.2 degrees. She was discharged cured on the 16th after nine days of treatment.

Cases 107 and 109.—Katie McC., and Jerry McC., aged respectively 5 years and 23 years (granddaughter and son of Case 106). These cases both showed decidedly characteristic symptoms of the disease, but recovered so rapidly that no records were kept.

Case 115.—John O'L., aged 28 years. This young man was taken sick on March 1 and was treated by an irregular practitioner who called two other physicians in consultation after the patient had been ill twenty-two days, during which time (according to the statements of the family) a diagnosis was made of la grippe, malaria, pneumonia and, finally, of pneumonia with typhoid malaria. On March 22, an unfavorable prognosis was given and I was sent for. I found a typical case of typhoid fever, complicated with pneumonia. His temperature was 103 degrees, pulse 118, and dicrotic; condition of nervous system very bad; he was sleepless and delirious; abdomen was covered with rose-spots; tympanitic distension enormous; bowels very tender; tongue very dry, brown and cracked; he was spitting blood and had three intestinal hemorrhages. On March 25 his temperature was 104.7. However, his condition improved rapidly indeed, he was sleeping naturally, without hypnotics, on the second night, when he was no longer delirious. Within three days his abdomen flattened out; the tympanites disappeared; his appetite returned and he declared that he was gaining strength on a milk diet. On April 1 and the following day,

the temperature being normal, he was discharged, cured. Dr. Cunningham, who is much interested in the abortive treatment of typhoid fever, saw the case with me, for the purpose of watching the effect of the treatment. He pronounced it wonderful.

Case 120.—Mary O'L., (sister of Case 115, John O'L.). I was called to see this case on April 24, and was given the following history: she had nursed her brother through a very severe attack of the fever a month before. During the latter part of his illness she had severe headache and general malaise. About two weeks before I saw her, her headache increased; her back and limbs ached; she became dull and apathetic, and as her mother expressed it: "Could hardly drag one foot after the other; she who was the most active and energetic of all the kith and kin." At this time she took the residue of the medicine I had left for another sister, whom I supposed was taking typhoid fever (from which the sister recovered at once) after which she felt quite well for several days. Six days before my first visit, the headache returned; the back and limbs began to ache; and all the characteristic symptoms of typhoid fever presented themselves; her pulse was 120; her temperature was 104.9; her tongue heavily coated; spleen enlarged; bowels very tender and tympanitic.

I left her in the care of Dr. Cunningham, on the ninth day of treatment, when I started to attend the

Case 115. John O'L.; age 28 years; date of admission March 22, 1895. Taken sick March 1, 1895; confined to bed March 4, 1895; spitting blood; tongue dry, margins red, etc.; tympanites; hemorrhages March 23, 24 and 25. Catheterized March 28.

meeting of the AMERICAN MEDICAL ASSOCIATION at Baltimore. During my absence she had a very severe intestinal hemorrhage, but made a good recovery. While Dr. Cunningham was making his daily visits, a sister was taken sick with the fever and proper treatment was instituted early, so the temperature never rose above 103.5 degrees, and on the seventh day, when she was doing very well, her husband came home drunk and brought an irregular practitioner who very promptly decided that she had no fever. It was very fortunate for his reputation that he was called in after Dr. Cunningham had aborted the disease.

Case 116.—E. S., aged 40 years (husband of Case 84). This patient resides about four miles from my office and he drove that distance to see me, about 1 o'clock each day. He consulted me first on April 1, when I found his temperature 100 degrees, and pulse 112. Although feeling at times miserable, he was able to be out each day, as I advised; and on the 15th his temperature was 99.4 degrees, pulse 80, and his recovery was excellent.

Case 114.—Mrs. Michael J., aged 32 years. (This was the

fourth case of typhoid fever in the same house at once; the other three cases will be reported in the paper which I read in the Section on Pediatrics, at the meeting of the AMERICAN MEDICAL ASSOCIATION at Baltimore.)

(A small son, Case 78, John J., and a little niece, Case 105, Annie W., had had the disease some time before). The symptoms were not well defined and an absolutely positive diagnosis was not possible, but as all the family used water from a well which was supposed to be the source from which several other cases had originated, she was treated as a case of typhoid fever, and assured that if the diagnosis were correct she would not be confined to her bed or be long sick or too sick to nurse her three children, who had the disease, as I had been able to treat her from the very beginning of her indisposition.

Case 110.—Frank S. This was a true ambulatory case and although the symptoms seemed to indicate that the patient was growing worse, his temperature being 103 degrees on the sixth day of the treatment, he felt fairly well after the first two or three days.

Case 118.—John S. This case showed premonitory symptoms of typhoid fever for more than a week before the patient consulted me. He drove to my office for a few days,

me to see him, saying that he was unable to control him. On several occasions he had stolen out of bed and secured bread and other articles of solid food, and once he was said to have eaten a pound of candy. I ordered him to be handcuffed to the bed, where he still remains but is nearly well.

Case 104.—Miss Ellen H., aged 20 years. Residing in a neighboring town, she had been sick ten days under the care of the family physician who, being one of those gentlemen who do not believe in the possibility of aborting typhoid fever, very naturally blundered in his diagnosis and treated her for la grippe, until about four days before I was called. At this time he corrected his diagnosis to typhoid fever, which caused no little excitement, as the other most prominent physician was and is an enthusiastic advocate of the "Woodbridge method." (He says, publicly, that no patient should die of typhoid fever.) Thus the friends of scientific medicine and the friends of "old fogysm" became partisans, and for days the young lady's mother, in her anxiety to save her daughter from death or needless suffering, was swayed from side to side. It would be hard to tell which party would have won had not the condition of the patient become alarming, for although the doctor was keeping the temperature down with acetanilid and sponge-baths, and was sustaining the heart with strychnin and digitalis, her mother could see that all was not right, and she at last telephoned to me to come down and meet the attending physician in consultation. I found both physician and friends exceedingly anxious about a "failing heart," a threatening danger which I assured them would disappear as soon as a little of the poison was neutralized. I discon-

Case 106. Mrs. McC.; age 70 years; date of admission Feb. 7, 1895.

with all the marked characteristics of the disease plainly to be seen, but finally had to go to bed for a week or more. The temperature ranged from 100 to 102.8 degrees for eight days, and he was discharged cured on the twelfth day.

Case 117.—George J., aged 14 years. He came to my office on April 14, and called daily for four or five days, when his afternoon temperature was only 101 degrees; but his other symptoms were sufficiently characteristic to justify a diagnosis of typhoid fever. I soon discovered that he was not doing well and warned him of the danger of neglecting to follow implicitly my instructions; after which he improved for few days, but again grew worse. Sending for his father, I found that he had been left to take his medicine or not, as he chose; and choosing the latter, he had been casting the expensive medicine which I gave him into the cuspidor. I refused to have anything more to do with him, unless he were properly nursed, when his mother gave up her situation and gave him her care; but more than two weeks had now passed, and instead of being well as he should have been, his symptoms were all aggravated; his pulse 136; temperature 103.4; the tympanic distension of the abdomen was enormous and his bowels were very tender and painful. Leaving him under the care of Dr. Cunningham, I went to Baltimore, and returning on May 13, the Doctor requested

Case 110.—Frank S.; date of admission Feb. 14, 1895.

tinued all heart tonics and stimulants, and all medicine, in fact, except the three prescriptions which I have advised in former papers; and before I made my visit the following afternoon, all the ill-omened heart symptoms had disappeared and the pulse had resumed a healthy tone. In two or three days all of the nervous symptoms, all of the tympanites, all of the abdominal tenderness were gone, never to reappear, and she was very comfortably sick; although, as you will see, the temperature did not touch normal until the eleventh day.

In conclusion, I wish to say that an apology is due the large number of physicians who have reported cases of typhoid fever treated and aborted by the "Woodbridge method" which I have been unable to reproduce here or in previous papers for want of time—an unintentional and unavoidable discourtesy, since the twenty minutes allowed me in the medical societies, or the space in the JOURNAL would have been wholly inadequate to admit of the briefest possible mention of all of the valuable and valued reports in my possession. But every case reported is an object lesson to those who doubt the possibility of aborting typhoid fever, and will aid in hastening the day when death or long or severe illness will be unknown. Hence the medical profession is to be congratulated that it has in its ranks proficient men, able enough to learn the truth and brave enough to teach it.

TOXICITY AS AN ETIOLOGY OF NERVOUS DISEASES.

Read in the Section on Practice of Medicine, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY ALBERT E. STERNE, A.B., M.D.

PROFESSOR OF NERVOUS DISEASES AND CLINICAL MEDICINE, COLLEGE OF PHYSICIANS AND SURGEONS; CONSULTING NEUROLOGIST TO THE CITY HOSPITAL; PATHOLOGIST TO THE CITY DISPENSARY, ETC.
INDIANAPOLIS, IND.

Of all branches of medicine, that represented by diseases of the nervous system has perhaps been least influenced by the science of bacteriology. In a minor way it has felt the effect of microbic theories, but until now, so far as my knowledge extends, no attempt has been made to explain more rationally upon this basis some of the vexed questions of the etiology of many nervous affections.

I shall undertake to bring forward a newer origin of many diseases of the nervous system. In these days of scientific medicine our profession rightfully demands proofs. I am aware that I have little incontestable proof in support of this theory to offer at the present time. Nevertheless, I think considerable evidence for the toxic origin of many affections of which the etiology has long been a source of doubt will be shown.

In speaking of the toxic origin of nervous diseases it was intimated that the idea was new. This is not entirely true. It is well known to you that of late years no inconsiderable rôle has been attributed to toxicity as an etiologic factor in a number of maladies. But in medical literature I have found little recorded relating to affections of the nervous system attributed to the effect of bacteriologic or analogous influences. For a long time it has become impressed upon me in my special study of nervous diseases, that the degenerations, respectively inflammations, of both the central and peripheral nervous organs are, in a great measure, due to the effect which certain discovered and undiscovered toxins exert upon them. In some instances this result is attained only after an extended period of time; in others the effect upon the nervous tissue is quite acute as, for example, in poliomyelitis anterior, the so-called "infantile paralysis." In some cases the toxin is the product of microorganisms, as in diphtheritic and typhoid affections; in others the poison is of an inorganic nature, as is the paralysis due to lead, arsenic, mercury and alcohol.

There are several reasons which prompt me to seek the origin of many abnormal conditions of the nervous system in a chronic or acute exposure to the influence of toxicity. It will be impossible to enter deeply into the subject, for the realm of nervous diseases is vast, and the number of agents which may be powerful to exert their action possibly still greater. I must necessarily simply allude to many things to which further study and experiments may attach considerable importance.

Now it has been the just aim of pathologists and neurologists for many years to attribute the lesions of well-known diseases of the nervous system to defects of a congenital nature. These defects vary in degree, and in some instances require the assistance of an exterior agent to unfold to such an extent as to impress us with their importance as factors producing disease. With this tendency and aim I am most heartily in accord, as is shown in a recent

paper by myself on "Syringomyelia."¹ It may be well, however, to caution against a too great willingness to search for congenital deficiencies or "retarded development," to the neglect of other causes, as in almost every case where such an etiology is apparent, prognosis is grave, except, perhaps, where surgical methods can be adopted.

We are all well acquainted with the patient's story of exposure to cold, to wet, to heat, etc., and doubtless such exposure, if it be long continued, can produce serious effects upon the entire nervous system, in fact upon the entire body. The popular notion concerning exposure is, perhaps, not so ridiculous as many of our fellow-physicians would have us believe. However, these histories of exposure of various kinds are to the inquiring mind unsatisfactory, to say the least. Guided by the light which the researches of the latest years have shed upon every field of scientific medicine, we should attempt to arrive nearer to the true causes in the production of all diseases. Therefore I would bring forward the following facts:

1. We find as sequelæ of affections of known microbic origin, inflammations and, secondarily, degenerations in both the central and peripheral nervous elements.

2. After and during the course of such illnesses as may be justly supposed to be due to bacterial invasion we find characteristic symptoms from the side of the nervous system denoting organic disease of the tissue of this system.

3. By analogy we may infer that both of the former classes are due to the effect of the microbes themselves or to the production of poisons by them.

4. This analogy is given by the two following subdivisions: (a), the inflammations and degenerations found in the nervous tissues as the result of toxins of non-microbic character; and (b), those notably due to the presence in the nerve elements of microorganisms or their products.

Under these classes we find affections of acute, sub-acute and chronic character. Again, among these we find affections of peripheral and central nature, both organic and functional. Into these conditions, which appeal to almost all of us as results of poisoning of shorter or longer duration, I shall enter but little, even though their importance for the worth of the toxic theory is of great value. I refer particularly to the nervous sequelæ or complications which follow the acute exanthemata and other febrile diseases. Some of these are undoubtedly, and others manifestly, due to the presence of microbes in the system. Of the former I mention diphtheria, typhoid and influenza as paradigms; of the latter, scarlet fever and measles. Paralysis, usually of peripheral origin, is comparatively frequent after the first named, seldom after the latter. It is still an open question as to the specific agent producing these paralyzes, whether it be the bacteria themselves or their toxins. It seems to me that the cause must be sought in the action of the latter alone. As has been intimated, these paralyzes are due to inflammations and often consequent degeneration of the peripheral nerves. We know that peripheral neuritis is frequently of toxic nature; as is seen in cases of lead and alcohol poisoning.

Speaking more particularly of affections of the nervous system we have among the acute forms due to

¹ Indiana Medical Journal, December, 1893.

toxic influences of *bacterial* nature, those presenting the clinical and pathologic conditions due to destruction in the central nervous organs. First, the poliomyelitis anterior or "infantile paralysis" with degeneration and atrophy of the ganglion cells in the anterior cornua of the spinal cord; also meningitis cerebro-spinalis epidemica and inflammations of the meninges, due to tubercular and other bacillary forms. Those rarer diseases, such as encephalitis and myelitis acuta appear from their clinical and pathological character to be toxic. Of the acute peripheral affections produced by the microbic toxins, I cite "beri-beri" and, in repetition, the diphtheritic pareses and paralyzes and the ascending paralysis of Landry.

It will be vastly more difficult to establish a toxic origin for those conditions, both organic and functional of the nervous system, which are commonly denominated as nervous diseases. The suggestion that the functional disorders which show themselves as epilepsy, hysteria and the mental perversions both of depression and exaltation as the direct manifestations of toxic action lies very near. Assuredly many parallels could be drawn to express the similarity in the effects of known poisons upon the cerebral and spinal functions, and the above mentioned affections. In this connection it will be necessary simply to allude to the action of strychnia, and of curare among drugs, and to recall the symptoms often supervening from the results of intestinal, biliary and renal intoxications. Disturbance in the physiologic action of many glands produces chronic nervous ailments. So for instance, is this true of the thyroid and presumably of the thymus where this persists after puberty. It is an achievement of modern science which has given to us a knowledge of myxedema, and of exophthalmic goitre, both of which seem due to the chronic action of some still obscure toxin.

That syphilis is due to bacterial infection there can be no reasonable doubt. That of extra-congenital conditions of nerve lesions we should seek the etiology preëminently in the action of the syphilitic virus may be considered almost equally true. The three agents which play a main rôle in the production, better said, induction of nervous diseases, both organic and functional, may be said to be syphilis, tuberculosis in some form, and alcohol. All three act, it seems to me, in a similar manner, by gradual intoxication. The channel through which this action is spread lies in the blood and lymph currents. The action of the poison is primarily exercised upon the vascular and lymphatic systems, the result of which is shown in subsequently produced lesions in the nervous elements. The above statements are liable to misconstruction. To become more explicit, I believe, not that many diseased states of the nervous system are either syphilitic or tubercular or alcoholic—though for each of these there exists a distinct specific disease of both central and peripheral nature—but that the ptomaines, respectively toxin, produced by constitutional syphilis, tuberculosis or alcoholism are factors which contribute more largely even, than is generally supposed to the development of various diseases of the nervous system. That an anti-syphilitic, an anti-tubercular or an anti-alcohol cure may have little or no effect upon the diseased nervous state against which the one or the other may be directed, seems to me to carry little weight against the

etiologic importance of these specific troubles in the production of nervous affections, as some authorities contend. We have in these cases to do with the results of specific infections, not with the infections themselves.

The most common and illustrious examples of the result of chronic bacterial toxicity are tabes dorsalis and lepra anæsthetica. These two affections have many similarities, though in fact they are entirely different processes. Whereas in lepra we find the specific bacilli in the nervous tissues, no such conclusive proof of the purely microbic origin of tabes has ever been discovered, and probably never will be, inasmuch as the systemic degeneration which forms the pathologic basis of locomotor ataxia may be best looked upon as the result of some primary process, *i. e.*, chronic toxicity. It seems to me to be an error to regard the only nerve lesions present in tabes (degeneration of the posterior tracts of the spinal cord) to lie in the central nervous organs. This lesion is doubtless the most important, but there are others, notably multiple degenerative peripheral neuritis, equally constant and, moreover, responsible for many of the characteristic symptoms of the disease.

Tabes should be regarded as a constitutional process, one which places distinct and separate lesions within the nervous system, and perhaps in other tissues. It is in the vast majority of cases a post-syphilitic affection, the direct consequence not of syphilis but of the ptomaines or toxins produced by the agents of the specific disorder. That few cases of well-developed locomotor ataxia are in any way benefited by mercury and iodid of potash need not appear strange. The action of these drugs directs itself against the microorganisms and their ptomaines, not against their secondary effects. That the syphilitic agent acts most powerfully upon the vascular system of the nervous organs can be readily demonstrated. The characteristic changes in the blood vessels of the central nervous organs are present in almost every microscopic section. To these changes of the vascular system the degenerations throughout the whole body of the tabetic individual may be, to a great extent, directly traced. Just how the process is to be explained, whether through inanition due to defective oxidation on account of the condition of the vessel walls, or whether the poison exerts direct influence upon the tissues supplied by these vessels, or whether the changes spread from the vessel walls, remains a matter of doubt. It seems certain, however, that the degenerations within the nervous system are changes secondary to those of the vascular system. They are interstitial, not parenchymatous. Moreover, I regard both as consequences of toxicity.

Whether or not it will prove possible to establish analogous relations for the many other essentially nervous diseases, amyotrophic lateral and multiple sclerosis, for the non-systemic degenerations, etc., I am not now prepared to say. However, we have affections of essentially nervous character which appeal to us even more, namely, tetanus and chorea. That tetanus is the result of the action of tetanin or tetanotoxin is beyond question. Experiment has proved that this product of the tetanus-bacilli causes the disease. Of the alkaloids, strychnia acts much in the same way. Whether the affection called tetany is also of a toxic nature it is yet impossible to state. Its endemic nature might lead us to infer that it is. That chorea associates itself very frequently with an

Endarteritis inefica, lues cerebro-spinalis. Very small brain artery. M E, Membrana Elastica.

Combined Sclerosis. Direct cerebellar tract, antero-lateral ascending tract, and Goll's columns. Vascular changes. Spinal artery. Arteritis, much broken up and thickened. Media, much thickened. Intima, almost intact.

Endarteritis specifica, lues cerebro-spinalis. A, Adventitia. M, Media. I, Intima. M E, Membrana Elastica.

Endarteritis specifica, lues cerebro-spinalis.

Combined Sclerosis (25). Pyramidal tracts and Goll's columns. Vascular changes. Walls of both vein and artery much thickened and destroyed. Leucocytes (L) are to be seen distributed throughout the vessel walls, notably in that of the vein (V). P.M., thickened pia mater.

Hemorrhage and subcortical gummi, ines cerebrials.

Gliosis Spinalis. Vascular changes. Small spinal artery. Stained to show proliferation of nuclei. Adventitia (A) much thickened, many nuclei near the periphery. Media (M) thickened, countless nuclei. Intima (I) somewhat loosened; no proliferation. N E, Membrana Elastica.

Tabes Dorsalis. Vascular changes. Minute spinal artery. Adventitia (A) thickened and in fragmentary destruction. Media (M) thickened. Intima (I) much thickened. M E, Membrana Elastica. Thrombus in artery.

Amyotrophic Lateral Sclerosis. Vascular changes. Small artery. Adventitia (A) fragmented and thickened. Media (M) thickened. Intima (I) loosened and thickened. M E, Elastic Membrane.

Syringomyelia. Vascular changes. Spinal artery. Adventitia (A) much thickened and fragmented. Media (M) very much thickened. Intima (I) fragmented and loosened; much thickened. M E, Elastic Membrane.

Polymyellitis Anterior. Vascular changes. Spinal artery. Adventitia (A) very much fragmented and loosened from media. Media (M) much thickened. Intima (I) torn from the media.

Syringomyelia. Vascular changes. Small spinal artery. Adventitia (A) thickened and broken up. Media (M) much thickened. Intima (I) nearly intact. M E, Elastic Membrane.

undoubted infectious disease, namely acute inflammatory arthritis, seems to me to prove at least the possibility of its toxic origin in the majority of cases.

Many other examples could be brought forward. Our daily experiences teach us many. We meet with the nervous sequelæ of the infectious fevers. We look for them from the action of poisons, either taken from without or generated within the body, arising from disordered functions in various organs, absorbed from the intestines or taken into the circulation from liver and kidneys. We seek the candidates for nervous and mental diseases preëminently from among those long exposed to chemic intoxication both of organic and inorganic character; in other words, from those subjected to toxic influences and the abuse of drugs and alcohol. Dementia paralytica may aptly be mentioned here.

Acting upon this line of thought and experience, I have carefully examined many specimens of the nervous system taken from different subjects suffering from the same affections, and several of these specimens I wish to submit to your inspection. In this investigation especial attention was devoted to the condition of the blood vessels, notably in cases of tabes, syphilis, dementia paralytica, amyotrophic lateral sclerosis, multiple sclerosis, primary lateral sclerosis, poliomyelitis and myelitis acuta, syringomyelia, gliosis spinalis and various combined systemic scleroses, among the organic diseases. Of the so-called "functional" affections, epilepsy and chorea were studied. Fatal cases of diphtheria and scarlatina in which no paralysis had supervened, and of the various cachexias, notably of tubercular subjects, of profound anemia due to intestinal intoxication, and of alcoholists were also examined, in order to determine how far the vascular changes might be due to toxic action or simple inanition, in cases which had shown no essentially nervous symptoms. In all of these affections the condition of the vessel walls differed markedly from the normal. It can not be said that there was any constant degree of pathologic alteration in any one case or in a given disease. The character of these vascular changes you can easily detect in those specimens beneath the microscope, and from the drawings near them. Unfortunately the detailed structure is not given in the latter. Taken altogether it will be seen that the walls of the vessels present very decided differences from the normal. The pathologic process appears more marked in cases of syphilis and in post-syphilitic tabes and dementia paralytica than in the other diseases. It seems more intense and widespread. However, it will be noticed that in those affections which have heretofore been less studied as regards their vascular condition than the above, advanced disease of the vessel walls is shown in many cases.

All the layers of the arteries are affected by the process, sometimes the one more than the others. In the main the process is one of cell-proliferation effecting increase in the volume of the vessel wall at the expense of the vessel lumen. Even where considerable fragmentation of the vessel walls has occurred, and where the intima or adventitia are loosened from the media this increase persists. Very often the lumen of the vessels is entirely obliterated just as in endarteritis syphilitica. In several specimens enormous quantities of leucocytes were present in the vascular tissues. In several instances slight

hyalin degeneration was present, but in no case observed by me was this peculiar change constant or widely diffused. Thrombosis seems more common in the more chronic, fragmentation more usual in the acute diseases, such as poliomyelitis and myelitis. In the cases of diphtheria and scarlatina, which were all rapidly fatal, evidences of acute inflammation and extravasation predominated over other changes. Fragmentation, *i. e.*, varying degrees of tearing and loosening of the intima, media, and adventitia, also obtained.

In the cases of epilepsy and chorea which I examined, the condition was closely allied to the above, minus the signs of acute inflammation. The innumerable minute hemorrhages present in these cases certainly indicated that some agent, probably toxic, had exercised considerable influence upon the vessel walls. It seems to me that this same toxic agent acts upon the nerve cells, perhaps only functionally or chemically like certain drugs, and causes the clinical symptoms of these affections.

It is interesting to note that the state of the vascular system in the marantic conditions investigated, namely in the cachexias of tubercular, profoundly anemic and alcoholic subjects showed no great divergence from that described above. The quality of the pathologic changes was very similar, only the intensity of the process was less marked. It seems, therefore, that in all of the affections in which some degree of toxicity was manifest, that the blood vessels are more or less intensely altered. These changes I consider the direct result of some toxic action, possibly chemical in its nature. In how far the period of exposure acts in producing varying grades of lesions it would be difficult to say. That the duration of time in which the toxic agent has exerted its influence may be a factor of great consequential importance can not easily be denied, when we reflect, that, in a notoriously long-lived intoxication *i. e.*, syphilis, the vascular lesions are most intense and widespread. How it is that different parts of the nervous system possess decided affinity for certain toxic agents it would be difficult to determine. That such an affinity exists, I believe that no one can gainsay. How else can we explain rationally the predilection with which lead attacks the radical group, or the diphtheritic toxins certain nerve territories? Functional overwork undoubtedly plays no inconsiderable rôle in this selective and elective play, but some peculiar chemic affinity seems clearly at work in many afflictions following given types. We are still far from a clear conception of nerve chemistry, the proper knowledge of which would render these problems more easily solved, and eventually teach us the way to reconcile our bedside and consultation experiences with pathologic processes and theories of diseases.

75 E. Michigan Street.

DISCUSSION.

DR. PRESTON, of Baltimore—I think the subject presented to us is one of extreme importance, and one which certainly is attracting the attention of neurologists very greatly. It is almost too vast to discuss, but there is a part of it that has attracted my attention for several years. I was particularly pleased to see the importance which Dr. Sterne attaches to vascular changes. There is one affection, namely, posterior sclerosis (tabes) which I think shows that in a very interesting and remarkable manner. If we consider that we very rarely ever have a cervi-

cal tabes, that is I think of itself a fact worth noticing. A few cases have been reported of purely cervical tabes but this is unusual. If we recall the blood supply of the spinal cord, we see that the lower part of the cord is supplied mainly by the branch of the intercostal artery, the upper portion of the cord getting very little from the artery. Here is a small branch coming off at right angles from the trunk, and the sclerotic material is heaped up just at the mouth of this intercostal artery. That being the fact, we see at once that the nutrition of the lower portion of the cord is certainly much diminished by this change in the intercostal artery, so that instead of getting its proper blood supply, the lower part of the cord does not receive proper nutrition. I think the branch of the intercostal supplies mainly the lower part of the cord, and if that can be demonstrated we could say, I think, that a large part of the cause of tabes was due to the fact that the proper nutrition was cut off on account of the arterial sclerosis of the intercostal arteries, just the arteries we would expect to find affected first. We have a great many toxic causes, alcoholism standing prominently forward, gout, rheumatism, lead poison, etc., and syphilis, all contributing to the production of arterial sclerosis, and these causes certainly act in the production of locomotor ataxia. The syphilitic process, while producing an arterial sclerosis unlike the other sclerosis of gout and lead poisoning, does produce a distinct change. Some years ago I began using nitro-glycerin in the treatment of early tabes, and I am satisfied that I have obtained some good results. I have been able to relieve the pain in early cases of tabes, I am sure, by the continuous use of nitro-glycerin, acting upon the idea that I might produce in that way a slight increase of nutrition to the spinal cord. I think that the fact that certain local applications have proved of advantage is perhaps due to that.

DR. PATRICK, of Chicago—I should like to vote a very decided aye, in regard to the first part of Dr. Sterne's paper, and a very decided no, in reference to another part of the paper. As to the influence of the various toxic agents upon the nerves I do not think there can be much difference of opinion. The influence of the various agents has been shown so conclusively that we are scarcely on debatable ground. Even toxico-pathic heredity has been very conclusively proved. This has long been known and generally established in regard to syphilis, morphin, etc. Parents subjected to lead, mercury, bisulphid of carbon, also beget children with neuropathic tendency. When the Doctor goes a step further, and would attribute almost all diseases of the nervous system to an affection which begins in the blood vessel, I think he will have extreme difficulty in maintaining his position. To group all these affections which he has enumerated, including locomotor ataxia, acute anterior poliomyelitis, etc., under one head, is decidedly going further than our present knowledge of pathology would justify. Our present knowledge would vote a decided no, to these propositions. These affections begin in the nervous structures themselves, and the change is in the nervous conditions primarily, and not in the blood vessels. When these diseases have gone on into an advanced state, we find a change in the blood vessel, but that is secondary. Tabes has been conclusively shown not to be a disease of the blood vessels. These cases begin almost always in the nerve cell, or in the nerve fiber, consequent upon atrophy, destruction, or disintegration of the nervous element. The connective tissue may take on changes, but these are secondary; it is not primarily a disease of the blood vessels at all. Even the changes which have been recorded chiefly by Nunez which were changes in the cord occurring in pernicious anemia, were primarily of the nervous tissue.

DR. STERNE—Dr. Patrick misunderstood me when he thought I classed all these cases together. I did not say that I class all these cases together, except in physiologic importance. It is very difficult, if not impossible, to say where you have these changes, whether they are secondary or primary, in cases of such long standing as tabes dorsalis. I do not believe that the ganglionic cells or the nervous fibers of the axis cylinder are primarily affected.

PERITONEAL SUPPORTS—(LIGAMENTUM PERITONEI).

BY BYRON ROBINSON, M.D.

PROFESSOR OF GYNECOLOGY POST-GRADUATE SCHOOL,
CHICAGO.

(Continued from page 67.)

THE GREAT OMENTUM.

Synonyms: mesogastrium posticum, posterior mesogaster epiploön, gastro-colic omentum, omentum majus, ligamentum gastro-colicum, apron or caul.

The great omentum is a double fold of peritoneum which stretches from the mid-dorsal line to the greater curvature of the stomach and concave surface of the duodenum. The mesogaster posterior and the meso-duodenum are one and the same mesentery. It is twisted into the shape of the letter S, with one loop of the S larger than the other on its

Fig. 17 (after Sappey, 1889) represents a front view of the great omentum. It is unusually well spread out and quite symmetrically located. It shows well the relations of the great omentum to the surrounding organs, especially the three great peritonitic regions, viz.: gall bladder, appendicular and pelvic. It does not cover the cecum (No. 11), nor does it reach the pelvis, and the top of the gall bladder (No. 5). 13, summit of bladder; 12, s. iliac; 10, points to loops of small intestines.

stomach aspect. The ligamentum hepato-duodenale has dragged the pylorus toward the right from the atrophy of the liver. The mesogaster (posterior) or the great omentum is very long and wide, and easy to inspect. But the mesoduodenum is so changed by the rotation of the great intestinal loop that it is not readily inspected. However, if one dissects up the transverse colon it will be seen that the whole mesoduodenum is still in existence except the serous covering which faces both sides of the mesoduodenum in early fetal life. In other words, the membrana mesenterii propria is still existing, minus its serous shining epithelium. One can dissect out the mesoduodenum and note the arches and arcades of blood vessels just as they are in the mesentery of the small intestines. The head of the pancreas lies im-

bedded in the membrana mesenterii propria as I have often proved by dissection. The great omentum in early fetal life is a simple double-bladed membrane which suspends the stomach and duodenum from the mid-dorsal wall. As time and growth progresses the mesogaster elongates. It stretches and elongates toward the left before the moving stomach. The mesogaster is at first a plain surface, later a shallow wide-mouthed bag and finally in the shape of a jug with its mouth at Winslow's foramen. The great stomach curvature which was originally at its posterior border has moved to the left, and by so doing the mesogaster has become extraordinarily long. The movements of the stomach (chiefly due to the liver) viz., axial rotation and twisting, with descension are supposed to be the main factors in regard to the elongating of the great omentum or mesogaster (posterior). However, these forces are inadequate to explain the excessive length which the great omentum attains. In man or the higher mammals the rôle played by the transverse colon aids in explaining some factors as regards the length of the mesogaster. Yet some obscurity still exists, for in the dog where the transverse colon is not connected with the great omentum there exists even a longer great omentum than in man. If one could place the fist against the right face of the mesogaster in a

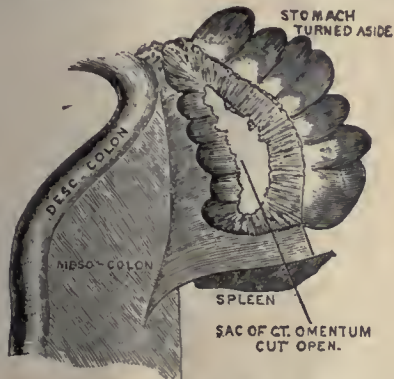

Fig. 18 (after Treves) represents a primitive condition of the great omentum found in the kangaroo. The omental sac is cut open to show that it has not formed a long pendulous omental bag, as in many mammals. In this animal the posterior mesogaster appears as if it were simply pushed slightly toward the left, forming a shallow, wide open depression with no Winslow's foramen. The neck, or rather circumference of the depression in the mesogaster never contracted to form a foramen.

fetus and continue pushing toward the left until the mesogaster was stretched into an irregular sac, the bag could be observed at the left of the stomach while its neck would be found at the right and behind (Winslow's foramen). The walls of the bag consist of a double-bladed membrane, the stomach mesentery which continues to elongate until its walls pass in front of the small intestines and normally to the pelvis. The layers of the great omentum start from the great stomach curvature where they arise from the convergence of the anterior and posterior serous blades of the stomach and pass downward in contact with the anterior parietal peritoneal layer. After descending normally into the pelvis, these two layers turn or reflect on themselves and pass upward in front and in contact with the small intestines until they reach the transverse colon, whence by divergence they embrace the colon and again come together to form the transverse mesocolon. The transverse mesocolon passes to the back wall of the abdomen where the upper blade ascends along the dorsal abdominal wall, while the under blade

descends on the dorsal abdominal wall. The chief variation in the mammalian peritoneum exists in the great omentum especially in reference to its relation with the transverse colon.

By reference to Fig. 18, a beautiful illustration of the great omentum of a kangaroo may be observed. In this cut the slightly pendulous bag of omentum is cut open to better show its construction. The part of the mesogaster which bulges is about midway between the pylorus and lower end of the esophagus. This is the case as far as I can determine in the

Fig. 19 (after Forabeuf) represents a beautiful profile view of the great omental bag. It is worthy of careful inspection. It is drawn in vertical section in the middle line; a, diaphragm; b, liver; c, duodenum; d, renal vessels; e, anterior face of the stomach; f, pancreas covered by the ascending or superior blade of the transverse mesocolon; g, inferior transverse colon; h, colon transversum; i, iliac vessels; j, S-iliac; k, small intestine; l, rectum; m, bladder; n, Winslow's foramen (orificium epiploon, foramen bursa omentalis plinum or hiatus Winslowii); o, gastro-hepatic omentum, lesser omentum, or ligamentum gastro-hepaticum; p, the lower blade of the lesser omental cavity, or the upper blade of the mesocolon transversum ascending over pancreas; q, mesocolon transversum; r, anterior or descending blades of the great omentum; s, posterior or ascending blades of the great omentum (the part below the colon Husccke called the omentum colliculum, and the part between the stomach and colon the gastro-colic omentum); t and u point to the upper blade of the mesenterium, which consists of three layers, (a) an upper and (b) a lower, shining, serous epithelial layer, and (c) a middle layer (membrana propria mesenterii); this middle layer is the real neuro-vascular visceral pedicle, composed of blood vessels, lymphatics, nerves, elastic and fibro-connective tissue; v, Douglas' pouch (excavatio-recto vesicles). It may be observed that the shining serous epithelial layers may be displaced or entirely dragged off of a viscus, but the middle layer, the membrana mesenterii propria is never displaced or dragged off of its original viscus, e.g., the pancreas in the human fetus lies in the gastro-colic omentum very distinctly, as it plainly does in the dog. In the adult human the shining, serous, epithelial peritoneal layer does not surround the pancreas, but simply lies against its anterior face. The epithelial layer has been displaced or readjusted. But the pancreas is enveloped by the middle mesenteric layer, i.e., by the membrana mesenterii propria, which holds in order as it always did the vessels, nerves and fibrous tissue. Again the duodenum is similarly deprived of its peritoneal epithelium on its posterior surface by displacement or readjustment; but the duodenum is definitely enveloped as it originally was by its real neuro-vascular visceral pedicle, the membrana mesenterii propria or middle mesenteric layer.

fetus of man and animals. If the largest bulge in the mesogaster does exist halfway between the cardiac end of the stomach and pylorus, it accords with what seems to me the method of formation of the omentum and that is through stomach movements. It appears to me that the existence of the serous membrane or peritoneum is due to free moving viscera, plus fixed and independent surrounding walls, *i. e.*, serous cavities depend on the coalescence of interstitial (lymph) spaces from fluid pressure and independent action of surrounding or adjacent walls. In the case of the great omentum its appearance is chiefly due to the liver. The liver enlarges and pushes the stomach toward the left and downward. The stomach coincidentally dilates and contracts. The liver enlarges so enormously in fetal life that it elongates the esophagus below the diaphragm and

Fig. 20 (after Luschka, 1868) represents a sagittal section of the peritoneum. It is an excellent cut. It may be noted that the peritoneum does not descend sufficiently on the anterior surface of the uterus. 1, navel, with adipose collection; 2, diaphragm; 3, liver; 4, stomach; 5, colon transversum; 6, intestine; 7, rectum; 8, uterus; 9, bladder; 10, pancreas; 11, pars horizontalis inferior duodeni; 12, aorta abdominalis; 13, art. iliaca communis dextra; 14, vena iliaca communis sinistra; 15, bursa omentalis minoris; 16, omentum minus; 17, omentum majus; 18, mesocolon transversum; 19, mesenterium; 20, Douglass' pouch (excavatio recto-uterina); 21, utero-vesicle pouch (excavatio vesico-uterina). Notice that Luschka shares the views of coalescence and not displacement at No. 18, which shows four layers instead of two layers for the mesocolon transversum.

forces the stomach to the left and downward to a surprising degree. The force that twists the stomach so much (as in the pig and dog) appears to reside in the irregular and unequal growth of the liver lobes. At one time in fetal life the left lobe of the liver enlarges so rapidly as to force the stomach extensively to the left and downward. Spigel's lobe enlarges enormously and produces the sharp bend in the lesser curvature of the stomach, beside forcing the

stomach downward and to the left. Again, at another time of life, the right lobe of the liver atrophies so rapidly that the pylorus is very much dragged over to the right side, thus increasing the apparent transverse position of the stomach. Yet this transverse position of the stomach is more apparent than real, for the line from the lower end of the esophagus is almost straight and parallel to the vertebral column. The delusiveness of the stomach position consists in the excessive bulging of the great curvature. But why there is such an excessive length of omentum is not clear. An explanation which I offer is that the force (liver) which produces the elongation of the mesogaster works continually on its base from beginning to end of formation. (Fig. 19.) The only method of explanation of the origin and method of formation of the great omentum must be sought through evolutionary development of the mammalian close connection with the condition and size of the liver. For example, Treves notes that in

Fig. 21 (after Gray, 1887) represents a profile outline of the peritoneum as it lines the abdominal cavity. It is quite diagrammatic. The coccyx is drawn entirely too low, as it should only reach the level of the junction of the lower and middle third of the pubic bone. Notice the colon lies between the layers of the posterior ascending omentum, *i. e.*, between the mesocolon. Neither the displacement or coalescence view is here hinted at.

the rudimentary disposition of the great omentum in the two-toed anteater a mere shallow bag is observed bending toward the left, but he does not say a word as to the condition of the liver, or why the anteater has such a simple mesogaster. Unfortunately I am not situated as Treves is, whereby his relations to the London Zoological Gardens enable him to examine the viscera of many animal species. In lower mammalia the mesogaster is a mere bag bulging toward the left with no relations with the mesocolon. The bag is a mere depression in the plane of the mesogaster and it can scarcely be considered to have a mouth or foramen. With the progress of

the mesogaster, bulging toward the left assumes more and more the shape of a bag lying around the great left bulge of the stomach. The wide circumference of the depression gradually contracts into a neck and, finally, jug-shaped, we have a bag (lesser omental cavity) and a mouth (Winslow's foramen). Now, the student would naturally suppose that the mouth of this bag formed by the elongated mesogaster would be at its mesenteric root, *i. e.*, on the vertebral column, but the atrophying right liver lobe has dragged the pylorus and lower end of the stomach to the right so that the neck of the sac or foramen of Winslow is also drawn to the right. But the relation of the foramen with the portal vein, hepatic duct and artery are not altered, for the whole apparatus, constricting the mouth, with the foramen, is dragged to the right. Hence the mouth of the sac (Winslow's foramen) is not situated at the root of the mesogaster on the vertebral column, but to the right where it is forced by the atrophying right liver lobe. An excellent diagrammatic illustration of the great omentum I have copied from the anatomy of Dr. Debierre which is from the valuable labors of Dr. Forabeuf. (Fig. 19). The involvement of the great omentum is inevitable where the rotation of the navel loop is so extensive as in man and higher mammals, because the right end of the transverse colon and the duodenum is so closely related.

All serous cavities are secondary. No serous cavity arises as a primary structure. Embryologic development teaches this fact in all animal life. Serous cavities are really points; points of motion. They regulate pressure, facilitate motion, modify circulation and allow visceral rhythm to have anatomic and physiologic functions. With the above views the anatomy and physiology and method of origin of the great omentum must be associated.

It is well to look at the root of the mesogaster for proof of origin and distribution of the great omentum. By examining the root of the mesentery it will be observed that the celiac vessel springs from the aorta at the middle of its origin. This short arterial trunk soon divides into three smaller arteries, *viz.*, gastric, splenic and hepatic. A knowledge of the distribution of these three arteries is essential in discussing the mesogaster. The gastric artery starting from the celiac artery passes forward and upward to gain the cardiac end of the stomach. In its course it projects a fold of the right blade of the mesogaster forward for one to two inches. This fold is called *ligamentum gastro-pancreaticum* and it partially divides the lesser omental cavity into two compartments. The right compartment of the lesser omental cavity we may call the *bursa omentum minoris*, and the left *bursa omentum majoris*. The aperture between the right and left divisions of the lesser sac is the *foramen omenti majoris* while Winslow's aperture is the *foramen omenti minoris*. The fold of peritoneum thrown up by the gastric artery varies much in size and length. Generally it is one and a half inches high and it reaches from the upper border of the pancreas to the junction of the esophagus and stomach where the gastric artery gains access to the stomach. In some cadavers I observed that the gastric vein would accompany the gastric artery intimately for three-fourths of its distance and then diverge from the artery and border of the fold. Generally the gastric vein does not accompany the gastric artery very far in the border of the fold. The

ligamentum gastro-paucreaticum is due to the gastric artery and not to the gastric vein in the vast majority of cases. The peritoneal duplicature produced by the gastric vessels projects from the upper and posterior surface of the omental sac, dividing the cavity into a smaller right cavity, containing a viscus, and a large left cavity containing no viscus. In quite a number of bodies I found another peritoneal duplicature projecting into the omental cavity beside the one due to the gastric vessels. However, they were small and inconstant, due to small blood vessels or to a past peritonitis. A practical method, to observe the peritoneal fold due to the gastric artery, is to well inject the arteries of a very spare subject and then to allow the subject to stiffen with cold, which will give a fixation and solidity to the viscera, so that their outlines and the borders of the peritoneal fold can be easily noted.

The hepatic artery which also springs from the celiac axis turns downward and runs under the right blade of the mesogaster until it reaches the *ligamentum hepato-duodenale* whence to gain access it turns and passes the liver. The hepatic artery passes directly downward from the celiac axis and slightly deviates to the right for several inches before it gains access to the *hepato-duodenal ligament*. During this whole course, from the celiac axis to its turn around Winslow's foramen, it generally does not raise the right blade of the mesogaster into a fold thicker than the width of the artery. One can easily observe the ridge produced by the peritoneal duplicature under which lies the hepatic artery. I never saw the ridge high enough to pass the point of the forceps between the artery and the anterior abdominal wall. As soon as the artery reaches the *duodenal ligament* it sharply bends forward, surrounding the foramen of Winslow and then producing peritoneal duplicatures. But after the artery has passed into the *ligamentum hepato-duodenale* it is beyond the pale of the mesogaster, so we drop its course at this junction. At this point the hepatic artery is important as it really forms the mouth of the sac known as the lesser omental sac. Though the distal end of the hepatic artery makes a sharp bend and hooks itself around a small aperture, *hiatus Winslowi*, yet the main trunk borders a larger foramen just to the left of the small one of Winslow, so that a careful examination on a well-prepared subject, fitted for the inspection, will reveal that an aperture exists to the left of Winslow's which is really a second Winslow's foramen. The aperture (*foramen omentalis bursa*) is bounded by the gastric artery in front and by the hepatic artery behind. It produces a constricted communication between the larger and smaller cavities of the lesser omental bag. We really have two foramina connected with the lesser omental bag. The first, *foramen Winslowii primus*, is the small end lying between the distal end of the hepatic artery and the inferior vena cava, and it leads into an anteroom (*atrium bursa omentalis*, or *bursa omenti minoris*) which contains Spigel's lobe. This anteroom of the lesser omental cavity is about the size of the fist, and is especially closed in front by the *pars flaccida* or middle portion of the *ligamentum gastro-hepaticum*. The second, *foramen Winslowii secundum*, is a constricted orifice, bounded by the gastric artery and trunk of hepatic artery or rather the peritoneal duplicatures produced by the vessels. The foramen

leads from the anteroom or right cavity to the larger sac (bursa omenti minoris) of the lesser omental cavity. This left cavity is more uncertain and irregular than the right, as toward the spleen above and the ligamentum phrenico-colicum there are frequent constrictions due to past peritonitis. Various spaces and sacs are constricted off at the left end of the lesser omental cavity.

(To be continued.)

SOCIETY PROCEEDINGS.

Chicago Pathological Society.

The regular monthly meeting, March 11, 1895.

DR. HOMER M. THOMAS, Temporary Chairman.

DR. BISHOP exhibited for Dr. John B. Hamilton the specimens from a case of extra-uterine pregnancy, and prefaced his remarks as follows: I regret that he is not here to give us the clinical history and the points connected with the operative procedure. The notes from which I shall presently read were furnished by the interne in charge of St. Joseph's Hospital where the operation was performed. Dr. Bishop then read the following clinical notes:

EXTRA-UTERINE PREGNANCY—DR. HAMILTON'S CASE.

Clinical notes obtained from records of St. Joseph's Hospital.

Mrs. G. H., age 31 years, housewife. Family history: father died of consumption, mother suffering from the same disease. Personal history: always in fairly good health except for some injury in sacral region eight years ago, followed by an abscess in the pelvis, which was opened and drained through the vagina. Entire recovery after four weeks. Uniformly good health continued until about two years ago, when she was ill for a short time, having a vaginal discharge, her physician telling her she had miscarried, the fetus being only a few weeks old. Her present illness began one year ago with pain in the right inguinal region. Menstruation became scanty. Amenorrhea for past fourteen weeks. About two months before entrance to the hospital, the pain in the right inguinal region became very severe and has persisted ever since. Four weeks later profuse uterine hemorrhage set in, continuing up to five days before operation.

The patient consulted Dr. Hamilton Jan. 10, 1895, who advised laparotomy. Operation January 15. The right ovary and tube with the hematoma and contained fetus were removed. The remainder of the clinical history deals with the progress of the patient, which was uniformly favorable, she leaving the hospital February 3.

It will be seen that the ovary itself is fibrous, and there are a few cysts upon its surface. The clot altogether is not larger than a hen's egg and the sac in which the fetus lay is demonstrable at the outer end of the tube which has been incised and held open. As will be seen by examination of the specimen this is an example of tubal gestation. The outer end of the Fallopian tube is expanded to the size named, by the clot, and the fimbriae can be seen coursing up over the extremity. It would seem that the implantation of the ovum took place very near the fimbriated end of the tube. The tube and clot were incised before reaching me; save for the incision the tube walls appear to be intact. The fetus (shown in a separate bottle) is about 2 centimeters long, probably four or five weeks old.

DISCUSSION.

DR. GEORGE HENRY CLEVELAND—I am sorry Dr. Hamilton is not present this evening, as I would like to ask him one or two questions, one of which is as to whether the diagnosis of extra-uterine pregnancy was made previous to operation or not.

DR. BISHOP—The notes make no statement on that point, and I have had no conversation with Dr. Hamilton.

DR. CLEVELAND—The question of diagnosis of extra-uterine pregnancy is of a good deal of interest. Tait has created the opinion, either by statement or by his practice, that it was next to impossible to diagnose a case of extra-uterine pregnancy previous to rupture, but that after rupture it was an exceedingly simple thing. Dr. Noble, of Philadelphia, does not agree with Tait, and I have lately observed that he reports some twenty-five cases, in the *American Gynecological and Obstetrical Journal*, of extra-uterine pregnancy, in nineteen of which a positive diagnosis was made. Noble says: "Of the cases in which a diagnosis was made (one strongly suspected) three of them were instances of unruptured tubal pregnancy, and seventeen (two strongly suspected) of cases in which rupture had taken place."

There is another exceedingly important and interesting point in connection with the subject, viz., the causation of tubal pregnancy. In looking over the subject I find it stated that the generally accepted opinion now is that the place of contact of the germ and sperm cell is always in the body of the uterus, and that subsequently the fecundated ovule passes into the tube, lodges there, and then develops. It is a pretty theory, if it is a tenable one.

DR. E. R. LE COUNT—I would like to ask Dr. Bishop whether the case was one of tubo-ovarian pregnancy? I did not exactly catch the description of the case so as to differentiate it.

DR. BISHOP—The specimen plainly shows that there was no relation with the ovary in this case. The ovary is remote from the tube, and was in that position when I received the specimen.

MICROSCOPIC SLIDES.

DR. HUGH T. PATRICK, in demonstrating microscopic slides, illustrating some of the more recent methods of staining nerve tissue, said in substance: The anatomist, histologist, and pathologist will probably agree that the nervous system constitutes the most difficult part of the field of their labors, notwithstanding the fact that enormous strides have been made in our knowledge of this system in the last fifteen or twenty years. As we follow the steps of this advance, we are forcibly struck by the fact that each step was due in large measure to some improvement in appliances or technique. For this reason it is essential that those who would keep abreast of the times and wish to do practical work in the anatomy, histology or pathology of the nervous system must be acquainted with the more recent methods of investigation.

Slides illustrating the following methods were exhibited: Kronthal's method which is particularly adapted for demonstrating the larger cells of the nervous system.

The Bevan Lewis stain is especially important for the cerebral cortex, and it is claimed for it that it shows details and changes not discoverable by any other method. It is particularly valuable in showing hypertrophied neuroglia cells. For the nerve cells the speaker considered it inferior to the Nissl stain which shows the structural details of the various ganglion cells with most exquisite distinctness. Nissl has gone so far as to make a classification of nerve cells based upon the findings by means of this method.

The Rosin stain is simply a modification of Ehrlich's blood stain, and the author would classify the cells of the nervous system on the same basis as Ehrlich divides the various blood corpuscles. His views have been fiercely attacked by Nissl.

The silver stain (Golgi, Ramon y Cajal,) has given us most of the later important discoveries in the structure of the nervous system with respect to both cells, fibers and the various systems. It is not adapted for pathologic work.

The chlorid of iron, dinitroresorcin stain, introduced by Platner, is particularly valuable for peripheral nerves. The speaker hoped to report more fully upon this method in the near future.

The Marchi method is adapted for following the degeneration of fibers not exceeding three months in duration, and in these cases it gives pictures excelling in accuracy and distinctness those of all other methods.

Slides were also shown, demonstrating the Flechsig developmental or embryonic method, the new Weigert neuroglia stain, and peculiar results sometimes obtained by the Weigert-Pal method.

DR. H. B. STEHMAN reported two cases, one of
SUBMUCOUS FIBROID OF THE UTERUS,
and the other of

CARCINOMA OF THE RECTUM,
and exhibited specimens. Mrs. C. J. V., age 55; the mother

of several children has never had any uterine trouble, and passed through menopause without any special disturbance. Two years ago she began to have an occasional uterine hemorrhage; these in time became not only very profuse, but she scarcely, of late, was free from them for any length of time. Upon examination a large tumor occupying the entire uterine cavity, attached to the left and entire fundus, was discovered. The cervix was split bilaterally and enucleated with great difficulty owing to its size. The uterine cavity was tamponed with iodoform gauze and the cervix repaired. Owing to careful aseptic precautions there was no febrile disturbance and the patient was up and about in ten days.

A striking feature of the tumor is not only its form but the depressions which make its resemblance to a fetal head all the more striking. Deep perineal stitches were then used to approximate the wound, leaving an opening of about one inch at the upper angle, which was partially packed with iodoform gauze, the same extending around a tube which communicated with the bowel. This dressing remained unchanged for forty-eight hours, at which time both tube and gauze were removed and re-inserted. The deep perineal sutures were left in ten days, when it was found that union was complete throughout. Several of the vaginal stitches sloughed, causing a fistula which remained open for several weeks, but under faithful dressing closed.

The external wound, which was left for an anus, showed a disposition to close, and a hard rubber tube attached to a plate, so constructed that it would barely reach the bowel, but sufficiently curved to fit it nicely, and held by soft rubber tubing, overcame this disposition and left the opening that had properly granulated. The tube is now worn at night, and the patient is quite delighted with her physical condition which has vastly improved since the operation, and also with the control she has over the fecal movements, provided the feces are not too liquid.

Miss M., age 65. About a year previous to the operation she began to feel some soreness in the rectum, which became in time quite distressing during the act of defecation. Accompanying the movements there was considerable mucopurulent discharge which was occasionally mixed with blood. On digital examination the rectum was found ulcerated, more particularly on the anterior surface and extending up about four inches on the left side. The infiltration involved not only the rectum but the cellular tissue separating it from the vagina. A modification of the Kraske operation was performed, removing the coccyx with the lower sacral vertebra. As you will notice by the specimen, the entire rectum was resected, the dissection including the sphincter ani, the perirectal fat *in situ* and the posterior wall of the vagina up to the fornix, while the bowel itself was amputated still beyond this point. The specimen has been in absolute alcohol for three months, and is quite shrunken. The vagina was then closed with the stitches on the mucous surface, leaving a canal of about one-half inch caliber.

Dr. E. J. SENN read a paper entitled

REPORT OF A CASE OF OSTEOMYELITIS OF THE ANKLE-JOINT,
ILLUSTRATING THE UTILITY OF BONE CHIP
IMPLANTATION.

The patient was 18 years of age, female, admitted to St. Joseph's Hospital with disease of ankle-joint. The case was of two years' duration. Diagnosis of chronic suppurative osteomyelitis resulting from a previous acute osteomyelitis. Patient was etherized, incision made over sinus into joint cavity. A sequestrum in lower end of tibia was removed and some superficial necrotic bone in the astragalus was dealt with by curettement. Cavity was disinfected with mercuric chlorid solution and hydrogen peroxid, dusted with iodoform and packed with decalcified bone chip. Recovery was uninterrupted, the patient bearing entire weight on foot in seven weeks. A point of interest in the case was that probably the osteomyelitis had its origin in the tibia above the epiphysis, and instead of the pus taking the usual course and discharging on the surface after penetrating the wall of the tibia, it extended to the epiphysis and emptied into the joint.

DISCUSSION.

Dr. H. B. STEHMAN—I do not propose to discuss Dr. Senn's paper, but simply to call attention to one point, and that is the method of securing asepsis. I would like to raise a protest against one thing that he has used, which is probably one of the most efficient remedies we have to secure asepsis under certain conditions, and that is peroxid of hydrogen. I believe I can substantiate what I say. While peroxid of

hydrogen is one of the most efficient aseptic agents we have, it does more mischief than any other agent we use in a great many cases; that is, we have a more extensive septic infection after the use of it. I am not criticising the manner in which the agent was used in this case, but I would call the attention of the members of the society to its dangers. Not very long ago I saw a case of death from the use of peroxid of hydrogen, and it is a very dangerous agent to use where we have not free drainage and where there is a great amount of cellular tissue. It is dangerous to use in tendons, as it travels along tendon sheaths and carries infection. I am satisfied I have seen infection carried up the arm where peroxid of hydrogen has been used in infection of the fingers. I simply ask you to beware of it.

THE PRESIDENT—Dr. Stehman's experience is perhaps a little remarkable. It may not coincide with the experience of others.

Dr. JOSEPH B. DELEE—The subject of the use of artificial means to procure obliteration of cavities is a very interesting one, and the use of ivory for this purpose instead of decalcified bone chips is now being worked upon by Professor Gluck, of Berlin. He takes discs of ivory an inch and a half in size and replaces defects with them, and in the active process which goes on the ivory becomes a part of the bone. I have seen dogs operated on in this way and in three or four weeks they would be jumping around the room as if nothing had happened to their femurs. He has taken a joint made of ivory, placed it in position with the normal joint, fastened it, and the joint has become active. This has been demonstrated on the human being. In one case in which the third phalangeal bone of the second finger was missing, by means of two platinum pins he fastened the phalanx, which was made of ivory, and the patient is moving the finger to-day as if he had the normal bone in it.

I think there is a large field open to us in the replacement of defects by means of artificial substances. Gluck has taken steel pins to replace defects in bone, which become so walled in by the tissues, and especially bone, that they will remain for years as a part of the body. In some sections of the joints that were made with ivory, it was not an easy matter to determine where the ivory stopped and where the bone began. The subject has not been as well worked up in this country as it should be.

Dr. GEORGE H. WEAVER—There was one remark made by Dr. Senn which particularly attracted my attention, and was to this effect, that probably the space at the time of operation was not perfectly aseptic. It has been demonstrated—as I presume most of you know—that it is not necessary to make the empty spaces absolutely aseptic. A series of experiments were made by Halsted, of Baltimore, in which he allowed large empty spaces to fill with blood and introduced a considerable quantity of pyogenic organisms into the cavity, finding that these were destroyed and taken care of; that the space was filled with granulation tissue, replacing the temporary blood clot that was formed. If the empty space is filled with various materials in this manner, the secretion from the wound following the operation will take care of a certain number of bacteria if they are not too numerous and of too great a degree of virulence.

Dr. E. J. SENN (closing the discussion)—I wish to say in reply to Dr. Stehman that in certain cases peroxid of hydrogen is harmful, that is, in those cases in which we have a circumscribed focus of suppuration, because the pressure due to the decomposition of peroxid of hydrogen will increase the pressure within the abscess cavity, and disseminate microbes into the connective tissue spaces, and from here enter the lymphatics, eventually becoming diffused. In a case like the one which I have described, the whole joint cavity was infected, and there was very little danger of the infection becoming more diffused by the use of peroxid of hydrogen. I would ask Dr. DeLee whether the ivory joint he mentions was expected to remain as a perfect joint. I was always under the impression that ivory became absorbed sooner or later, but not as readily as catgut. In the cases which I have seen, where ivory bone nails were used in ununited fracture, they eventually became absorbed, and I should think that ivory used in a joint would also in the course of time be absorbed.

Dr. DELEE—The part of the ivory that had become united was infiltrated by the bone cells, so that it is possible in the course of time that the ivory will be entirely replaced by bone and perform the functions of a natural joint. In the case I have reference to, the ivory joint remained for several months, finally suppuration took place and it had to be taken out. The wound was entirely united and we could hardly tell where the bone ended and the ivory began.

American Electro-Therapeutic Association.

Fourth Annual Meeting held in New York Academy of Medicine
New York, Sept. 25, 26, and 27, 1894.

WILLIAM J. HERDMAN, M.D., President.

(Continued from page 70.)

DR. W. S. HEDLEY, of Brighton, Eng., read a paper on
THE HYDRO-ELECTRIC THERAPEUTICS OF THE
CONSTANT CURRENT.

This paper chiefly concerns itself with the electric water bath. Those localized applications by douche, by water introduced into cavities, or by local immersions are, it is understood, to be dealt with in other communications. To designate respectively that form of bath in which the water constitutes only one pole of the circuit or that form in which both poles are in the water the terms "monopolar" and "dipolar" are adhered to. It seems scarcely necessary, however, to admit the words "multipolar" of recent introduction. To regard the multiplication of electrodes as a divided anode or a divided kathode is probably simpler and certainly more correct. The question of exact dosage in the dipolar bath is one of pure physics. In other words the following is the problem that presents itself: with a given current running through a given bath what proportion of such current will find its way through the body of a patient immersed therein? This question, however, does not enter into the scope of the present paper. It is one of extreme difficulty, and well worthy the attention of those distinguished physicists who are about to discuss it. One of the chief difficulties lies in ascertaining body resistance under the conditions of immersion. It is obvious that the body then becomes part of a compound conductor and that it will take its share of current according to definite physical laws. As to what that share is, various estimates have been hazarded. These have varied between 5 per cent. of total current flowing and 20 per cent. and within an even wider range. But so far as the present writer is aware, neither by direct measurement of body resistance nor by more indirect methods has this question ever received a satisfactory answer. Under these circumstances therefore dosage can only be expressed in terms of a certain current, running through a certain bath, containing a human body under certain conditions of immersion. It also becomes evident that if results are to be compared and any approach to exactness arrived at, in no form of electrization is "standard" apparatus of greater consequence than in the case of the electric bath. The dimensions and construction of the bath tub which the writer has found useful in practice are given in an appendix to this paper. With so large a number of electrodes the current is easily manipulated by means of a suitable switchboard. This subdivision of the two poles presents advantages, both in the way of diffusion and localization. Until after investigations more extended than any that have yet been carried out, it will be difficult to assign to the constant current bath its exact place in therapeutics. So far as the present writer is concerned it is still on its trial. He does not hold a brief in its favor. Indeed so far from being its apologist he has to confess that he now finds himself using it much less frequently than the bath with sinusoidal and other alternating currents. But at the same time he feels bound to ask himself how far his practice is based on careful inquiry, and how far it is a mere experiment; how far carried away by the enthusiasm of others; how far borne along on one of these irresistible fashion-waves that every now and then in medicine as in other things sweep everything before them. It may at least be well to suspend judgment until some of the excitement has passed over which, for the moment at least, seems to have placed alternating currents everywhere in the ascendant.

Before proceeding to details, it is well in the first instance to clear the ground by distinguishing between the electric and the purely thermal effects of a bath. The warm bath (i.e. the bath at 95 to 104 degrees F.) slightly increases the activity of the circulation and somewhat retards tissue metamorphosis. It is a valuable soothing agent, but in other respects its effects on the system are almost inappreciable (Shelly). It appears therefore that we have not much to expect from the warm bath *per se*. As a means, however, of applying electricity to the body it is invaluable.

With the dipolar form of bath and a bath tub of the construction and dimensions indicated¹ the writer finds that he uses a current strength of 50 to 280 milliampres. With the cervical, dorsal and terminal electrodes in action the

first bath begins at the lower figure (the current being gradually turned on through a cell collector or rheostat) for the first five minutes. A somewhat greater strength is gradually attained during the rest of the time—which altogether extends to eight or ten minutes for the first bath. Both duration, direction and strength will vary according to the therapeutic result aimed at, the strength and electrical capacity of the patient, the number of electrodes in action and other circumstances. The case is then watched for a day or two, and another bath given with an increasing current. In another day or two, a third bath is administered. Tolerance having thus been attained and no contra-indication having manifested itself, a series of half a dozen baths are taken in successive days. Then follow two or three on alternate days; an average "course" thus extending over about three weeks and consisting of twelve baths. The position of the patient in the bath will vary according to circumstances—completely immersed if desirable to act on the whole length of the spine or sitting upright on the gluteal electrode in the direct line of current between the two laterals in cases where it may be intended to influence the hips or the organs of the abdomen and pelvis; the arms being allowed to lie across the line of current flow or carried to the front of the patient so as to avoid it. Temperature will vary according to circumstances, but 94 to 100 degrees F. is a sufficiently wide range in this climate. It is often considered useful to allow a faradic current of moderate strength to run for a few minutes before the patient emerges from the bath, or while he stands up in the water a cold affusion in some form or a mild faradic douche is applied, according to individual toleration. The patient who finds it necessary to undergo a course of electric baths has not generally any considerable resisting power to cold; he is moreover often nervous or hyper-sensitive. Therefore if stimulation either by cold affusion or by the electrized douche be attempted it is obvious that the operator must have his apparatus well in hand. It is scarcely too much to say that the success of the electric douche depends upon the easy graduation and the perfect controllability both of its electric and of its hyriatic strength. A quarter of an hour's rest is taken and weather and strength permitting, the patient walks at least part of the distance home. In administering a bath to insane, paralyzed, anesthetic and other helpless people, special precautions must be taken especially if the patient be heavy as well as helpless. In certain cases, paralyzed in the lower extremities only, I have availed myself of the suspension tripod ordinarily used for locomotor ataxy. With this placed across one upper corner of a low bed and with an improvised seat or "chair" made of straps or stout webbing, a patient can easily be swung into a bath placed alongside the bed as seen in this rough sketch.

If wholly helpless, the apparatus figured and described by Mr. Stephen for the cold bath treatment of typhoid may be used. Of this, also, I attach a very rough reproduction.

In all such cases the greatest care must be exercised, not only in placing the patient in the bath, but in looking for wounds, ulcerated surfaces, skin abrasions, etc., and protecting them from the action of the current.

Before being placed in the bath the condition of the patient's "sensibilities" (tactile—pain—temperature—muscular sense) must be carefully inquired into. It is within the writer's knowledge that in the case of tabetics who were also anesthetic, serious ill effects have followed the administration of electric baths by incompetent persons whose only limit to dosage is what the patient will bear.

The question of polarity will have to be decided on general principles, or rather by a process of cautious experimentation. The late Dr. Stevenson states that the direction of current flow should generally be from the feet to the head. No reason seems to be assigned for this rule and it is not altogether easy to feel satisfied of its usefulness; but always necessary to bear it in mind, as being the opinion of an admitted authority and the outcome of a large experience.

Although the douche is the subject of a special paper, it will not be out of place to advert to it here as a means of applying the constant current for the purpose of general electrization. To avoid the necessity for repetition and to secure at the same time a certain amount of completeness, some details of apparatus with explanatory remarks thereon, already published by the writer, are added as an appendix to this paper.

Rules for administration, intensity—direction and duration of current flow—the necessity for a *gradual* making and breaking of circuit (unless when the special effects of sudden rupture or reversal are desired), all these things are as in ordinary electrical applications and need not be entered

¹ In Appendix.

upon before a society like this. It will be noticed that the douche apparatus is *single*, not double. The latter has recently been recommended and the details of application as given in a recent essay² are as follows: there are two douches, or jets, one attached to each pole of the battery. While one is directed upon the body of the patient, the other is directed downward on the cemented floor of the cabinet, until a sheet of water is formed surrounding the patient's feet, thus constituting the second or indifferent electrode. This seems a very unnecessary application of douche to the floor, and it is difficult to see why the second electrode be not in metallic communication with the source of supply. There are circumstances when two jets might be useful to secure a strict localization, but any one who has tried to manipulate two jets held at a definite distance apart, and both at equal distances from the body, and at the same time to watch the galvanometer, will not be slow to express a preference for a purely polar application and an "indifferent" electrode. Those who are familiar with what has been already written on this subject will not materially add to their knowledge by a perusal of this essay unless, indeed, it be by the following electrical discovery. Its writer finds to his surprise that not only water but watery vapor will conduct his currents; and the reason why he thinks so is this: the wire connecting one pole of the induction apparatus to douche No. 1 having been detached from the latter, rolled up and hung

about 3 meters from the patient (its other extremity being still connected with the coil), and the second wire still attached to the second pole of the induction apparatus as well as to the metallic part of the second douche, and the cabinet full of a thick cloud of watery vapor—behold, a current was established. The patient said he felt it and the fact, it is stated, was further verified by a galvanometer and a constant current. "Evidently, therefore, the circuit was completed by the watery vapor surrounding the body of the patient."

Before publishing this conclusion it might have been well if the writer, leaving behind him his douches and cabinets and moisture-laden air—but taking with him a large coil and (say) two bichromate cells to drive it, had proceeded to a dry room and there carried out the following experiment: attaching a conducting wire by one of its ends to the secondary of the coil, the other end of this wire being free and the other pole of the coil being "idle," let the coil be put into action. If now the free end of the wire he touched by the finger, a current is felt to pass each time contact is made. A person slightly insulated might then take into his hand an ordinary electrode attached by its rheophore to one (secondary) pole of the coil. If now the "operator" lightly touch the person's forehead a distinct electrical sensation is felt; other things being as in the last experiment—the "idle"

pole of the coil might be connected with a gas or water pipe. Then if the arm be touched by a second person standing "to earth," a distinct effect just short of muscular contraction will be produced. These are not mere experiments, but modified in a variety of ways they are most useful in practice. But the present point is this, that in all these cases, there is a circuit completed—one pole is "idle" and—where is the moisture-laden air? A few experiments with this "idle pole" work might have suggested to the writer in question, that when he hangs up his wire or carbon plate attached to one pole of the coil, he is perhaps in reality only making a good "earth" for his idle pole—via ceiling, wall and floor, and that the earth rather than the watery vapor is the medium of conduction. But there is the control experiment to deal with. It is stated that when a galvanic battery was substituted for the coil, a galvanometer in circuit showed a deflection. Nothing is stated as to the character of this deflection. Was it a steady and persistent rise denoting leakage—or was it a "kick" denoting some possible capacity effect, or was it neither, or only an error of observation? Be the explanation what it may, the following simple experiment will exclude the one (watery vapor conduction) offered in the essay referred to. Let the experimenter provide himself with a tea-kettle boiling and with a

good jet of steam issuing from the spout. Then taking a metal tube say two inches long by two inches diameter, connect it with one pole of a c.c. circuit having a pressure of 115 volts, placing in circuit a galvanometer, and a rheophore of (say) 600 ohms. Hang this tube at the end of the kettle spout so that the steam issuing from the spout becomes condensed in the metal tube and assumes the appearance of a dense cloud of watery vapor. To the other pole of the source of supply, attach by its rheophore an ordinary metal disc electrode having a wooden handle. Now, holding this handle, let the watery vapor driven through the tube play upon the metal disc held at say one-fourth of an inch or as near as possible to the tube. The ordinary galvanometer will not betray the completion of a circuit by the very faintest "kick." How, then, can it be hoped to convey a therapeutic current by such means? Now all this is very elementary and I owe an apology for bringing it before this society. But the case quoted is no solitary instance of that loose and inaccurate work which has again and again brought medical electricity into disrepute. Better than to theorize is simply to try.

Speaking broadly, the painless and evenly distributed current of the electric bath makes it one of the best methods of general electrization, with, at the same time, a considerable power of concentration on special parts, according to the indications of the case. In all states of general debility

² Sur une nouvelle méthode d'application des courants électriques à l'aide de l'eau et de la vapeur d'eau. Par le docteur P. Guyénot.

and impaired nutrition (Erb), in weakness or exhaustion of the spinal nervous system, "nervous dyspepsia," palpitation hysteria (Erb), neurasthenia, ("nervous breakdown,") and many of those diseases referable to some derangement of the nervous system without appreciable lesion, commonly called neuroses, it may be resorted to with excellent and unique results. Neuralgias, sciatica (whether perineuritic or purely neuralgia), paralyzes both of central and peripheral origin, chorea, primary lateral sclerosis, muscular rheumatism, gout, rheumatoid arthritis, and occasionally chronic articular rheumatism are all recorded to have been cured or alleviated by its use. It is said that it has been used with good effect in some irritative conditions of the spinal cord, in alcoholic or mercurial tremors, plumbism, and even paralysis agitans (Lehr, Erb), and peripheral neuritis from whatever cause, though not, perhaps, in every stage.

Of the cases which the present writer has found himself able to treat by the constant current bath with a fair measure of success, perhaps the largest is that of rheumatoid arthritis. He, comparatively seldom, is fortunate enough to encounter this class of case in an early stage when it can be dealt with as a trophoneurosis—but even when of old standing with articular mischief well established, locomotion may be improved and pain relieved more frequently, at least, by this than by any other remedial measure with which the writer is acquainted—with the exception perhaps of baths with the current from alternating light circuits, having a pressure of 100 volts and about 8,000 alternations. His experiences of this treatment in other diseases may be summarized thus: muscular rheumatism frequent and rapid cures—not superior, however, to other electrical methods. Chronic articular rheumatism—results on the whole disappointing. Gout often improved after a course of baths in suitable cases, but being generally combined with other remedies and *always* with dieting, the exact relationship of cause and effect becomes comparatively obscure. Sciatica, good results—not superior to alternating current baths but perhaps superior in the majority of cases to other electrical methods. Urethral synovitis only yields to these baths when the disease has continued for some time and is probably waning in the ordinary course of events. Locomotor ataxy—occasional alleviation in symptoms but not always easy to separate results from those periods of arrest which usually characterize the disease. Not all cases suitable. Chorea—ordinary cases sometimes get rapidly well under a course of these baths as after faradic baths or any other form of treatment, or after no treatment at all. But that comparatively small class of cases (occurring before 20) which not only do not cure themselves but often resist even rest and arsenic, and known as "relapsing" chorea have been treated with only temporary benefit, lasting perhaps for only a few hours after each immersion, seldom with a permanent success. In amenorrhea, a current localized between the lateral and gluteal electrodes has in several instances been found quickly successful. Among the rarer cases one of melancholia and one of hysterical paralysis have been greatly improved. In the insomnia of neurasthenia this form of bath has been found useful as a beginning of electrical treatment. A case of "ataxic paraplegia" has been notably benefited and in Parkinson's disease the tremor temporarily alleviated. In the four last-mentioned cases, however, alternating currents were also used.

The following result of treatment by electric baths has been kindly sent me by Dr. Lewis Jones from recent records of the Electrical Department of St. Bartholomew's Hospital:

A.—GALVANIC BATH, ANODE TO FOOT.

Sciatica:

1. Louisa F., 41, twelve baths, 200 milliampères, sciatica, cured, general health improved much.
2. Louisa F., 41, eight baths, cure.
3. Henry G., 64, relieved after four baths; returned five months later; eight baths, but no relief.
4. Henry G., 64, cure after four weeks; eight baths.
5. M., gonorrhœal rheumatism, nine baths, no definite improvement.
6. F., rheumatoid arthritis, twelve baths, slight improvement.

B.—FARADIC BATH.

7. H. B., male, 43, 7 baths; induction coil; cure.
8. Male, 47, seven baths; induction coil; cure. A long previous treatment with anode to thigh (without baths) ineffectual.
9. F., 50, rapid cure, number of baths not given.
10. Thos. H., 25, galvanic baths first, then anode to thigh. Then faradic baths last, most useful—relieved.

C.—ALTERNATING MAINS.

11. R. E., 60, male, fifteen baths, sinusoidal, cure.
12. F., 30, female, four baths, sinusoidal, cure.
13. F., 30, female, same patient with general rheumatic pains two years previously, had galvanic baths, twelve, and was cured.
14. W. H., 23, male, five baths, much relieved. Left London; wrote a week later that improvement continued.
15. G. T., 25, female, severe neuralgia (cervico-brachial), ten baths, sinusoidal, cure—old standing case.
16. F., rheumatoid arthritis, twenty baths, no improvement.
17. F., rheumatoid arthritis, twenty baths, doubtful.

Those rarer uses of the constant current bath consisting of the introduction of medicinal substances, or the elimination of metallic impurities ("medication and de-medication") must be considered. The latter is demonstrable and certain. Apart from other evidence, a case has occurred within the writer's knowledge where an appreciable quantity of lead which could have come from no other source than the tissues of the body, was found in the deposit on the copper plate. To carry out the process in a case of plumbism, a little sulphuric acid is added to the water of the bath into which a large copper plate connected with the negative pole of the battery is introduced.³ The patient then grasps the anode (outside the water) and the current is gradually turned on. The lead from the patient's tissues becomes deposited on the copper plate according to the law well known to electro-platers. For metals other than lead, nitric acid takes the place of the sulphuric. The question of making use of the constant current bath as a means of introducing medicinal substances into the body deserves a close and patient investigation. Now that the process of cataphoresis has passed the experimental stage, this method is not without a promise of tangible results. Its practicability will depend upon the density of current necessary to secure with a given substance cataphoric transference through the skin. If, in order to secure a large surface for the anodal diffusion, the bath be made monopolar and the water anode, the density of current per square centimeter of body surface must be exceedingly small. If the external electrode be anode, it is difficult to see any advantage of the bath over ordinary methods of cataphoric medication. Speaking in the absence of experiment, which alone can decide such questions, it would seem that the dipolar bath, in which large currents are practicable, will be found the only efficient form of bath for this purpose. For use with mineral waters, and equally for medicated water, Gartner has, it appears, introduced a division or diaphragm into baths. The present writer has not seen this arrangement, but presuming that the body passes through the diaphragm and even without supposing the possibility of securing an actual electro-tight junction between the two, the arrangement seems practicable. (It may be suggested that (supposing an electro-tight junction), the same expedient might also perhaps be available to determine body resistance under conditions of immersion.) The questions, then, for the experimentalist seem these: What is the current density required to pass a certain substance in a solution of a certain strength through the skin? Is such a density theoretically secured on the surface of the body by the current proposed to be used? Can the medicinal substance be found in the secretions or excretions of the body after having been subjected to the conditions named?

The treatment of skin disease by electrical methods is one of great and growing importance. The material in possession of the present writer does not enable him to deal with it in any satisfactory way so far as the constant current bath is concerned. Judging, however, by the few cases in which he has seen it used (urticaria and eczema), and by the effects of other forms of electrical treatment with which all are familiar, this form of bath would seem to deserve a patient and extended trial. No doubt there are those present who have valuable experience on this point. For purposes of the present paper and his own information the writer has consulted special works on cutaneous disease, but without adding materially to his information. Among these works, however, there lies before him a brochure on "The Bath in Diseases of the Skin,"⁴ wherein (at p. 81) he finds a passage so interesting and instructive that he ventures to extract it: "It will naturally be expected that I should say something of the galvanic baths. . . . I frequently employ them

³ Unless the bath itself be of copper.

⁴ The Bath in Diseases of the Skin, by J. L. Milton, Senior Surgeon to St. John's Hospital for Diseases of the Skin; Lecturer on Diseases of the Skin; Member of the Harveian Society; Corresponding Member of the New York Dermatological Society, etc.

through the medium of a foot bath; one foot being placed on each handle and the force being given by the 100 cell Becker Muirhead used at the hospital, or a good-sized wheel magnet." After indicating this latter novel source of galvanic supply the author proceeds: "But to suppose that a galvanic bath possesses any power beside that inherent in galvanism . . . I certainly say that if such be the case it has entirely escaped my powers of observation." So say we all, and it would be pleasant to leave the question at a point where none can differ, but the following passage seems too instructive to omit: "In matters of charlatanry an amount of credulity is constantly met with even among the educated classes of this country which would be considered abject superstition in a Hottentot. The opinion may seem a strong one but . . . what are the proper words to use respecting the confidently expressed statements by patients that they know that the disease has been drawn out by the electricity and that they have seen it deposited at the bottom of the bath in the shape of shreds." To those who know anything of the matter an interesting question here suggests itself. Was this a case of metallic poisoning? Is it possible that a patient in describing the disease as "drawn out by the electricity," might have been making a practically accurate statement of what sometimes is known to occur? Is it within the bounds of possibility that this was an instance of the elimination of metallic impurities from the body by the agency of the constant current bath—a case of "de-medication?" Perhaps, after all, a patient without the learned author's medical (and electrical) knowledge in speaking of such a deposit had scarcely done anything so outrageous as to deserve to be called a Hottentot. We must, however, tear ourselves away from this fascinating and instructive volume; this paper has already grown to undue length and its writer owes and offers an apology.

APPENDIX.—(Not forming part of the foregoing paper, but explanatory of it and inserted here to secure a certain measure of completeness without the necessity of repetition.)⁵

Against the hydro-electric methods, more, perhaps, than against any other form of electrical treatment, has been levelled the charge of empiricism. And, perhaps, not without reason. Never having been adequately investigated, their real power is but little known, and their real province but little understood. Could anything, for example, be looser and more haphazard than the way in which that commonest and best of hydro-electric methods, the electric bath, is commonly prescribed and administered? For carrying out treatment by these methods, the electrical equipment must be not less complete than that for other purposes. The requirements will be:

1. A constant current supply in the shape of a battery with a low resistance which will work up to a powerful current strength through the estimated R. If we take our supply from an electric light circuit, it will have to be safe-guarded by shunts and appropriate resistances in addition to a reliable "cut-out."

2. A means of opening and closing the circuit, and regulating strength by easy gradation so as to avoid pain or shock, *i. e.*, "current-collector," or rheostat or, in dynamo circuits, an adjustable rheostat or a sliding shunt.

3. A milliampere meter, *i. e.*, a galvanometer graduated in milliamperes, and registering up to, say, 500.

4. A powerful induction coil for faradic bath or supply from an alternating dynamo.

5. Some means of suddenly reversing the current ("current reverser" or "pole changer") as well as an arrangement for throwing the two currents together for combined use ("current combiner" or "De Watteville key").

6. As an adjunct but not an actual necessity may be mentioned a voltmeter, useful for occasionally determining the electro-motive force of the battery, or any particular cell, and for other purposes. Some galvanometers are also voltmeters.

The ordinary electric bath is best made of oak or porcelain, perhaps porcelain for choice, if expense need not be considered. Insulation must be carefully attended to, both of conducting wires and waste-pipe, the latter being insulated from earth by a short length of rubber tubing let in near the bath.

The bath may be an ovoid oak tub, four feet ten inches long and two feet six inches at greatest width, which is about two inches nearer head than foot. Height at head one foot eleven inches, height at foot one foot five inches. There are five fixed electrodes of bright metal covered only by light removable open wooden framework, size as follows:

Cervical, 28 x 29 cm.

Lumbar, 24 x 17 cm.

Lateral (2), 26.5 x 18 cm.

Gluteal (circular), 30 cm. (diameter).

Terminal (foot), 22 x 38 cm.

In addition to these there is an electrode for monopolar purposes, consisting of a removable metal rod, one inch in diameter, covered with wash leather. This is fixed across the widest part of the bath, and can be conveniently grasped by the hands. These electrodes are connected, by carefully insulated wires, with seven terminals, and these in turn lead to a switch-board, so arranged that by the insertion of plugs any electrode can be brought into action, either as anode or kathode. The connection with the battery, coil, or other source of supply, is by means of well-insulated connections leading to two ordinary "binding-posts" on the plug switch-board.

It is best in the interests of cleanliness, if for no other reason, that the electrodes be of bare bright metal, as the cleansing and changing of covers is often very imperfectly attended to, and is a matter of serious consequences sometimes, as several unfortunate instances show.

The size of the electrodes will depend upon the theoretical considerations already advanced, looked at in the light of experimental results which are detailed elsewhere.⁶ But, speaking generally, the sizes and positions of those electrodes already mentioned are suitable. The only further addition (and a very useful one) is the so-called "paddle" electrode. By means of a long insulated handle this electrode can be applied to the vicinity of any part of the body upon which it may be desirable to concentrate the current.

For the comfort of the patient it is sometimes considered advisable to use some support for the shoulders. Individual views and ingenuity will here be the guide. One way of effecting the purpose is to use straps, one under the back of the neck, the other supporting the body under the arms. Another method is to have an open framework, made of wood and webbing, somewhat like the invalid appliance known as a "bed-rest." For spinal affections the wooden "back-rest" may be modified by having it made solid, excepting a longitudinal opening throughout its whole length opposite the vertebral column, the upper electrode being of such size, shape, and distance from the part as to allow the lines of current flow to concentrate themselves on this opening. My experience, however, is that with the bath shaped as described—the fixed metal electrodes in the positions named, and controlled by a switch-board—the current can be so handled as to concentrate it, or diffuse it, or send it longitudinally, or transversely, or obliquely, through the water as may be desired.

The question of "density," which is so important a factor in "dosage," and which in ordinary electrical applications depends upon the size of the electrodes, becomes a very complicated one in the dipolar bath. Here it is evident that not only the size of the electrodes is to be considered, but also the amount of diffusion the current undergoes in passing through the water from the electrode to the body; and this will depend partly on the size of the electrode, partly on distance, and partly on the conductivity of the water. In other words, we have not only to consider the size and position of the electrodes electrizing the water, but we have to look upon the whole extent of water in contact with the body, as a huge electrode carrying a widely diffused current with a density diminished in proportion to its diffusion.

The device of placing a partition or diaphragm across the bath through which the immersed body passes seems well worthy of a trial. It must in an important degree influence current diffusion, and if further investigation and experience prove its usefulness it ought to become a constant feature of the "standard" electric water bath.

(To be continued.)

American Climatological Association.

Twelfth Annual Meeting held at Hot Springs, Va., June 13 and 14.

The President, DR. S. E. SOLLY, of Colorado, made a brief introductory address, congratulating the society upon the good attendance and the choice of such a pleasant place for meeting.

DR. GUY HINSDALE, of Philadelphia, read a paper on "Recent Measures for the Prevention and Treatment of Tuberculosis," reviewing the provision made in England, Germany, France and the United States for the care and treatment of the consumptive poor.

⁵ The Hydro-electric Methods in Medicine, W. S. Hedley, M.D., July 1, 1892.

⁶ Hydro-electric Methods.

DR. FREDERICK I. KNIGHT, of Boston, reported that the committee having this matter in hand in Massachusetts had recently secured an appropriation of \$150,000 from the Legislature for the erection and maintenance of a hospital.

DR. H. L. TAYLOR, of St. Paul, under the title "Clinical Results of the Use of Tuberculin," gave a report of seventy-two cases, with a complete analysis of thirty-nine cases, treated by this method. Eighteen were third stage cases; of these seven died; five became worse; five improved, and one improved greatly. Taking the first and second stage cases together—the only cases in which the physician would encourage a patient—there was a total of twenty-one cases with a mortality of 10 per cent. In the early cases by themselves, 84 per cent. improved greatly. While not considering tuberculin a certain remedy, Dr. Taylor held that its careful use is not dangerous, and that, in beginning cases, its use should be encouraged.

In the absence of DR. V. Y. BOWDITCH, chairman, Dr. E. O. Otis, Boston, presented the Report of the Committee on Health Resorts in the United States. The work of this committee will appear from year to year in the transactions of the society and will ultimately be published in book form.

"Sunshine Statistics" was the subject of a paper by PROF. MARK W. HARRINGTON, Chief of the Weather Bureau, Washington. The sunshine—that is, the presence of a direct ray of the sun, not shut off by cloudiness—forms one of the most interesting elements of meteorology, from a sanitary standpoint. The data considered were all from the United States, with the exception of two stations in Canada. The number of years during which these data have been collected in the United States is smaller than in Great Britain, and there is a large literature and a long series of observations in English and other European publications. Professor Harrington's paper was divided into three parts: a description of the photographic sunshine recorder, with the results obtained from it; a discussion of the thermometric sunshine recorder; a comparison of the results obtained in the United States from these two records.

DR. W. F. R. PHILLIPS, of the Weather Bureau, read a paper on "Mean Atmospheric Temperatures." Throughout the month of July the average daily temperatures exceed 70° in the States bordering on the South Atlantic and Gulf coasts and in the greater part of the Middle Atlantic States.

The paper gave statistics as to the mean minimum temperatures and the mean maximum temperatures in July.

The variability of temperature or average difference from day to day is less in July and August than in any other months of the year, and it is so nearly alike in either that it is not practicable to discriminate between them in this respect. In other words, July and August are the most equable months of the twelve as regards temperature. On the Pacific and Gulf coasts the variability is little more than 1 degree. As we go northward and inland the variability gradually increases. In the latitude of Savannah it is equal to 2 degrees, and in that of Washington City 3 degrees. The greatest variability is observed in Montana and in the Dakotas, where it reaches 4 to 5 degrees.

East of the Rocky Mountains the highest one day mean temperatures have been observed generally in the central valleys and in the South Atlantic States.

The lowest mean temperatures for one day have ranged from 75 degrees on the Gulf to 55 degrees in the northern portions of the United States. In the greater part of the country the lowest mean temperatures range between 60 and 65 degrees.

DR. RICHARD C. NEWTON, of Montclair, N. J., read a paper on "Some Observations which appear to establish the Aerial Transportation of Malarial Germs." After reviewing the evidence brought forward to prove the transmission of malaria by water, he took up the literature bearing upon the belief in aerial transmission. He believes it fair to assume that in places ordinarily non-malarial the drinking water is probably the more frequent cause of ague, when it does appear, than the atmosphere; but that in places like the Campagna of Rome, the Orinoco River in South America and the jungles of East India, where malaria is so constant and so deadly, the atmosphere is the usual method of its transportation.

"The Geographical Distribution of the Mineral Springs of the United States," was read by DR. A. C. PEALE, Washington. Dr. Peale has recently compiled two maps; one showing the distribution of the 330 springs, the waters of which are put upon the market to the amount of 20,000,000 gallons annually, with a valuation of from four to five million dollars. Upon the other was plotted nearly seven hundred mineral spring resorts. The majority of the springs used

commercially are in the Eastern United States and the Mississippi Valley; not because the number of springs is much greater in these regions, but because the resources are better utilized. The writer gave an interesting discussion of the subject, including a description of the springs of the various districts and showing their dependence upon the geologic structure of the country.

DR. S. E. SOLLY, of Colorado Springs, read a paper upon "The Influence of Heredity upon the Progress of Phthisis," to be published in full in this JOURNAL.

At this session, papers were also read as follows: "Etiology and Treatment of certain kinds of Cough," Dr. Beverly Robison, New York; "A Case of Simple Chronic Pleural Effusion; its Final Outcome," Dr. J. C. Mulhall, St. Louis; "Two factors in the Production of Disease in New York City," Dr. Thomas Darlington Jr., New York.

Officers for the ensuing year were elected: President, Dr. James B. Walker, Philadelphia; Vice-President, Dr. C. E. Quimby, New York; Treasurer, Dr. James E. Hart, Colorado; Secretary, Dr. Guy Hinsdale, Philadelphia.

DR. FREDERICK I. KNIGHT, of Boston, was elected Representative to the Executive Committee of the Congress of American Physicians and Surgeons, and Dr. R. G. Curtin, of Philadelphia, alternate.

On motion of DR. F. I. KNIGHT, the following resolution was unanimously adopted:

WHEREAS, Since tuberculosis has been demonstrated to be a communicable disease, it has become doubly desirable that hospitals for the reception of the poor afflicted with this disease should be established.

Resolved, That the American Climatological Association recommend the establishment of such hospitals in every State, not only for the great suffering attending this disease among the poor, but also as a protection to the community against its spread.

At the request of the Association, DR. C. E. QUIMBY presented the following resolution:

Gentlemen of the American Climatological Association:

Duty and established custom makes it fitting that in formal manner your committee report to this Association the death upon Jan. 23, 1895, of our former President and member, Alfred L. Loomis, M.D., LL.D.

Love and respect make it imperative that in so reporting we dwell for a moment upon the many ties which united us, and make some record by which his many and varied gifts and qualities which have enriched us may be made a powerful influence upon those who are to continue this Association.

Dr. Loomis was born in Bennington, Vt., in 1831. His early education was largely under private tutors at Woodstock, Vt., while his academic degree was taken at Union College. After graduation in 1852, at the College of Physicians and Surgeons, he served the usual term in Bellevue Hospital. Very soon after starting in private practice he was appointed visiting physician to the same hospital, where he continued in active duty until the day of his final illness. For more than thirty years Dr. Loomis held the chair of pathology and practice in the Medical Department of the City of New York, and to his energy and wise efforts, more than to any other force, may be attributed the growth and prosperity of that institution.

In his professional life, Dr. Loomis was preëminently an active, energetic, sagacious physician. In all his relations to medicine and medical progress he was conservatively but uniformly progressive; never assuming an advanced position until fully or even superfluously convinced of its accuracy, he was unfaltering in its defense. A similar faith in the eventual success of truth, made him unable even to consider the possibility of failure in any purpose once undertaken.

Dr. Loomis was one of the faithful band who originated this Association, and we all know how faithfully he worked for its advancement and success. He was its first President and was again its President during the first Congress of American Physicians and Surgeons in Washington assembled and, as our delegate, was elected the President of the third Congress.

At one time efforts to merge the American Climatological Association into another national organization threatened to destroy it. Dr. Loomis averted the danger if any such existed. He had a most enviable reputation; not only in his professional but also in his private life. He was a frequent contributor to the proceedings of this Association.

In expressing our sense of personal as well as united loss in the death of Dr. Loomis, we realize that we can do him no greater honor than to present this record of his work for a perpetual stimulus to members of this Association.

W. H. LOWDERMILK & CO., WASHINGTON AGENT.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 86 Fifth Avenue, Chicago.

SATURDAY, JULY 20, 1895.

DEGENERACY.

This term has suddenly come into prominence, as describing a class of popular modern literature. DR. NORDAU'S work on "Degeneracy" has created a profound impression and roused bitter criticism and extravagant praise. He attempts to show that the literature and many of the popular authors of today are degenerate and diseased. DR. NORDAU is not only a physician and practical student of mental disease, but a clear, vigorous thinker and writer and has made out a very strong case. While a large number of physicians are not very familiar with many of the authors described, they will recognize the evidence presented, and will follow the author with keen pleasure in his grouping of symptoms and the deductions which follow. There can be doubt from the writings alone, that a large class of books widely read are the products of thoroughly diseased minds. Stories, essays, poetry and discussions of popular topics have certain stigmata of diseased and disordered reasoning that are unmistakable. The reader is referred to DR. NORDAU'S work for a full discussion of these topics.

The question is often asked by thoughtful men, why medical literature should be so vague and confusing? Why the ordinary journal articles from the *British Medical Journal* and *London Lancet*, down to the latest-born periodical which boasts of coming to "fill a long-felt want," should have so many signs of egotism, mysticism and dogmatism? Why so many writers and teachers should manifest such hysterical confidence in every new theory and alleged discovery in medicine? Why should the practice of medicine develop in certain persons intense selfishness, cre-

dulity and ego manias? These and many similar questions have often recurred to close observers, and are unexplained except on NORDAU'S theory of degeneracy. The rush of half-trained, incompetent young men to obtain entrance into the profession of medicine; and the selfish, grasping teachers and colleges who encourage this; and the isms and pathies, mystical, confused and narrow that gather up these men, are symptoms of degeneration. There is arrested development, imperfect growth, degeneration both physical and mental, with vicious training at the bottom. They come into the profession prepared to foster all sorts of errors and new beliefs, to follow blindly the teaching of some prominent medical man; gathering round the flaring lights of some novel theories, and accepting them without question. Or they may mount some pedestal of their own fancies and go down through life supporting wild theories and defending strange, unhealthy views of science, superstitious egotists, impressionists, medical mystics. Clearly they have passed over into the army of degenerates, and leave unhealthy influences and memories behind them.

All these men lack soundness of mental development; they are inharmonious in conduct and judgment; they seldom advance the cause of truth, and rarely ever do any scientific work that is sound and true. In medicine they are pessimists and critics, pulling down every good work, and pointing out bad motives in others who are working for truth. In medical colleges they are bitter rivals for places and supposed honors, and boating manias; mechanical teachers, and call themselves practical, as an explanation for want of technical knowledge. As journalists, they are chiefly noted for frantic efforts to become popular with their readers and avoid offense on every topic. The reader readily recognizes the vast number of books, papers and journals on medicine that are as dreary and destitute of scientific life as the alkaline plains of the West. The authors are simply writing out their own degeneration, pointing out evidence of dementia, melancholia, deliriums, symbolisms, mysticisms, decadents, and general failure of healthy vigorous thought.

NORDAU'S degenerates are not all writers of fiction and teachers of philosophy. They are found in medicine, in law and theology. Men who oppose reforms in preventive medicines; men who oppose laws for the regulation of practice; who want all barriers thrown down and a free open field for all kinds of practice; who would like to follow medicine as a trade and use the papers to advance their interests, the same as a circus, are evidently away over the border lines of health. Physicians who are looking for truth in the mysteries of quackery and concealment; who expect figs of thistles and grapes from thorns; who expect facts by intuition and

without labor, and become enthusiastic defenders of theories that are untested and unproven, are clearly of NORDAU'S class. Medicine, like other sciences, is not a great camp-ground for parade and show and trade. It is a road narrow and rough, leading out into the unknown; a road for discovery, for investigation, lined with facts and new truths. No man of health properly trained can traverse this road without observing new facts and new laws governing them, and be impressed with the vastness of truth and his limited capacity to understand it. Modesty, conservatism and persistent study of the constantly changing evidence, are signs of health. Dogmatism, assertiveness, credulity and hysterical enthusiasm in defense of facts show an involved brain. The mania to write, to teach, to lead as authority, with no bases but the inner consciousness and some acquaintance with cotemporary medicine, and a morbid faith in the writings of foreign authors, is a sad sign of decadents.

What we need is a larger, clearer, more vigorous literature; a literature of facts, urged by robust men, who stand on strong ground and who write and teach for the purpose of stimulating further study and inquiry along the same lines.

THE EARLY DIAGNOSIS OF DIPHTHERIA AND THE PHYSICIAN'S DUTY WHEN CONFRONTED WITH CASES OF DOUBTFUL CHARACTER, PRESENTING SYMPTOMS OF DIPHTHERIA.

The existence of the Klebs-Löffler bacilli in the secretions or exudations, upon an acutely inflamed pharyngeal mucous membrane, or upon the tonsils, as demonstrated by microscopic examination of cultures, is relied upon at the present day as the prime indication that diphtheria, or, to be more specific, diphtheritic angina is the correct diagnosis in the case. Similarly, when the colonies of bacilli are located beneath the epiglottis, we recognize the presence of a diphtheritic laryngitis, which may or may not be preceded, attended, or followed by angina, but is still truly diphtheria. So firmly is the bacteriologic diagnostic test relied upon, that communities and boards of health all over the world are establishing expensive laboratories mainly for the purpose of making these culture-tests, the finding of the Klebs-Löffler bacillus in doubtful cases being held to be conclusive evidence of the presence of diphtheria. Since the diagnosis of diphtheria often involves forced isolation and so-called household quarantine, with all the vexation, inconvenience and disturbance of social and business relations resulting therefrom, it becomes a matter of considerable moment, at least to the city physician, that he shall avail himself, in all cases of supposed diphtheria, of the assistance offered by the municipal laboratory. This is the more important, because as it appears to us, in thus coming to the aid of the physician, the authorities for-

mally relieve him of the risk and responsibility of making the positive diagnosis of diphtheria.

It must be borne in mind that under the regulations prevailing in our principal cities, the diagnosis of diphtheria falls upon a family like a veritable calamity. The Health Officer enjoys the unenviable distinction of adding new terrors to death. His advent in the family circle is regarded with undeserved but undisguised aversion, and his departure is the occasion for general rejoicing and libations of disinfectant solutions. Under these circumstances it is only natural for a physician to proceed with due caution when confronted with a case of suspicious-looking sore throat; if it be diphtheria and he should neglect to report it, he may find himself in the disagreeable position of becoming the object of official censure, in addition to being treated as a criminal and being forced to pay a heavy fine; or he may report it and incur unreasonable enmity, the consequences of which he can not foresee. Should he be so unfortunate as to make a mistake in diagnosis, or should such a mistake be only asserted by the patient, the results may be sufficiently serious, as in a case occurring in Philadelphia recently, where damages to the amount of \$50,000 were claimed for an alleged error in diagnosis, the patient having been taken to the municipal hospital on the physician's diagnosis of diphtheria. In such an emergency, the possession of an official certificate from the public bacteriologic laboratory, stating that the characteristic diphtheria bacilli were present in the secretions, would have a very soothing influence upon the mind of the doctor defendant.

The duty of the physician, when called to attend a suspected case of diphtheria, is stated in a recent monograph by L. FURST¹ in terms which may be regarded as expressing the most recent views held in Europe, with reference to the early diagnosis and treatment of this important disease. In diagnosis, he gives the first place to the clinical complexus and states that the symptoms alone will enable us to make a diagnosis between diphtheritic anginas and the non-infectious forms with approximate certainty and sufficient promptness; but the bacterial diagnosis forms a valuable supplement, which should not be neglected. In the great majority of cases of supposed infective anginas, the positive proof of the presence of the diphtheria bacillus turns the scale in favor of the diagnosis of diphtheria. Where the bacteriologic tests yield no evidence of the presence of the characteristic bacillus, but only of pseudo-diphtheritic forms, streptococci, etc., the disease, according to FURST, is still to be regarded as diphtheria and is to be treated accordingly, provided the clinical symptoms call for such treatment. On the other hand, even though the diphtheria bacilli be

¹ Berliner Klinik. Sammlung Klinische Vorträge, Marz, 1895.

found, the diagnosis is not to be regarded as conclusive, unless the usual local appearances and general symptoms warrant it. As physicians can not be expected to provide themselves with bacteriologic laboratories at their own expense, the duty of making the clinical diagnosis is imperative; but it is deemed also necessary that public institutions of this kind shall be established by the health authorities in all large centers of population, in order to positively determine the character of the infection in doubtful cases of diphtheria.

As regards treatment, serum-therapy now has the floor. The duty of the attending physician is stated—rather dogmatically it may be thought in view of the unsettled questions still remaining to be solved with reference to the so-called antitoxin—as follows: the physician, in cases of suspected character, or supposed diphtheritic angina, should at once proceed to apply local treatment and administer serum injections, while adopting prophylactic measures, isolation, etc., without waiting for the report of the bacteriologic examination. Should the examination yield a negative result, the injections possibly being unnecessary, FURST regards this as only an insignificant evil in comparison with the very decided risk which had been set aside by the early treatment. He strongly urges that in all convalescing cases of diphtheria, attendants, children of the family, school companions and others, in short, wherever there is a possibility of the spreading of the bacillus diphtheriticus, that the throats should be subjected to the same bacteriologic examination, even when they present no symptoms of disease. All of those who have been exposed to infection should, without exception, be immunized.

This may be regarded as a summary presentation of the most advanced treatment of to-day. That it will be still regarded as sound doctrine ten, or even five years from now, very few will be bold enough to affirm. The argument from analogy and experience with other new remedies, would rather favor the view that the serum-therapy of diphtheria is still destined to undergo important modifications before it can be regarded as permanently established; unless, indeed, our health authorities shall take the unprecedented step of imposing, by legal enactment, this special method of treatment upon medical practitioners of all kinds, including the several restricted schools of practice—a step which they are not likely to take, or, at least, not very soon.

This subject has been under discussion at various society meetings during the past year, and it was a special feature of the session of the Association of American Physicians at Washington. DR. W. H. WELCH very accurately summed up the situation in his statement that: "The decision as to the efficiency of the diphtheria antitoxin is in the hands of the

clinician and not of the pathologist." The clinician, however, was ably represented by DR. JACOBI, who declared himself to be a practical man, desirous of saving his patients, and advised that the local and systemic measures which experience has proved to be useful should not be laid aside while also resorting to serum-therapy, in cases where it seems likely that it may be beneficial. This advice is sound and the course of proceeding prudent, following both the letter and the spirit of the injunction to "prove all things and hold fast to that which is good."

THE ASSOCIATION AND ITS JOURNAL ABROAD.

In his appreciative, genial and always interesting gossip of the month MALCOLM MORRIS, editor of *The Practitioner*, takes occasion in the current mensural to say some very pleasant things about the AMERICAN MEDICAL ASSOCIATION and its JOURNAL, which it will, no doubt, gratify the members of the one and the readers of the other to see reproduced.

While it is pointed out that our ASSOCIATION is a much smaller, and less wealthy body than the British organization, MR. MORRIS, basing his judgment on the reports of the recent Baltimore meeting, holds that the scientific work which it does is no whit inferior in quality and but little inferior in quantity to that of its cis-Atlantic homologue. "The general level of the communications was high, but I was particularly struck by the importance of those dealing with surgical and gynecologic subjects." Particularizing as to these he cites the Address on Surgery by DR. C. A. WHEATON of Minnesota, who "raised a voice of warning against what the late PROFESSOR VERNEUIL called the *furor secandi*, which has sometimes given the enemies of medical science cause to blaspheme and which is looked upon with disfavor by the more conservative spirits among hospital surgeons. DR. WHEATON said that a retrospective examination of surgical literature since the introduction of anesthesia 'does much to make the thinking student wonder whether the longevity of the human family has been conserved or its physical welfare materially enhanced by modern surgery.' Has not, he asked, our feeling of safety engendered by our acknowledged perfection in surgical detail opened a wide field of surgical speculation and experiment that serves rather to enrich the surgeon (the orator refers, I presume, to intellectual enrichment) than to minimize disease and prolong life? DR. WHEATON, however, spoke with enthusiastic appreciation of the achievements of a score of brilliant men, whose work had been instrumental in placing surgery in its present advanced position."

MR. MORRIS does not agree with the orator as to the decline of the "family physician"—at least in England, where he says there is no such decline. "Some years ago it was predicted that the general

physician would in time be forced out of existence by the inevitable development of specialism; but I find it simply impossible to conceive of an evolution of the medical profession which would cause the family doctor to disappear. He is the foundation on which the whole superstructure rests. Perhaps, however, by the words 'family physician' DR. WHEATON means the general physician as distinct from the specialist," which is, of course, precisely what DR. WHEATON did mean.

In the Section on Diseases of Children, MR. MORRIS thinks one of the most interesting papers was that read by DR. LOUIS FISCHER, of New York, on "Antitoxin in Diphtheria." "He has probably tried the remedy more extensively than any other physician in the United States, and he said that while, before the introduction of antitoxin, his mortality, as nearly as he could estimate, was about 55 per cent., the proportion of deaths in over two hundred cases reported by him in April last, in which the antitoxin had been used, was about 15 per cent. He declared he would not treat diphtheria without the antitoxin any more than he would treat intermittent fever without quinin or syphilis without mercury."

We do not look aside to see whose heads the following charge may strike: "Too many American medical journals are, on the face of them, mere advertising media, evidently conducted on the principle that all is grist that comes to the mill." It is of more interest to us to note that MR. MORRIS has learned that the "AMERICAN MEDICAL ASSOCIATION is taking the lead in a movement for reform in this particular, and has shown an excellent example as regards the management of its own journal, as may be gathered from the following passage in the report of the Trustees"—the passage being that relating to the character of advertisements which is quoted in full, and the fact noted that "the report was unanimously adopted." Can it be that MR. MORRIS had in mind any other association and its journal which might participate in "a movement for reform in this particular," even if it would now have to follow an American 'lead'?"

MAY A PHYSICIAN PREPARE HIS OWN DEATH CERTIFICATE?

The above question is propounded and answered by the editor of the *Medical Press and Circular*, June 12, although the phraseology of the question is somewhat different. His question reads: "Can a Medical Man sign his own Certificate of Death?" The following is his answer:

"This question seems a somewhat paradoxical one, but everything depends upon when this particular duty is discharged. The impossibility of the act could not be disputed should the medical man have joined the great majority; on the other hand, while life remains, it would not be a difficult matter for

him to fill in and sign the familiar document, and record the means by which he expected to die. A case of this description is said to have actually occurred a short time ago. In an Italian town the death took place of the communal medical officer, one of whose duties consisted in visiting the dead in the public institutions, and in writing death certificates. Among his papers was found his own death certificate, with the disease from which he suffered duly recorded, the certificate being complete in all particulars save the insertion of the date of his death. When, therefore, the new medical officer appeared on the scene, all that was deemed to be necessary was to fill in the date, and the certificate was then regarded as valid. This, it must be conceded, is something quite novel in the matter of death certificates. Perhaps objection might be taken to it in a legal sense were the practice to be adopted in this country. Nevertheless, in the case of a medical man suffering from an incurable malady which was destined to destroy his life, it could only be said that he was anticipating events were he to fill up and sign his own death certificate some time before his actual decease took place, leaving some one else to add the precise date of death."

This case of the Italian physician is one where the medical certifying officer lived in an isolated locality. His certificate was, in point of fact, one of existing disease before death, not a certificate of death; and this certificate, if not countersigned by the new communal certifiant, would not be valid for any official purposes whatever. The *causa mortis* was presumably well understood by the dying physician; the fact and date of death became well known to the new-coming officer. These two or three data being brought together, a valid certificate is the result.

THE NEW YORK QUARANTINE.

Notwithstanding the fact that yellow fever has been unusually prevalent on the islands of the Spanish Main, necessitating stricter precautions at our ports of entry, the *Saratoga*, of the Ward Line Steamship Company, arrived in New York July 8 from Havana after a fast passage of a little more than three days.

No fact is clearer than that the extreme limit of the period of incubation of yellow fever is only reached at the end of the fifth day.

Some of the passengers of the *Saratoga* had provided themselves with certificates from DR. BURGESS at Havana, showing that they had been "acclimatized," that is to say, that they had had yellow fever, and therefore were not likely to transmit the disease, or to acquire it after landing. Others, however, were not so fortunate, and the Health Officer, DR. DOTY, very properly directed that those not provided with proper certificates, coming from an infected port, must either be removed to Hoffman's Island detention station, or remain in quarantine on board the ship. The steamship company preferred the latter alternative, and although there has been much growling, sanitarians generally will sustain DR. DOTY in his course.

THE AMERICAN MEDICAL ASSOCIATION PRESS.

It is with some satisfaction that we point to the illustration in colors accompanying Dr. Sterne's article on "Toxicity as an Etiology of Nervous Diseases." This was printed on our own presses and is a handsome specimen of press work. The ASSOCIATION PRESS imprint will in years to come, we trust, stand for all that is excellent in mechanical work, and good in itself as well.

CORRESPONDENCE.

A Post-mortem Examination in a Case of Appendiceal Abscess.

TECUMSEH, MICH., July 13, 1895.

To the Editor:—Mrs. B., age about 54 years, was confined to her bed on the first of July of the present year. The family sent for a homeopath, who appears to have had not the slightest idea of the nature of her illness, but apparently satisfied the gullibility of the friends until the death of the patient, which occurred ten days from the commencement of the attack. After death, the friends became anxious to know the cause, and whether, or not, the patient died from neuralgia of the heart, which was the cause assigned by this ignorant homeopath. At the solicitation of the family, three physicians (including the writer), and two homeopaths attended the post-mortem examination. Upon opening the abdominal cavity, there was found a ruptured appendiceal abscess which occurred a few hours before death; doubtless the rupture was produced by the attendant pressing upward upon the cervix of the uterus, in such a manner that the fundus came in contact with the abscess, in an effort made by him a few hours before the death of the patient to reduce an imaginary displacement.

The point which the writer desires to make in bringing this case before the profession is the necessity of making an early diagnosis in appendicitis, and the absolute necessity of calling in a competent surgeon, upon whom shall fall the responsibility of operating or not operating.

Very respectfully, J. F. JENKINS, M.D.

Treatment of Hernia Cerebri.

CORONADO, CAL., July 6, 1895.

To the Editor:—Moved by a very interesting and instructive paper, recently published in the JOURNAL, on brain surgery, in which Volkmann's treatment of fungus cerebri by the curette is mentioned, I wish to report a case successfully treated, in my first year of practice, by a different process.

In July, 1838, my father (University of Pennsylvania, 1809) was called several miles in the country to a child about 3 years old, who had been kicked by a horse, and I went with him. We found a tumor over the left parietal, the child in deep stupor, and other indications of compression. The knife was given to me and I made a crucial incision, brain and clots of arterial blood following the knife. The dura was much torn and was trimmed after eleven pieces of bone were removed. Fearing erysipelas few sutures were used and water dressings were applied.

The case was left in my charge, and to our surprise and gratification the recovery was complete.

A few weeks after I was called, and found a fungus cerebri, half the size of an egg, cut horizontally in two. I proposed to excise it, but the mother objecting, I took an old tea caddy, hammered it so as to make a convex compress, and, after first covering the fungus with lint smeared with cerate, applied my lead compress, and over that a bandage. This

was removed and reapplied every day, and the result was complete absorption, and a most satisfactory cure, without any impairment of the intellect.

F. W. TODD, M.D.

To Prevent Accidents.

CHICAGO, July 12, 1895.

To the Editor:—I noticed that in several of the eastern cities it was the custom of the street car companies to have cable and electric cars stop before crossing the street. It seems to me that this would be much safer for pedestrians and drivers than the plan followed here, and it would add much to the safety of bicycle riders.

Yours truly, I.

American Medical College Association.

RIDGEWAY, S. C., July 12, 1895.

To the Editor:—I want the list of names of all medical colleges belonging to the American Medical College Association. Where can I get it and how much will it cost?

Respectfully, S. S. L.

ANSWER:—Apply to Dr. Bayard Holmes, Secretary, 104 E. 40th Street, Chicago, Ill.

Dr. Jas. E. Reeves.

CHICAGO, July 14, 1895.

To the Editor:—Why don't you publish the address of Dr. James E. Reeves? I would be glad to send 50 cents for a copy of his report, if I knew his address. D.

ANSWER:—The address is Chattanooga, Tenn.

BOOK NOTICES.

A Treatise on the Nervous Diseases of Children, for Physicians and Students. By B. SACHS, M.D. Cl., 8vo., pp. 666. New York: William Wood & Company, 1895.

American medical literature will soon rival the French in the extent and variety of its monographs, and works devoted to specialty subdivisions. We should also add that the quality of American medical literature is constantly improving. The book under consideration is well written and exhaustive. It contains eleven chapters devoted to General Nervous Diseases; twelve to Organic Diseases of the Nervous System; eight chapters to Diseases of the Brain, an introduction and an appendix; a copious index concludes the work. There are 162 illustrations. The author's conservatism is well shown in the chapter on chorea, wherein he rejects the large doses of arsenic recommended by some, and takes issue with Erb regarding the use of electricity. In regard to the question of school-going the author says: "A special caution is necessary as regards the question of attendance at school. Every choreic child, however mild its attack may be, should be kept from school, both for its own sake and for the sake of the other pupils who might imitate the disease. I have sometimes allowed myself to be persuaded to permit a child with a mild form of chorea to continue at school; in almost every instance I have had reason to regret it, for nothing is better calculated to bring out severe chorea than the competitive spirit that obtains in most schools. Periods of examination are fraught with greatest danger to those children who have had attacks in early life. The atmosphere of the school-room seems to have a depressing influence upon such children, and among the wealthier classes far better progress can be made in the ordinary studies if the child is instructed at home than if it is taught at school. It is necessary for the physician to take a firm stand on this question, or else his treatment of the case will be thoroughly unsatisfactory."

The book is a valuable one, and worthy of praise.

Remote Consequences of Injuries of the Nerves and Their Treatment. An examination of the present condition of wounds received in 1863-65, with additional illustrative cases. By JOHN K. MITCHELL, M.D., Assistant Physician to the Orthopedic Hospital and Infirmary for Nervous Diseases, Philadelphia; Lecturer on Physical Diagnosis in the University of Pennsylvania. In one handsome 12mo volume of 233 pages, with 12 illustrations. Cloth, \$1.75. Philadelphia: Lea Bros. & Co.

More than thirty years have elapsed since Acting Assistant Surgeons S. Weir Mitchell, George R. Morehouse and William W. Keen made their special investigations on gunshot and other injuries of the nerves, in the temporary U. S. Army Hospital in Christian Street, Philadelphia. The report which these gentlemen prepared in 1864 may be read now with all the interest which attaches to the recital of a traveler upon a new and hitherto unknown territory. "Never before in medical history has there been collected for study and treatment so remarkable a series of nerve injuries," say the authors. The opportunity was afforded by the setting apart of a hospital for diseases and injuries of the nerves, by order of Surgeon-General Hammond, and the report cited is now a medical classic.

The book now under consideration, by the son of the senior medical officer mentioned, may be said to be the sequel to that report, since it is a pretty successful attempt to trace the history of many of the cases treated in the Christian Street and Turner's Lane Hospitals in 1863.

The military surgeon and the neurologist have alike an interest in this class of cases, and we predict that the little book will meet with favorable reception. The records of the Pension Office, which should long ago have been published as a whole, under proper editorial supervision, are here made use of with reference to this class of cases, with judgment and skill.

Indigestion. An Introduction of the Study of Diseases of the Stomach. By GEORGE HERSCHELL, M.D. Lond. Second Edition 8vo., cl., pp. 343. New York: G. P. Putnam's Sons. London: Baillière, Tindall & Cox. 1895.

This book "does not profess to be a complete treatise upon all the disorders of the digestive apparatus, nor to exhaust the subject of diseases of the stomach." It is intended as an elementary manual for students and as such it very fairly meets the indications.

The general nutrition of the body depending, as it does, upon the function of stomach and intestinal digestion, it follows that the pathologic processes of all tissues, are profoundly affected by the manner in which that function is performed. The study of digestion, and its derangements or disturbances, must therefore be of interest to specialists as well as general practitioners desiring to bring their knowledge up to date. Therefore too many fundamental works of this character can not be had, and the book of Dr. Herschell is very welcome. That it has already reached a second edition is a testimonial to the intrinsic merits of the work.

The Art of Massage. Its Physiologic Effects and Therapeutic Applications. By J. H. KELLOGG, M.D., 8vo., cl., pp. 282. Battle Creek, Mich.: Modern Medicine Publishing Co. 1895.

Massage properly applied is of interest to all divisions of medicine and surgery and in some is indispensable. The author has in this volume well classified the different procedures employed by expert masseurs, and the work is well illustrated. As a text-book for nurses' training schools we think it admirably serves the purpose. Less elaborate than Graham it is still complete enough to furnish the necessary information, but perfection in massage can only be reached by a few. No amount of drill can supply delicacy with strength to persons naturally deficient. All, however, may be improved by study and practice. The style of the book is such as to adapt it to recitations and reference rather than continuous reading. We commend the book.

Transactions of the New York State Medical Association for the year 1894. Volume XI. Edited for the Association by E. D. FERGUSON, M.D. 8vo., cl., pp. 751.

This large and handsomely printed volume contains the proceedings and papers read at the meeting of the Association held at New York City Oct. 9 to 11, 1894, under the Presidency of Dr. Charles D. Strong, an account of which was printed in this JOURNAL in due course.

Memorial notices are inserted of Drs. J. B. Andrews, M. K. Hogan, William Goran, N. M. Perry, W. T. White and John Young.

Reports of the District Branches, and the annual report of the Council are included in the volume, which is printed in New Hampshire. The widely distributed lecture of Dr. H. O. Marcy on Hernia, adorns the volume, with its usual grace and perspicuity.

The Association is flourishing, having upwards of 800 Fellows on the active list, and the papers in this volume are many of them of such merit as to permanently enrich medical literature.

Transactions of the Medical Association of Central New York. Buffalo: Buffalo Medical and Surgical Journal print. 1895.

This brochure contains the papers and proceedings of the twenty-seventh annual meeting of the Medical Association of Central New York, held in Buffalo, Oct. 16, 1894, under the Presidency of Henry L. Elsner, M.D.

The fortunate subscribers of our contemporary, the *Buffalo Medical and Surgical Journal*, have had the opportunity of reading these papers. Others will be instructed and entertained by reading the little volume, which contains sixteen excellent papers.

Transactions of the Southern Surgical and Gynecological Association. Vol. VII. Published by the Association. 1895.

This elegant volume of 336 pages comprises the proceedings and papers of the seventh session, held at Charleston, S. C., Nov. 13, 14 and 15, 1894, under the presidency of Cornelius Kollock, M.D. We printed in our issue of Dec. 15, 1894, a full abstract of the papers read at the meeting. The biography of Warren Stone, by the late A. B. Miles, and the sketch of Marion Sims by Edward Souchon can not fail to be read and re-read with interest.

SOCIETY NEWS.

Third International Congress of Physiologists.—Bern, Sept 9 to 13, 1895.—At its opening session on Sept. 10, 1889, the first International Congress of Physiologists adopted the following resolutions:

1. An International Congress of Physiologists shall be held triennially, with the object of contributing to the advancement of physiology by affording physiologists of various nationalities an opportunity of personally bringing forward experiments, and of exchanging and discussing their views together, and of becoming personally acquainted one with another.

2. Membership of the Congress shall be open to all professors and teachers of biologic science, belonging to a medical faculty or any other similar scientific body, as well as to all scientific men engaged in biologic research.

3. The sessions of the Congress shall be devoted to physiologic communications and demonstrations. Further, communications relating to original research in anatomy, general pathology, and pharmacology, are acceptable in so far as they present features of general biologic interest.

4. It is desirable to keep the communications as far as possible demonstrable and experimental in character.

5. No official report of the work of the Congress shall be published.

The following regulations were discussed and adopted for conducting business at the sessions of the Congress:

1. The languages recognized as official at the Congress are English, French and German.

2. At each sitting, two presidents for the next sitting are chosen by the meeting, on the proposal of the chairman.

3. At the opening of the Congress, the meeting elects for each of the official languages, a general secretary, who shall superintend the preparation of the minutes of the meetings.

4. The minutes are written in the three official languages by three Secretaries chosen at each sitting, by the President in the chair. Each person who makes a communication shall sign the protocol of his own communication. The President in the chair shall confirm the correctness of the minutes for the whole sitting.

5. The length of a communication may not exceed fifteen minutes. When that period has been exceeded the President must ask the meeting whether it desires the communication to continue farther.

6. A motion backed by three members for the closure of a communication or of a discussion, must be immediately put to the vote.

7. The press shall not be officially admitted to the Congress; each member is free to send private communications to scientific journals.

On Sept. 12, 1889, the first International Congress of Physiologists passed the following resolutions:

1. The signal success of the Congress shows the appropriateness of its inception and the desirability of continuing its meetings.

2. The second International Congress of Physiologists shall be held in the year 1892 in Belgium or in Switzerland, and, if possible, in a town in which the community employs the French language.

Accordingly in August, 1892, the second International Congress of Physiologists was held at the Liège in the Laboratory of Professor Fredericq, and, as before, official meetings were held for three successive days, and were devoted chiefly to demonstrations and experiments.

The second Congress, which met at Liège, resolved on the recommendation of its Executive Committee that the third International Congress of Physiologists be held in September, 1895, from the 10th to the 14th of the month, at Bern, Switzerland. Professor Kronecker, Director of the Physiologic Institute of the University of Bern, has kindly expressed his readiness to afford to members of the Congress all facilities for demonstration and experiment, as well as for the exhibition of scientific apparatus. It is particularly desirable that those intending to avail themselves of Professor Kronecker's assistance should let him know what their requirements are not later than June 30.

In connection with the Congress, an exhibition of physiologic apparatus will be held. Exhibits may be contributed by all members of the Congress, by the directors of physiologic laboratories, and by makers recommended by any member of the Congress, or by the director of a physiologic laboratory. The exhibition of apparatus will open two days before the Congress, and will close two days after the Congress.

I desire hereby, on behalf of the Executive Committee, to invite you to attend the third Congress, September 9 to 13 of this year, at Bern. Should you intend to be present, kindly notify your acceptance, and, if possible, the title of your communication, either to Professor Hugo Kronecker, Bern, or to myself, before August 1.

Each member of the Congress is required to contribute the sum of 10 francs toward defraying the expenses of the meetings; he will obtain in receipt from the President, Professor Kronecker, a card of membership of the Congress.

Titles of communications may be sent to Frederic S. Lee, Secretary of the American Physiological Society, Columbia College, New York City.

I am, dear Sir, yours truly,

C. S. SHERRINGTON,

General Secretary for the English Language,

On behalf of the Executive Committee.

27, St. George's Square, S.W., London.

NECROLOGY.

E. R. PALMER, M.D. The sudden death of this eminent physician and surgeon, which occurred on the night of the 6th inst at the Norton Infirmary, Louisville, Ky., produced a profound sensation of sorrow, not only in that city, his home from early boyhood, but throughout the whole land wherever

his name and reputation were known. While returning from a pleasure ride on his bicycle on the night in question, when crossing the railroad tracks at their intersection with the boulevard, the Doctor lost control of his wheel, which ran against the curbing and caused him to fall to the pavement. His head struck the curbing when he fell and the skull was fractured. He was removed in an ambulance to the Norton Infirmary, but died just after midnight, about two hours after the accident occurred, without recovering consciousness, although nearly a score of his fellow-practitioners were at his bedside, busily and anxiously engaged in using their best efforts to save the life of their friend and co-worker. Dr. Edward R. Palmer had lived in Louisville since he was 6 years old. He was born in Woodstock, Vt., Nov. 18, 1842. His father was Prof. Benjamin R. Palmer, who was a leading physician in Vermont, and moved to Louisville in 1848. He accepted the chair of surgery in the Medical Department of the University of Louisville. Dr. Palmer graduated from the University Medical College in 1864, during the war. He immediately became assistant surgeon in the U. S. Army and was assigned to hospital duty in Louisville. He also served in the same capacity at Lebanon, Ky. At the close of the war he located in his father's office in Louisville, which he was occupying at the time of his death. His father died in 1865.

Dr. Palmer was extremely successful in his practice, which at that time was that of a regular practitioner. He continued in this manner until ten years ago, when he began as a specialist in genito-urinary troubles. His career as a physician was unusually brilliant. He was called to the chair of physiology in the medical department of the University of Louisville in 1868, just before his marriage. Since then, Dr. Palmer has occupied the chair without interruption, and was noted for his splendid lectures. He was also clinical teacher of diseases of the chest and of genito-urinary diseases. In 1893 he was elected President of the Association of Genito-Urinary Surgeons, of which he was a member at the time of his death. He was also one of the promoters and members of the Surgical Society of Louisville, and a member of the Louisville Academy of Medicine, Medico-Chirurgical Society, Kentucky State Medical Society, AMERICAN MEDICAL ASSOCIATION, and a Fellow of the College of Physicians and Surgeons of Louisville.

The Doctor was a brilliant and forcible writer, and his contributions to the medical and surgical journals were always interesting and instructive. He was enthusiastic in everything he undertook. He was a prominent club man and was welcomed everywhere for his genial temperament. He had a reputation for after-dinner speeches and brilliant conversation—moreover, he was a good singer, and his rendering of such selections as "My Old Kentucky Home" has charmed many brilliant companies around the festal board.

Dr. Palmer leaves a widow and three grown children—a daughter and two sons. The latter, Edward R. Palmer Jr. and J. B. Palmer, were recently graduated from Princeton University and are now attending the medical department, University of Louisville, from which they will graduate next March.

Dr. Palmer's funeral took place from Christ Church Cathedral on the 8th inst., and was one of the largest that ever occurred in the city. The principal physicians and surgeons of the city were in attendance, a large number of whom served as active and honorary pall-bearers. Many of the professional brethren of the deceased from neighboring cities were also in attendance.

FIDELIO B. GILLETTE, M.D., formerly of Brooklyn, died July 1, at De Ruyter, N. Y., in his sixty-first year, from an attack of renal disease. He was an alumnus of the University of Pennsylvania, class of 1856. He was a resident of Brooklyn for over twenty years, and early joined the county medical society. He was a member of the Physicians' Mutual Aid Society. He was a gentleman of refinement and those generous traits of character that naturally and readily tend to popularity. Interment took place at Shiloh, N. J.

PAUL J. TAYLOR, M.D., of Hoboken, N. J., died July 6. He was taken seriously ill while at the bedside of a patient. He

became comatose soon after being taken to his home and did not rally. His death is attributed to cardiac disease. He was a graduate of the University of New York in the class of 1870. He was city physician of Hoboken from 1886 to 1887, for fourteen years examining physician of the Metropolitan Life Insurance Company, and was the medical examiner for several fraternal benefit societies. He was a member of a large number of social organizations and an influential officer in several. A widow and four children survive him. He was 58 years of age.

GERRARD GEORGE TYRRELL, M.D., of Sacramento, Cal., died June 8, 1895, aged 64. He was born at Dalkey, Dublin County, Ireland, in 1831, and was graduated from the Royal College of Surgeons, Ireland, in 1856, and from King's and Queen's College of Physicians in 1859; after graduation he came to the United States and established himself in practice in Milwaukee, Wis., where he remained until 1861, at which time he moved to Grass Valley, Nev., and in 1868 to Sacramento. He was an old and honored member of the AMERICAN MEDICAL ASSOCIATION.

PUBLIC HEALTH.

Limited School Quarantine for Infectious Diseases.—The following scale of school detention of scholars and teachers has been adopted by the Pennsylvania State Board of Health. The recommended time of quarantine, for persons who have been exposed to the infective diseases, after which those persons may safely be admitted again to schools, if they continue in good health and have taken proper measures for disinfection: for diphtheria after twelve days; smallpox eighteen; measles, eighteen; chickenpox, eighteen; mumps twenty-four; whooping-cough, twenty-one. Adults may be admitted at once, if they disinfect their clothes and persons.

Death Rates of European Cities in 1894.—Following are the death rates per 1000 of the principal European cities for the year 1894: Bristol 15.4, Frankford-on-Main 16.5, Berlin 17.2, London 17.7, Leeds 17.8, Brussels 18.1, Hamburg, 18.1, Amsterdam 18.3, Birmingham 18.5, Leipzig 18.7, Copenhagen 18.7, Turin 18.8, Zurich 18.9, Genoa, 19.0, Stockholm 19.4, Rome 19.6, Christiana 19.6, Nice 19.7, Glasgow 20.0, Paris 20.2, Rotterdam 20.2, Manchester 20.4, Lyons 20.9, Dresden 20.5, Berne 21.0, Venice 21.6, Bordeaux 21.9, Bologna 21.9, Prague 22.1, Vienna 22.8, Cologne 23.1, Munich 23.7, Liverpool 23.8, Budapesth 24.4, Dublin 24.7, Milan 25.0, Naples 27.7, Marseilles 28.3, Barcelona 29.6, Havre 29.8, Bucharest 29.9, Trieste 30.1, Rouen 31.3, St. Petersburg 31.4, Moscow 34.1.¹

Nature's Compensations.—Vital statisticians have frequently commented upon the fact that after a period of devastating wars the birth rate runs high, that after an epidemic the death rate falls. Whatever the principle involved it is obviously operating in Milwaukee this year. One of its local journals of the 9th inst., says: "This morning there were only two cases of contagious diseases in the city and these were cases of scarlet fever. Last Saturday the weekly report gave the number of scarlet fever and diphtheria cases in the city as eight each. To-day diphtheria is wiped out, smallpox has given no signs of revival and scarlet fever dropped down to two cases. Never in ten years past has this record been equalled or even approached and the members of the Health Department feel correspondingly pleased."

Did Not Blame the Americans.—Two severe outbreaks of ptomaine poisoning have recently occurred in Great Britain—in one of which all the members of two families, numbering twenty-two persons became seriously ill after eating "tinned"

meat and one died; in the other, a man purchased some veal on a Saturday and, having shared it with two other families, all partook of it on the Sunday, and the following morning nearly a dozen persons who had eaten of the veal were attacked with violent purging, vomiting, etc., and one also died. The singular feature, common to both these outbreaks, is that in none of the accounts which have come under observation has there been any charge that the sickness and death were due to the poisonous meats which, it is well known Americans are in the habit of putting up for export to the unsuspecting foreigner.

Preventing a Stench Nuisance.—The Conseil d'Hygiene of Paris has suggested to the municipality that all butchers in that city be required to prevent the nuisance arising from the putrefactive decomposition of bones, fat, meat trimmings and other *debris* accumulating about their shops and premises. At the request of the Conseil, M. Nocard has recommended a disinfectant for this purpose, which is at once cheap, easily applied, free from danger, effective and does not destroy the value of the *debris* for industrial purposes. This consists of a 2 per cent. zinc chlorid solution to be used in the following manner: the butcher will provide a large wooden vat of 120 liters (30 gals.) capacity, in which will be mixed 2 liters of zinc chlorid solution at 40 degrees, with 100 liters of water; the scraps, bones, etc., will be thrown into this vat and kept there until removed. A sufficient quantity of the 2 per cent. solution must be added from time to time to maintain the strength necessary for disinfection and exhausted by use.

Errors of Diagnosis in Infectious Diseases.—In *Public Health* for July we find a brief analysis of cases of the above nature, in the last Annual Report of the Metropolitan Asylums Board of Greater London. This monster organization has under its control accommodations for 12,000 patients, and carries an average population of not less than 9,000 a day. In this figure are included the "imbecile" as well as infectious classes. The number of admissions to the infectious disease hospitals was nearly 17,000 in 1894; of scarlet fever alone there were 11,596 admissions. These figures are quoted solely to show the enormous volume of business conducted by the Board. Concerning the question of errors in diagnosis, the analysis in *Public Health* remarks:

"In the course of 1894 no fewer than 864 patients, or a percentage on the total admissions of 5.2, were, after admission at the fever hospitals of the Metropolitan Asylums Board, found not to be suffering from the diseases mentioned in the medical certificates upon which they were removed to hospital. The largest number of cases of mistaken diagnosis admitted at any one hospital was, as in previous years, at the Eastern Hospital, where 253, or 9.8 per cent., were received. Of the patients admitted to the hospital ships, 24 were not suffering from smallpox at the time of admission. Of this number: four were mothers admitted with their infants; nine were infants admitted with their mothers; one had no symptom of disease at the time of admission, but was sent to hospital as convalescing from smallpox; and ten suffered from other diseases, a list of which is given in the report of the medical superintendent. From these figures it appears that the actual number of mistakes in diagnosis among the patients admitted to hospital was 10, or only 0.8 per cent. If, however, we consider the total number of cases certified as smallpox, and removed to the wharves and medically examined there, we find that of 1,263 cases 155, or 12.2 per cent., were in the opinion of the managers' medical officers not suffering from smallpox, and were returned to their homes, with the exception of four, who were transferred to fever hospitals. It would be interesting to hear the other side of these cases. Did any of these patients, after being returned home prove to have the diseases originally notified? Do mistakes in diagnosis occur only on the part of private medical practitioners? There is a general consensus of opinion in large towns that isolation accommodation for doubtful cases form an indispensable part of the administrative machinery of fever and smallpox hospitals; but this is almost entirely wanting in the metropolis."

¹ Rev. Int. Med. et Chir. Prat., No. 11, 1895.

Cause of Cancer.—Dr. James Braithwaite of Leeds, Eng., editor of the *Retrospect of Medicine*, does not positively assert, but he confidently believes, that he has discovered the cause of cancer and sarcoma in a spore-bearing mycelium which he has succeeded in fully demonstrating to his own satisfaction and which he illustrates in a descriptive paper.¹ So well satisfied is he of the correctness of his conclusions that he leaves to others their disproof, and proceeds to discuss the question, Is any practical result likely to accrue from this discovery? So far as he can see at present the answers may be given as follows: 1, the cure of a cancerous growth actually in existence does not seem more probable [by reason of this discovery] but less probable, because the enemy is so subtle, so penetrating, and so indestructible—proved by immersion in liquor potassæ for an hour without killing it—that it almost seems impossible to eradicate it; it is, however, better to have an enemy exposed to view than one invisible. But it seems likely that, after removal of a growth by operation, it would be better not to close the wound absolutely, but to keep the surface in contact with dressings soaked in glycerin containing liquified carbolic acid and also perchlorid of mercury—the carbolic acid partly to relieve the pain; glycerin penetrates the tissues and carries with it any substance in solution. 2, it seems not improbable that cancer of the breast in women past the child-bearing period may be altogether prevented by closing the orifices of the milk-ducts in the nipple by a small surgical operation or by the use of a fine electric cautery; for the fungus must enter the breast *via* the milk-duct orifices. 3, it is possible that men may have to return to a certain Mosaic rite in order to save wives from uterine cancer, unless the daily use of soap will do away with this necessity. 4, in order to prevent the fearful mortality from cancer in low-lying, wet-soil districts the bodies of persons dying from cancer must be buried at a great depth or they must be cremated. Moisture is absolutely necessary for the formation of zygospores, spore masses and spore-bearing mycelium. It does not seem probable that the fungus necessarily spends part of its life in the earth, but no doubt when the interment is at no great depth the earth will become infiltrated if it is constantly wet and floods will carry the spore masses all over the country. 5, a fungus can attack only effete tissues. We are, ourselves only tools of nature; we must not rust from luxury and idleness. Business men must be careful how they retire—for, just as tuberculosis is favored by excessive work and poor food, so the growth of a fungus is likely to be favored by the effete material present in the system and engendered by opposite conditions.

Prophylaxis of Consumption.—The researches of Professor Cornet into the mode of propagation and the life history of the tubercle bacillus and the methods of prophylaxis based thereon which he suggested have profoundly influenced the restriction of tuberculosis all over the world. As is so frequently the case many of his disciples, with more zeal than discretion, have carried prophylactic measures to extremes and have advocated wholly unnecessary precautions and restrictions. In a paper recently read before the Berlin Medical Society¹—the gist of which was the results obtained in the Prussian prisons by caring for the sputum—Cornet makes it clear how comparatively simple are the means necessary to limit the spread of consumption. He pointed out that microorganisms with a moist surface could not be detached by a stream of air passing over them, and exploded the idea that the breath was the source of infection in pulmonary tuberculosis, making clear at the same time that this source must be looked for in the excretions from the patient. He proved that the bacillus showed its earliest and widest development at its point of entrance into the organism or in the corresponding lymph glands, and that in man the lungs and bronchial glands formed this point in the large

majority of cases. He looked upon the sputum and especially dried sputum, as almost the sole cause of the extension of pulmonary tuberculosis, and was confirmed in the conclusion that by preventing the sputum from drying and becoming dust, an efficient prophylaxis of tuberculosis was possible. Precautionary measures in this direction have been in force for the last few years in Germany, and especially in Prussia, where the authorities have interested themselves in the question. Cornet gives statistics showing the mortality from tuberculosis in the prisons in Prussia and Bavaria. The figures in both countries show much the same proportion from 1881 to 1887. Since 1887 the rate in Prussian prisons has fallen very rapidly and in the period 1892-94 was only 81.2 per 10,000 inmates—hardly one-half the former figure. These prophylactic measures are not, however, generally adopted, and in Bavaria, the view of Bollinger—that predisposition is a potent factor in tuberculosis—has interfered considerably with their adoption. Cornet's ideas have lately made progress, and now the figures, which have remained stationary up to 1891, have begun to show a reduction. Similar results are obtained from asylums: a fall from 184 to 150—*i.e.*, about one-sixth—is seen in Prussia, while no reduction takes place in Bavaria. The statistics of the Catholic nursing orders of Prussia are very interesting. In these, the disposal of the sputum has been attended to with great care, and in consequence, during the last six years, a decided improvement is shown; while in 1887 the rate stood at 100 in 10,000, in 1893-94 it had sunk to 67. Going into larger figures, Cornet quotes those issued by the Royal Statistical Bureau of Prussia. From the year 1875, when reliable information was first obtained to 1887, the death rate from tuberculosis averaged 31 in 10,000 inhabitants. Since the latter year it has sunk from year to year to 25 in 1893. Stated generally, there were in Prussia alone between the years 1887 and 1893, 70,000 fewer deaths from tuberculosis than were expected from the average of previous years. A similar disease has been noticed in Hamburg, where precautionary measures have been instituted, and a comparison made with towns which have not adopted them shows that in the latter little or no decrease in the mortality from tuberculosis has occurred.

Health Reports.—The following health reports have been received by the Supervising Surgeon-General, Marine-Hospital Service:

SMALLPOX—UNITED STATES.

Michigan: Smallpox reported July 6 at Battle Creek, Danby Township, Detroit, Olivet and Warren.
Ohio: Cincinnati, July 5 to 12, 1 death; Cleveland, June 1 to 30, 1 case, 1 death.
Wisconsin: Milwaukee, June 1 to 30, 2 deaths.
Tennessee: Memphis, July 7 to 13, 2 cases.
Louisiana: New Orleans, June 8 to 29, 6 cases, 7 deaths.
Pennsylvania: Philadelphia, June 30 to July 6, 1 death.
Missouri: St. Louis, June 1 to 30, 2 deaths.

SMALLPOX—FOREIGN.

London: June 22 to 29, 25 cases, 1 death.
Dublin: June 22 to 29, 18 cases.
Antwerp: 15 to 22, 1 death.
Batoum: June 18 to 25, 5 cases, 3 deaths.
Birmingham: June 22 to 29, 1 case.
Calcutta: May 28 to June 1, 34 deaths.
Gibraltar: June 16 to 23, 1 case.
Hiogo: June 1 to 8, 1 case.
Hong Kong: May 25 to June 1, 1 death.
Liverpool: June 22 to 29, 1 case.
Manchester: June 22 to 29, 1 case.
Montevideo: June 1 to 8, 1 case, 1 death.
Moscow: June 15 to 22, 2 cases, 1 death.
Naples: June 15 to 22, 2 cases, 2 deaths.
Odessa: June 15 to 22, 3 cases, 1 death.
Rio de Janeiro: June 8 to 15, 9 deaths.
Rotterdam: June 22 to 29, 1 case, 1 death.
Warsaw: May 26 to June 2, 2 deaths; June 8 to 15, 1 death.

CHOLERA.

Bombay: May 28 to June 4, 1 death.
Calcutta: May 25 to June 1, 45 deaths.
Hiogo: June 1 to 8, 6 cases, 5 deaths.

YELLOW FEVER.

Santiago de Cuba: June 30 to July 6, 25 deaths.
Vera Cruz: June 27 to July 4, 9 deaths.

MISCELLANY.

Change of Address.—Dr. W. Xavier Sudduth, from Minneapolis, Minn., to 100 State Street, Chicago.

Was this "Writ Sarkastik?"—We find the [following in the "Literary Notes" of our esteemed contemporary and namesake, the *British Medical Journal* of June 29: "Medicine is the name of a new monthly journal of medicine and surgery published at Detroit under the editorship of Dr. Harold N. Mozer. Our new contemporary presents a very creditable appearance, and to judge from the first three numbers it will be a valuable addition to medical journalism. We congratulate both the editor and the publisher (Geo. S. Davis, whose name is favorably known in connection with the *Index Medicus*), on the fact that the trail of the advertiser is not over their journal as it is over so many trans-Atlantic periodicals." The *Journal* is itself so immaculately free from the "trail of the advertiser" that our colleague will, no doubt, appreciate the "congratulations" not less highly than the change made in the orthography of his patronymic.

Origin of Syphilis.—At the beginning of the sixteenth century it was claimed on the authority of Roderigo Diaz and Oviedo that syphilis was a disease imported from America by the companions of Columbus. This theory held undisputed sway until near the close of the last century and it is still held by many physicians. It was about 1493 that the disease first came to be spoken of and it was natural to attribute it to the most marked contemporary event—the discovery of America. It would seem very astonishing, however, that it should suddenly have such a great extension over Europe if it had not existed there before. Puschmann has collected evidence which proves to him that the disease existed in Europe during the Middle Ages and even in antiquity. The disease remained unknown, however, until about the time of Columbus' discovery when it caused serious epidemics which attracted attention to it. The American origin was rendered all the more probable because the guaiac wood, then used in its treatment, came from America. It seems probable, nevertheless, that it existed before in several lands—especially among the negroes and the Moors driven from Spain.¹

Diagnosis of Serous Effusions by Acetic Acid.—It is sometimes a very delicate task to determine in cases of serous effusion whether we have to deal with an inflammatory exudate, as in pleurisy or peritonitis, or a simple transudation, as in hydrothorax and mechanical ascites. Primavera has facilitated this research by showing that acetic acid precipitates the paraglobulin held in suspension in inflammatory exudates. Rivolta points out a practical means of using this test for differentiation. Two successive examinations are made, controlling each other. In a small quantity of fluid, attained by puncture and filtered, is placed a drop of slightly diluted acetic acid; in the case of an exudate a slight white precipitate is immediately formed, which follows the drop as it falls to the bottom; in the case of a transudate the liquid is colored throughout. 2, in a test tube are placed 200 to 300 c.c. of distilled water to which has been added one drop of glacial acetic acid to each 100 c.c. of water; a drop of the liquid to be examined is allowed to fall into the tube, when, in case of an exudate, it will form a whitish-blue flocculent precipitate which falls to the bottom. If some more drops of acetic acid be added this precipitate completely disappears. This test must always be carried out to exclude a precipitate of insoluble mucin.²

Disinfection of Wells.—Wells are frequently infected, especially when the country has been inundated. As they are

often situated close to dung hills the drainage of the latter often becomes mixed with the well water, forming a culture medium for microbes. It will be some months before the well furnishes pure water again—that which trickles from the walls being contaminated from the deposits left on the surface of the bricks and between them. Frank has recently recommended the following procedure which he employs on the banks of the Rhine. A plate, containing 50 to 100 grains of bromin, is suspended in the mouth of the well; as is known, bromin is volatilized in air, and its vapors are heavier than the latter, hence there is formed a cloud of vapor which falls slowly into the well, skirting the surface, penetrating into crevices and completely destroying organic matters. At the bottom of the well the bromin is dissolved and, being heavier than water, the mass of liquid is completely penetrated by the disinfecting agent; the water retains a slight taste of bromin for some time, which is not very agreeable, but it is purified and made perfectly healthy.¹

The Index Medicus.—The following paragraph, quoted from the *London Lancet*, for June 29, shows that there are in England medical workers who duly appreciate the *Index Medicus*. There are endowed medical organizations in that country that could legitimately and "without feeling it,"—as the saying is—contribute to the \$2,000 subscription suggested by Librarian MacAlister.

"In another column will be found a letter from the Resident Librarian of the Royal Medical and Chirurgical Society concerning the imminent decease of that invaluable publication, the *Index Medicus*. When it is remembered that this work is a carefully classified index of the whole of medical literature, not only books but pamphlets and original articles in the medical journals, and that on a reference to it any articles which have been written on medical subjects can be easily found, it will be seen that the cessation of this work would be an incalculable loss. Our correspondent's suggestion that £400 a year should be subscribed by this country is well worth the consideration of the profession and the medical societies, and as such we commend it to them."

"To all who have profited by the wealth of information in the *Index Medicus*, the news that its publisher, George S. Davis, has felt obliged to discontinue its publication will be read with regret. It seems that since 1885 the annual loss which has been borne by Mr. Davis has been from \$500 to \$1,000, and that this year it bade fair to reach \$2,000, and no one can blame him for discontinuing his philanthropy. An endeavor was made by his friends to raise the number of subscriptions to a paying basis, but unfortunately was unsuccessful. The *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION* states, however, that if its subscription list could be placed at twelve thousand that publication could and would carry on the *Index* with profit, and it is to be hoped this may be done. No one who has used the *Index* can fail to appreciate its value."—*The Atlantic Medical Weekly*, July 13, 1895.

Transmission of Tubercle Bacilli.—At the *Société de Biologie* of Paris at its session of June 29, 1895, M. M. Bar and Rénon reported that they had undertaken the elucidation of the question of the direct transmissibility of the tubercle bacillus of Koch, through the placenta, to a human fetus. In five cases they took at the moment of birth of the child a certain quantity of blood from the umbilical vein, and injected it under the skin of abdomen of guinea pigs. In three cases the results were negative, and the guinea pigs did not become tuberculous, but in the remaining two, results were positive. In the first case the mother was in the third stage of phthisis, the sputa contained the bacilli. The placenta in this case presented no apparent lesions. The blood from the umbilical vein was injected into a guinea pig, which showed a chancreous ulcer at point of inoculation, and died two months later, with tuberculosis of the liver and spleen. The spleen pulp and the caseous masses of the chancreous ulcer contained the bacillus. The autopsy of the stillborn infant was practiced immediately after its expulsion; the result was

¹ Bulletin Medical, No. 47, 1895.
² Bulletin Medical, No. 47, 1895.

¹ Le Province Medicale, No. 25, 1895.

negative, but the injection of three guinea pigs with the juice of the pulp of the lung and liver, and peritoneal serum, caused the death of two. In the second case the mother had pulmonary cavities, but examination of the sputa was not made. The child born living, died on the fortieth day with bronchopneumonia. The placenta appeared to be normal. At the moment of the birth of the child, blood from the umbilical vein was injected into two guinea pigs; one of the pigs survived but the other died with a chancre of inoculation and generalized tuberculosis. The careful technique of the authors make the results obtained by them all the more certain, and when corroborated by other observers, no doubt may be left on this subject.

Will of the late Manufacturing Pharmacist, S. M. Burroughs.—The late Silas Mainville Burroughs, former head of the young but famous house of Burroughs & Wellcome, of London, has left a considerable property, a part of which is in this country. In New York City, on July 12 "application was made to Surrogate Arnold for ancillary letters of administration upon the estate of Mr. Burroughs, a celebrated chemist, who lived in London. The estimated value of the estate is £125,926, of which a small portion is in this country. Mr. Burroughs made bequests to Stanley, the African explorer, Henry George, and the Presbyterian church in Medina, N. Y."

Nearly Two Million Patients in 1893.—The following is a kind of half protest, in an English journal, concerning the misuse of hospitals in London: "The dependence of Londoners on their hospitals is very strikingly shown by the fact that out of a population of 4,306,411, the population of the administrative County of London in 1893, no less than 1,717,187 received aid from them. In other words, one out of every two men went to the hospital for relief, one woman in every three, and nearly one child in every two. Ought this to be? In towns in the north they seem to help themselves a good deal more. This is a form of eleemosynary aid which carries no stigma with it, and to which many resort who surely ought to be above doing so. Or is this one of the features of city life to which we must submit as inevitable?"

The Overclothing of Children in Summer.—The following taken from the *Archives of Gynecology and Pediatrics*, is seasonable:

"Much misery would be avoided if mothers and nurses could be made to realize that in hot summer weather children are far more likely to suffer from heat than from 'taking cold.' There is one source of cruel suffering and dangerous or even fatal illness in very hot weather which is often overlooked, because it is unsuspected: it is want of water. At 11 A.M., of one of our hottest days, I found in my consulting-room a woman, and with her a weak, rickety, 3-year-old child, with big head, groveling on the floor, pressing its forehead against the cool oilcloth; was clad in thick woollen overcoat and heavy "Tam O'Shanter." The child had become restless and almost convulsed at night; eyes rolling, face and fingers twitching, sweating profusely and passing urine in small quantities every ten minutes, crying with pain. I asked why the thick overcoat and heavy cap, and elicited the reply she was afraid to bring the child out without an overcoat, as it was "subject to bronchitis." I inquired if it ever received water to drink, and the mother indignantly answered in the negative, asserting it was allowed only pure milk and, being weakly, strong beef tea. I gave it half a glass of water, which was seized upon with a joyous sound and eagerly drank. When the greater part was gone I took away the glass, but the poor creature screamed for it and drained it to the last drop. The change was immediate and marked. The little one no longer groveled, sweating, restless, panting, miserable, hardly conscious of its surroundings, but sat up cheerfully and began to look around and even to talk. I took off the thick coat and cap and ordered it to be lightly clad, to be kept as cool as possible, and to have its hair cut short; also to be given a little water frequently, and to have its milk and beef-tea diluted. I saw it three days later. Though the hot weather had persisted the child was bright and well; had no more twitchings, no more

convulsions, no more restless nights; micturition was no longer painful or too frequent, and there was no excessive sweating."

Washington Notes.

HEALTH OF THE DISTRICT.—The report of the Health Officer for the week ended July 6 is as follows: number of deaths (still-births not included): white, 61; colored, 71; total, 132. Death rate per 1,000 per annum, white, 17.28; colored, 42.43; total, 25.34. As the season advances the death rate of the city increases. The number of deaths reported at the Health Department during the past week was 132, as compared with 105 in the week previous, and the rate rose from 20.0 to 25.25. The increased mortality was confined to infants under 5 years of age, of whom seventy-seven died. This exceeds the average mortality of this class by nearly 60 per cent. The principal causes thereof were cholera infantum, teething and various inflammatory ailments of the intestines. Among adults there was less fatality, of which heart and kidney maladies were the most prominent causes. The city remains comparatively free from contagious diseases in mortal form. There was one death from scarlet fever and no death from diphtheria reported. While there was no reported death from typhoid fever during the week, there were thirty deaths therefrom during the last half of the fiscal year, as against fifty-one during the corresponding period last year.

INSPECTION OF MILK IN THE DISTRICT.—The systematic inspection of milk will be pushed to the full extent of the law passed during the last session of Congress. Under this law little chance is left to those who have for sale milk not up to the standard, and when detected the penalty is a fine of not less than \$5 or more than \$25 for the first offense, with imprisonment for thirty days in the work-house in the discretion of the court. For the second offense the fine is from \$50 to \$100 with an imprisonment for ninety days and suspension for six months of permit to sell. The standard for milk is stated in the law and other safeguards are provided. Prosecution will issue after warning to the offenders, although the warning may not be given in each instance. No one may sell or have for sale unwholesome, watered, adulterated, swill milk, milk from cows fed on swill garbage or any other like substance, skimmed milk, without conspicuous notice of the same on the can containing it, or milk containing less than 9.3 per cent. of milk solids, including fat, milk taken from cows less than ten days before or the same time after parturition, or from any cow known to be suffering from any general or local disease liable to render milk unwholesome.

SMALLPOX HOSPITAL.—The contract for building the new smallpox hospital has been awarded and the work will begin at once in order to complete building by November 1. There will be a model disinfecting plant and all will be inclosed within a high masonry or brick wall. It is to be located near the Eastern branch and almost directly east of the District jail.

GARBAGE DISPOSAL.—The Commissioners are having a thorough investigation made by the Health Department to determine the best method of disposal of garbage. The different plants in the large cities have been inspected and reported upon, but no decision has been reached so far.

BOVINE TUBERCULOSIS.—The report on bovine tuberculosis, by Dr. Theobald Smith, Chief of the Division of Animal Pathology in the Agricultural Department, is in the hands of the Secretary, and contains many valuable suggestions for the suppression of the disease and its detection. Among other things, the report says: "The situation certainly demands a most rigid periodical inspection of all animals furnishing milk to consumers, the prompt removal of all suspicious cases, and, above all, a more thorough control of the dairy in the interests of public sanitation."

Hospital Notes.

THE GOVERNOR OF PENNSYLVANIA has signed the following appropriation bills for Philadelphia institutions passed by the Legislature during the session just closed: University of Pennsylvania, \$200,000; and the Hospital Department of the same, \$55,000; Jefferson Medical College Hospital, \$112,000; Medico-Chirurgical Hospital, \$150,000; Kensington Hospital, for Women, \$5,000; Maternity Hospital, \$5,000; Memorial Hospital, Roxborough, \$7,000; Philadelphia Lying-in Charity, \$6,000; Gynecean Hospital, \$25,000; Philadelphia Orthopedic Hospital, \$5,000; St. Christopher's Hospital for Children, \$4,000; Woman's Hospital, \$8,000; Rush Hospital for Consumptives, \$10,000; German Hospital, \$20,000; Philadelphia Home for Infants, \$5,000, also, Homeopathic Medical and Surgical Hospital and Dispensary, \$50,000; Children's Homeopathic Hospital, \$8,000; Hahnemann Medical College Hospital, \$57,100. Outside of Philadelphia, provision was likewise made for the following: Columbia Hospital, \$3,000; Scranton West Side Hospital, \$4,000; Reading Hospital, \$15,800; Reading Homeopathic Hospital, \$10,000; South Bethlehem, St. Luke's Hospital, \$20,000; Easton Hospital, \$15,000; Conemaugh Valley Memorial Hospital, \$10,000; Chester Hospital, \$10,000; Scranton Lackawanna Hospital, \$25,000; Lebanon, Good Samaritan Hospital, \$6,000; Pittston Hospital Association, \$14,000; Carbondale Hospital Association, \$12,000; Pottstown Hospital, \$14,500; Pottsville Hospital, \$10,000; Charity Hospital, Montgomery County, \$9,500; Lancaster General Hospital, \$4,000; Chester County Hospital, \$6,500; Jefferson County, Adrian Hospital Association, \$10,000; Altoona Hospital, \$12,000; Westmoreland Hospital at Greensburg, \$6,000; Wilkes-Barre City Hospital, \$25,000; Williamsport Hospital, \$12,000; Pennsylvania State College, \$212,000; Western University, \$50,000. Among the bills vetoed by Governor Hastings were the following: a bill establishing, purchasing land and erecting buildings for a State Hospital for the Homeopathic Treatment of the Chronic and Epileptic Insane near Titusville, \$150,000; Philadelphia Polyclinic, \$30,000; Wells' Eye Hospital, \$5,000, and several others, including one for establishing hospitals at Allentown and at Punxatawny. Some of these institutions which have received substantial aid from the treasury of the commonwealth are practically under the control of the State since the Governor *ex-officio* is a member of the board of managers, himself, or he appoints one or more representatives of the board. Others are county or municipal institutions; but the greater number are independent or private institutions and, in some instances in fact rivals, to some degree, of the public charities existing in their vicinity.—The Pittsburg Eye and Ear Hospital was formally opened July 8.

TRAVELERS' PROTECTIVE ASSOCIATION.—At a meeting of the directors of the Illinois division of the Travelers' Protective Association held in Peoria, July 13, action was taken relative to the establishment of a system of hospitals for the benefit of the members of this organization who may require medical services.—A new pavilion hospital is to be built in Montpelier, Vt., and presented to that city by the Hon. Homer W. Heaton. The cost of the building will be \$25,000.—The new Santa Fé hospital at Topeka, Kan., will be finished October 1.

Philadelphia Notes.

ACCIDENTAL ADMINISTRATION OF BICHLORID.—Prompt treatment saved a man's life after he had swallowed by mistake 15 grains of corrosive sublimate, at the Polyclinic Hospital recently. An operation of minor character had been performed without ether, and at its conclusion the surgeon, Dr. Thos. G. Morton, directed a resident physician to give the patient half an ounce of whisky. The young man went to the medicine closet and returned with a small amount of liquid in a glass which he handed to the patient, who swallowed it just as Dr. Morton remarked that it did not look like whisky. The victim replied, "It did not taste like whisky either." The resident was immediately directed to produce the bottle, which was marked, "solution of corrosive sublimate, 30 grs. to the ounce." Inside of the next four minutes the patient had swallowed the albumen of half a dozen eggs and in another minute a stomach tube was introduced and the stomach thoroughly washed out. The effi-

ciency of the treatment is evident from the fact that the patient has not exhibited a single symptom of mercurialism and has suffered no inconvenience from the energetic treatment to which he was subjected.

PENNSYLVANIA HOSPITAL MEMORIAL WARDS.—The new memorial wards of the Pennsylvania Hospital are now in use, and the older portion has been vacated of patients in order that extensive plans for renovation and extensive improvement may be carried out before next winter.

IODOFORM GAUZE.—The methods of making iodoform gauze in different hospitals are far from being uniform. The following formula is used in the service of Prof. J. William White in the Hospital of the University of Pennsylvania: to a pint of distilled water, add a small quantity of castile soap (the amount is a matter of experience), boil for ten minutes, allow to cool, add a portion of iodoform, mix and steep in this a quantity of sterilized gauze. If the color does not indicate that sufficient iodoform has been used, more is added, and the steeping process continued. When the gauze has assumed the proper color it is wrung out, folded and wrapped in waxed paper, which has been sterilized in bichlorid solution. The exact strength is of little practical importance, since the iodoform is also freely used as a dusting powder over the surface of the wound.

INTERESTING CASE OF HEAD INJURY.—A man, while playing base-ball, was struck by a pitched ball on the side of his head. He did not seem to be badly hurt and made no special complaint, but walked home from the ball-grounds, ate his supper and went out to make a call on a young lady. During the evening he became sick, and the symptoms were so grave that he was taken in an ambulance to a hospital, where he shortly afterward died. It was found that he had sustained a fracture of the skull and that sub-dural hemorrhage had taken place; the latter accounting for the late development of the symptoms of compression.

THE PUBLIC SERVICES.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from July 6, 1895, to July 12, 1895.

Lieut.-Col. JOHNSON V. D. MIDDLETON, Deputy Surgeon-General, is granted leave of absence for one month, to take effect on or about the 23d inst.

Capt. WILLIAM W. GRAY, Asst. Surgeon, is granted leave of absence for two months, to take effect on or about August 1, 1895.

Capt. REUBEN L. ROBERTSON, Asst. Surgeon, resigned July 3, 1895.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending July 13, 1895.

P. A. Surgeon R. P. CRANDALL, detached from the U. S. R. S. "Vermont," and ordered to the New York Navy Yard.

P. A. Surgeon GEORGE MCC. PICKRELL, ordered to Washington Hospital.

P. A. Surgeon H. T. PERCY, detached from Naval Hospital, Washington, and to the Navy Yard, Washington, D. C.

LETTERS RECEIVED.

Atkinson, W. B., Philadelphia, Pa.; Armstrong, S. T., Asbury Park, N. J.; Adams, F. A., Syracuse, N. Y.

CHICAGO, JULY 27, 1895.

No. 4.

ADDRESS.

THE PRINCIPLES OF MEDICAL CLIMATOLOGY.

Delivered at the Twelfth Annual Meeting of the American Climatological Association, at Hot Springs, Va., June 13, 1895.

BY S. E. SOLLY, M.D.

PRESIDENT OF THE AMERICAN CLIMATOLOGICAL ASSOCIATION.
COLORADO SPRINGS, COLO.

In presenting to you some thoughts upon medical climatology and its underlying principles, I am mindful that while the profession as a whole are lamentably ignorant of the principles of climatology, and sadly careless and ignorant in their application, and need instruction in the very grammar of the subject, I have now the honor of addressing those whose reputation and presence here are assurances of their knowledge and serious interest in climatic study. I shall therefore, as far as possible, avoid dwelling upon well-known facts, but it would seem wise to first define the subject we are to consider.

Climate implies the physical peculiarities of a given locality, while climatology is the study of these various climates with their special correspondences and their effects upon man.

Medical climatology, in the arrangement of its various departments, may be compared to a pyramid, the broad base of which is formed of the study of climatic physics which include the essence of meteorology and certain portions of geography, geology, botany and zoology. Resting upon this physical foundation is the tier, formed of the physiologic effects of climate, this being the study of the influence of the various physical elements of climate separately, first, and then in combination, upon the natural human being, the first consideration being the influence upon special organs and functions, and then upon the human organism as a whole. When this point is arrived at we reach the next department or tier in our pyramid, where inquiry leads to the distinctions of race; how they have been located and modified by special climates, first in their physiologic peculiarities and next in their pathologic, so that we have placed upon the layer of physiology one of ethnology and upon this, again, a tier of geographical pathology. By the latter, we are taught the special tendencies and dangers of each climate. Next, the classification of climates followed by the study of special climates and localities should claim our attention.

We have at length arrived at a sufficient elevation on our pyramid of knowledge to undertake the building up of the apex of our structure with climatic therapeutics, beginning with a tier composed of general climato-therapy, that is, a consideration of what diseases and what stages and forms of them are likely to be benefited by any climatic change. Next, the particular climates suited for the special diseases. Then the study of the influence of climate upon the

various temperaments and diatheses and, finally, the point is reached of the individual case and its appropriate climatic treatment.

Thus, climatology is based upon:

1. Physics.
2. Physiology.
3. Ethnology.
4. Geographical pathology.
5. Classification of climates.
6. Special climates.
7. General climato-therapy.
8. Individual climato-therapy.
9. The individual case and its appropriate climate.

Under the head of physics, we find certain matters connected with meteorology, worthy of emphasis and consideration. The meteorology of a given locality is broadly divided between the general meteorology of the hemisphere, State and latitude, and the local. General meteorology is being developed most efficiently by the Government Weather Bureau, and we must do all we can to aid them, especially in their new department of medical climatology, in which by collecting the necessary morbidity and mortality statistics from all parts of the country, the relations of sickness and death to the state of the general weather will be made apparent; and in time, perhaps, warning may be given to the delicate, as it now is to mariners and farmers.

The comparison of the general weather and its results with that of special localities and their health will serve to show how the general weather of a given week is modified or intensified by local conditions. In local weather reports it behooves us to urge the stating of them more fully, especially with regard to humidity, sunshine and wind and a separation of reports into seasons, and again a showing of what I have termed, in reporting upon Colorado Springs weather, as an *invalid's day*; that is, the average state of the weather during the hours the invalid can and should be out. While night air that is not too damp or chilling to permit of open windows is desirable, especially on account of its purity, yet the influence of the night climate when injurious can be much more easily modified than that of the day, and should be considered separately.

Under the head of physical conditions there is one point that is far too infrequently reported and too little dwelt upon by the physicians of this country,—the soil; whereas, in Europe, experience and the teachings of science have made it one of the prime factors in judging of a health resort, although a distinguished American physician, the late Henry I. Bowditch, was the first to study and demonstrate the importance of considering the soil in selecting a residence, which has been since abundantly confirmed by the labors of others. It is not only the material of which the soil is composed that must be considered, but also its natural drainage and the disposition of

its watershed. The importance of this consideration, while we all present here admit, perhaps we do not sufficiently dwell upon to our clients and our colleagues; often do we find a town in a health-giving air with good surrounding soil, yet situated in a river bottom, recommended for invalids; or a flourishing health resort under benignant skies, built upon a clay bed, or in a basin which can not drain.

Again, while the meteorology of a place is of great importance *per se*, it is very much more so in connection with the other conditions, such as elevation, aspect, shelter and soil, as these together make climate; the other alone only weather, and paradoxical as it may appear, it sometimes happens that the climate continues good even when the weather is temporarily bad.

There is another point that is worth remembering, that the pleasantest climate to the invalid is not always the best for him. While to come "unto a land where it was always afternoon" is well suited for some, others fare better where the cry of "Cease, rude Boreas," is often heard. Thus while a sedative climate is frequently called for, a tonic one is still more often needed. Remember, all our climatic prescriptions can not be sugar-coated.

Passing now to the study of physiology in connection with climatic therapeutics, we see a field white for the harvest, and it is only from the corn gathered in this field that the bread of knowledge can be made which is alone worthy to be served on the table of the climatologist. But, alas, to produce good physiologic work, time and money are the first requisites, in neither of which do we as a profession abound. There is a crying need for well trained and well paid physiologists in well-equipped laboratories in all the chief sanatoria of the world, and it is only by placing the knowledge gained through them freely before the therapist that our branch of medicine can advance from the present gloom of fiction and tradition, which now is but faintly illumined with a few isolated facts, and from which the health-seeker endeavors to emerge, guided more often by the rushlight of empiricism, or led astray by the will-o'-the-wisp of false theory, than by the lamp of science. Some of these lines of investigation are a fuller study of the influence of sunlight and sun heat upon physiologic and pathologic conditions, and some good work has lately been done in their effects upon bacteria. This work could be carried on most efficiently in climates where sunlight was most brilliant. The influence of atmospheric electricity, and the influence of humidity with both high and low temperature also needs study.

Further experiments are needed upon the effects of diminished barometric pressure; while excellent work has been done by Paul Bert, Muntz, Regnard, Viault, Egger, Woolff and Koeppe, in which the blood changes have been noted, yet they need carrying on further, and particularly by physiologists resident in high altitudes, so that it can be demonstrated clearly what are the permanent and what the transitory effects. These investigations have gone far to make it probable that the blood changes, such as the increase of red corpuscles and hemoglobin, are the reason for the undoubted clinical fact that altitude is *per se*, the most valuable climatic factor in combating the progress of tuberculosis. While this can be reasonably inferred it is not yet absolutely proved.

It should also be demonstrated what are the blood

changes, if any, brought about by residence upon the ocean or sea islands, as similar results upon tuberculosis to those in mountain air are sometimes brought about. The effects of sea and mountain air upon the nervous system need much elucidating. Again, the influence of atmospheric electricity upon the human organism stands ready for explanation.

To you, I need scarcely enumerate the many branches of study that require more extended work by the climatic physiologist to make way for the pathologist, with the therapist in his wake. While we ask for more workers and more means, we must not be unmindful of those who have already entered into, and are still laboring skillfully and manfully in this field.

In ethnology much good work has been done, but we need the collaboration of the ethnologist with the climatologist, so that the lessons ethnology can teach us of climatic influence, especially in transplanted races, extending over long periods of time, can be applied to the elucidation of the more immediate effects of climatic changes upon individuals in the present.

In geographical pathology the volumes of Hirsch stand out as a monument of systematic, elaborate and successful research in this field, while the work of Davidson and studies such as those of Matthews on the North American Indians, have added much to this department of climatology.

Passing on to the classification of climate, we are confronted with one of the greatest stumbling blocks in the way of placing climatology upon a really scientific basis. The interlacing and interdependence of the various factors which go to make climate and the modifications of their relative and combined influences by seasons, by local conditions, and also by remote influences makes it wellnigh impossible to formulate any classification of climates that is not imperfect and open to many objections. Therefore at present, at least, this can not be accomplished with scientific accuracy, but only in a broad and general way.

The geographical divisions of climate are comparatively easy, as into sea and land; the former with its subdivisions of ocean, island and coast, and the latter with its divisions by elevation, and again, a classification by position to the equator is not difficult. But it is when we come to classify the whole by important meteorological conditions then we find the serious difficulties. What do we mean by a dry, or what by a damp climate? Of course, when we think of extreme instances we know what we mean. But where are we to draw the line, and are we to judge by the absolute amount of moisture in each cubic foot of air for comparison, or by this relation to the temperature. Is it the absolute or the relative humidity reached or both together which determines the class in which the climate is to be placed? The meteorologists themselves are not yet prepared to clearly explain this question. Though work is going on among them which will assist in clearing off the fog hanging over it, of this nature is the work of Professor Harrington upon what he very happily terms "sensible temperatures." The amount of evaporation from the skin is regulated by the amount of watery vapor present in the air, that is its humidity, and the greater and more rapid the evaporation from the skin, the greater the coolness of its surface, so the cooled blood of the cutaneous

vessels carried into the circulation aids in preventing the general body heat rising above normal. Thus we see the value of recording the temperature of the wet, as well as the dry, bulb of the thermometer. This is an interesting subject to pursue into its therapeutic aspect, but *verbum sapientis*.

Passing to the tier composed of special climates, I will merely say that in my opinion too little consideration is shown to the circumstances of the particular place as regards food, lodging, work and amusements. So often, while the general climatic conditions are favorable, yet after all, the sending of that particular patient to that particular place is a failure, it is a case of a round man in a square hole, or *vice versa*, and while the disease may have been placed in the appropriate climate the individual has not. As Julius Braun said so admirably in his classic work on "Baths and Health Resorts:" "You have to consider not only the individual sickness, but the sick individual in climatic therapeutics." There is much to be said, from which the clock's warning face bids me refrain, but do let us remember the advice I heard Frank Buckland, the naturalist, once give: "When you get hold of a fact, pin it down for future use." When found, make a note of it. It is the slow accumulation of these, brought together by many hands, in many lands, which will ultimately give us a scientific climatology. In the recording of cases of phthisis, treated by climate, especially as to results, the history must be sought and reported over long periods to be of real value, and I know full well, this entails much labor and can, with the best endeavors, be only followed in a few out of many cases that are seen.

It is not the results of any one man or place that are of so much value as their use with many others; their family likenesses as it were, are brought out and one report aids and corrects the other. Again, for comparison, do let us receive more facts concerning the natural history of phthisis as seen by city physicians, where no climatic change could be noted. Sometimes we congratulate ourselves that while a case of phthisis did not recover, yet it lived for some time, say for fifteen years, and think that here at least we see the retarding effects of a certain climate; but turning to the pages of such careful observers as Flint, we are led to doubt this special influence when we find similar cases recorded living as long without using such climates.

I must now cease giving you these scattered suggestions concerning the principles of climatology and close this brief review of the general subject, to make way for the more important discussion of its various branches, of which the program with its names of authors promises us a rich feast. This is a gathering where the men of the sea, of the plain, of the mountain, of the city and hamlet are drawn from their homes, in many cases hundreds of miles apart, to study and advance the science of climatology.

FOURTH OF JULY SURGERY.—A recent issue of *Puck* has the following timely skit: "Physician (as he finishes bandaging up Mr. Oldboy, who has unsuccessfully set off some fireworks): 'Well, how do you feel?'" Oldboy (in muffled tones): "Just like a boy again."

LAUGHTER IS THE STAFF OF LIFE.—Mr. Joshua Billings believes that "Every time a man laughs he takes a kink out of the chain of life, and thus lengthens it."

ORIGINAL ARTICLES.

THE TREATMENT OF MALIGNANT TUMORS BY THE TOXINS OF THE STREPTO- COCCUS OF ERYSIPELAS.

Read in the Section on Surgery and Anatomy, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY N. SENN, M.D., Ph.D., LL.D.

PROFESSOR OF PRACTICE OF SURGERY IN RUSH MEDICAL COLLEGE; PROFESSOR OF SURGERY IN THE CHICAGO POLICLINIC; ATTENDING SURGEON TO THE PRESBYTERIAN HOSPITAL; SURGEON-IN-CHARGE TO ST. JOSEPH'S HOSPITAL, CHICAGO.

It has been known for a long time that in exceptional cases an attack of erysipelas has exerted a curative effect on malignant tumors. A number of years ago Billroth reported a case of inoperable sarcoma of the pharynx cured by a severe attack of facial erysipelas. The tumor mass sloughed and the large defect healed rapidly by granulation, leaving a healthy scar upon the site occupied by the tumor. Isolated cases of this kind have been reported from time to time, but the diagnosis was not always established by sufficiently careful clinical observations and microscopic examination of the tumor tissue. The discovery of the microbe of erysipelas by Fehleisen, and the cultivation of the streptococcus upon artificial nutrient media outside of the body enabled investigators to produce erysipelas artificially in the uncomplicated form in man and the lower animals. As soon as it was demonstrated experimentally that simple uncomplicated erysipelas is a disease attended by but little danger to life, the suggestion was made that, if the disease could be artificially produced in man by inoculation with pure cultures, the local and general conditions thus produced might prove useful in the cure or amelioration of inoperable malignant tumors. Of seven persons the subjects of malignant tumors, inoculated by Fehleisen with pure cultures, six developed typical erysipelas; in the seventh case the patient had passed through an attack of erysipelas only a few weeks previously and was, in all probability, still protected against a new attack. This patient was inoculated a second time with a negative result. Fehleisen has seen, by this treatment, a cancer of the breast become smaller, while a case of fibro-sarcoma and another of sarcoma were not materially affected by this method of treatment.

Janicke and Neisser have recorded a death from the erysipelas thus intentionally produced, in a case of cancer of the breast beyond the reach of an operation. At the post-mortem it was shown that the tumor had almost completely disappeared, and the microscopic examination of portions that had remained appeared to prove that the tumor cells had been destroyed through the direct action of the microbes.

Biedert saw in a child suffering from a sarcoma, involving the posterior part of the cavity of the mouth and pharynx of the left half of the tongue, the nasopharyngeal space and the right orbit, the tumor disappear almost completely during an attack of erysipelas.

Kleeblatt reports the case of a lympho-sarcoma followed by infection of the cervical glands, in which the tumors diminished markedly in size under the influence of an inter-current attack of erysipelas, but resumed its former malignant tendencies as soon as the disease had subsided. The patient was afterward intentionally inoculated with a pure culture of the

streptococcus of erysipelas, but the beneficial effect was, as before, only a temporary one, as the tumors steadily increased in size, the patient dying of exhaustion. In another somewhat similar case, the inoculation caused a typical attack of erysipelas, under the influence of which the tumor rapidly disappeared.

Cases, on the other hand, have been reported in which, after an accidental or intentional attack of erysipelas, the malignant tumor began to grow more rapidly. Neelsen describes a case of carcinoma of the breast in which, after two severe attacks of erysipelas, the tumor not only began to grow faster, but at the same time regional infection progressed more rapidly.

Bruns gives an account of the effect of erysipelas on tumors in twenty-two patients. Among these, three cases of sarcoma were permanently cured. Two cases of multiple keloid after burns were also permanently benefited. In four cases of lymphoma of the neck, some of the glandular swellings disappeared completely and some were reduced in size. In three cases of carcinoma of the breast, one was not influenced by the treatment, in one the tumor was diminished one-half in size, and in the third it contracted to the size of a pea, in which condition it remained at the time the report was made. A multiple fibro-sarcoma was greatly benefited, while an orbital sarcoma was not improved.

Spraenth concludes as the result of his observations that the products of the erysipelatous inflammation in certain cases can act in a curative manner upon malignant growths. He injected subcutaneously at a point distant from the tumor the sterilized toxic products of the microbes of erysipelas. Improvement and even complete disappearance of the tumors followed, although recurrence usually took place. The effect was much more marked in sarcoma than in carcinoma.

Burch observed that as a result of accidental or intentional infections with the microbe of erysipelas, tumors such as sarcoma disappeared by fatty degeneration.

Janicke and Neisser demonstrated by microscopic examination that cancer cells were actually destroyed by erysipelas streptococci. In view of the uncertainty of the result and the not inconsiderable danger to life which attends the inoculation of live cultures of the streptococcus of erysipelas, in patients debilitated by antecedent disease, it is safe to predict that this therapeutic resource will be abandoned in the future treatment of malignant tumors.

Coley, of New York, has made the treatment of malignant tumors with live and sterilized cultures of the streptococcus of erysipelas a special study since 1891. In 1893 he reported ten new cases of malignant tumors treated by repeated inoculations with erysipelas. From a study of the literature of this subject at that time it was found that there were recorded thirty-eight cases of malignant tumors in which an attack of erysipelas had occurred, either by accident or intent. In thirty-three cases the erysipelas was accidental and in fifteen it was the result of inoculation. Of seventeen cases of carcinoma, three were permanently cured. Of the seventeen cases of sarcoma, seven were free from recurrence from one to seven years after the attack of erysipelas. Ten cases showed quite marked improvement; one patient died as the result of an accidental attack of erysipelas.

In the summary of the analysis of recorded cases,

Coley excluded eight cases of his own, treated by repeated inoculations with erysipelas cultures; in none of these cases did an actual attack of erysipelas result, and yet the inoculations appear to have been followed by marked improvement, and this would indicate that there exists in the cultures some substance which is antagonistic to the tumor growth.

In view of the fact that the artificial production of erysipelas by inoculations with active cultures of the erysipelas microbe is not devoid of risk to life, and that improvement in certain cases followed, by inoculations with live cultures, which did not produce erysipelas; these facts led Coley and others to employ sterilized cultures, which appear to have produced the same therapeutic effects as the active cultures.

It was also ascertained by experiments that the efficiency of the dead cultures is increased by the addition of the bacillus prodigiosus, a comparatively harmless microbe. In a recent article on the treatment of malignant tumors with the toxins of these two microbes, Coley maintains the efficiency of the mixed dead cultures of these two microbes in the treatment of some cases of malignant tumors, especially sarcoma. In the same publication he reports nine cases of inoperable sarcoma permanently cured by repeated inoculations with the mixed toxins of these two microbes, that came under his own observation, and refers to a few successful cases in the practice of other physicians. The toxins which he uses now are prepared in the following manner:

Method of Preparation of the Toxins.—To make the toxins of erysipelas and prodigiosus, ordinary peptonized bouillon is put into small flasks, containing 50 to 100 cc., which, after proper sterilization, are inoculated with the streptococci of erysipelas and allowed to grow for three weeks at a temperature of 30 to 35 degrees C. The flasks are then inoculated with bacillus prodigiosus, and the cultures allowed to grow for another ten or twelve days at room temperature. At the end of that time, after being well shaken up, the cultures are poured into sterilized glass-stoppered one-half ounce bottles, and heated to a temperature of 50 to 60 degrees C. for an hour; sufficient to render them perfectly sterile. After cooling, a little powdered thymol is added as a preservative, and the toxins are ready for use. The toxins when prepared in this way are very much stronger than when filtered through a Pasteur, Chamberland or Kitasato filter, the active principles contained in the germs themselves being preserved. If, as is sometimes the case, the preparation is found to be too strong to use with safety, it can be diluted with glycerin or sterilized water.

"The best method of making the bouillon is to soak a pound of chopped lean meat over night in water. In the morning strain it through a cloth, make up to 1,000 cc., and boil for one hour. Then filter through a cloth, add peptone and salt, neutralize and boil again for an hour. The bouillon will then pass through filter-paper perfectly clear, and be ready to put into the flasks. It is not, however, necessary to neutralize the bouillon, as the streptococci will grow even more readily in acid bouillon, and the resulting preparation is, if anything, stronger than when neutralized bouillon is used.

"In order to keep up the virulence of the cultures they are put through rabbits in the following way: the hair of the ear is clipped close with a pair of scissors, and the skin washed with weak carbolic

acid, and then sterilized water. A minute quantity of a bouillon culture, forty-eight hours old, is then injected subcutaneously in four or five different places in the ear. Forty-eight hours later, after again washing the ear with carbolic acid and sterilized water, a flat needle sterilized in the flame is inserted under the skin at or near the point of inoculation, and the layer of the skin cut off with a sharp sterilized scalpel. The piece of skin is then rubbed well over the surface of an agar tube with a thick platinum-wire needle. After twenty-four hours in the incubator the colonies of streptococci will show as minute white specks, and from them a pure culture can be obtained. If the agar is made with 75 per cent. of bouillon and 25 per cent. of urine, the streptococci will grow more freely than if bouillon alone is used. The dose of this preparation varies from 1 to 8 minims; I have had a temperature of 105 degrees F. follow the injection of 2 minims. I usually begin with the minimum dose and gradually increase until the desired reaction, *c. g.*, temperature 103 to 104 degrees F. is reached."

Coley does not say that this treatment is successful in all cases, and reports his failures with his successful cases, but his satisfactory results are out of proportion to those of any other practitioner, in the employment of the same remedy in similar cases. It is generally known that carcinoma has proved more refractory to the toxins of the streptococcus of erysipelas and the mixed toxins than sarcoma.

A distinction should be made between the therapeutic action of non-malignant tumors of erysipelas and the subcutaneous injections of sterilized cultures of the microbe of this disease. In erysipelas involving a malignant tumor, the superficial lymphatic channels are the seat of an active inflammation, the product of which always temporarily obstructs the pathways through which local, regional and general infections occur and, in exceptional cases, permanent interruption of the lymph current may limit or arrest the growth of the tumor. No such anatomic changes are produced by the injection of the toxins.

The treatment of inoperable sarcoma and carcinoma with the mixed toxins, as advised and practiced by Coley, has been given a fair trial in the surgical clinic of Rush Medical College, and so far it has resulted uniformly in failure.

The accompanying table is a brief summary of the cases subjected to this treatment.

The injections were made daily, gradually increasing the dose until the desired reaction was produced. In most of the cases the reaction was initiated by a chill, or at least a sense of chilliness. The temperature reached the maximum height in the course of a few hours, and continued from six to twenty-four hours. The toxins used were obtained from three different sources, the last supply directly through the courtesy of Dr. Lambert, of the laboratory of the Cancer Hospital, New York. A temporary swelling and diffuse reddening of the skin at the point of puncture was a common occurrence; abscess formation was seldom observed. Loss of appetite, restlessness and insomnia were some of the general symptoms most constantly produced by the injections, when used in doses large enough to provoke febrile reaction. In all of the cases, the injections failed to effect even temporary improvement, and in some of them the local and general conditions appeared to be aggravated by the treatment. The results of this

treatment have been most discouraging in my hands, and although I shall continue to resort to it in otherwise hopeless cases in the future, I have become satisfied that it will be abandoned in the near future and assigned to a place in the long list of obsolete remedies employed at different times in the treatment of malignant tumors, beyond the reach of a radical operation.

DISCUSSION.

DR. W. B. COLEY—I wish to thank you for the courtesy you have extended me by asking me to open the discussion on a subject in which I have been deeply interested during the past four years. I hesitate to offer my own experience against that of so distinguished a surgeon as Dr. Senn, and I will first say that I heartily commend Dr. Senn for bringing before you his own results from the treatment with the toxins, —failures though they be. No scientific opinion as to the value of the treatment will be possible unless the failures as well as the successes are recorded, and I myself have conscientiously endeavored to follow this method in my own work.

Since May 3, 1891, I have treated eighty-four cases of inoperable malignant tumors with the toxins of erysipelas and bacillus prodigiosus, and it seems to me that a careful study of these cases, extending over a period of four years, ought to enable us to formulate some definite conclusions as to three very important questions:

1. Have these toxins a destructive effect upon malignant tumors?
2. Is this effect merely temporary, or permanent?
3. What forms of tumors are most susceptible to the action of the toxins?

A study of my own cases shows that of forty-three cases of inoperable sarcoma treated with the toxins, eleven have been successful. One of these has since had a return of the trouble; one has gone nearly four years; two, more than two years; and two, one and one-half years, without relapse.

Within one month I have presented three cases before the Surgical Section of the New York Academy of Medicine, two of which had gone more than two years since treatment, and still remain in perfect health. These results are indisputable facts, the diagnosis having been established, not only clinically by the leading surgeons of the East, but confirmed microscopically by the best pathologists; and if further evidence were needed, the fact that a number of them had rapidly recurred after operation, would be enough to establish

their malignancy. If the diagnosis is still doubted, after having been subjected to all these tests, it seems to me that we had better at once abandon the discussion as to the treatment of sarcoma, and employ our time in learning how to make a diagnosis.

In regard to carcinoma, up to the time of my last paper read before the Academy of Medicine, Nov. 15, 1894, I had nothing but improvement follow the treatment in cases of carcinoma, and I have never advocated the toxins in carcinoma except as a matter of experiment, though I confidently believed that in time good results would be obtained in this as in sarcoma.

Since November I have had two cases of epithelioma entirely disappear. One was a very rapidly growing epithelioma, involving the lower jaw and floor of the mouth and chin. The case was sent to me by Dr. George R. Fowler of Brooklyn, in July, 1894, and was treated about three months at the New York Cancer Hospital. She has had no treatment since November; no evidence of the growth can be found, and the woman is now in perfect health. The entire tumor had developed in a space of four months, and the involvement was so extensive that Dr. Fowler regarded it as hopeless from an operative standpoint.

Against this positive evidence, based upon eighty-four cases, extending over a period of four years, Dr. Senn has presented on the other side nine cases, covering a very brief period of observation. If we analyze them, what do we find? We find first, three of the cases were carcinoma, a class of tumors in which I have not advocated the treatment. A fourth case was a melano-sarcoma, a rare form of sarcoma, of which I have treated three cases without success. The fifth and sixth cases were very advanced osteo-sarcoma, which I distinctly stated in my paper were the least influenced by the toxins. There remain but three cases upon which he can justly base an argument against the value of the toxins. With this limited experience, covering so short a period of time, Dr. Senn tells you that the treatment is valueless, and in another year will be entirely abandoned. I can only say that, if I continue to have as many successes in the coming year as I have in the past, I venture to predict that I for one shall be using the treatment, and I do not believe that I shall be the only one.

ON SOME POINTS IN REGARD TO STERILIZATION IN PRIVATE DWELLINGS, WITH THE DEMONSTRATION OF SOME NEW ASEPTIC APPLIANCES.

Read in the Section on Surgery and Anatomy, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY CARL BECK, M.D.

NEW YORK.

Since the experiments of Petri and Cleves-Symmer have demonstrated that by bacteriologic test, what long before appeared to be probable on the base of clinical observation, namely, that the atmosphere has practically no bearing upon infection, but that the human body is invaded by bacteria by contact; in other words, by the wounding instrument, by the hands of the surgeon, by clothing or by the skin of the patient, the question of operating inside the hospital has entered a new stage.

As besides Lister, the father of modern wound treatment, there is still a considerable number of surgeons who maintain that the atmosphere has at least some bearing upon infection, I thought it to be well worth while to refer to the experiments alluded to from a strictly surgical standpoint.

Petri fixed the special forms of microbes suspended in the atmosphere and ascertained at the same time the number of microbes present in a determined volume of air. He determined the presence of microbes by pumping a measured volume of air through a filter of sterilized sand. This sand, to which all the microbes of the atmosphere adhere, he distributed on Petri's plates containing sterilized gelatin. On this gelatin the microbes multiplied by forming as many

separate colonies as there were microbes, so that the latter could easily be counted. By determining the next question, namely, that of the number of microbes settling within a fixed time upon a wound surface of a certain area, he found that a parallelism could not be assumed between the microbe capacity of the air and the quantity of the deposits. It would naturally be expected, that air containing only a few microbes would deposit but few upon wounds, and *vice versa*. But this parallelism does not always exist, as the microbes are not equally distributed in the air, but some regions are densely and some are sparsely populated. This fact can be shown, if according to Cleves-Symmer several gelatin plates are exposed at the same time and if the different plates are kept in the same part of the room. Then a great difference as regards quantity and quality is found, for neither the same kind nor the same quantity of microbes settle upon the plates.

Cleves-Symmer also exposed gelatin plates for seven days simultaneously in three surgical wards. This exposure was made five times a day; the first at 5 o'clock A.M., while the patients were asleep, and the second at 7 o'clock A.M., after the floors were first washed and then scrubbed. Similar exposures were made at 9 A.M., when operations were generally performed, and the last exposures were made late in the afternoon. The sterile gelatin was contained in round, flat, large-surface Petri dishes. After they had been exposed each time for twenty minutes, they were covered and preserved in a moist incubator in which the temperature was that of the room. The developing colonies, as soon as they could be recognized by the naked eye, were counted daily, and were observed so long as they could be distinguished from one another. Among 4,613 microbes so developed there was found but one pathogenic microbe, which was the bacillus pyocyaneus. At a time when nearly every third case in the hospital suffered from a wound in the secretion of which this bacillus was contained, there were certainly ample opportunities for it to permeate the atmosphere; if, despite this, a pathogenic microbe was found but once, it is proof enough that the air contains necessarily very few pathogenic microbes.

Clinical experience accords with this. The operating rooms of Billroth at the old "Allgemeines Krankenhaus" in Vienna were far from being an anti-infectious ideal. The same remark applies to many other celebrated operating rooms, among which I may only mention the Albert Amphitheater in the same city and the one of the eminent surgeon, Gussenbauer, in Prague. As far as my own experience is concerned, I may state that it is also in accord with these theoretical propositions. So, for instance, were the average results in St. Mark's Hospital, New York, about just as good in its old building (the very poor accommodations in which premised all the elements of atmospheric infection, since the most rigid observations of aseptic principles were carried out in reference to all objects that came into direct contact with the wound), as those obtained in the new building, which merits the designation of a model hospital, particularly with reference to modern aseptic appliances.

If, then, success does not depend upon the marble floor of a modern operating room, and upon more or less complicated apparatus, but upon carrying out the principles of asepsis so far as direct contact with

wounds is concerned, there is no reason, why aseptic operations could not be performed almost anywhere.

If it would really be as Neuber, one of the most distinguished pioneers of aseptic principles, maintains, that the arrangements of the operating rooms are the main requisites for success, it would be no less than a crime to operate outside of the hospital. Neuber lays great stress upon having separate operating rooms (he himself uses five different operating rooms in his own private hospital) and demands at least two different operating rooms for even the smallest hospital; one at least, for septic and one for aseptic cases, each possessing separate furnishings and supplies. There can be no doubt that it is *desirable* to have at least two operating rooms. Their absolute *necessity*, however, is open for discussion. The whole question, after all, seems to converge more and more to the one point, that operations performed in private dwellings entail a great deal more trouble to the surgeon than they would in a hospital, where everything can be carried out with the greatest convenience, so that it is quite natural that a surgeon, when having the choice, would prefer operating in a hospital.

The advocates of atmospheric infection seem to regard every operation performed outside the hospital as a criminal act, more or less. But opinions change quickly nowadays and to quote Schiller: "There is nothing more permanent than constant change." It is only a few years ago since a reputable German surgeon demanded prosecution by law of every surgeon who omitted using carbolic acid during operation. I should not be surprised if the same energetic colleague would demand the arrest of the same unfortunate Esculapian who did not do the contrary now. It seems to me that there was never a time when operations outside of the hospital were more justifiable than under the present auspices of asepsis. I sincerely hope that this statement will not be mistaken for an endeavor to encourage an inexperienced practitioner to perform major operations. Beside asepsis there are required a great many other points. In the first place, a surgical routine of years' standing; second, there must be at hand well-trained assistance, without which a surgeon is hardly justified in performing major operations.

It is absurd to advise a surgeon to take a bichlorid bath every day, and unnecessary to remove all furniture, paintings, carpets, etc., before operation in a private dwelling, or to wash the walls of the private operating room with bichlorid and scrub them afterward with crumbs of bread. The latter procedures will certainly do no harm if undertaken a few days before the operation, but if done only a few hours before the operation, they will be apt to impregnate the atmosphere with many more microbes, probably also with "pathogenic" microbes, as such maneuvers can not be done without stirring up a considerable quantity of dust, which will settle upon clothing or such other objects, which may afterward come into indirect contact with the wound. It is therefore advisable not to disturb the operating room shortly before operation. But great care should then be taken to keep the tables, chairs, or whatever else should be required for the operation, covered with sterilized, or at least with freshly washed and ironed sheets or towels. If it should have happened that dust was stirred up shortly before operation, floor and walls should be sprinkled, as moisture precipitates the microbes.

For an operating table, a strong kitchen-table may serve, if the surgeon should not prefer to take a portable operating table along. Upon two other tables of medium size the instruments, trays, dressings, sponges, etc., are placed. If such tables are not available, wooden chairs have to answer the purpose. If possible, all such objects as chairs or tables should be scrubbed with soap and hot water and with bichlorid of mercury (1 to 500). Such arrangements can be made under the supervision of an assistant or a nurse, who may be sent to the house of the patient the day before the operation is to take place. They should also see that the patient takes a warm bath and is also shaved in case there should be any hairs present on the field of the operation. Scrubbing with ether and bichlorid should follow these procedures. Then the field of operation should be covered with a large poultice of green soap, which may remain until shortly before operation, except there are signs of susceptibility to dermatitis, in which case a bichlorid solution should be substituted. The nurse must also instruct the family that an abundant supply of boiling water must be ready in large vessels and that there must be at hand a sufficient number of bed sheets and plenty of towels. If tin boilers must be used, they should be scrubbed with sapolio and be covered with sterilized towels. China pitchers and basins may also be prepared in the same manner and afterward washed with a strong bichlorid solution, etc.

As a surgeon must always be prepared for an outside call, he should have a set of asepticized surgical appliances ready in a satchel at his office. I found it convenient to preserve the instruments generally required in linen cases, having a separate one for abdominal sections, one for operations upon the bones, one for the uropoetic system, one for tracheotomy, one for general use, etc. These linen cases may be rolled up and tied in the middle with a cord after being used. The case designated for general use contains such instruments as are required in any operation—that is, scalpels, scissors, forceps, retractors, spoons, probes, needles, etc.—and is carried along with the one designated for a special operation. For instance, if a herniotomy is to be performed, the "general set" is accompanied by the laparotomy set. These instrument cases can be carried along with the other necessaries in a satchel. I use a satchel of rectangular shape about 42 centimeters long, which gives ample space for the instruments required, as well as for the other necessaries, consisting of my folding sterilizer, of a sufficient quantity of trays fitting one into another, of gauze, cotton or moss bandages, silk, catgut, rubber gloves, green soap, soda, bichlorid tablets, ether (resp. chloroform, morphin tablets, camphorated oil for hypodermic use, brushes, etc. It will sometimes be convenient, to carry the surgeon's coats, towels, sheets, etc., to the house also. The brushes for scrubbing the skin surface, if sterilized, can be carried in sterilized towels, as well as the gauze and the other dressing material. The ligatures are kept best in one of the metal boxes, devised by Schimmelbusch or Braatz or myself. Iodoform gauze, if required, may be carried conveniently in a "Duehrssen" receptacle. In reference to my sterilizer, I may be allowed to state that its main advantage consists in its compactness, as its separate parts can be easily put together. Its lower division, which is also the smallest one, consists of a reservoir which fits into a larger division. If desirable, a fourth divi-

sion can be set up. The reservoir of the lowest division must be half filled with a solution of soda. A wire net on which the instruments are to be placed fits into this reservoir. Into the projection of the walls of the second or third division, wire sieves to receive the dressings, towels, sponges, etc., have to be inserted. To the lower division are attached two folding supports between which, when in use, is placed the alcohol lamp which is so constructed as to allow of its being carried along with safety when filled with alcohol. Beside the regular attachments—that is, the alcohol lamp, the wire sieves for the instruments, two hooks for pulling out the latter and the thermometer—a few instruments, a silk box, etc., find ample space in the lower division (reservoir). After being folded together, the height of the apparatus amounts to 6 centimeters. This height is less than one-fourth of that of the whole apparatus when ready for use, which amounts to 27 centimeters. The sterilizer can either be put into an instrument satchel or be carried under the arm. Two quarts of water will be so heated (as indicated by the thermometer fitted into an opening in the lid) as to fill the whole sterilizer with steam of a temperature of 212.1 degrees F. Anthrax spores dried on silk ligatures showed no cultures after they had been exposed to the steam for fifteen minutes. The apparatus is made up now in five different sizes.

37 E. 31st Street.

PROPHYLAXIS IN SURGERY.

Read in the Section on Surgery and Anatomy at the Forty-sixth Annual Meeting of the American Medical Association at Baltimore, Md., May 7-10, 1895.

BY GEORGE WILEY BROOME, M.D.
ST. LOUIS.

In briefly discussing the subject of the prophylaxis of infection in operative surgery, it is my intention to speak also of the measures necessary to prevent unnatural union between tissues under the title given to this paper, and I shall first speak of the operation of amputation as it relates to the prophylaxis of infection and, in connection therewith, the prevention of the amalgamation of heterologous structures in the reparative processes of the wound. But before entering upon the subject I may be permitted to preface the discussion with the observation that there is but one author in the world, so far as I am aware, who holds and advocates the theory that the apposition of peritoneum to peritoneum is a surgical error, although I am clearly cognizant of the fact that thousands of operations terminate in the unnatural union of tissues; that is, the union of tissues of a different kind or nature. But I am also quite certain that such results were not intended by the operator. Mr. J. Greig Smith bases his arguments on the doubt of the principle of sero-serous apposition in connection with intestinal operations, and particularly with the means of providing intestinal drainage. "Many of these operations," he says, "had to be repeatedly performed, and in some of them I dared to ignore the time-honored habit of 'shutting off the cavity' by suturing parietal peritoneum to bowel, and both to skin; often, indeed, I omitted to place sutures of any kind. The practical outcome of this has been, that where I want temporary drainage, with loose adhesions and mobile bowel—as in temporary enterostomy—I suture parietal peritoneum, bowel and skin; but where I desire firm, permanent and intimate adhe-

sion, with no mobility of bowel on parieties—as in celio-colostomy—I implant bowel directly on raw surface, and if this raw surface is small, as it is in thin subjects, I increase it by unfolding or peeling from the parieties more peritoneum, and turning its raw, not its serous, surface from the bowel.

"Further evidence in favor of the strength and durability of sero-fibrous adhesions is supplied by the occurrence and persistence of adhesions when surfaces are left after operation uncovered by peritoneum. Adhesions between bowel and raw surface (such as the stump of a pedicle) may, as we know, be strong enough to cause obstruction. A recent hospital case, where I had to re-open the abdomen for obstruction a week after removal of the appendages for myoma, was a striking example of this. The intestinal wall was positively incorporated with the surface of one of the ligated pedicles; it was quite impossible to tear them apart; it was necessary to cut away a piece of the stump and liberate the intestine. Such adhesions remain to give further trouble also.

"Sero-serous adhesions, on the other hand, tend to disappear; often they disappear very quickly. Indeed, as I have said, where loose and temporary fixation is desired, as in temporary drainage of intestines for obstruction, sero-serous apposition I now believe to be better than sero-fibrous. *One prime advantage of sero-serous union is that it takes place very rapidly, that in a few hours it is water- and gas-tight.* But such union is no more rapid than when peritoneum is opposed to a raw surface. If we bear in mind the histologic forces at work, we can readily understand how this should be; the layer of lymph and young cells which lie between the serous surfaces have little cohesion, and being shut off by a double layer of endothelium from vascularization and from ingrowth of plasma cells, are long in being converted into true granulation tissue. Vascularization is slow and fibrillation is slow, and while they are going on, nature is beginning to get rid of the exuded lymph. Such adhesions often disappear; if they remain they nearly always get thinned and elongated. If there is little to choose between the two, as regards prevention of extravasation of fluids for the first few hours, the sero-fibrous has a decided advantage as time goes on. The lowly organized, inert and loosely coherent plug of lymph is easily disturbed and would be easily broken up in the presence of fluid. This we know to our cost; it is on the second or third day that leakage takes place. A sero-fibrous junction that lasts for a day is practically safe forever, for it goes on improving in strength and solidity.

"The practical application of these principles is as wide as abdominal surgery, and includes not only results to be encouraged, but results to be avoided. Where it is desired to secure quick, strong and permanent union, sero-fibrous apposition is better than sero-serous. Where the union sought need not be strong, and is desired to be only temporary, sero-serous apposition may be adopted.

"In ordinary work, the carrying out of these principles involves some such processes as the following: fibro-fibrous as against sero-serous apposition is carried out in the closure of the parietal wound; in operations for the cure of ventral and umbilical hernia and in kolpo-hysterectomy. Closure of the parietal incision is made by apposition of the raw peritoneal flaps outfolded, and not of the intact se-

rous surfaces inturned. This may incidentally be mentioned, that by abolishing the inward dip of the united peritoneal flaps, it helps to prevent ventral hernia."

I have quoted from Mr. Smith's address upon this subject rather extensively, for the purpose of giving a tolerably clear understanding respecting his arguments and data for the benefit of those who may not have read the article, but desire to know the position assumed in the matter by one so capable of making reliable clinical observations. But going back to my subject, as an illustration of the unintentional, as I take it, of the amalgamation of tissues following the operation of amputation, I have here several photographs taken, regardless of any effort to select the cases, from among the membership of a society in St. Louis organized under the name of the "Knights of Willow." Each one of these knights has at one time or another undergone an amputation of a limb, and, I may add, perhaps 90 per cent. of the members of this society suffer to some certain degree from the consequences of either unnatural adhesions between the tissues or in consequence of the vulnerable position of the cicatrix of the stump. The prophylaxis of these, to say the least, unfortunate sequences consists, from my standpoint, in the following steps in the procedure of an amputation:

1. Purification of the instruments, the disinfection of the hands of the operator and of the entire limb of the patient.

2. The production of artificial anemia by elevating the limb and the application of the constrictor several inches above the point at which it is proposed to amputate.

3. Fashion a long anterior flap by extending the incision down to the sheaths of the muscles and tendons. The entire flap is reflected by dissecting closely to the muscle and tendon, a short posterior flap is reflected backward by a like dissection, when the muscles are severed by a clean circular sweep of the knife down to the bone.

4. About one inch of the periosteum is then exposed below the point at which it is proposed to saw the bone. The periosteum now being incised is reflected upward, after the fashion of a cuff.

5. The soft parts are now to be retracted by an assistant by means of iodoform gauze. The bone is then sawed at an oblique angle for about a quarter of its thickness, when the saw is withdrawn and placed at a right angle with the shaft of the bone and the bone is sawed off.

6. The end of the bone is now carefully trimmed and rounded, the periosteum brought down accurately over the sawed surface of the bone and carefully sutured by means of a small needle armed with very fine, perfectly sterilized silk.

7. The sheaths of the artery and vein are now carefully dissected up, these vessels exposed, the artery first ligated, then the vein ligated separately, after which a single ligature is thrown around both and tied. The sheaths with the attached connective tissues are then carefully sutured over the ends of these vessels by the same means as were employed in covering the bone.

8. The nerve is now dissected from its connective tissue attachments and exposed for two or two and a half inches above the divided muscle, then cut off by means of blunt-pointed scissors. The sheaths and remaining connective tissues are now brought

over the ends of the divided muscles and sutured in a similar way to that adopted in covering bone and vessels.

9. A large compress of iodoform gauze is now folded tightly against the stump and the skin flaps brought down over the gauze and held firmly and forcibly against the stump in both hands of the operator, when after the lapse of four or five minutes the constrictor is quickly removed. After the expiration of several minutes more, the operator's hands are relaxed, the iodoform gauze tamponade is removed and the stump carefully inspected, when, if all hemorrhage has ceased and the conditions are favorable for rapid and uninterrupted repair, the flaps are carefully and accurately sutured by means of medium-sized, perfectly sterilized silkworm gut.

10. The wound is now dusted with powdered iodoform, several layers of iodoform gauze brought in contact with the stump, then over this and including the entire leg is placed a heavy layer of absorbent cotton. This is held in position by means of a neatly applied roller bandage.

11. The limb is now placed upon a well-padded posterior splint and another roller made to include this splint and limb.

12. The patient is then put to bed and the limb kept elevated at an angle of about 45 degrees.

I consider the details briefly outlined above, to be absolutely essential in order to secure the prophylaxis of infection, unnatural adhesions and proper position of the cicatrix. These rules will apply to amputations at other points than this.

The chief points to be observed in performing an amputation, according to most of the text-books do not entirely cover what I deem to be wholly essential in order to secure the very best results. For example, if we turn to this subject in the "American System of Surgery," a book which has just passed through the press, we find the subject matter embraces about the following precepts:

"If the conditions essential to a sound and useful stump are constantly kept in view, any of the stereotyped or extemporized methods may with patience and dexterity be made to yield good results. The recognized methods of amputation are circular, the single flap, the double flap, the rectangular flap, the bilateral flap, the periosteal flap.

"The wound must be closed and dressed according to certain principles. The application of hot water by rapid douches to amputation wounds is an excellent method of arresting hemorrhage and preparing the surfaces for prompt union. The hot water must not be allowed to remain in contact with the limb. The vessels having been secured, if the fibrous sheaths are seen, as in amputations at the metacarpal phalangeal articulations, close them with two or three fine sutures, then close the wound with two or three deep and several superficial interrupted sutures. Place in the angles of the wound proper drainage tubes, so as to relieve it of all accumulating fluids. Support the parts in such a manner, by splints, or slings, or pads, that they need not be moved in dressing. Apply such dressings as will support and protect the wound, but admit of easy change."

I do not agree with this teaching, for, in the first place, I think that the indiscriminate use of the drainage tube is unscientific and certainly a prolific source of infection, and hence a practice that is likely to terminate in destroying all the good effects which

would otherwise have been obtained by the scrupulous observance of the steps described above, for when the stump becomes infected, then follow suppurative inflammation and ulceration, with all the baneful sequences. In the repair of inflammation; that is, in the restoration of the tissues to their normal integrity, not only must the inflammatory exudation be removed, but the injury of the tissue caused by the inflammation in the first place must be repaired. In any inflammation there is always a destruction of tissue. Disorganization of the effects of your handicraft on the tissues destroyed must be replaced by a new formation of tissue. Furthermore, by careful and somewhat extensive clinical observation I am clearly convinced that the irrigation of a stump for simple hemostatic purposes is unnecessary, unscientific, and many times a cause of infection. Dry sponging after careful hemostasis by means of the ligature and pressure are productive of far more satisfactory results. Drainage is unnecessary to relieve the accumulation of blood beneath the flaps if the vessels have been properly secured, for the clot which forms to fill up the space underneath the flaps proves to be one of the wisest provisions of nature in hastening permanent and accurate healing. The clot itself being entered by leucocytes in the first instance and subsequently plasma cells penetrate; the latter of which organize into fibrous tissue, while epithelium after a time spreads over its surface.

In the next place, I do not agree that the best results can be obtained by amputating in such a manner as will leave the cicatrix directly over the end of the stump, either transversely, vertically or obliquely. The position of the cicatricial tissue should be remote from the end of the stump. The suggestions of C. W. McCullough, the artificial limb maker of St. Louis, in this respect, I dare say, possess great value, for he tells us that "in all amputations of the leg and thigh, as well as knee disarticulations, the cicatrix should, as far as possible, be placed well away from the extremity of the bone, preferably along the posterior aspect. Contiguity or adhesion of the cicatrix with the extremity of the bone is frequently the cause of suffering. All stumps should be provided with ample flaps, not redundant flaps; a redundancy of tissue on the extremity of a stump is of no advantage. The prime office of a flap is to protect the extremity of the bone, and it should be only ample to effectually perform that function. Whether the flaps are anterior or posterior, exterior or interior, or a combination of any of the four, it matters not so long as the extremities are well protected. Periosteal flaps are desirable, as they give additional protection to the bone and prevent integumentary flaps from becoming adherent to the bone. If an amputation is to be done below the middle third of the leg, bones should be sacrificed in order to obtain a suitable flap. If the amputation is to be made above the middle third, bone should not be sacrificed, even if transplantation is necessary in order to secure a flap. Every inch of healthy bone above the middle third is desirable for leverage purposes. If a thigh amputation is to be done close to the knee, bone can be sacrificed in order to secure a flap. The nearer the amputation is to be done to the body the greater should be the care to save bone."

While our methods to secure aseptic surgical results are almost perfect, it has been conclusively demonstrated, I believe, to the mind of every observ-

ant surgeon, that it is in some instances impossible to render the skin of the abdomen through which a given operation is to be made perfectly free of pathogenic microbes. The circumstance is constantly being forced upon the surgeon's clinical observation that there are pyogenic bacteria living beneath the external layer of the skin which can not be removed from their habitation by measures that will not entail destruction or at least impair the function of the skin of that particular area. We furthermore realize that pathogenic bacteria never migrate beyond the integument unless an avenue is established for their passage. We know also that the integument is the great bulwark against the entrance of pathogenic microorganisms to the underlying tissues, but which when reached there is every requisite for their rapid growth and multiplication and the production of their toxins. So it may be said that the intact skin is invulnerable to these bacteria while, on the other hand, the underlying tissues are positively vulnerable; that is, the former is an absolute hindrance against the pathologic effect of the pus microbe, while the latter furnishes an ideal soil for its growth. These facts must be kept constantly before us if we hope to attain something approaching the ideal in the prophylaxis of infection in operative surgery. I am impressed with the belief that it is absolutely incumbent upon us, in the light of our knowledge respecting this subject, to undertake to revolutionize the unscientific and the unfortunate practice of closing a wound through the abdominal wall by including the skin, fascia, muscle and other tissues by one single suture. It is in dealing with the abdominal cavity that the greatest exploits of surgery have been achieved—exploits surpassing everything that was formerly conceived. The peritoneum which used to be a *noli me tangere* is now entered and closed as fearlessly, especially by the gynecologist, as if it were the playground of surgery.

I have here several photographs intended to illustrate the same idea of prophylaxis in operative surgery that is conveyed in the steps describing an amputation. The flap method and the plan of uniting the underlying tissues should be extended to all of the operations through the surface of the body, particularly in celiotomy, herniotomy, in exposing the stomach, gall bladder and the kidneys. So that it may be understood that my chief aim is that in opening the abdomen, in opening joints, in shortening tendons, in which the skin is non-adherent, in operations upon the patella, skull, or elsewhere, the surgeon should avail himself of the advantages of the prophylactic flap. The chief advantage, as I have already said, consists in placing the wound in the deeper parts at a distance from the skin wound; that is, the skin over the deeper wound is not interfered with, but supports the deeper tissues which have been divided, and rapid healing must take place, hence the risk of infection of the deeper parts from impure skin is reduced to a minimum. In suturing the skin, silk worm gut is always used. The suturing material for the underlying tissues may consist of very fine silk. I need not refer to the necessity of having these suture materials perfectly pure. The former may be boiled five minutes in alcohol, and the latter kept in an Arnold sterilizer for fifteen minutes.

The many advantages of the preliminary flap, recognized by both Horsley and Chiene, are truly of great value, but the scope of general usefulness of

this plan of operating is almost without limitation. I repeat, that as a prophylactic measure against infection, it possesses advantages that can not be equaled by any other known plan, but as a prophylaxis against unnatural adhesions between the skin and subjacent tissue composing the area of a surgical wound, its value can scarcely be estimated. Consider, for example, the remote effects of a straight cut through the skin immediately over the breach of a transverse fracture of the patella, where the fragments have been operated upon for the purpose of securing direct fixation of these fragments. We see a strong unyielding fibrous union between the two cicatrices. The cicatrices becoming amalgamated, the mobility of the patella is lost, and there can be no motion of the patella without dragging the skin with it. This circumstance renders motion of the knee-joint not only painful, but limited. Impairment of function of the entire joint is an unavoidable consequence, and the weight of the person's body can never be supported upon the bended knee, an unfortunate condition that lasts as long as the individual himself, all resulting from defective surgery and not from the actual effects of the original injury, as is too frequently charged.

I have formulated the salient ideas of this paper in the following conclusions, viz.:

1. The value of prophylaxis, in operative surgery as it relates to the formation of the flap and the apposition of homologous tissues, is not apparently fully appreciated by surgeons.

2. In order to derive the greatest benefit from the prophylaxis of infection and the unnatural union of tissue, a flap should be so fashioned in all operations as to carry the cicatrix of the skin away from the incision wound through the underlying structures, and each tissue brought in apposition with its own kind.

3. The particular point at which an amputation is made is not so important with reference to the adaptability of the stump to prosthetic apparatus, as is the execution of the proper technique of the operation.

4. The artificial limb maker of St. Louis appears to be able to adjust artificial limbs to a great variety of stumps and at the same time afford the patient every facility of easy and perfect locomotion by the use of any compensating appliance manufactured, provided the operative procedure outlined in this paper has been completely executed.

5. The flap should be reflected with subsequent suturing of homologous tissues in operations upon all parts of the body, under the same general principles as are above described, of amputations including herniotomy, supra-pubic cystotomy, celiotomy, gastrotomy, cholecystotomy, nephrotomy, etc.

6. If a wound is made and the operation completed in manner outlined, through unbroken skin and not in the vicinity of, or in communication with some mucous canal and suppuration takes place, it indicates that the surgeon has certainly committed some unavoidable error in his methods.

7. Drainage is never necessary, following an operation conducted in this way through unbroken skin, and into an area free from infection. All such wounds should be tightly closed without drainage, for if the surgeon's aseptic measures are perfect there can be no other necessity for drainage.

8. In the light of Muttman's investigations we may draw the inference that the drainage tube ex-

poses the patient at the deep end of the tube to seventy-eight different species of cutaneous bacteria, and Welsh has shown clearly that one pyogenic variety is resident in the epidermis normally and occupies such a position as to render it safe from any known means of cutaneous disinfection but is prone to travel down along the sides of a drainage tube, and in this way to cause the wound to suppurate.

9. Blood in a wound is not dangerous and where, for the obliteration of cavities therein, the choice lies between a blood clot and the introduction of a drainage tube, which is not only a foreign substance but a prolific cause of infection, it is therefore safer to take the chances with the blood clot.

10. Blood furnishes bactericidal properties, and experiments made by three gentlemen of this city who have become justly distinguished in their respective branches (I mean Welsh, Howard and Halstead) show that virulent pyogenic staphylococci injected into blood clots which have been allowed to fill wound cavities did not multiply and occasioned no suppuration. Irritation of an aseptic wound should never be employed, and the irritation of such a wound with chemic antiseptics can only be contemplated as a coarse and unscientific practice.

11. Iodoform is the ideal antiseptic powder for dusting the line of union of a sutured wound, despite all that has been said against it. It must be conceded that no equivalent for iodoform as a prophylaxis in surgery has been found.

12. The chief aims which the surgeon should try to achieve are: the rapid and undisturbed healing of wounds, the prevention of deformities and the resulting suffering of the patient which cause many to become the victims of evil and vicious habits, the prolongation of human life and usefulness, and, for the attainment of these ends the science of prophylaxis demands prominence and careful consideration in the practice of surgery.

THE MEDICO-LEGAL EXAMINATION OF THE RED STAINS FOUND ON THE CLOTHES OF CHARLES FORD, WITH A PLEA FOR THE USE OF THE CAMERA LUCIDA IN THE MICROSCOPIC EXAMINATION OF BLOOD STAINS.

Read before the Denver and Arapahoe County (Colo.) Medical Society.

BY E. R. AXTELL, M.D.

PROFESSOR OF HISTOLOGY AND BACTERIOLOGY AND CLINICAL LECTURER IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF DENVER; PROFESSOR OF MICROSCOPY IN THE DENVER COLLEGE OF PHARMACY, AND PATHOLOGIST TO ST. LUKE'S HOSPITAL.
DENVER, COLO.

The following is the newspaper account of the tragedy which made my services necessary to the district attorney. It is taken from the *Denver Republican* of Sept. 16, 1894:

"In a dingy brick shack, where scarcely a ray of sunlight ever warms the interior, the dead body of Sadie Smith, a woman about 45 years of age, was found yesterday afternoon about 1:45 o'clock. All the evidences of foul play were upon the body, and little room for doubt remains that the unfortunate woman was the victim of a foul and atrocious murder.

"The murdered woman had been living for nearly two years with a colored man named Charles Ford. They had occupied three rooms in the little brick building in the rear of 1435 12th Street since they became acquainted. Their lives since then have, it is said, been an almost continual round of quarrels and some of the people resident in the

neighborhood say that the white woman and colored man led an existence full of bitterness and struggle.

"Little of the immediate events which led to the terrible deed of yesterday are known. The most that can be gleaned of the woman's movements is that she was alive about 10 o'clock yesterday morning, when she was seen by Mrs. Kleufer, who lives near by. At that hour she went to the fence of Mrs. Kleufer's home and piteously asked Mrs. K. for a nickel. She did not give any reason for the request but Mrs. Kleufer honored it, thinking it was for some necessity. The dead woman had a cut over her right eye which Mrs. Kleufer noticed as she handed her the coin. Beyond this, she says, she noticed nothing unusual about Mrs. Smith. Another neighbor said that Mrs. Smith passed along the alley way shortly after 10 o'clock with a can in her hand as if she was on an errand for beer. This woman avers that Mrs. Smith said "her old man had beaten her again," but further than this observation she did not pass any comment.

"Subsequent to this, nothing appears to be known of the woman until her dead body was found by Ford and some of his friends at 1:45 o'clock. When found she was lying on the bed clothes in a clean undershirt, and with every indication that the body had been very recently subjected to a washing process. Ford did not betray any unusual excitement when confronted with the spectacle, and was loth to express any opinion.

"On every side in the illy furnished house was evidence of a deliberate and consistent attempt to obliterate all traces of the killing. The floor had been scrubbed, the walls here and there wiped down and the bed rearranged.

"The condition of the body when discovered presented a revolting picture. The back of the skull was beaten in until a large hollow was formed, which was filled with blood and hair. A contused wound was over the right eye, while the face was one discolored piece of flabby flesh. The woman's clothes had been removed and an undershirt of cotton texture had been placed on the body. An examination of the lower portion of the body disclosed deep scars upon both thighs. They were of such character as would be inflicted with some blunt instrument.

"The murder was probably committed in the third room, or that which Ford says he occupied. The floor of this room was covered with blood. Near the bed a large pool, about a foot in diameter, had formed. In this pool portions of the woman's hair remained. Between this room and where the woman was found is the kitchen, which was also utilized as a sitting and dining room. Undoubtedly the body was carried from the scene of the murder through the kitchen to the room where it was discovered.

Ford's movements after 9 o'clock are not defined. At 4 o'clock in the morning he left the house, to work in Mike Harris' saloon at 15th and Wazee Streets. His story is that he went to the market to get some meat and returned to his house about 9 o'clock. He knocked for admission and called, "Sadie" several times, but could get no reply. He put his meat on top of the shanty and went away and came back between 11:30 and 12 o'clock and made inquiries for the woman. Not learning anything definite of her, he sought a colored friend named Abe Brown and together they went and broke in the door of the shack. His story is that when they broke in the door they found the woman in the condition she was in when found by the officers, to whom Ford went with the information of the murder.

"Ford's story does not tally exactly with those of reported witnesses to his movements. It is said that he was seen entering the house between 9:30 and 10 o'clock, and that about 10:45 o'clock he left with a bundle of clothes wrapped in a newspaper, outside of which was a coat wound around the whole. He was absent about half an hour and came back then without the bundle and with the coat thrown loosely over his right shoulder. After this his actions appear to be lost in darkness, as no one has been found who saw him later than 11:30 o'clock. When Ford was arrested he had on clothes which he had not worn for any length of time. His underclothing had been recently put on and to all questions concerning the location of the clothing he had worn early in the day, he maintained a stolid silence.

"From a study of the wounds, the murder was evidently committed with a flat iron weighing nearly two pounds. This instrument was found in Ford's room, besmeared with blood and with portions of the woman's hair clinging to it."

This, in detail, was the story as first told. Slowly a net of circumstantial evidence was wound around Ford until the presumption was very strong that he was the murderer. He persisted in his story, how-

ever, and denied that he had killed the woman. His old clothes, the ones which witnesses stated he had on in the morning when he went to work were found in a distant out-house. Here and there over the clothes were a number of red areas and stains which looked like blood. When questioned about it he said that it might be blood, that he had been hunting a few days before and that he had carried his game across his left shoulder. He was asked as to the nature of the game and he replied: "Oh, some rabbits, a few birds and a black snake." He stoutly denied that he had worn his old clothes within a recent date.

On his shoes, which he wore when arrested, there were a few spots of red staining. When asked about this he said it came from a nose bleed which he had had that morning soon after getting up. Later it was proved that he had had his shoes blackened at about 9 o'clock of the morning the murder was committed, yet the staining was clear and outside of the blacking.

In October, 1894, District Attorney Robert W. Steele had worked up a most astounding array of circumstantial facts which tightened about Ford very closely. Finding that Ford had engaged counsel and seemed to be ready to make a determined fight, he asked me to examine the blood stains on Ford's clothing and on his shoes and to determine, if possible, whether they were of human blood. The following articles were accordingly put by him into my possession, Oct. 22, 1894:

One coat labeled, "worn by Charles Ford in the early morning of Sept. 15, 1894."

Shirt, pants and vest, labeled, "worn by Charles Ford in the early morning of Sept. 15, 1894."

One sombrero, without label, but understood to be the hat which Ford had on when arrested.

One pair men's shoes, labeled, "worn by Charles Ford, Sept. 15, 1894."

With these articles were a great number of odds and ends such as buckets, brushes, pillow cases, flat irons, handkerchiefs and a whip stock—all blood stained and all appropriately labeled. After the examination of the coat as labeled above, I dictated the following: "coat old and ragged, a faded blue check. Nothing like a blood stain is found on inner facing or lining or on sleeve lining. There are a number of grease spots on the right side but nothing resembling a blood stain. On the left sleeve, on its outer side, from the elbow down there are a great number of small and large areas of red staining, which are prominent to the naked eye and which look as though they had been brushed over with a cloth." On applying the chemic test for blood, this gave me a brilliant reaction. Of this test I shall speak later. Of the vest, shirt and pants, the following notes were made: "The vest shows no blood, neither on inner nor on outer side. The shirt is a flannel one with no blood on it. A few stains found on inside of the wrist of the right sleeve prove to be not blood on chemical examination. The pants are badly worn, especially in the seat. They are patched in a number of places, are very dusty and are very much wrinkled as though recently washed. On the right leg of the pants, at the bottom on the outer side posteriorly are five areas of reddish staining, varying in size from one-fourth to one inch in diameter, which to the naked eye give but slight appearance of blood, but by chemic test give blood reaction. Other obscure stains on front

of this leg gave blood reaction to a slight extent. The left leg presents a number of areas, some very large, which present all appearances of blood stains and which when tested give the blood reaction."

"The sombrero, of a dull gray color, is old, worn and torn. On the crown are eight or ten small spots and one large one, all of which present appearances of blood and all of which give blood reaction to the chemic test. On the upper surface of the brim there is one streak of blood, one inch in length and one-quarter of an inch in width. This is a very prominent blood streak. The right shoe shows a thin brownish film over the outer side of the upper for a distance of two inches. This film is external to the blacking and can be scraped off without disturbing the blacking. On the instep of the sole of this shoe there is a small blood stain. On the left shoe, on the inner side of the upper, there is seen a small brownish film, external to the blacking."

My first examination was thus purely one of general appearance, plus the use of the chemic test. In my examination of the general appearance, I used a small magnifying glass constantly. The chemic test for blood, for any kind of blood, is a simple one but of great value because of its accuracy. It is called the guaiacum test for blood. When a red substance is thought to be blood, a bit of it can be moistened, if necessary, by distilled water and after it is gotten in solution, placed on a piece of white blotting paper. On the stain thus formed a drop of the tincture of guaiacum is added. This tincture should be fresh and made from the inner portion of the pearls of the gum. If the stain turns blue with no other treatment it is not blood, but if it contains blood it also contains starch, a salt of iron or some other foreign substance. If no change follows the application of the guaiacum, drop upon it a little watery solution of peroxid of hydrogen, when if it is blood, it will quickly assume a beautiful sapphire-blue color. By this test I have detected a particle of blood which was scarcely visible to the naked eye. It has a few fallacies which must be spoken of. Never must the guaiacum and peroxid of hydrogen be mixed before application. Always apply the tincture of guaiacum first and add the peroxid afterward. Any acid containing iron vitiates the guaiacum test. Some kinds of paper sized with alum contain iron and turn blue with guaiacum. Gluten and starch turns guaiacum blue without peroxid. If no blue color is produced by adding tincture of guaiacum and if then hydrogen dioxid is added and a blue color is produced quickly the substance examined is almost certainly blood.

In my examination of the stains in this case, I either scraped a small bit away and got it in solution, or I added to the stain a bit of water and later a drop of tincture of guaiacum, and later still a drop of hydrogen peroxid. Then by pressing white paper against it, paper free from alum and iron, I got the blue color from the stain, printed on the paper.

The chemic test told me positively that I had blood on the clothes examined. But I followed up this test by getting a quantity of the blood stain in solution and boiling it in a test tube. Heating caused a deposit of gray flocculi, a mixture of fibrin and albumin. This flocculi was readily dissolved by liquor potassæ, while chlorin, hydrochloric acid or nitric acid caused it to reappear. This is characteristic of a solution of blood.

Another property that my solution had was that a

small quantity of liquor ammonia did not change its color, but that heat did. There is no other red solution that will present such a characteristic beside blood.

Lastly, I obtained from the stain, the hæmin crystals. There are easily obtained by digesting for twenty-four hours the scraping of a stain in glacial acetic acid to which has been added a trace of chlorid of sodium. By allowing this red acid solution to evaporate slowly, a great number of crystals appear in the form of rhomboidal plates of a yellowish red or brown color. In a systematic examination of blood, my next one should have been a spectrum analysis of it, but I did not own a micro-spectroscope and as yet have not obtained one.

I proceeded next to the microscopic examination. My first consideration in this examination was how best to bring back the dry blood stains to a solution in which the corpuscles would regain their usual size. Many formulæ were found, for all of which it was asserted that the solution would not increase nor decrease the dimensions of dry blood corpuscles beyond their normal size. I made use of five fluids.

Robin's distilled water with chlorid of sodium, 1 per cent, and bichlorid of mercury one-half of 1 per cent.

Hayem: distilled water with sulphate of sodium, $2\frac{1}{2}$ per cent., pure salt $\frac{1}{2}$ per cent. and bichlorid of mercury $\frac{1}{4}$ per cent.

Richardson: a three-fourths of 1 per cent. chlorid of sodium solution.

Sherman: a 33 per cent. solution of caustic potash.

Glycerin and water mixed in such proportions as to give a specific gravity of 1028. After an extended trial of the various solutions, I discarded all but the last two. With these, I obtained corpuscles perfectly restored and presenting all the appearance of the fresh living cell. The caustic potash solution gave me quick results and fine corpuscles, but after a short time the field would have a multitude of small air bubbles through it, so that I could not study the fields as I wished. I do not know why these bubbles appeared. Prof. J. A. Sewall, in a medico-legal case in which he investigated some blood stains, found the same objection to its use.

The glycerin solution was slow in getting the stain in solution, but beautiful cells were found after a time. It kept some fields in excellent shape for several days. Usually I added some carbolic acid to the water with which I made my glycerin solution.

In making a cover-glass preparation for study, I took a bit of the blood stain from the clothes by gently scraping the stain with a tracing needle and receiving the dust stain upon a glass slide. I then placed a large cover-glass over it and introduced by capillary attraction the fluid destined to separate the corpuscles and restore them to their normal condition.

I first studied the restored corpuscles to get their general characteristics. I found that they were all circular, that all of the corpuscles which appeared fresh were bi-concave disks, that they had a fairly uniform size and a faint yellowish or brownish color. No nucleus was apparent in any cell and in size the corpuscles with a medium power, approached closely that of human blood.

After examining many different stains, I could positively say that not a single oval nor elliptical

corpuscle was present and that not a nucleated cell was to be found. I could now rule out from consideration that part of Ford's statement in which he asserted that these blood stains were stains from "some birds and a snake," as the red corpuscles of both birds and snakes are elliptical, generally large, with a nucleus; while those of man and all mammalia, except the camel tribe, are circular and small.

His statement that the stain might be rabbit's blood was the one that caused me to earn my fee. I had now to measure the corpuscles found in the stain and to compare this measurement with that of human blood. The diameter of the human red blood corpuscle is given by Gulliver, Wormley and Treadwell as 1-3200 of an inch, and that of the rabbit by Gulliver at 1-3607, by Wormley at 1-3653, by Treadwell at 1-3984 of an inch. Assuming that 1-3600 and 1-3700 of an inch is the ordinary range of the size of a rabbit's corpuscle, we would have between such a corpuscle and that of the human blood a difference of fully 1-450 of an inch. With a medium power such a difference could not be easily detected, but with a high power we could magnify the difference, as it were, and thus could easily detect it. This is the secret in the comparison of blood discs.

In the West we have a rabbit that is not common in the East. I refer to the long-eared jack-rabbit. I could find no measurement of its corpuscle. The defense might insist that the blood stain was that of a jack-rabbit, so it had to be considered.

For the sake of comparison, I proceeded next to make permanent mounts of blood. I made a mount of my own blood and in a similar manner made mounts of the blood of the cotton-tail and jack-rabbit. As my working time was short, I was not able to procure live rabbits but bought rabbits which had been killed a few hours previous and took the blood examined, from the cavities of the heart. My method of making these permanent mounts was as follows: films of the blood were spread on cover-glasses in the usual way, and placed while yet moist in a saturated watery solution of mercuric bichlorid for half an hour. At the end of this time the solution was washed away with a $\frac{2}{3}$ per cent. solution of sodium chlorid. The film was next hardened by immersion for a few minutes in methylated spirit and subsequently in absolute alcohol. Staining with eosine and hematoxylin was then performed in the usual manner. The nuclei of the leucocytes were stained by the logwood, while the red corpuscles were stained entire by the eosine. By this method I made some beautiful mounts which are as good to-day as they were when first made.

I had now gotten to the place where the measurement of the corpuscles of my permanent mounts and their comparison with the corpuscles found on the clothes was all that remained, provided that I could be sure that my permanent mounts lost nothing by the method employed, and that my solutions employed for restoring the blood stains did all that they were supposed to. The method of making my permanent mounts was first recommended by Dr. Muir in the *Journal of Anatomy* and he asserted that the corpuscles retained their exact shape and size. I measured a number of my corpuscles, both in a fresh state and in my permanent mount and they showed no variation, so I could eliminate the first doubt. As regards the second, I found that by taking a known blood stain, that with my solutions

I could restore the corpuscles in it to the exact size that they presented in a fresh state.

The next question was how best to present the matter of measurement of blood corpuscles to an ordinary jury. I decided upon the use of the camera lucida. I was largely guided in this matter by the following extract taken from Carpenter, "The Microscope and Its Revelations," Seventh Edition, page 226:

"It is of the utmost importance to be able with accuracy, and with as much simplicity as possible, to measure the objects or parts of objects that are visible to us through the microscope. The simplest mode of doing this is to project the magnified image of the object by any of the methods described under 'Camera Lucida and Drawing.' If we carefully trace an outline of the image, and then, without disturbing any of the arrangements, remove the object from the stage, and replace it with a 'stage micrometer,' which is simply a slip of thin glass ruled to any desired scale, such as tenths, hundredths, thousandths of an inch and upward. Trace now the projected image of this upon the same paper and the means are at once before us for making a comparison between the object and a known scale, both being magnified to the same extent. The amount of magnification in no way affects the problem. Thus if the drawn picture of a certain object exactly fills the interval between the drawing representing the .01 inch, the object measures the .01 inch, and whether we are employing a magnifying power of a hundred or a thousand diameters is not a factor that enters into our determination of the size of the object.

"In favor of this method of micro-measurement, it will be noted: 1, that no extra apparatus is required; 2, that it is extremely simple; and 3, that it is accurate."

I had at my command an Abbe's camera lucida and with a Fasoldt stage micrometer graduated in 1-5000 of an inch, I projected upon paper this scale, using my highest power.

The combination of power was as follows: Leitz's Ia stand, oil immersion objective 1-12, No. v eyepiece, draw tube at 160 m.m.

Having this scale carefully and accurately drawn and proved by several careful observers, it was an easy matter to make any number of such scales by simple measurement and the use of my drawing instruments. Each division of the scale represented 1-5000 of an inch as projected by my combination. By dividing each division up into fifths, I was able to measure 1-25000 of an inch, and not only do it accurately but easily, and demonstrate it to any one.

I now measured twenty corpuscles of the permanent mount of my own blood. The following shows these corpuscles in the scale:

In dividing up the scale and by a careful computation, I found the average diameter of these corpuscles to be 1-3175 of an inch, a little less than the measurement usually given.

Next I measured the cells found in the blood of the jack-rabbit. These cells proved to be very small

and, as far as I have been able to ascertain, have not been previously measured. Diagram No. 3 shows twenty of these corpuscles. A careful computation of the average size of one hundred of these corpuscles by the camera lucida method gave a diameter of 1-6250 of an inch.

My next step was the measurement of the blood cells found in the blood of the cotton-tail. Diagram No. 4 shows by comparison the size of these cells as compared with those of human blood and blood from the jack-rabbit.

On diagram No. 4, I demonstrate the method of measuring up to 1-70000 of an inch. I do this by simply dividing my 1-5000 scale up into fourteen parts. The corpuscle on this scale occupies eighteen of these parts. It is then 18-70000 of an inch in

be found in a scraping of a blood stain: bits of cloth-fiber, pieces of fibrin, masses of stain, granular *débris*, broken and twisted cells, bacteria, can be found and must be differentiated from the blood corpuscles. Unless one becomes very familiar with this subject, it is apt to be a perplexing study. Any round flat mass, though it may present irregularities is apt to be a blood disc. If it presents some straw or brown color and a marked different appearance on slight focusing, it is very probably a blood disc. If when the cover-glass is touched with a teasing needle it rolls over and you can get another view of it, you can often be absolutely sure that the mass is a bi-concave disc, a red blood corpuscle. Frequently you

No. 2— Human blood.

No. 3—Fresh jack rabbit's blood.

No. 4—Fresh cotton-tail's blood.

diameter or 1-3888 of an inch. This corresponds closely to the measurement given by Treadwell. This is but the measurement of one corpuscle. My permanent mount of cotton-tail's blood was not the success that my other mounts had been, as many of the corpuscles appeared to shrink by the treatment given them. Having now accurate diagrams of human blood and of rabbit's blood I was ready for the examination of the blood stains. These I prepared as has been detailed.

Diagram No. 5 shows the outline of the restored corpuscles as taken from the sleeve of Ford's coat. Twenty-five corpuscles are pictured of which eighteen correspond in size and measurement with human blood; seven are below this size.

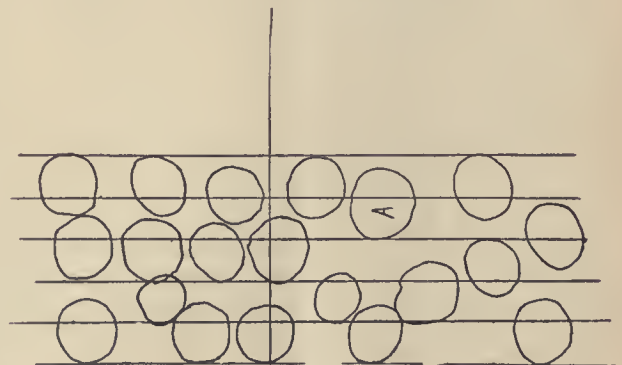

It is surprising what an array of odds and ends can

No. 5—From sleeve of coat.

No. 6—From trousers.

No. 7—From hat.

will find a cell that is just as clear as a fresh one can be. Such cells should be carefully drawn and designated. Cells A in the accompanying diagrams are such cells.

Diagram No. 6 shows the blood cells from the stains on the leg of Ford's trousers. For some reason these cells were the most perfect ones I found. Any tyro could tell that they were bi-concave discs and any one could have drawn their outline as easily as I did. There is hardly a cell shown that has not the outline of a human red blood disc.

Diagrams Nos. 7, 8 and 9 show the corpuscles found in the stains of the hat, shoe and whipstock, with which he was supposed to have killed the woman.

As can be seen, most of them are of the diameter of the human red blood corpuscles, and but few approach in size those of the rabbit.

Having my exhibit thus arranged, I reported to the district attorney that the stains found on the clothes were blood stains; that the corpuscles found in those stains were not from the blood of a fish, reptile or bird; that they belonged to the blood of one of the class mammalia and corresponded very closely with those of human blood, and that they did not belong to the blood of the rabbit—neither the cottontail nor the jack.

I was summoned to appear before the court two days later. I intended demonstrating my method of work to the jury and showing them in detail how my results were obtained. When ready to visit the court I received word that my services would not be necessary, as Ford had pleaded guilty and that he had been sentenced by the judge to the penitentiary for life.

Thus my results received quick proof of their accuracy and reliability. By the simplest method known to the microscopist for the measurement of objects, I had settled a knotty problem, and had brought into a case of circumstantial evidence some positive evidence, which the prosecution needed.

No. 8.—Blood from shoe.

No. 9.—Blood from whipstock.

The method of micro-measurement by the camera lucida has certainly much to commend it in such cases as the one presented. It brings to the jury's eye your own observations, and it throws on them some of the responsibility which by other methods you must share alone.

It puts on paper for subsequent reference more than simple figures. This makes its value in work of this kind very pronounced. In the case just presented, the diagrams of comparison speak stronger than any array of figures. It can be used with accuracy by those who have had no previous experience in work of this kind, and by those who have not and can not obtain the expensive screw micrometer eyepiece.

The method and apparatus is simple and the calculation of the size of objects is easy. To get the diameter of a corpuscle in any direction, one has only to reverse the paper bearing the reading scale. This scale can be either in millimeters or in inches—according to the stage micrometer in use.

With it, one does not have to designate whether his measurement was taken from the outside or inside of the dark border of the corpuscle. A faint light is used, a flat image is thrown in every case and the corpuscle is drawn without shadowy borders.

The method employed in this case is certainly one to be commended in these examinations.

THE TREATMENT OF SMALLPOX PRINCIPALLY BY MEANS OF THE INTERNAL USE OF THE TINCTURE OF THE CHLORID OF IRON.

BY BEDFORD BROWN, M.D.

ALEXANDRIA, VA.

My personal experience in the observation and treatment of variola comprises about one hundred and fifty cases. About sixty of these were seen in the Confederate Army during the late war. The remainder were seen in an epidemic soon after the close of the war, and in an epidemic in this city about the year 1871. Of these cases, at least one-third were of the confluent form. The remainder were of the discrete type. Only about one-fourth of these cases had been vaccinated. In all those vaccinated the type was mild, what is known as varioloid.

In the year 1863, smallpox appeared in the Confederate Army in the department of North Carolina, extending from Petersburg, Va., to Wilmington, N. C., and threatened to assume dangerous proportions, as an epidemic. As medical director of the department at that time, I received from the General commanding, G. W. Smith, plenary powers to apply every means possible for its extinction. A universal system of vaccination was inaugurated throughout the department and re-vaccination in every soldier, when the epidemic was promptly arrested. This much can be said as evidence in behalf of the efficiency of vaccination as a prophylaxis of smallpox.

Of the ninety cases seen after the close of the war one was pregnant, a married woman with three children, all of whom had the disease. This woman was at about the eighth month of pregnancy when attacked and miscarried of a dead fetus when the secondary fever began. The fetus had incipient variolous eruptions on its body. The mother passed through the most severe case of confluent smallpox that I ever saw and finally recovered. She and her three children had never been vaccinated but all recovered. In the case of the mother, for the first three or four days after confinement there was a distinct effort on the part of the breasts at the secretion of milk, but it was soon suppressed. On the contrary, the lochial discharge continued for a period of two weeks in a normal condition.

Influence of Season on the Type of Smallpox.—I have seen cases of smallpox in all seasons of the year. In the dead of winter when the earth was covered with snow, and the temperature below zero, and again in the soft season of spring, in the torrid heat of July and in autumn and winter. I am really not aware that the type is affected in any way by these influences. I have seen confluent cases in the intense cold of January, and in July when the temperature was 96 degrees, pass through the stages safely. I have attended smallpox in both country and city practice, and I am constrained to believe that in the aggregate the type of smallpox in the unvaccinated

among country residents is milder than in city denizens. That is, there is a decidedly greater proportion of discrete cases among the former than the latter.

In the epidemic alluded to, which occurred in the spring just after the close of the war, in a southern village of some twelve hundred population, smallpox appeared in May; was contracted by the negro population just then liberated and the infection was spread throughout the surrounding country. There were hundreds of cases of the disease among this population, and probably not one in a hundred had ever been vaccinated. Yet not one-third of the cases were confluent, and a fatal termination was a rare occurrence.

This fact would indicate that the type of smallpox is favorably modified by pure fresh country air, free from overcrowding and the septic influences of a city atmosphere.

Inoculation with Smallpox Virus.—During this epidemic there were eight or ten persons who had been exposed to the infection of smallpox, accidentally, several days before they discovered their danger. Neither of these persons had been vaccinated and at that time it was too late for vaccination to afford them protection against infection. As they were very solicitous to be saved from an attack of smallpox, I determined to inoculate them with genuine smallpox virus taken direct from the pustule. They all assembled at the house of the smallpox cases and were inoculated directly from the pustules. They all did remarkably well. Every case proved to be a mild type of the discrete form.

Treatment.—The mild discrete form of smallpox needs but little treatment except cleanliness and careful nursing. An occasional aperient, soap and water to the inflamed skin and proper diet.

On the contrary, the confluent and more malignant forms of the disease, in my experience require active and energetic treatment from an early period, and the treatment in this form may be divided into the local and general, the antiseptic and sustaining. The pathologic condition of the system in the confluent variety would appear to be very analogous to that in which there is an enormous internal abscess filled with infectious matter which is constantly being absorbed into the circulation, causing genuine septicemia or pyemia.

When pus begins to form in the pustules of confluent smallpox, the secondary fever begins and not before. While the pustule contains pus, the primary fever which produces the pustules, or rather accompanies its development, when the pustule is fully developed suddenly subsides, and then ensues a period of apyrexia or rest. But when pus begins to collect, the whole phase of the case is promptly changed, and there are developed symptoms in rapid succession of septicemia or pyemia. This secondary fever must be accepted as a measure of the extent of blood poisoning.

The entire surface in confluent smallpox is denuded of its cuticle and is surrounded with a layer of poisonous pus, is literally bathed in pus for days, from which there is constant absorption of poisonous material.

From my earliest acquaintance with this disease, I was impressed with the fact that to counteract this condition of blood-poisoning, there were two classes of remedial agents necessary; the one sustaining, the other antiseptic.

General Treatment.—I do not know any better general remedy to counteract the effects of septicemia or pyemia than the old-fashioned tincture of the chlorid of iron. I so regarded it more than thirty years ago, when I witnessed the first cases of this disease, and then resorted to it freely. I published soon after the war, my experience with it in an article in the *American Journal of Medical Sciences*, and I have used the remedy in every case of confluent smallpox since, with the best results.

I begin the remedy in every case of the confluent form, from an early stage of the disease, previous to the appearance of the septicemic or secondary fever, and maintain it to the end. Twenty drops of the agent in a little water and glycerin is given every three hours. In addition to this, about 10 grains of quinin are given a day. In all bad cases, I give stimulants in the form of milk punch or egg-nog, and nourishing broths.

Local or Antiseptic Treatment.—My experience with antiseptic treatment convinces me that its value can not be overestimated. This can only be applied locally to the diseased surface.

In my first cases, I used chlorin water, the liq. chlori., diluted with water. The entire surface was bathed every three or four hours. The effect of this antiseptic bath administered at short intervals was excellent. Every pustule on the face should be split open with two incisions, crossing each other, with a delicate knife, the pus gently pressed out and the cavities subjected to an antiseptic, by bathing with either the liq. chlori., or a solution of permanganate of potash, two grains to the ounce.

This local antiseptic treatment will go far to prevent pitting. The case of the woman who aborted with confluent smallpox, alluded to above, was subjected to this chlorin treatment and she escaped without a pit. In addition to the chlorin and permanganate treatment, I should be tempted, now, in cases of this kind, as a further antiseptic measure, to resort to an ointment composed of ichthyol, aristol and euophen, to be applied over the entire surface after bathing with chlorin water. The mortality under this practice has been exceedingly small, not more than 3 per cent.

Believing as I do, that all the indications point to the secondary stage of smallpox as the period of danger, and that the danger of that stage lies in the presence of an enormous quantity of infectious pus being constantly absorbed, and acting on the blood of the patient as an infectious poison, I have, acting on this principle always treated smallpox as I would any other case of septicemia or pyemia arising from infectious causes, and the results have been satisfactory. The pustules on the skin constitute the local lesion which furnishes the septic poison, and while we sustain the vital powers of the general system, we must at the same time, be busily at work in disinfecting the local lesions, the source of the poison.

SERUM-THERAPY—STATISTICS UPON THE USE OF THE DIPHTHERIA ANTITOXIN.

BY G. C. CRANDALL, B.S., M.D.

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE, MARION-SIMS COLLEGE OF MEDICINE, ST. LOUIS, MO.

In following the abundant literature which has appeared during the past year upon serum-therapy, we find that the interest of the profession has been

gradually aroused, and with the many investigators in the field we may trust that the question will be fairly examined with every means and method at our command.

Before the discovery of the germ causation of disease, it was known that an attack of certain diseases effected a longer or shorter natural immunity against those diseases; and in more recent times since the germs of certain diseases have been isolated and cultivated, those best acquainted with theoretical and practical bacteriology have entertained favorable views concerning the possibility of artificially producing immunity against the diseases caused by certain germs.

In some diseases immunity can be established by the use of a modified, less virulent form of the germ, but this is not sufficient; more desirable is an immunity and therapeutic action which can be effected without the introduction into the human system of even the modified germ. For these purposes various investigators are experimenting with the so-called toxins, antitoxins and nucleins.

The present knowledge of physiologic chemistry is inadequate to fully explain the physiologic origin and action of these new elements, but it suggests the way, and many are now diligently searching for such anti-disease remedies, which may prove to be more worthy the name of specifics than any so-called drugs of the pharmacopœia.

The first of these remedies which has gained at least a temporary recognition by the profession, is Behring's diphtheria antitoxin. Having recently had access to the Library of the Royal College of Surgeons of England, I gathered as fully as possible, statistics upon the use of the anti-diphtheritic serum.

The following table includes most of the serum treated cases which have been reported. The results of some of the most extensive observations are given separately:

		No. Cases treated with serum.	Mortality in per cent.	Previous Mortality in per cent.
Vierordt	Heidelberg	55	14.6	58.0
Ganghofner	Prague	110	12.7	50.0
Wiederhofer	Vienna	100	25.3	42.8
Kossel	Berlin	350	16.7	84.7
Baginsky (quoted by Virchow)	Berlin	303	13.2	47.8
Sonnenburg	Berlin	107	20.6	27.6
Aronson	Berlin	190	14.0	37.0
Ranke	Munich	85	18.8	48.5
Saltmann	Lelpsic	122	18.0	
Risel	Halle	114	8.0	
Roux, Martin and Chailion	Paris	300	26.0	51.7
Lehreton	Paris	253	12.0	
Molzard	Paris	231	14.7	50.0
Washhourn, Goodall, Card and others	London	195	18.6	31.1
White	New York	32	25.0	42.7
Withington	Boston	80	16.0	45.0
Total number of cases		2,632		
Average mortality per cent.			16.8	
Previous average mortality per cent.				42.0
Collective report of other observers in different countries		4,022	17.1	

The above table shows a much lower mortality than has ever been generally attainable under former methods of treatment. Those who have used the remedy most extensively, report that the incidental action of the serum seems to be due to avoidable impurities and to the idiosyncrasy of the patient; also that paralysis, albuminuria, lung complications and necessities for operative procedures occur less frequently than under previous methods.

The relatively inexact method of determining the strength of the serum has been a barrier in the way

of exact dosage. If the chemist can separate the antitoxin element in a stable form, the dosage may be made more accurate, the administration simplified, and incidental action may be less frequently observed.

With the experience of the past year as a guide, the investigators hope to be able to show greater evidences of the value of serum-therapy. At the Pasteur Institute in Paris, experiments analogous to those with diphtheria, are being made with the virulent streptococci which cause certain severe, acute, inflammatory, suppurative conditions. A horse has been rendered immune against virulent cultures of the streptococci, and its serum is being used with suitable patients.

Dr. Paquin of St. Louis, is meeting with favorable results in his systematic experiments with tubercular antitoxin, and we shall anxiously await further reports upon his work.

Whatever may be our prejudices for or against serum-therapy, we should assist or at least encourage the investigators, and patiently await the development of such facts as will prove the question at issue.

PROFESSOR SENN'S NOVEL PLASTIC REPAIR OF CONTRACTURE.

BY MAJOR A. C. GIRARD, SURGEON U. S. ARMY. FT. SHERIDAN, ILL.

The following ingenious method devised by Professor Senn in his clinic at Rush Medical College, to replace scar tissue by sound skin, is well worthy of general notice. Without going into the history of operations tending to repair defects I will at once proceed to a description of the case:

Contractured fingers.

A child about 3 years old had been burned in the left hand some four months before, to such a degree that the cicatrization bound down and flexed the thumb and little finger in an absolutely useless and immovable position. The little finger was liberated by excision of the tendinous bands with comparative facility. To do the same with the thumb would leave a large raw surface. A flap from the anterior chest wall with fixation of the arm, was not feasible, owing to the tender age and consequent lack of co-operation of the child. A flap from the forearm twisted and turned into the palm of the hand, would probably become necrotic and leave matters in a worse shape. Skin grafting would not prevent contracture, and skin transplantation could not be thought of, on account of the lessened vitality of the tissues adjoining the defect.

After much deliberation, Professor Senn determined on a novel method by dissecting off a flap from the dorsum of the hand, adjoining the thumb, leaving both ends of the flap attached, and slipping it over the thumb into the place vacated by the excised scar.

A.—Volar side with flap in place. Dorsal side with outlines of flap.
B.—Grafted triangle.

An incision was started from the base of the first finger, carried obliquely upward to near the base of the metacarpal of the thumb; the second incision was parallel to this, about one inch toward the middle finger. The flap was carefully dissected off, preserving the subcutaneous veins. The doubt as to the possibility of slipping it over the bent thumb was soon removed by the ease with which it was made to assume its new place, where it was anchored by two rows of interrupted sutures. A small triangular defect between the flap and the base of the little finger was filled by Thiersch's grafts. The dorsal wound was easily united by interrupted sutures and the usual splint and dressings applied.

At the clinic, a week later, the child was exhibited; the flap had united *per primam*, the grafts adhered, the dorsal wound was closed and the thumb in its proper place. The prospect of permanent cure of the contracture was assured.

ENEMATA OF WHITES OF EGGS. MEMORANDUM.

BY JOHN ASHBURTON CUTTER, M.D.

NEW YORK.

Albumen of eggs is valuable to feed patients when other forms of nourishment can not be taken or to reinforce other nourishment. I have known patients to take the whites of eighteen eggs in one day with evident advantage, in some cases the result appearing almost life-saving.

Exhibition by the mouth is made in three ways: 1, raw; 2, raw with milk; 3, dropped in boiling water and slightly cooked.

Enemata of uncooked whites I have lately used with decided benefit. Administration by a Davidson hard rubber syringe No. 494, one ounce. Eggs vary in size and weight and should be sold by weight; the albumen of an egg varies in bulk from one-half to one ounce as eggs run.

Drugs can be administered with the raw albumen; sometimes a little laudanum is needed, but rarely, to quiet bowel. Patients state that an enema relieves the faint gone feeling in stomach, and such relief is longer than when the whites are administered by the stomach.

Equitable Building, New York.

PERITONEAL SUPPORTS—(LIGAMENTUM PERITONEI).

BY BYRON POSTINSON.

PROFESSOR OF GYNECOLOGY POST-GRADUATE SCHOOL,
CHICAGO.

(Continued from page 110.)

The splenic artery perhaps throws more light on the disposition of the mesogaster than do the gastric and hepatic arteries. The splenic artery arises from the celiac axis and passes at first, slightly downward and then toward the left along the upper border of the pancreas. It is a large spiral artery, but does not project the peritoneum into a very prominent fold, yet the outline of the fold is especially prominent in those animals in which the omentum and transverse colon do not have contact relations, especially at the left end. The prominent feature of the splenic artery in regard to the mesogaster is that the artery in its course lies to the left of the right blade of the mesogaster until it suddenly turns upward to gain access

Fig. 22 is copied from the excellent anatomy of Prof. Gegenbaur (1884 German edition). It is chiefly to represent the views of an eminent comparative anatomist as regards the transverse colon and omentum. It may be observed that his idea is that of coalescence, for his mesocolon transversum consists of four layers (No. 3). 1, gastro-hepatic omentum; 5, lesser omental cavity; *p*, pancreas; 8, mesocolon transversum; 4, mesenterium; *d*, duodenum; *c*, colon; 2, anterior layers of great omentum; *r*, rectum; 6, great omental cavity; 7, reflections of coronary ligament; *j*, intestine. However, Gegenbaur mentions in his text-book the displacement theory without committing himself to it.

to the space between the blades of the ligamentum gastro-lienalis, but the other equally important feature is that the splenic artery for all its straight horizontal course lies against the posterior abdominal wall, *i. e.*, it does not lie against the left blade of the mesogaster, for that blade has by developmental processes been re-adjusted, displaced, or as some would argue, coalesced. In the process by which the liver forced the stomach to the left and downward and gave origin to the elongated mesogaster and lesser omental bag, the left blade of the mesogaster has been displaced to the left, hence the left and posterior surface of the splenic artery is without a serous cavity for the most of its trunk, or until it turns upward into the gastro-splenic ligament. The splenic artery being devoid of its serous covering for the length of the chief trunk, on the left side reveals

a developmental process in the original process of formation of the mesogastrium posticum or great omentum. This bearing of the splenic artery gives an actual demonstration that the left blade of the mesogaster is displaced to the left by some force. In fact, the left blade is displaced several inches or more to the left of its original insertion.

The process of re-adjustment, displacement (or even coalescence) is in accord with the previous assertion that serous cavities and their walls are nowhere primary, but always a secondary process which

Fig. 25 (after Luschka, 1863) is a beautiful and accurate transverse cut at the level of the twelfth dorsal vertebra. This figure corresponds more exactly with my own dissections as regards the splenic relations of the peritoneum than any known to me. 1, liver; 2, stomach; 3, spleen; 4, kidney; 5, adrenal; 6, diaphragm; 7, thoracic aorta; 8, inferior vena cava; 9, cavity of the lesser omentum. Observe that there are two points where the spleen is uncovered by peritoneum, i.e., a strip at its hilus and a strip at its posterior border, e.g., near the adrenal at No. 5. This elegant and natural cut was also adopted by Dr. Bochdaleck, Jr., in 1867, as a natural model.

is very active up to the sixth fetal month. Now, as the developmental process is the only key to the adult condition, we can only expect to understand the origin and formation of the great omentum by sticking close to the evolutionary processes in ani-

Fig. 26 (after Toldt, 1879) is introduced to show the shape of the epithellum which covers the surfaces of the mesentery. It is taken from the surface of the great omentum of a six weeks old child. It is magnified by Hartnack's system, xi ocul. 8.

mals. Man's embryo passes through all lower mammalian stages, but the transitions are so rapid and complicated that it is almost impossible with limited material to establish consecutive and logical facts in regard to such a delicate structure as the great omentum. However, in animals we find the evolutionary stages permanent in some animals, not reached in others and in still a few stages just approaching that

of man. So that the thread of development can be demonstrated by investigations in embryologic and mammalian life, far below man in structure.

In one series of fifty autopsies, I recorded the position of the omentum in regard to the cecum and found the omentum covered the cecum in about eight cases. This is significant, as the omentum is a highly important organ in an inflammatory peritonitic district like the appendicular. The omentum when it lies out of its normal position is apt to be rolled up behind the transverse colon. This, I think, is due to the emptying and filling of the colon with gas and feces. It may also be due to an occasional sudden filling and emptying of the small intestine with gas

Fig. 27 (after Toldt, 1879) represents the three layers which compose a mesentery: *mp*, membrana propria mesenterii, i.e., the real neurovascular visceral pedicle; *ss*, subserosa; *pp*, peritoneal layers of epithellum. It is drawn from a cross section of the middle portion of the mesentery of a four year old boy. Enlarged seventeen times.

by acute indigestion, from disproportionate secretions and consequent fermentation. In some autopsies it was evident that the great omentum had been rolled up behind the transverse colon for some time, for it was fastened there by peritonitic bands. Also it seemed to become rolled up behind the colon by a slow gradual process. It is not a suddenly acquired position. The omentum was found rolled up over the colon some six to eight times in one hundred cases. The chief rolling is accomplished near the flexura coli lienalis, but in one case in a series of fifty autop-

Fig. 28. I present cut to illustrate a cross section of the peritoneal cavity at a level of Winslow's foramen. *Pp*, parietal peritoneum; *vp*, visceral peritoneum, stomach; *R*, round ligament of the liver; *Lo*, lesser omentum; *P*, pancreas; *V*, vena cava; *A*, aorta; *K*, kidney; *F of W*, foramen of Winslow (the arrow points to lesser cavity of omentum). By this figure it will be noted that the spleen is uncovered in two strips, viz.: hilus and strip on posterior border.

sies, I noticed that it was definitely rolled up over the flexura coli hepatis; however, old peritonitis existed in this case. No doubt the position of the omentum is due to peculiar contractions and dilatations of the bowel, due to gases and feces and also to local peritonitis. In the case of the cecum, whenever very severe inflammations had existed in that region, the omentum was fastened there, but I noted with care that as a rule the omentum did not cover the cecum, but was no doubt displaced from the cecum by its

frequent contraction and distension by gases. It was common to find the lower edge of the omentum in all positions between the floor of the pelvis and the transverse colon, but generally ascending or shortening mainly along the left side. The contraction and distension by gas of a long large sigmoid no doubt aids in forcing the omentum upward. It does not appear from autopsies that repeated pregnancies induce the great omentum to enlarge and roll up.

Fig. 29 (after Abey, 1871) represents a sagittal longitudinal section of the body of a new-born near its middle line. It is one-half natural size, and shows the left cut surface. *a*, lung; *c*, heart; *b*, thymus gland; *a1*, lower lobe of right lung; *d*, liver; *b*, inferior vena cava; *g*, lesser omental cavity; *f*, pancreas; *e*, upper and *e1* lower cross section of duodenum; *g*, small intestine; *h*, colon transversum. Observe how its liver and vena cava divide folds of peritoneum. The peritoneal line is white.

Fig. 30 (after Abey, 1871) is another fine cut from the excellent Swiss anatomist. It is a longitudinal section of a new-born, showing the right cut surface, one-half natural size. *a*, upper and *a1* lower lobe of left lung; *b*, heart; *c*, stomach; *d*, liver, with ligamentum phrenico-hepaticum; *e*, adrenal; *f*, pancreas; *g*, kidney; *h*, colon transversum; *i-s*, iliac and bursa omentalis and ilium. Notice Abey accepts the coalescence view of the union of the omentum and transverse mesocolon by the representation of four layers of peritoneum between the colon and dorsal wall.

Neither is it always connected with local inflammation. Yet it is often associated with local peritonitis. No doubt the chief causes which induce the

Fig. 31 (after Sappey, 1880) is a cut excellent for its simplicity. It is quite diagrammatic. It shows a vertical section of the serous cavity of the abdomen. 1, parietal peritoneum just before it passes over the bladder; 2, visceral peritoneum covering bladder; 3, recto-vesicle fossa (excavatio recto vesicellae or Douglass' pouch); 4, envelope of the rectum; 5, the beginning of the meso-sigmoido mesenterium; 6, mesenterium surrounding the small intestine; 7, superior blade of mesentery; 8, continuation (into omentum) of superior blade of mesocolon; 9, anterior abdominal parietal peritoneum; 10, peritoneum covering diaphragm; 12, peritoneum covering under surface of liver; 13, peritoneum covering posterior under surface of liver and forming superior lining of lesser omental cavity; 15, gastro-hepatic omentum; 16, superior blade of lesser omentum covering posterior surface of stomach; 17, union of anterior and posterior blades which inclose the stomach (gastro-colic omentum); 18, great omentum (anterior and posterior blades or descending and ascending folds); 19, mesocolon transversum; 20, pancreas; 21, a continuation upward over the pancreas of the superior blade of the transverse mesocolon.

Fig. 32 (after Cruveilhier). This cut represents the method of coalescence of the superior blade of the mesocolon transversum with the posterior (under) ascending blade of the ascending fold of the great omentum. The figure is to illustrate how the cavity 2 (recessus peritonei) becomes obliterated by coalescence, i.e., the two layers of the peritoneum forming the pocket (2) unite their surfaces as far as indicated by the figures 4, 4. The three layers of peritoneum above the inferior blade of the mesocolon transversum coalesce, by loss of endothelium, to one blade, making the superior blade of the mesocolon transversum. This theory of coalescence is approved throughout in the labors of this work. The view 1 holds is that the membrane of peritoneal layers forming the cavity (2) marked 2 is gradually displaced or dragged out, which would leave the dotted line which ascends over the pancreas as the superior blade of the mesocolon transversum. 1, stomach; 3, colon transversum; 5, intestine; 2, the recessus peritonei, peritoneal pocket; 4, indicates the point to which the two peritoneal blades coalesce. The dog or cat are good examples to observe the displacement or readjustment of the peritoneum. The white lines found along the meso-sigmoid and descending colon are evidences, I think, of displacement of the serous layers, and not of coalescence.

great omentum to ascend and roll up are: (a), distension and contraction of the bowels by gas or feces; (b), local peritonitis. The bowels essentially concerned in displacing the omentum appear to me from autopsies to be (a), transverse colon; (b), cecum; (c), sigmoid flexure; (d), small bowels; and (e), a few cases of peculiar bladder distension. So far as I can see, the chief use of the great omentum is to prevent the invasion of infection, and hence the main effect of its displacement will be to allow inflammation to cause adhesions in localities where its presence would have prevented it. However, the use of the omentum will be discussed in the department of physiology. It does not appear that bodily position particularly induces the displacement of the great omentum, for in dogs whose bodily position is quite different from that of man, I never once found the omentum rolled up toward the diaphragm. But a dog has no real transverse colon, cecum or sigmoid flexure as man has. A displaced great omentum is one abnormally fixed, whether it be by peritonic adhesions or peritoneal fossa due to loops.

The normal position of the great omentum is outlined by the left border of the esophagus, greater curvature of the stomach, a portion of the duodenum, and occasionally the outline passes down the ascend-

Fig. 33 (Gray, 1877) represents the shape and outline of the lesser omental cavity (bursa omentalis). It is diagrammatic. The lesser omental cavity I have divided into two cavities, greater and smaller. Winslow's foramen leads into the smaller right cavity, which contains Spiegel's lobe of the liver (a viscus). Huschke's foramen leads into the great cavity which lies behind the stomach and contains no viscus. I named this foramen after Huschke because he was the first, so far as I am aware, to describe it, and I also consider Huschke's description of the peritoneum in 1844 as the first and most scientific description of the peritoneum. Either or both Winslow's and Huschke's foramen may become closed by inflammation.

ing colon for a variable distance (in some fetuses it extended to the cecum). This constitutes the upper outline of the insertion of the great omentum as seen on opening the abdomen. The lower outline will be the lateral walls of the abdomen, the floor of the two iliac fossa and the pelvic floor. With a large, fat, thick and stiff omentum the above outline may be followed mathematically. The outline of the insertion of the great omentum as regards the colon is from the ligamentum-phrenico-colicum on the left costal wall along the transverse colon to the flexura hepatis, and frequently the omental insertion extends a variable distance down the ascending colon. This part of the great omentum (right lower border) is known as omentum colicum Halleri. This outline can be traced by lifting up the great omentum and following the base line of insertion along the colon transversum. In fetal life, childhood and in some

early adolescent life, one can separate the layers of the great omentum. The same view holds in dogs.

Perhaps one of the best methods to make the outline of the insertion of the great omentum clearly visible is to force air through Winslow's foramen, but in such cases it must not be forgotten that old peritonitis may have constricted off considerable of the lesser omental sac, thus disturbing the original anatomic line of insertion.

Now as regards the names which should be applied to the different parts of the great omentum or mesogaster posterior; they should be natural and indicate their office and location. I shall attempt to describe parts of the mesogaster under such appropriate names. It is absolutely necessary to have names for parts and localities of such a long, pendulous, wide fold as the mesogaster or great omentum. In order to follow a simple plan with simple names, we will begin at the left border of the esophagus and follow the great omentum to the right lower border of the omentum colicum Halleri. The first part which we will name is the ligamentum phrenico-esophageus, a thick dense fold of peritoneum reaching from the diaphragm to the left border of the esophagus and as far down as the cardiac end of the

Fig. 34 (Gray, 1887) is to represent the greater cavity of the peritoneum; quite diagrammatic.

stomach. Some of the fibers of this peritoneal duplication pass from the diaphragm to the upper cardiac end of the stomach. This band consists of two fine epithelial or serous layers indorsing a white connective tissue collection which appropriately may be compared to the mesenterii membrana propria. Its milk-white color is due to accumulations of connective tissue. The ligamentum phrenico-esophageus is entirely analogous to what I have termed the pars tendinous ligamentum gastro-hepaticum. The ligamentum phrenico-esophagus is a triangular fold of peritoneum containing considerable white fibrous tissue between its layers. It gives much substantial support to the stomach and esophagus. It generally reaches to the cardiac end of the stomach. It is the most dense part of the whole great omentum. Some authors have named this band ligamentum gastro-phrenicum, but I prefer the name above given. The ligamentum gastro-esophageus is not inclined to fat any more frequently than the pars tendineus of the ligamentum gastro-hepaticum.

The next portion of the great omentum is a double-

bladed band of peritoneum which extends from the greater curvature of the stomach to the hiatus of the spleen, and then intimately surrounds the spleen, blending with its capsule. The band is known as the ligamentum gastro-lienalis or gastro-splenic ligament. The peculiarity of the splenic ligament is that the part passing to the body of the spleen is intimately and closely blended with the organ. In fact, the peritoneum and splenic capsule coalesce. The ligamentum gastro-lienalis has the vasa brevia lying between its blades and a short part of the distal part of the arte-

Fig. 35 (after A. Thomson, 1882) represents a sagittal longitudinal section of the peritoneal cavity. It is an excellent figure. The author of the cut adopted the theory of peritoneal coalescence, as may be noted in the four layers of the mesocolon transversum in the drawing. The section is intended to be in the median line of the body. *lc*, is placed above the diaphragm opposite to the coronary ligament of the liver; *l*, liver; *l1*, Spiegel's lobe projecting into the right end of the lesser omental cavity; *s*, stomach; *c*, transverse colon peculiarly drawn to suit the theory of coalescence; *i*, small intestine; *pa*, pancreas covered by serous epithelium only in front; *a*, aorta; *d*, duodenum covered by serous epithelium only in front; *u*, urinary bladder covered only its upper part by serous epithelium, but surrounded by a bed of sub-peritoneal tissue; *u*, uterus; *r*, rectum; *r1*, its lower part, with a portion of its lateral wall cut away; *v a*, vagina; *pp*, the parietal peritoneum lining the abdominal wall. The line representing the reflections of the greater sac of the peritoneum can be traced from the coronary ligament at *lc*, where it passes from the diaphragm to the upper surface of the liver, over the upper and under surfaces of that organ to the gastro-hepatic omentum, *gh*; it continues on to the front of the stomach down to *o1*, which is the anterior or descending double-bladed layer of the great omentum; thence it reflects on itself and passes to the vicinity of the pancreas, *pa*, whence by displacement or being drawn out the colon transversum (*c*) becomes located between its blades (not by coalescence as indicated in the drawing). The lower blade of the mesocolon transversum, *m c*, now proceeds to the root of the mesenterium, *m*, where it envelops the small intestines, producing the mesenterium and curves at the root, again making the left (under) blade of the mesentery. The membrane thence passes over the rectum, *r*, descends into the pelvis and covers a small portion of the posterior wall of the vagina, *v a*, the whole of the posterior surface of the uterus, *u*, and the anterior surface of the uterus, *u*, as far down as its internal os, whence the membrane passes over the bladder, covering only the dome of the organ, thence to the anterior abdominal wall, *p*, to the ligamentum coronarium hepatis to the point of beginning. The figure in cut just to the right of the median line, therefore shows the foramen of Winslow, *W*, as an aperture. The lesser omental cavity is shaded dark and shows Spiegel's lobe, *l1*, projecting into its right and upper cavity indicated by *oo*. From *lc*, the layer of peritoneum lining the cavity can be easily traced from *lc* to *o1*. Of course both cavities are really one, and Winslow's foramen is only a constriction of the whole bag placed nearer one extremity than the other, i.e., the constriction represents an unequal hour glass, *l*.

ria lienalis. The reason of this is that the main trunk of the splenic artery, three-fourths, lies behind the posterior blade of the lesser omental sac until a short distance from the spleen, when it suddenly turns upward to gain access to the space between the layers of the gastro-splenic ligament when the arteria lienalis is conducted to the spleen. In fetal life the ligamentum gastro-lienalis can not be said to possess any length as the spleen develops close against the stomach, but in the progress of development the spleen travels more and more toward the left until it lies in contact with the costal wall. The splenic ligament elongates rapidly after the sixth fetal month. There is considerable connective tissue lying between the blades of the gastro-splenic ligament beside five to seven arteria lienalis. This duplicature of peritoneum is of considerable strength, inclined to fat accumulation and frequently subject to local peritonitis.

The next short band belonging to the spleen and a part of the mesogaster is the ligamentum phrenico-lienalis. This band of peritoneum extends from the

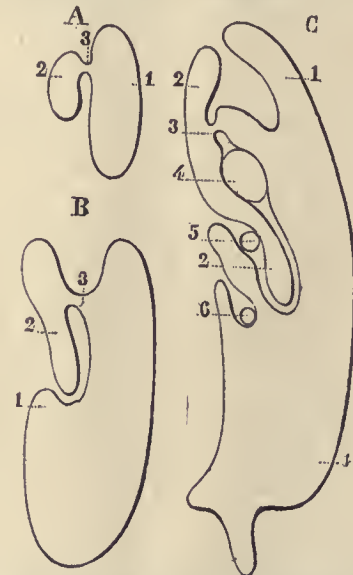

Fig. 36 (after Sappey, 1889) gives a diagrammatic illustration of the development of the peritoneal cavities. *A*, shows the beginning of the two cavities; 1, great omental cavity; 2, lesser omental cavity; 3, Winslow's foramen. *B*, shows the elongation and invagination of the smaller cavity (2); 1, great omental cavity; 2, lesser omental cavity; 3, foramen epiploicum. *C*, shows a vertical section of both peritoneal cavities.

diaphragm to the spleen. The part of this ligament which is in contact with the spleen intimately blends with its capsule. As the band passes from the diaphragm to the spleen, it returns from the posterior surface of the spleen in such a manner that it leaves a small strip of the posterior border of the spleen uncovered. So that the gastric, splenic and phrenico-splenic ligaments which both cover the spleen leave a strip of the spleen uncovered at the hilus where the vessels and nerves pass in and out, and also a small strip of spleen uncovered on its posterior border. This I have carefully investigated personally and think, though disputed by some authors, it represents the true state of matters in regard to the splenic ligaments. The ligamentum phrenico-lienalis is a strong, whitish, dense fold of peritoneum which reaches from the top of the spleen to nearly its lower pole. It falls short of the full length of the spleen on account of the ligamentum reno-lienalis, a short duplicature of peritoneum reaching from the spleen to the kidney. This ligament is not always the same

in every individual on account of the varied position of the spleen and kidney. Hence, authors dispute in regard to its complicated relations, as there is no doubt that in certain bodies occasionally there exists a portion of spleen uncovered between the upper pole of the kidney and the lower pole of the spleen. The cut that accords with my investigations is that of Prof. Hubert Luschka in regard to the splenic relations to its ligaments.

The next lower portion of the mesogaster which deserves a name, and over which volumes have been written, is what I shall term the ligamentum phrenico-colicum. The synonyms of this ligament are, ligamentum costo-colicum, or pleuro-colicum. This ligament is the lower left border of the great omentum, *i. e.*, a continuation of the mesogaster from the flexura coli lienalis on to the surface of the diaphragm. The ligamentum phrenico-colicum serves as a support for the spleen. It is an extension of the last acquired relations of the transverse colon and great omentum. It is composed of four layers, and often in the left recesses of the ligamentum phrenico-colicum there exists constricted off sacs, closed or unclosed, due to local peritonitis. The position of the spleen no doubt frequently depends on the length and strength of this ligament. If the ligament be normal the spleen rests on it in a normal height, but if the ligament elongates it gives origin to wandering of the spleen. The ligamentum phrenico-colicum extends from the greater curvature of the stomach and transverse colon to the surface of the diaphragm on the left costal wall. Its width consists of the distance between the lower border of the splenic pole and the transverse colon. It is a strong ligament composed of four blades of peritoneum containing some connective tissue fibers between its blades. In the region of this ligament nearly all adult bodies show local peritonitis. It produces a sharp angle (flexura coli lienalis) at the junction of the descending and transverse colons, by dragging this portion of the bowel well upward toward the costal wall. No doubt much of the local peritonitis existing around the spleen is due to wandering through the bowel wall of microbes or their products by reason of trauma of the micosa from sharp foreign bodies passing around the acute angle.

The next portion of the mesogaster entitled to a distinct name is the ligamentum gastro-colicum over which men have disputed for centuries. The gastro-colic ligament is a double-bladed fold of peritoneum extending from the greater curvature of the stomach to the transverse colon. The ligament acquired its relations with the transverse colon during fetal life, gradually from right to left, beginning in the second month. Its origin is due to the intimate relation of the right end of the large bowel with the duodenum and mesoduodenum. It consists of two layers which afford a bed for the gastric arteries, epiploica dextra and sinistra. Its posterior blade forms the anterior wall of the lesser omental bag and its anterior blade is next to the parietal peritoneum anterior. Its left end extends to the costal wall and merges into the ligamentum phrenico-colicum.

How does the posterior border of the spleen become uncovered by peritoneum? I examined quite a number of fetuses and adults in order to convince myself of the process. In an early fetus it is easy to trace the posterior mesogaster to its insertion in the mid-dorsal line. In adults one can not do it very

easily, if at all, in most adult cadavers. This is because the left blade of the mesogaster during the leftward shifting of the stomach, is displaced or shifted toward the left of the vertebral column. The fold of peritoneum which forms the left blade of the mesogaster meeting the fold of peritoneum which crosses the dorsal wall at the root of the mesogaster simply withdraws itself toward the left. Considerable of the root of the left mesogastric blade is pushed from its original mid-dorsal insertion by the leftward moving great stomach curve. This leaves only the right root of the blade of the mesogaster inserted in its original mid-dorsal line. This process forces the blades of the mesogaster at the root apart. The separating process of the mesogaster at its origin continually proceeds until a small strip of the spleen becomes uncovered at its posterior border. The force which separates the blades of the mesogaster at its base and exposes a narrow strip of the posterior border of the spleen is analogous to the separation of the blades of the mesogaster in exposing a part of the pancreas in its middle portion, for the tail and head of the pancreas may still remain in the mesoduodenum and gastro-colic omentum, while its body or middle portion may be entirely out of the meso-colon, *i. e.*, a retro-peritoneal organ so far as the epithelial layer of the peritoneum is concerned. This anatomic fact as regards the pancreas being an organ which can be both retro-peritoneal and entirely in a mesentery, I have observed in cadavers.

Hence, we may affirm that the spleen becomes uncovered from the peritoneum on its posterior border by the separation of the blades of the posterior mesogaster at its base, in the same manner as the pancreas become uncovered by peritoneum by the separation of the blades at the base of the mesocolon transversum. The strip of spleen not covered by peritoneum does not reach to the lower pole of the spleen in cadavers examined by me, but stops short one-fourth to one-third the length of the spleen. The process which exposes the spleen retro-peritoneally, includes an apparent oblique insertion of the mesogaster in the adults. It is, however, purely a secondary or acquired change, brought about by the pressure of the liver exercising itself on the stomach, forcing the stomach to the left, and pressing the root of the mesogaster firmly against the left dorsal, resulting in displacement of the left blade leftward, and fixing the right blade as dorsal parietal peritoneum.

(To be continued.)

SOCIETY PROCEEDINGS.

American Electro-Therapeutic Association.

Fourth Annual Meeting held in New York Academy of Medicine, New York, Sept. 25, 26 and 27, 1894.

WILLIAM J. HERDMAN, M.D., President.

(Continued from page 115.)

DR. W. S. HEDLEY also presented a paper on

THE ELECTRIC DOUCHE.

In the electric douche we have a therapeutic expedient of undoubted promise. Yet in the way of accurate experimental investigation, singularly little seems to have been attempted. Sufficient, however, has been done to demonstrate both its electrical power and its therapeutic possibilities. The idea of the present paper is to point to the nature of the inquiry which has led to these conclusions, to supplement that inquiry by some further experiences, and espe-

cially to enter into greater detail as to how the method may be best systematized and applied.

That the electrized water bath possesses many unique advantages as a means of applying electricity to the body has long been recognized. That it is the best form of application for a certain class of cases is very generally admitted. Not only is it the pleasantest, but it is, of all other methods, the one that best deserves the name of "general electrization." Its efficacy, however, depends in most cases on a general and distributed action rather than on any strictly localized effects. The electric douche has been devised as a means of retaining the advantages of the electro-hydratic method and at the same time presenting facilities for strict localization and accurate dosage, and seeing the advantages of a labile as well as of a stabile action.

Attempts have been made to attain the above ends by the use of spray or vapor; but such attempts have failed, because the conducting medium had been so broken up and disintegrated that it ceased to act as a conductor. It is manifest that any stream of conducting fluid can only retain its conductivity so long as it remains whole, continuous, and unbroken. Spray is composed of numerous small globules, sometimes appearing as many fine continuous streams, but actually possessing no real conductivity in the sense that applies to the matter under consideration.

The method of application, apart from certain non-essential details, is much of the nature of what would be known in hydrotherapeutics as the "movable jet douche" (douche mobile), and the nozzle is so arranged that the electrized stream escapes in the form of a more or less condensed jet or jets, which, with a certain minimum of pressure, remain unbroken and continuous for a reasonable distance after emerging from the pipe, and therefore for that distance retain their electric conductivity. (There ought to be a means of regulating temperature and pressure.) With this arrangement one pole may be placed in contact with some indifferent part of the patient's body, while the other is connected to the internal metal of the douche, with the result that when the douche is set in action the second pole is brought to the patient by and in the fluid, and may be concentrated as a single jet, or distributed as many small jets. The fluid is, in fact, the second electrode.

Let us inquire, then, by direct experiment, how much current this water conductor carries, and how much enters the body of the patient. The following experiments are necessarily only a selected few, but a sufficient number of results are quoted to give some general ideas. Details of the apparatus are also as much as possible omitted. It need only be mentioned that, permanent water pressure not being available, a hand pump, drawing from a suitable vessel, was used for the douche, which was fitted with a nozzle or rose (having its outer edge insulated with india rubber) of the size mentioned below. The electric apparatus consisted of a Leclanche battery of 74 cells (with a milliampère meter in circuit) and a fair-sized induction coil. One pole was attached to a large electrode on which the patient sat, and the other connected with the metal of the nozzle or rose, well insulated wire being used for the connections. The following results were obtained:

TABLE A.*

Plain water at 98° F., continuous current.

Nozzle.	E. M. F.	Pole to douche.	Distance of nozzle from body.	Current passing.
1. 1/4 in. jet (single)	75	—	1.5 in.	5 milliampères.
2. Do. do.	"	"	0.5 in.	15 milliampères.
3. Rose 2-in. dia., forty-nine perforations	"	"	1 in.	5 milliampères.
4. Single jet	"	+	18 in.	Deflection (taken on reflecting galvanometer) right off scale. Probably quite 100 microampères.

* Table to show the influence of temperature on the electrical conductivity of water.

R. of bath water taken as it cooled. (By Wheatstone Bridge.)

Temp.	R.
98° F.	165
92° "	194
87° "	261
70° "	440

These figures only show the alterations in R. owing to temperature, and the actual R. in this particular bath. R. varies with volume as well as with temperature.

TABLE B.*

Salt water (3/4 lb. to 7 gal.) temperature 98° F., continuous current.

Nozzle.	E. M. F.	Pole to douche.	Distance of nozzle from body.	Current passing.
1. Rose	75	—	1.5 in.	7.5 milliampères.
2. Single jet	40	+	18 in.	20 milliampères.

TABLE C.*

Plain water, temperature 98° F., alternating current.

Nozzle.	E. M. F.	Pole to douche.	Distance of nozzle from body.	Current passing.
1. Rose	x	+	1.5 in.	Subject cried out "Stop." Milliampère meter (alternating current) in circuit did not register.
2. Single jet	"	+	12 in.	Noise marked in telephone. Subject felt current.

* The above tables and some of the explanatory matter have already been published in the *Lancet*.

Several readings were taken with alternating current and salt water, all showing that the effect was much stronger with salt water than with plain. These experiments seem to show that electricity can be imparted to the human body by means of the electric douche, provided that sufficient electro-motive force be used and the stream of fluid be continuous. Table B shows that when salt water is used strong currents may be passed over considerable distances with a very moderate electro-motive force. Table C shows that by using coil currents, which always possess a comparatively high electro-motive force, as much current as a patient can comfortably bear may be passed over many inches of space. Its current-carrying capacity being thus established, we may glance for a moment at its therapeutic effects.

Though the apparatus necessary for the electric douche need not be elaborate nor complicated, there are certain essential details of construction which must not be lost sight of, and without which not only is its efficiency impaired, but the risk of administering objectionable shocks to operator or patient becomes by no means inconsiderable. The main points are somewhat as follows: a proper mechanical arrangement to secure that the fluid conductor shall pass out in unbroken streams or jets for a sufficient distance to conduct the electric current to the patient's body. Irregularly-shaped orifices will often to such an extent break up the column of fluid, even when issuing at considerable pressure, that its conductivity becomes practically nil, or, as sometimes happens, it is so intermittent that the current passes in a series of jumps, which are worse than useless for the purpose in question. Further, in the case of "rose" nozzles, if the site of the orifices fall below a certain gauge, relatively to pressure, the issuing jets are too fine, there is no continuity of stream, and consequently no electrical conductivity; or, again, if the orifices be not all of the same diameter, irregular conduction will result. Careful attention must be paid to insulation. Want of due care in this point will soon be notified to those concerned by the unpleasant reminder already adverted to. When it is considered that currents of a fairly high electro-motive force have to be used for the douche, and that nothing is more probable than the occurrence of some unexpected, and perhaps for the moment unavoidable, movement of the patient, whereby the instrument comes in contact with his skin, it is evident that unless the metal nozzle be well insulated a violent, perhaps serious, and certainly unnecessary shock will follow. Attention to insulation is also necessary in connection with the metal pipes and taps which control the water supply, in order that electrical leakage may be avoided. The apparatus consists of a short length of flexible rubber tubing, having an inside conducting wire, one end of which is brought out and connected to a terminal about two inches from the brass union which joins on to the supply pipes. The two inches or so of rubber tubing thus interposed between the metal pipes and the conducting wire act as effective insulation at this end of the arrangement. The other end of the internal wire is soldered to the inside of the metal screw, to which different nozzles are attached. The nozzles are two in number, one a single "jet," for current concentration, the other a "rose," for current diffusion. Each nozzle has an inner base of brass covered with a sheath of vulcanite, which projects one-eighth of an inch beyond the brasswork. The orifices are true circles, and their metallic surfaces carefully smoothed, so that

the issuing columns of water are kept intact for a considerable distance. It will be seen that perfect insulation is thus secured at all points, and even if through accident the nozzle does approach too near the patient, it is the insulating vulcanite, and not the conducting metal, that makes the contact.

By the use of such an apparatus it has been found that, with the ordinary domestic water supply, continuous currents of useful strength may be passed with an E.M.F. of 50 to 60 volts (from a battery of 40 Hellen cells) when the nozzle is held several inches from the patient. Alternating currents from a fair sized bath coil pass through a much greater distance. Reference to the foregoing table of experiments shows that if saline or other special conducting fluids be used, the distance through which the current passes is of course much increased.

One drawback to the use of the electric douche is undoubtedly the amount of splashing which it causes. This difficulty, however, is easily overcome by simple expedients; the simplest, and perhaps the most effective, being the use of waterproof curtains, suspended round the ordinary bath. These curtains must be of sufficient width to completely enclose the patient when sitting or standing, and should so hang that their lower ends fall just inside the bath. When in use the curtain will be pulled slightly aside so as to admit the douche nozzle. All splashing is thus kept within the inclosed space, and it drains down into the bath.

There was a time in the days of "brutal hydrotherapeutic empiricism" when both physician and patient had a (not altogether inexplicable) dread of the "hydrostatic douche." This, however, has given way before a more enlightened method of administration, and the douche is acknowledged to possess stimulating and alterative properties of no mean order. It seems not unreasonable, therefore, to suppose that in the combined electric and hydiatic procedure we may have a therapeutic agent of considerable power. It claims that according to variations in temperature, force and duration, it may be resorted to as an agent more gentle and adaptable than even the "electric hand" of the physician, or may be made to become so potent and concentrated as to prove a veritable electro-hydiatic moxa. It presents itself as a means of general electrization by bringing the various parts of the body successively under its influence; it claims an action that may be strictly localized; and, further, offers itself as a means of producing, through various motor inhibitory and secretory reflexes, those influences on nervous centers and glands which can undoubtedly be brought about by other and more painful methods of peripheral electrical excitation. If it can establish claims of this kind, a field of usefulness seems to lie before it in a class of cases which readily suggest themselves.

It can not be attempted here to particularize the multiplicity of cases to which such a very adaptable method may lend itself. There are a few leading features, however, in connection with its possible therapeutic uses which may briefly be adverted to.

The action of the electric douche as a means of electrization by bringing the various parts of the body successively under its influence, and as a local application by bringing it to bear on any special part, have already been referred to. Used in this way we shall not fail to find it in a nervine tonic "heightening cutaneous sensibility and quickening motor excitability." It will influence nutrition and absorption by its control over the distribution and circulation of the blood current. It will act favorably also on local diseases, such as chronic joint affections, and promote absorption through its influence on the circulation. Its usefulness in states of general debility and malnutrition, neurasthenia, spinal debility, exhaustion, and any case in which want of "tone" is the prominent feature, needs no showing. These effects will be brought about in more ways than one, but chiefly, perhaps, by the enormous range of reflexes that, by so effective a method of cutaneous stimulation, are brought into action. Its adaptability to some forms of internal application can not fail to suggest itself. Recent therapeutic experiences leave me in no doubt as to the usefulness of the electric douche. I have lately brought it to bear on a case of pressure-paralysis with rapidly satisfactory results. I have called it into requisition for the peripheral portion of the treatment of an old standing paralysis of central origin. I have found it a most useful adjunct to other electrical methods in the treatment of that ensemble of symptoms known as neurasthenia, and in several cases of anesthesia I have found it of such infinite service that, so far as anesthesia is curable at all, I have come to regard the electric douche as a sovereign remedy.

DR. O. S. PHELPS, of New York, presented a paper on
SOME LANDMARKS IN ELECTRO-THERAPEUTICS.

That the wonderful development of electrical appliances within the present decade has not been altogether an un-mixed good, may we think be asserted without fear of contradiction. We will not consider its commercial aspect, but confine our remarks to its therapeutic uses. The widespread belief among the laity, that in the latest discoveries in electro-therapeutics, is found a panacea for all their ills, is a rock that should be carefully noted on our charts. It has been a potent influence in putting an electrical outfit in many a doctor's office, with more or less disastrous results to the cause of electro-therapeutics. In this connection an aphorism might be offered—don't use unfamiliar tools. The unsuspecting doctor is too often led into purchasing an "all around outfit" from the enterprising agent for electrical goods—"neat and compact," with which to do all the brilliant work of which he and his patients have read and heard so much—without knowing even the first principles of electro-physics, or the construction of the simplest form of battery. I can not refrain from relating a recent occurrence which illustrates the demand on the part of the laity for electrical treatment, and incidentally an example quite refreshing of the honor of one of our manufacturers of electro-medical apparatus. Mr. B. had been for some time failing in health and was advised to procure a battery for self-treatment. He accordingly went to a well-known dealer and manufacturer to purchase the instrument that was to restore him to health. Instead of selling one to him, he sent him to the writer for advice as to whether he needed electrical treatment or not. An examination revealed the fact that the man had phthisis approaching the third stage.

I am often asked the question, What kind of a battery shall I buy? and in answer to my query, What do you wish to do with it? the reply usually given is: "One suitable for doing all kinds of work." Gynecologic, from A to Z; neurologic, ditto; epilation, cautery, and the general treatment of tumors and rheumatism thrown in. Gentlemen, this would be ludicrous were it not sad. That the picture is not overdrawn, the writer will here confess that it is not many years since his own ignorance of electricity was just as dense, and the object of this paper is to point out some of the stumbling blocks in the way of progress.

Grand and brilliant as is some of the work already accomplished, there is no royal road to success in the cure of disease by electricity, and it goes without saying that those who have attained success in its use began at the bottom rung. The best advice which could be given to those who are unfamiliar with the subject would be:

1. Make a thorough study of at least elementary electro-physics.

2. The construction of the more common forms of medical batteries, and the adaptability of each to the different uses for which medical batteries are needed. One should be able to construct, if need be, or repair any of the apparatus he uses. I do not mean that it would be practical to do so, but to be able to do so makes you master of the situation, and you can not be imposed upon by ignorant or designing vendors.

3. Should come the study of electro-therapeutics—a subject at the present moment illusive, seductive, progressive, having garnered some truths from the chaff of speculation and some successes on a road strewn with many failures; a very useful addition to the physician's armamentarium; a vigorous, promising infant; we hope much for its majority.

Important results in even a single case undoubtedly reached by the use of a particular agent are at least a landmark, and may help to establish a principle.

A little over a year ago the writer was consulted by Mrs. W. Her previous history indicated that she had had several attacks of—in common parlance—pelvic cellulitis, with varying intervals between, though they were at the time diagnosed as peritonitis. An examination proved it to be a case of peri-uterine inflammation, with considerable exudation, compressing the left ovary and involving the broad ligament and tube. She complained of pain in the region involved, increased by any attempt at walking, defecation, or voiding of urine. Her temperature was continuously abnormal—from 100 to 102 degrees. The patient was ordered to bed and a high tension faradic current applied *per vaginam* with a bipolar electrode, with the result of relieving the pain and lowering the temperature. This course was pursued with the object of reducing the inflammation to a point where galvanism could be used. Progress was often interrupted by the indiscretions of the patient, till the family

became impatient and upon the advent of a visit from a brother from Boston, and his decision to have "something done," she was taken to one of our prominent hospitals and pronounced to be a case for operation. However, when her husband was told that probably the pelvis would have to be cleared, and that she might not come off the table alive, he weakened—took her home and sent for her former physician. She was found with all her symptoms aggravated, the exudation having extended to the right side and in front, so that the pressure against the bladder made it impossible to retain more than an ounce of urine, which it was agony to void. The pressure around the left ovary kept her vomiting almost constantly. Dr. Goelet was called in consultation and confirmed the diagnosis and the opinion that surgical interference was out of the question. He advised the continuation of the electrical treatment carried out with the utmost vigor, and for a time the high tension faradic current was used three to six times a day, vagino-abdominal and vagino-bipolar, with the result of reducing the inflammation and modifying the other symptoms to such a degree that galvanism could be brought into requisition. A current of 30 milliamperes was used every five days, with the cathode in Douglas' cul-de-sac, and anode to abdomen. The electrodes consisting of a pad, 6x6, in one case, and a suitable vaginal electrode in the other; time of application seven to ten minutes, followed by a fifteen minute séance with the bipolar faradic, which relieved all pain and irritation caused by the galvanic treatment. In four weeks the patient was able to come to the office. The case has steadily progressed till now there is only a small nodule the size of a walnut. She can stand upright, walks, rides, and performs household duties, without pain or inconvenience. Has gained in weight from 75 to 145 pounds.

I do not cite this case as an argument against surgical interference when indicated; or a cure-all in all the pelvic diseases common to women. But will submit to you that granting in this case a hysterectomy to have been feasible and followed by the best results that operation can afford, is the patient to be envied because she has not played a part in so brilliant a procedure?

Case 2.—Miss D., aged 17 years, first noticed slight leucorrhœa in November, 1893; a little later constipation and slight abdominal pains after defecation, and also some pain when the urine was voided. These symptoms, slight at first, gradually increased, and in January she was taken from school, the bowels regulated and rest enjoined. This was followed for a short time by some improvement; but in March so much anxiety was caused by her condition that the family physician was called, who made an examination and informed her parents that he found a growth in the pelvis to the left of the uterus. He advised a course of medication looking toward absorption, tonics, good feeding, etc. For a time there was some amelioration of the symptoms; but a slow reduction in weight from 120 pounds in November to 104 pounds in April, was not encouraging. In June she became much worse, great pain in the bladder and inability to retain the urine. She was in fact treated for inflammation of that organ. This last exacerbation so alarmed her friends that steps were inaugurated to have something more radical done, and they were advised to bring her to New York for an operation for removal of the growth. She came under the writer's care on July 6. Her condition at that time was very unpromising, pain continuous and increased by the slightest move and more particularly upon evacuating the bowels or bladder or tension of the abdominal muscles, the body being bent forward to quite an angle. She was greatly emaciated, weighing only seventy-three pounds; temperature from 100 to 103 degrees, no appetite, and extremely weak. This, in a general way, was the picture she presented. An examination made under an anesthetic showed a fibrous growth which had pushed the uterus well over to the left, flattened and reaching well up toward the umbilicus. Whether part of this was an exudation from the peri-uterine inflammation could not then be fully established, but subsequent treatment proved that it was. The left ovary was involved in an exudation and the bladder was impinged upon, causing the bladder symptoms which had given so much trouble earlier in the case. After a rest of a few days, Dr. Goelet was called in consultation and under an anesthetic she was again examined, confirming the above and advising a continuation of the treatment already inaugurated, viz., the high tension faradic current vagino-abdominal and sacro-lumbar, with the view of reducing inflammation, pressure and pain, and improvement of her general condition, so that some radical measures could be taken, among which would be galvanism and ligation of the uter-

ine arteries. For some time very little progress was made, but finally all the symptoms began to yield; pressure, pain, temperature and improvement was unmistakable. During the past four weeks the temperature has been normal, entire freedom from pain, weighs eighty pounds, can stand erect, walks about the house, and says she is much more comfortable in every way than she has been for ten months. The next step in the case will be galvanism, the result of which will determine whether the knife will be resorted to or not.

These cases will suffice to illustrate a very interesting field in electro-therapeutics and in gynecology as well. They prove that congestion and inflammation can be successfully treated by electricity under proper conditions with a suitable apparatus discreetly applied, our past instructions notwithstanding. They also indicate that many cases which are at once relegated to the surgeon's knife can be cured without the ordeal of an operation and the unsexing of the patient, and many others prepared for an operation, better I believe than in any other way. I also believe there are many cases where a hysterectomy would at first seem to be the only course to pursue, that with preliminary electrical treatment and the modified operation for ligating the uterine arteries, devised by our worthy ex-President, Dr. Goelet, the patient can be cured with the pelvic organs left intact.

To recapitulate: we would again say to the would-be electro-therapist: there is no royal road to the cure of disease by electricity. Each case is a law unto itself, and must be carefully studied as such. Make yourself master of the situation both by knowledge of electro-physics, construction, character, and quality of apparatus and knowledge, to date, of electro-therapeutics—remembering as well that the best specialist is the best all round doctor—following which, all other means such as appropriate hygienic conditions, diet, rest, and proper medication, will be brought into requisition. As physicians we should seek the glory of a cure, rather than the glory of any agent.

DISCUSSION.

DR. GOELET said he had seen with Dr. Phelps the cases reported in the paper, and the outlook had been certainly very unfavorable in both at first. The results obtained by Dr. Phelps served to convince him that much more could be accomplished with the faradic current than even he had hitherto supposed. In the second case the continuance of the current was suggested simply to improve the patient's general health and prepare her for operation. Dr. Phelps was to be congratulated upon the result he had been able to accomplish in these two cases. He wished to correct the impression which may have been made that he had devised the operation of ligation of uterine arteries. That however, was Dr. Martin's, of Chicago.

DR. ROSS thought that with the mild current employed one would hardly have expected that there would have been the rise of temperature in the case reported.

DR. PHELPS, in closing the discussion, said that he had understood that Dr. Goelet had modified the operation of ligation of the uterine arteries, and it was to this he had intended to refer. In the second case related, the very low condition of the patient and the long continued abnormal temperature without any change, so far as could be detected, would have certainly have discouraged him from continuing its use had it not been because of former successes following the persistent use of the current.

DR. ROBERT NEWMAN, of New York, read a paper on

REICHARDT NEW GALVANIC BATTERY FOR ELECTRIC ILLUMINATION.

This battery consists of four cells each 2 volts, and all four cells will give 6 amperes. Experiments on July 7 and 8.

The battery can scarcely be used as a galvanocautery, and will heat only a small platinum burner. It is intended to illuminate cavities, particularly with a lens used as a head mirror.

Test with a Leiter's cystoscope which needs 7 volts; a bladder (manikin) was well lighted up, with one inch left burning outside of the elements of the fluid. The light was bright for five minutes. Agitation of the fluid kept the light up for five minutes longer, when polarization made the light a little uncertain. Then the elements were lowered into the fluid its full length, and the light was restored to the same capacity as it was when first tried. This kept up five minutes longer. Hence a constant continued light could be kept up for fully fifteen minutes with this battery—after that time more polarization took place, so that the light faded after twenty minutes. However, even then an examination could be made. After twenty-five minutes the light

grew uncertain and the cells were so hot that the elements had to be raised out of the fluid and the test discontinued.

After an intermission of ten minutes the battery gave again an excellent illumination, but the cells were overheated and could not be used. It takes about one hour to cool off the cells respective of the fluid.

It can be stated that this battery will give a good light for examination fully fifteen minutes, whenever 7 or 8 volts are required.

The battery fluid used for these tests was weak, only 1 part sulphuric acid to 9 parts of water with bichromate of potasse, which solution is sufficiently strong. A stronger solution may be used for this battery which, however, is not needed, as the one just described works well enough, and is more economical, saving the zincs of the elements. After each use, the elements should be cleansed by letting water run over it.

Description of the battery: the battery stands on a platform four and three-fourths inches square. The height of the whole instrument is twelve inches and when the elements are immersed in the fluid only seven inches. Four cells, each five inches high by two inches square, each may contain five ounces.

Elements: each cell contains two carbons and one zinc and can be used with either one, two, three or all four cells.

Instead of the rheostat, the potential can be regulated by the distance the elements are immersed in the battery fluid and also by the number of cells used.

Weight is four pounds and thirteen ounces.

SECOND DAY, SEPTEMBER 26—EVENING SESSION.

BUSINESS MEETING.

The meeting was called to order by the President at 8:40 P.M. On motion, the reading of the minutes was dispensed with. The report of the Secretary was then read.

THE PRESIDENT—It has been customary to have these accounts transferred to a committee for auditing. Is this the desire of the Association? On motion, the President was requested to appoint such a committee, consisting of two. Dr. Charles R. Dickson and Dr. Brown were appointed. Upon their suggestion and approval, the report was accepted, as read.

The Secretary's report on matters from the Council was then read.

A report of the meeting of the Executive Council, of Monday, Sept. 24, 1894, and its recommendation was then read.

THE PRESIDENT—It is your duty to confirm this action of the Council. A motion was duly made and carried, confirming the recommendations of the Council.

The Treasurer's report was then read and accepted.

The Secretary announced that the Council had decided that the papers might be published where the authors desired, but that a copy must be placed in the hands of the Secretary before the adjournment of the meeting.

A lengthy discussion was entered into by Drs. MASSEY, CLEAVES, SMITH, DICKSON, NUNN and WALKER, as to the question of having papers, which had been read before the Society published elsewhere before being published by the Association.

DR. KELLOGO moved as an amendment that the members be permitted to publish *abstracts* of their papers. Seconded by DR. DICKSON, and carried. The original motion was amended was also carried.

THE PRESIDENT—The next thing is the matter of continuing Standing Committees on Instruments. A motion was made and carried, postponing action on this matter.

ELECTION OF OFFICERS.

THE PRESIDENT—The next in order is the election of a President, two Vice-Presidents, a Secretary, and a Treasurer, and five members for the Executive Council.

DR. A. H. GOELET—I take great pleasure in nominating a man who was a pioneer in modern methods of electricity in America. I am sure you will all agree with me that we could procure no better man to fill the high office of President than DR. A. LAPTHORN SMITH, of Montreal.

DR. W. J. MORTON seconded the nomination, and on motion, the nominations were closed.

On motion, the Secretary was instructed to cast one affirmative ballot on behalf of the Association for DR. A. LAPTHORN SMITH as President.

DR. A. LAPTHORN SMITH—I thank you very heartily for the honor, which was entirely unexpected. Your confidence in me will lead me to make greater exertions in the interest of the Association, and I promise you I will not allow the work to deteriorate during my term of office. Again, I thank you heartily.

DR. MASSEY—We went to Canada for a President; let us go West for a Vice-President. I take pleasure in nominating DR. J. H. KELLOGG, of Battle Creek, Mich.

DR. DICKSON seconded the nomination.

DR. GOELET—I take pleasure also in nominating DR. C. R. DICKSON, of Toronto, for Vice-President.

DR. KELLOGG seconded the nomination.

DR. HOLFORD WALKER, of Toronto, was also nominated, but declined.

On motion, the nominations were closed. Ballots were distributed, and the tellers announced that DR. KELLOGG had been elected first Vice-President, and DR. DICKSON second Vice-President.

DR. GOELET—I take pleasure in placing before you in nomination the name of a man well known for his executive ability and to whose energy we are indebted for the very excellent exhibit in the adjoining room, and furthermore he is a New York man. I nominate DR. EMIL HEUEL for Secretary.

On motion, the nominations were closed.

On motion, the Secretary was instructed to cast an affirmative ballot for DR. EMIL HEUEL for Secretary.

DR. W. J. MORTON—I take pleasure in nominating for Treasurer the same sunny-faced gentleman we have had heretofore—DR. NUNN, of Savannah, Ga.

On motion, the nominations were closed, and the Secretary was instructed to cast one affirmative ballot for DR. NUNN for Treasurer.

The following gentlemen were then nominated and elected to the Executive Council: DR. W. J. HERDMAN, G. BETTON MASSEY, W. J. MORTON, A. H. GOELET, and O. B. DOUGLAS.

DR. R. J. NUNN—In rising to make this motion I am about to appeal to the sensibilities of every member in the Association. I desire to express the obligations we are under to our retiring Secretary. We appreciate the work she has done, which has been so great as to cause her health to give way in the interests of the Association. I therefore move that by a rising vote the thanks of the Association be now tendered to DR. MARGARET A. CLEAVES for the able and self-sacrificing manner in which she has performed the duties of Secretary of this Association.

THE PRESIDENT—As retiring President I would say to you that every word of this motion has its full meaning. No one could have done better work than she has done. It is out of regard for her that we do this.

The motion was then put, and carried unanimously.

DR. A. LAPTHORN SMITH then expressed the wish that the Association would decide to meet in Montreal next September, and assured them that if they did so they would have a hearty welcome.

On motion, the Association then adjourned to participate in the reception tendered them by the resident members.

THIRD DAY, SEPTEMBER 27—MORNING SESSION.

BUSINESS MEETING.

The meeting was called to order by the President at 10 A.M.

THE PRESIDENT—The suggestion I made at the first part of the meeting has apparently met with general approval. These committees were organized two years ago with the object of having some person responsible for looking after the apparatus which is being prepared for our purposes by the mechanics. Until recently we have been largely in the hands of the mechanics who have made up our machines, and have told us how we should use them. Now we have got to the point where we can dictate to them, and tell them just what we want. In this pioneer work, however, it is necessary that some person should be responsible for the construction of our apparatus, and also that we should be able to place ourselves in a representative position before the profession at large. The members of the various committees have not fully understood the scope intended for their work, as I originally suggested it, but they are beginning to understand it now. They should make practical tests of the various apparatus, and also give us an epitome of the work of the year in their respective departments. It is my desire, and that of many others in this Association, that these committees be put upon a more comprehensive basis. If you will turn to the Constitution and By-Laws you will see the list of the various committees. It was our original intention to adopt standard coils, and standard machines of various kinds, but we have since come to the conclusion that by so doing we would become more or less embarrassed, becoming the aiders and abettors of some particular manufacturer. All that we need to do is to state what is required in a particular instrument or apparatus, and to adopt certain stand-

and principles, and hence I suggest that we should leave out the word "standard," wherever it occurs in connection with the titles of these committees. Lastly, I would suggest that a committee on Electric Light Apparatus for Diagnosis and Therapy be formed. I would also introduce the following sentence: "The following committees are expected to col- late information and make careful tests as to the nature and efficiency of all instruments put on the market in the class assigned to them, and to make full reports of their investi- gations at the annual meeting." I would introduce a sen- tence of that sort as explanatory of the functions of these committees. You must take action in order that the com- mittees be continued, and I will appoint the members for these different committees. I am ready to entertain such a motion.

DR. GOELET—I make a motion to that effect. Seconded by DR. BEAVER, and carried.

DR. BEAVER—We all know that instrument makers have their own methods of connecting the conducting cords to the battery and with the electrodes—by springs and screws of various sizes. I think we should make an effort to get the instrument makers to adopt some uniformity in this respect. I move therefore that the Committee on Electrodes be instructed to communicate with the manufacturers and endeavor to have them adopt some uniform connections. Seconded and carried.

DR. GOELET announced on behalf of the Council that the Association had been invited to Montreal, and he thought it would be eminently wise that the Association accept this invitation, especially as the next President was from Montreal.

DR. DICKSON—I have been asked by DR. A. LAPHORN SMITH to urge the Association to meet next year in Mon- treal, as he has found it rather difficult work to excite suffi- cient interest among the profession there in the subject of electro-therapeutics. I am assured that you will meet with a hearty welcome, and I am positive that you will not be sorry for choosing this for the next place of meeting. There are many places of interest in the surrounding country, and the city is easy of access.

DR. BEAVER—I move that the next meeting of the Associ- ation be held in Montreal, the date being left to the Council. Seconded.

THE PRESIDENT stated that DR. SMITH had told him that he could get the support of the laity in Montreal, but per- haps not of the medical profession.

DR. BEAVER—I would change the motion then so as to read Toronto instead of Montreal.

DR. WALKER assured the Association of a hearty welcome at Toronto.

The motion was then put and carried that the Association should meet in Toronto.

The Secretary moved that the Association pass a vote of thanks to the New York Academy of Medicine, to MR. NI- KOLA TESLA, to the Edison Manufacturing Company, to the Resident Fellows, and to the Committee of Arrangements. Seconded and carried.

The Secretary announced that DR. GEHRUNG had sent a letter of regret at his inability to be present at this meeting.

SCIENTIFIC SESSION.

Report of the Committee on Constant Current Generators and Controllers, by DR. W. J. HERDMAN, of Ann Arbor, Mich. (The report was not read, but the main points were briefly stated.)

DR. NEWMAN presented a separate report on this subject. (MS.)

MR. BROWN also presented a report on Secondary Bat- teries. (MS.)

On motion of DR. WALKER, the report of the Committee was received and referred to the Council for publication.

"Notes on the Effects of High Frequency Electrical Dis- charges passed through the Body," by PROF. ELIHU THOMSON, M.A.I.E.E., of Lynn, Mass., was read by DR. HERDMAN.

(To be continued.)

The Ohio State Medical Society.

Annual Meeting held at Columbus, May 15, 16 and 17, 1895.

FIRST DAY—AFTERNOON SESSION.

The Society convened in the Chamber of Representatives, State Capitol Building, Columbus at 2 P.M., the President, D. N. KINSMAN, M.D., occupying the Chair.

DR. W. T. HOWARD, of Cleveland, Ohio, read a paper on

THE ANTITOXIN TREATMENT OF DIPHTHERIA.

After considering the methods of arriving at a standard, giving preference to that of Behring as being the most accu- rate, and dwelling upon the mode of production of antitoxin in the body and the manner of its action, Dr. Howard con- tinued as follows:

From the beginning of the use of antitoxin in the treat- ment of diphtheria, there has been a marked lowering of the death rate. Thus the German hospital statistics, with their mortality of from 35 per cent. to 65 per cent. showed under the influence of the new remedy, a mortality rate of from 11 per cent. to 25 per cent. Kossel reported 233 cases with a mor- tality of 23.2 per cent. Katz reported 128 cases in Baginsky's wards a mortality of 13 per cent. Virchow gave the treatment the weight of his authority when he reported 303 cases treated with antitoxin with a mortality of only 13.2 per cent., and 230 cases treated without antitoxin with a mortality of 47.8 per cent. In Roux's first series of 448 cases there was a mor- tality of 24.3 per cent. while at the same time the mortality from cases not treated with antitoxin in the Hospital Trou- seau was 60 per cent. Later Roux's mortality has fallen to below 10 per cent. In Vienna 100 severe cases were treated with a mortality of 24 per cent. Foster of Washington (*Medical News*, Feb. 2, 1895) has gone to the trouble of tabulat- ing the comparative results of diphtheria cases treated with antitoxin and by the ordinary methods. He found that in 2,740 cases—selected and unselected—collected from literature treated with antitoxin, 509 died, a mortality of 18.54 per cent.; of 4,445 cases selected and unselected, and including as did the other cases upon which tracheotomy and intubation were done, not treated with antitoxin, 2,017 died, a mortality of 45.36 per cent. Probably the most interesting series of cases reported in America is that of Biggs, in which 255 cases of diphtheria were treated in the Willard Parker Hospital and in the tenement houses of New York. There were in these 255 cases, 40 deaths, or a mortality of 15.69 per cent. If 15 cases in which death took place in less than twelve hours after the serum was administered are deducted, the mortal- ity was only 10.4 per cent. During the same period, according to the statistics of the Health Department, the mortality from diphtheria in New York was from 25 per cent. to 35 per cent. At the recent German Congress of Internal Medicine held at Munich, Huebner and Baginsky of Berlin, and Wed- erhofer of Vienna, among others, indorse the serum-therapy and note striking lowering of the mortality following its use. The experience of the writer in the recent Ashtabula epidemic was gratifying. In 40 cases treated with antitoxin there was a mortality of 7.5 per cent., while of 82 non-selected cases occurring during the same epidemic treated by ordi- nary means the mortality was 27 per cent. A series of 150 children with diphtheria treated with Roux's antitoxin, have just been published from Paris, with a mortality of 10 per cent. The experiences of individual observers might be multiplied almost indefinitely. The difference in the results obtained according to the day upon which treatment is be- gun, first emphasized by Kossel, is striking. It is however, what, *a priori*, one would expect. In Kossel's 233 cases, of those treated on the first day of illness 100 per cent. recov- ered; on the second day 97 per cent.; on the third day 89 per cent.; on the fourth day 77 per cent.; on the fifth day 60 per cent.; on the sixth day 47 per cent.; and between the seventh and fourteenth days 51 per cent. The accumulated experience since Kossel's publication fully bears out his figures. For instance, Foster, analyzing 2,740 cases, of those treated on the first day of the disease none died; on the second day the mortality is 2.83 per cent.; on the third day 9.99 per cent.; on the fourth day 20 per cent.; on the fifth day 33.33 per cent.; after the fifth day 41.38 per cent. The mortality is also always higher in children under 9 years than in children above this age and in adults.

Clinical Observations.—An early and rapid improvement in the general condition of patients treated with antitoxin has been noted by nearly all who have used the remedy. The pallor and blueness of the countenance usual with diphthe- ria patients quickly disappears, or if the case is treated early in the disease this symptom does not develop. Chil- dren with large masses of false membrane in their throats are bright and playful. This improvement in the general condition, in the writer's experience often takes place in from twelve to twenty-four hours. It is not uncommon to see severe and malignant cases sitting up in bed playing, within from twenty-four to forty-eight hours after the be- ginning of the treatment. The earliest and a very charac- teristic effect is a marked improvement of the heart's action

and of the pulse. The heart beats are slower and the sounds louder. The pulse falls rapidly in frequency, at the same time increasing in strength and volume. In the writer's experience the pulse rate would fall even in the worst cases twenty beats in the first twenty-four hours. In from twenty-four to forty-eight hours it was not unusual to find the pulse 80 or 90 per minute. Often within fifteen minutes after an injection, a rise in the arterial tension was noted. No change in the respiration due to the remedy itself is described, except in young children, in whom it may be accelerated. The only effect upon the respiration is its improvement incident to the removal of mechanical obstruction, due to the presence of false membranes in the air passages.

According to Roux, if the remedy is given at the very outset, the temperature rises only slightly above the normal. In fully established cases of the disease the temperature falls in a marked manner, often on the day succeeding the first injection. The fall is rapid, the temperature line descending almost vertically. In severe cases the temperature fall is gradual, and it may not reach the normal for several days. When the temperature remains high, in the absence of mixed infection, it is usually to be regarded as an indication for more of the remedy. In the writer's experience the fall in the temperature was usually marked. In mild cases and in cases of medium severity this fall was usually sudden; in severe and malignant cases it was more often gradual.

The changes in the local lesions are marked and striking. In the writer's cases, for the first twelve to twenty-four hours there was no change in the appearance of the false membrane. In severe and malignant cases, it sometimes was increased during this period. But usually its formation ceased within twenty-four hours after the first injection. Generally after the first twenty-four hours the false membrane lost its dry, opaque grayish appearance, and became moist, somewhat translucent and milky white. Slight filmy false membranes would rapidly disappear. The thick false membranes in from twenty-four to forty-eight hours begin to separate both from the surface and from the borders. It is quite characteristic to see the false membrane curling up and separating at the borders, where it joins the mucous membrane of the part. The false membrane disappears in the majority of cases by the third day. It may disappear earlier or later, as late as the seventh day in our experience. The swelling of the cervical glands usually begins to subside before the disappearance of the false membrane. The glands, however, not infrequently remain somewhat enlarged and tender and appreciable to the touch for some time. If the glands are not already swollen at the beginning of the treatment, they do not usually enlarge.

Some observers have held that diphtheria antitoxin causes albuminuria. This is one of the most actively investigated questions now in the antitoxin treatment of diphtheria. Much will depend upon its decision. The question is a very complex one, for it is well known a very large proportion of severe cases of diphtheria, treated by any mode of treatment, have more or less albuminuria. According to v. Jaksch, all severe cases of diphtheria have albumin in the urine. The injection of large amounts of the antitoxin into dogs has failed to produce albuminuria. The presence of the carbolic acid used to preserve the antitoxin has been objected to as a possible cause of nephritis. But it has been found that the injection of carbolic acid in solutions of the same strength used in the Behring antitoxin causes neither albuminuria nor nephritis in dogs. Altogether, the weight of evidence points to the conclusion that diphtheria antitoxin lessens the percentage of cases of albuminuria in diphtheria and does not cause nephritis. It will, however, require the study of a large number of carefully investigated cases to settle this, as well as other mooted points. Roux is positive that albuminuria is less common when antitoxin is used. Most observers hold that albuminuria existing before the antitoxin was given is not only not augmented, but is soon lessened and disappears.

From the beginning, it has been asserted by all, that cases of mixed infection fail to show the rapid improvement under the influence of antitoxin, so striking in cases of pure diphtheria. The antitoxin does not seem to increase the immunity against the organisms of mixed infection (the streptococcus and staphylococcus), in the slightest degree. However, it appears to be established that cases treated early with antitoxin are much more liable to escape mixed infection than cases coming late to treatment or treated by ordinary means. It is also established that cases of mixed infection do better under the antitoxin treatment than under any

other. The explanation here is that if the diphtheria toxemia is eliminated from the case, the body is in a very much better condition to struggle against the microorganisms causing the mixed infection, and the patient's chances are improved by that much. Clinical observation on this point has been substantiated by Roux on animals. It may be said that while antitoxin when given early very much lessens the chances of mixed infection, any considerable lowering of mortality in cases of well-established mixed infection is not to be looked for.

When antitoxin is used, the proportion of cases of "descending croup" is very much diminished. Results show that intubation is very much better adapted to cases of laryngeal diphtheria, whether primary or secondary, than is tracheotomy. The tube is quite sufficient in the large majority of cases to keep the air passage open until the false membrane is thrown off. Intubation is to be looked upon as the "complement of antitoxin." Several cases of recurrence of diphtheria after the use of antitoxin have been recorded. Gaebel reports two such cases. The re-infection occurred in one case on the twenty-seventh and in the other on the twenty-eighth day. Both cases rapidly yielded to injections of antitoxin.

The amount of antitoxin given must depend upon the effect produced in each individual case. The best guides are the effects upon the pulse and the false membrane. According to Ehrlich and Kossel, the amount necessary is from 400 in light cases to 1,000 to 1,500 antitoxin units or more in severe cases. The amount in cubic centimeters will vary with the strength of the preparation. For instance, 1 cc. of the Behring No. 1 contains about 60 antitoxin units; 1 cc. of Roux's from 50 to 60; 1 cc. of the Behring No. 2, 100. The antitoxin used at Ashtabula was found by Dr. Arey, in my laboratory, to have an antitoxic value of 60 units. Janowski has found Aronson's antitoxin about the same strength as Behring's No. 2. Some of the antitoxin obtained from the horses of the Health Department of the city of New York is stronger than Behring's No. 3. Kinyoun, of Washington, has also obtained a very strong antitoxin.

The remedy is to be injected subcutaneously with a large hypodermic syringe, of from 10 to 20 cc. capacity. It is of the utmost importance that the syringe should be kept sterile. Several special syringes with asbestos sponges which will stand steam or hot dry air disinfection have been invented. But probably the one most generally used will continue to be the old style syringe with the leather plunger. This can be quite safely sterilized with a thorough washing with a 5 per cent. carbolic acid solution before and after using. The skin at the point of injection should be cleansed and sterilized. It is probably not necessary to use a dressing after the injection, though it can do no harm. In the experience of the writer, the buttock is at once the most accessible and least painful point for injection. It is usual to give in severe cases 1,000 antitoxin units at once, and to repeat in twenty-four hours. One may, however, divide the dose and give half at first and the rest after ten or twelve hours. Mild cases usually require only from 400 to 600 antitoxin units. Severe and malignant cases often require from 4,000 to 5,000 or more. It does not seem to make much difference whether the antitoxin in solution is concentrated or diluted, provided always the necessary number of antitoxin units are given. Other things being equal, however, it is better to use an antitoxin of a high immunity grade. High temperature, rapid pulse and symptoms of toxemia, unless clearly due to mixed infection, are always indications for more of the remedy.

For the production of immunity, small doses are sufficient. From 60 to 400 or 600 antitoxin units are usually given. The size of the dose will depend upon the body weight and age. The artificial immunity thus produced lasts for a variable time, from a few days to six or more weeks. In a diphtheria-infected household, every one should receive immunizing injections. If others take the disease after a few days the injections should be repeated. Almost invariably individuals contracting diphtheria after these injections have mild cases, which yield readily to small doses of antitoxin.

Nearly all of the dread sequelæ of diphtheria are either entirely absent or very mild in cases treated with antitoxin. The proportion of cases having paralysis is very much reduced. In the forty cases of which the writer has notes there was only one case of paralysis, while in cases in the same epidemic treated by the ordinary measures paralysis was common. Heart lesions, both mural and endocardial, are very much less common in the antitoxin cases. In the writer's forty cases, in only three was there cardiac irregularity following the disease. All of these cases made rapid and perfect recoveries. One case, however, in which treatment was

not begun until the sixth day, died suddenly of acute dilatation of the heart.

With the earlier disappearance of the false membrane in antitoxin-treated cases, it is probable that the diphtheria bacilli disappear earlier from the throat than in cases treated by other means. However, there is not enough evidence at hand to decide this point. The writer's experience has not been sufficiently large to draw positive conclusions. It will take the study of a large number of cases to arrive at a definite solution of the question. Cases should be isolated until they have been proved free from diphtheria bacilli. By immunizing individuals in diphtheria-infected houses, epidemics of diphtheria can be rapidly controlled. Although in cases coming early under treatment, antitoxin may be regarded as a specific against diphtheria, in some cases, especially cases treated late in the disease and in cases of mixed infection, the use of other measures the value of which is well established, should not be neglected. The writer has seen such cases, which in his opinion, would have certainly died but for the timely use of stimulants. An abundance of good food is of the highest importance. It is advised to gargle or to spray the throat at short intervals with some mild non-corrosive antiseptic solution. In the opinion of the writer, copious irrigation of the affected surfaces would be more efficacious. It seems probable that as ordinarily used the local application of antiseptic agents is of little value. In many cases, certainly, they do not reach the source of the trouble, which lies buried in the false membrane. As the latter is thrown off under the influence of the antitoxin, the proper use of antiseptic solutions is of the highest importance, as the diphtheria bacilli can then be reached and acted upon. Although the bacilli may not be killed outright, their virulence is at least very much lessened. After the disappearance of the false membrane, it is important to destroy diphtheria bacilli remaining in the throat, thereby not only lessening the chances of the patient infecting others, but very materially shortening the period of quarantine. The ideal treatment of diphtheria in the future must aim first at the destruction of the infectious agents *in situ*, and secondly at counteracting the poison absorbed into the system. The latter requirement is undoubtedly filled by the antitoxin. The first is apparently accomplished by the early and frequent application of the solution recommended by Löffler. The use of this latter agent is very promising in cases of mixed infection. Recently the streptococcus antitoxin has been successfully used in the treatment of puerperal fever, erysipelas and other streptococcus infections. If these results are confirmed by others, a great step forward will be made in the treatment of mixed infections in diphtheria.

From the first it has been observed that a certain proportion of cases treated with antitoxin, after from three to fifteen or more days developed painful skin eruptions, usually urticaria and erythema multiforme. The occurrence of joint and glandular swellings and severe muscular pains is met with in a certain proportion of cases. These with the skin eruptions appear to depend rather upon the preparation of antitoxin used and the individual susceptibility of the patient than upon the size of the dose. Their occurrence is not to be looked upon as due to the presence of infectious agents in the antitoxin, but to some unknown chemic body in the horse's blood serum which is poisonous for certain human beings. Although the symptoms produced by the poison are distressing, they are not dangerous to life and disappear without treatment in a few days.

In the diphtheria antitoxin we have a specific for the diphtheria poison when applied early in the disease; and the later the use of the remedy the greater the mortality. The agent is antitoxic and not bactericidal in its action, in the sense that it kills diphtheria bacilli present in the affected part.

Dr. F. D. CASE of Ashtabula, Ohio, read a paper on

A CLINICAL REPORT ON THE DIPHTHERIA EPIDEMIC AT ASHTABULA.

As the title of this paper implies, it is not my intention to write a systematic essay on diphtheria, but rather to present the salient points of the recent epidemic at Ashtabula, the following distinctive features of which make it worthy of your attention.

1. It is one of the few well authenticated instances of an extensive epidemic of diphtheria due to infected milk.¹
2. It was the first epidemic of the disease in this country in which a general use was made of antitoxin, and an oppor-

tunity afforded to contrast the result with other accepted modes of treatment.

Most of the time, for three years or more, there have been cases of diphtheria in the first and sixth wards which adjoin Lake Erie and contain a large foreign population employed on the coal and iron docks. Among these people the enforcement of quarantine restrictions is extremely difficult. The disease was of a severe type with large mortality. In these wards in 1891 there were three deaths from diphtheria; in 1892 seven deaths; in 1893 nineteen deaths; and in 1894 nineteen deaths. During these years up to September, 1894, the other four wards were entirely free from the disease. In September and October, 1894, there were eight cases confined to a small section of the fourth ward. This was speedily stamped out, no cases being reported from that ward in November.

The first case ushering in the epidemic under discussion, resided on West Street in the fifth ward and was taken ill Dec. 4, 1894. December 5 there were six additional cases located on Bell Street in the third ward; Center and Henry Streets in the fourth ward, and Bond Street in the fifth ward. On the 6th, eight more cases was taken ill on Station Street in the second ward; and on Center, Henry, Gary, Main, Tyler and Chestnut Streets in the fourth ward. On December 8 it was estimated that there were thirty cases in the second, third, fourth and fifth wards of the city. The first death, that of the first person taken ill, a lady 30 years of age, occurred December 9. On the 10th it was estimated that there were forty cases in the four wards mentioned, and the Board of Health declared the disease epidemic in that part of the city south of the main line of the L. S. & M. S. Railway. The public schools in these wards were ordered closed.

The simultaneous occurrence of such a large number of cases excited great alarm on the part of the public, and led to a rigid investigation on the part of the health authorities.

For two weeks previously a model of a Swiss village had been on exhibition, both day and evening, at 235 Main Street. Hundreds of children from the infected first and sixth wards as well as from the other parts of the city had been in attendance and the opinion soon became general that this furnished an explanation of the sudden outbreak of the disease. An investigation showed this theory untenable, as a large number of those taken ill had not visited the exhibition. The sewerage and water supply were each in turn inquired into and found free from suspicion.

When attention was called to the food supply, it was found that all cases up to December 10 were in families that procured milk from a wagon of Smith's milk line, driven by Henry Smith. An inspection of Smith's dairy showed the cows to be in good condition and free from any indication of disease. They were supplied with pure spring water and the barns and yards were in good sanitary condition. Henry Smith, driver of the wagon that supplied the infected families, was suffering from sore throat as early as December 2 and perhaps a day or two earlier. He continued on the wagon, however, except on the 5th and 6th, when his place was taken by another man.

December 12. The Health Officer reports that since December 4 there have been forty-nine cases of diphtheria reported, forty-seven of which were in that part of the city south of the L. S. & M. S. track. Of the forty-seven cases, forty-five are in families that used Smith's milk. By resolution of the Board of Health, Smith was prohibited from delivering milk for fifteen days after December 11. In this connection the following cases are of interest:

Mr. P. and his two sons, aged 6 and 12 years, were taken ill with diphtheria in the early morning of December 5. Mrs. P. had gone from home December 3, and was at this time in Binghamton, N. Y. On the evening of December 2 they all partook freely of milk for supper. The milk was procured of Henry Smith. Other members of the family did not use the milk and did not contract the disease.

Mrs. S. usually procured her supply of milk from another source, but on the morning of December 2 purchased one quart of Henry Smith. December 5 and 6 she was ill in bed with sore throat but did not call a physician. On December 19 her son, aged 14, was taken ill with diphtheria, received the antitoxin and recovered. There had been no known exposure to the disease, except from the mother.

Many instances like the above could be cited. It is true that the evidence pointing to infected milk, as the cause of the epidemic is entirely circumstantial, since after repeated examinations the bacillus of diphtheria was at no time found in cultures from the milk or from the throat of Henry Smith. Yet most of our opinions in clinical medicine and

¹ See Powers report to Local Government Board, Universal Med. Sci., Vol V, p. 230; also Clark's report in same.

therapeutics, like most decisions in law, are based upon circumstantial evidence. As Chief Justice Gibson has said: "You see a man discharge a gun at another; you see the flash, you hear the report, you see the person fall a lifeless corpse and you infer from all these circumstances that there was a ball discharged from the gun which entered his body and caused his death, because such is the usual and natural cause of such an effect. But you did not see the ball leave the gun, pass through the air and enter the body of the slain; and your testimony to the fact of killing is therefore inferential, in other words circumstantial. It is possible there was no ball in the gun, and we infer that there was, only because we can not account for death on any other supposition."

It is true that many persons used milk from this same wagon who did not contract the disease. It is of course not known whether every can of milk on a given day was infected and if such was the case, the inherent resisting power of many persons to infectious disease would explain the exception. The array of a large number of negative cases—those in which exposure is not followed by disease—is of little importance, unless at the same time an explanation having more elements of probability is at hand. The chances of such a series of admitted coincidences not due to a common cause is too small for calculation.

In Watson's "Practice of Physic," in the chapter on Continued Fevers is the following: "A man might say, 'I was in the battle of Waterloo and saw many men around me fall down and die, and it was said they were struck by musket balls; but I know better than that for I was there all the time and so were many of my friends and we were never hit by any musket balls. Musket balls therefore could not have been the cause of the deaths we witnessed.' And if, like contagion they were not palpable to the senses, such a person might go on to affirm that no proof existed of there being any such thing as musket balls."

December 13. Dr. Miller of the State Board of Health, accompanied by Dr. W. T. Howard Jr., Professor of Bacteriology in the Western Reserve University, arrived for the purpose of investigating the epidemic. December 14. The Board of Health authorized the Health Officer to procure from the Pasteur Institute, New York, a supply of antitoxin. Health Officer reports to date sixty-four cases in forty-two families with eleven deaths. December 16. A quantity of antitoxin was received and administered to three cases. December 17. To date sixty-seven cases; forty-four houses quarantined; thirteen deaths. December 18. Seventy-five cases; forty-seven houses quarantined; fifteen deaths. December 21. Eighty-seven cases; fifty-one houses quarantined; eighteen deaths. December 22. Ninety cases to date; twenty deaths. Forty-seven patients convalescent; twenty-three under treatment. December 28. The Board of Health declare the epidemic at an end. There are still seventeen cases under treatment, most of them for sequelæ.

There were 111 cases and 23 deaths during the month of December, 1894, of which 100 cases with 21 deaths were in families supplied with milk from the wagon driven by Henry Smith. The public schools reopened January 7, after a vacation of four weeks.

From the beginning of the epidemic, a rigid quarantine was enforced against the sick and all coming in contact with them. The convalescent were discharged from quarantine only after four weeks detention, unless a bacteriologic examination showed them to be sooner free from the disease. All infected houses were disinfected under the direction of an employe of the Board of Health. The adequacy of the means employed is evidenced by the fact that with over fifty houses quarantined there was no general spread of the disease, and in twenty-four days from the time the first patient was taken ill and eighteen days after the disease was declared epidemic, the Board of Health were able to declare the epidemic at an end.

Of the total number of cases of diphtheria occurring in that section of the city in which the disease was epidemic, I have received a detailed report of eighty-two cases. Of these fifty-nine cases received the usual treatment with iron, chlorate of potash, quinin and whisky internally; and peroxid of hydrogen or bichlorid of mercury as a spray. Of these forty-four recovered and fifteen died.

Of five cases treated with bichlorid of mercury and whisky internally and peroxid of hydrogen and lime water as a spray, four recovered and one died, or 20 per cent. mortality.

Of eighteen cases treated with antitoxin, sixteen recovered and two died, or 11.1 per cent. mortality.

In order to secure a broader field for comparison, I have obtained a report of 48 additional cases occurring in the city

between Dec. 1, 1894, and April 15, 1895, making a total of 130 cases occurring in the practice of ten physicians. An analysis of these cases gives the following result:

Total number of cases of diphtheria treated, 130.

DETAILS OF TREATMENT.

	Ages of patients.		
	Under 2 years.	Between 2 and 10.	Over 10 years.
54 treated with serum.			
Recovered	2	26	22 —50
Died	1	1	2 — 4
76 treated without serum.			
Recovered	2	15	41 —58
Died	1	9	8 —18

Average age of those treated with antitoxin, 12 years.
Average age of those treated without antitoxin, 18 years.

Cases treated:

Bacteriologically proved to be diphtheria	47
Of these, treated with antitoxin	29
" " " without "	18
Not bacteriologically determined	83
Of these, treated with serum	25
" " " without "	58

Amount of serum used to each patient varied from 12 to 113 cubic centimeters,

All the cases recovered that were treated with antitoxin before the fourth day of illness.

The foregoing statement, while statistically correct, would be to a certain extent misleading without further explanation. In all the fatal cases the antitoxin treatment was begun after several days' illness.

Case No. 1, a boy 12 years of age, had been ill six days, was profoundly septic and had diphtheritic laryngitis which later necessitated intubation. He lived two days after the first dose of antitoxin.

Case No. 2, a young lady, age 28 years, had been ill six days and had received during that time the iron treatment. Like the previous case, she was suffering from both diphtheritic laryngitis and septicemia when she received the first injection of antitoxin. She lived five days after the first dose.

Case No. 3, a child four months old, received the antitoxin on the fourth day. It died of septicemia on the evening of the third day thereafter.

Case No. 4, a child 3½ years old, suffering from diphtheritic laryngitis, received an injection of antitoxin on the fourth day after the development of croupy symptoms. Intubation was done the evening of the same day. She lived three days and died septic. This child had had sore throat with swollen glands for several days previous to the beginning of the laryngitis, but a physician was called only when suffocation was imminent.

In the opinion of the attending physicians, life was prolonged in each of the fatal cases by the use of antitoxin. The two first cases were almost in *articulo mortis* when the remedy was injected, and yet lived two and five days, respectively, and in the latter case with good prospect of recovery.

In cases not treated with antitoxin, heart failure, occurring about the time of or shortly after the disappearance of the membrane, was a frequent cause of death. In one case, death in a patient 40 years of age was due to a piece of membrane being drawn into the larynx during a violent fit of coughing. In another case a violent urticaria developed on the tenth day of illness and was followed two days later by persistent vomiting and threatened heart failure. Patient recovered.

The most frequent sequelæ in cases not treated with antitoxin, were paralytic in character. These varied in degree from slight aphonia or difficulty of deglutition to complete hemiplegia. Difficulty in locomotion, somewhat resembling the gait in ataxia, was observed in two cases. Double vision in two cases. Irregularity or intermittence of heart's action was frequent. In one case the symptoms were so alarming that the recumbent posture in bed was insisted on for a period of two months. Patient made a good recovery. Hemiplegia occurred in the case of a young lady 18 years of age, and was accompanied by aphasia. There was no loss of sensation. Motion of upper extremity is still confined, after five months, to flexion and extension of wrist and fingers and supination of forearm.

The sequelæ following antitoxin treatment were in general quite different in character, but in two instances where it was not given until after the third day, mild paralytic symptoms were developed. Urticaria was reported in seven cases and was probably present in some degree in others.

Rheumatism was reported in five cases and was in some instances quite severe for several days. Both urticaria and rheumatism also followed the use of antitoxin for immunization. Slight inflammation of the joints was reported in two cases. In no instances have abscesses followed the use of antitoxin, nor have there been other local symptoms, save mild erythema and some muscular soreness at the point of injection. Nor in a single instance have the constitutional effects of the antitoxin been such as to cause the slightest anxiety to the attending physician.

In most cases all other treatment has been omitted after the antitoxin was given, but in a few instances whisky was administered and an antiseptic spray used locally. There is no question in therapeutics upon which the local profession are more fully agreed, than upon the efficiency of antitoxin in diphtheria.

All the serum used at Ashtabula was procured of the Pasteur Institute, New York.

I regret that there is occasion to call in question many of the statements in an article entitled "A Dangerous Antitoxin," which appeared in the March number of the *Cleveland Medical Gazette*. Similar statements emanating from the same authority, have appeared from time to time in the public press. In the *Gazette* article the writer says: "Through the courtesy of Dr. A. W. Hopkins, Health Officer at Ashtabula, Ohio, I received a sample of a diphtheria antitoxin which had just been received from New York. This antitoxin was obtained from the same source as the supply which had been employed during the epidemic at Ashtabula a short time previously. Dr. Hopkins informed me that he took the sample from a freshly used bottle and then transferred it inadvertently to an empty bottle which had previously contained some of the same material."

Now, the facts are, and Dr. Hopkins authorizes the statement, that the empty bottle to which the fresh sample was transferred, had lain uncleaned in a warm room from four to six weeks. He further says that he informed the writer of the papers before their publication, of the facts and apologized to him for sending the serum under such conditions, "even to inject guinea pigs." If we recall the fact that blood serum furnishes one of the very best culture media, it will not excite surprise that an examination of other bottles kept under like conditions shows in every instance the adherent serum to have undergone putrefaction. The serum is described by the writer as "a thick slightly yellowish fluid containing a pronounced flocculent white precipitate; and it had a strong odor of camphor." Dr. Hopkins tells me that out of the whole amount of serum used in Ashtabula, about 100 bottles of 25 cubic centimeters each, in not a single instance has there been a precipitate even on keeping six or eight weeks, and in no instance have the results of a dose so long on hand been different from those of a fresh article. I think you will agree with me that the exhibition of serum obtained under such conditions that it could hardly escape infection, scarcely called for such startling head lines in the public press as the following: "Putrid Antitoxin. The Stuff used in Ashtabula. A Doctor's Discovery." Or the following: "Swarms of Bacteria. They are Found in a Sample of Antitoxin Such as Has Been Used at Ashtabula." But I will not weary you by a further discussion of the papers in question (since perhaps the author belongs to a class so pithily described by Dr. Holmes as being "always positive and sometimes inaccurate"). We are still using the same brand of antitoxin in the cases that are of frequent occurrence in the first and sixth wards.

In conclusion, I would summarize our present knowledge of diphtheria as follows:

Diphtheria is an acute specific contagious and infectious disease.

It is primarily a purely local disease, caused by an external parasite—the Klebs-Löffler bacillus.

The condition necessary for the production of the disease is the presence of the bacilli in quantity and activity sufficient to overcome the individual's power of resistance.

Diphtheria always results, either directly or indirectly, from a previous case, but unsanitary conditions have a great influence on the propagation and virulence of the disease.

As a rule, one attack confers immunity for a limited period.

The constitutional symptoms are due to the absorption of the poisonous products of the primary disease from the local lesion.

Changes occurring in the blood and tissues, and the various sequelæ, are caused by the direct or indirect action of the toxins or toxalbumins.

And finally, the discovery or rather the development of

the antitoxin treatment of diphtheria is the greatest achievement of modern therapeutics.

DISCUSSION.

DR. H. M. W. MOORE, of Columbus—Beginning with December last, I have examined for the Health Board here in Columbus some eighty-one cultures, made at the bedside with the ordinary outfit. Of these cases, thirty were diphtheria and fifty-one were something else. The system of distribution of test tubes was to leave them in drug stores, and the outfits were collected by the Health Officers as they came in, in the evening. Under the extreme poverty, this was perhaps the best plan that could be adopted. However, the Health Officer was not likely to pass a drug store or call in immediately after test tubes were left, and it was often forty-eight hours before test tubes came into my hands after they were inoculated. That period was too long, but the system was probably the best that could be adopted under the circumstances.

DR. J. S. HALDEMAN, Zanesville, Ohio—I find upon close observation and comparison, that the European and American hospitals do not differ very materially in their percentum rate of mortality. This new method has drawbacks, and great ones, which the old one has not. It has them in the manner of its manufacture, the cost attending its purchase and administration, and in not being able to furnish it in sufficient quantities, and in due time for use in city, town and country. By the old method, all places can be penetrated and all classes reached and satisfied. Now, which should we adhere to, the impracticable or the practicable? Wisdom says, the latter. Let us improve it, if possible. The mortality rate is not high in my own practice, which covers a period of about forty-one years. During that time I have practiced in several diphtheria epidemics. In the year 1878, when I was physician to the John McIntyre Children's Home, Zanesville, Ohio, there were thirty of the inmates down with it at one time, in its most malignant form. All recovered but one, and the matron thought he would have recovered if they could have made him take the medicine. This was a mortality rate of a small fraction over 3 per cent. Furthermore, I never lost but one patient in a family, and never in more than two families in the same epidemic. However, some practitioners in the same epidemics lost whole families.

DR. E. B. FULLERTON, of Columbus—I doubt very much whether we are to have in America the reported fatality of this disease in European countries, 40 to 60 per cent. I doubt whether in Columbus, Ohio, it has ever much exceeded 25 per cent. In some thirty cases there were but four deaths, that is 13½ per cent. In New York, Dr. Jacobi said the epidemic last winter, in his belief, would not, under the ordinary treatment, exceed 25 per cent. mortality. It has been claimed to be but 23 per cent. under the serum-therapy. Reasoning deductively we would take the serum as the least vitalized substance in the body, consisting principally of water and a few salts. How is the effect produced? Does it act as a poison to the microorganisms? Or, do we obtain a good result from it because it feeds the phagocytes? What has been the effect upon statistics, as to mortality, of methods of diagnosis? Have not there been introduced a larger number of cases under the same title? If we, by bacteriologic examination introduce many mild cases, we can easily reduce the percentage of deaths under any treatment. Was Henry Smith, who distributed the milk, among the cases that recovered; or, was he among the mild cases, which ordinarily would be called something else? I know when I was in Columbus even good physicians would reserve their diagnosis until they knew whether the patient would die or not. By introducing these mild cases is there not a chance for fallacy in the statistics? I have long believed the ordinary treatment of diphtheria is fallacious. What good can the tincture of iron do? We know iron is very little assimilated; it requires days, or perhaps weeks. What is the use of giving chlorate of potassium? One man has died under it, and we know that it is an irritant upon the kidneys. The tearing off of the membrane and the application of caustics is, in my opinion, faulty. I have had very little trouble with diphtheria since I have quit using these means, and have not used quinin.

DR. I. S. EBAUGH, of Akron—Because Smith did not die, but got well, after he distributed diphtheria in Ashtabula, does not argue that you must not give certain remedies. I have been passing through an epidemic of diphtheria, where the antitoxin has been used in some cases, and in some cases it has not been used. I am physician in the Children's Hospital at Akron, and am also Health Officer, and have had an opportunity to study the epidemic since the fourth day of

March. On March 21 I saw a boy with what I believed was diphtheria. Afterward I found him convalescent. Later, I found a boy who had scarlet fever. On the 28th the nurse was aroused by a peculiar cough from this boy. I was called at 5 o'clock and saw him at 6. I diagnosed diphtheria. My prognosis was unfavorable. The boy died March 30. In that hospital there were forty boys occupying a common bedroom; and sixteen girls in another common bedroom; and the children in the nursery in a common bedroom; and all eating in a common dining-room. I went to Cleveland, and Professor Ohlmacher came back with me on Saturday. We began with the antitoxin, and from the time we began using it in that hospital and in my private practice, I have not had a case of diphtheria, except two, that have not been examined bacteriologically, and there has not been a case but cleared up within twenty-four to forty-eight hours. There has not been a child, out of twenty-seven cases I have seen, but could drink from a bowl of water shortly after introducing the antitoxin, as well as any time before the attack. For instance, a colored boy, 7 years old, was seen on Friday when he was so hoarse he couldn't speak above a whisper; temperature 103.20; pulse 140. He looked like ashes. I fully anticipated he would follow the way of the white lad who didn't get any of the antitoxin. I gave him 5 ccm., and afterward 5 ccm. more, and at 4 o'clock the next day he sat up and sang with a clear voice. A German child, 7 years old, who had worn a tracheotomy tube since January 9, was seen by me on Thursday. I believe the tracheotomy was performed for polypi in her throat. When I saw her, her pulse was 140, and she had all the evidences of diphtheria. I gave 10 ccm. of the antitoxin at 4 o'clock in the afternoon. The next morning her throat was clear, and she has not taken a dose of medicine since. I saw her yesterday, sixteen days afterward, and she is well.

Dr. J. A. MURPHY, of Cincinnati—There are hardly two cases in any epidemic, or under any circumstances that are alike. Take cholera or scarlet fever, for instance. And I have heard men, years ago, stand up in Cincinnati and say they never lost a case; and lo and behold, there comes an epidemic and they lose every case they have. Now, take this disease, diphtheria. We have a mild epidemic and the diagnosis is made by the good old practitioners who from their experience are able to make a clinical diagnosis. Few cases are lost. Then comes another epidemic and about one-half the cases will be lost. The Doctor has claimed the most remarkable results within forty-eight hours, or even less. Sir, he has had a very rapid action from this antitoxin injection, which is contrary to what I have read from others and what I have been told in the city of Cincinnati.

Dr. Case has laid down a proposition that these children, or a large number of them, contracted the disease from the man who carried milk around. He has given us no results of a bacteriologic examination of that man's throat. If he had diphtheria, how would the bacilli get into the milk? Would he spit them out? (Remark: Perhaps he drank out of the dipper.) Now, our friend says, if you get a Löffler bacillus in the throat you are sure to have the diphtheria. Why, gentlemen, these bacilli are found for six weeks after the clinical manifestations of the disease are gone; and further, they are found in the normal throat. Now, there must be some little phagocyte or worm or bug, very virulent, which afterward destroys this Löffler bacillus weeks after the patient has had diphtheria, or where he has not had diphtheria. Now, if you find two or three, four, five, or six of these bacilli in the mouth, what does it mean? Should the patient have antitoxin? Will he have diphtheria? Will our friend from Akron propose to throw in 5 ccm. of the antitoxin? He says patients with Löffler bacilli in the mouth or nose are in danger. Of what? Of the toxins these bacilli make, and these toxins producing sepsis.

Now, the next point. The bacteriologist with skilled eye and a good microscope fails to find the Löffler bacillus in a good many cases of diphtheria. Such cases are diagnosed by your old-fashioned practitioners from clinical experience and observation. The gentleman who used the microscope to make a bacteriologic examination, will not deny that these are cases of true diphtheria, and yet he will stop and say, "I don't know," which is a very proper answer. Now, this is one of the conundrums. Facts often lie, but the quickest liars are figures. What has taken place in Germany? Hundreds and hundreds of people have rushed with their children to the hospitals, with mild and with malignant cases, greatly lowering the mortality. The same thing takes place without the antitoxin treatment. A hospital in New York has been mentioned. It has been said the statistics of that hospital in the last four or five weeks

have had a doubt thrown upon them. In all these cases nothing is said about the local treatment and about stimulation. Dr. Eichberg said, when I asked him directly: "By no means will I throw aside the local treatment, peroxid of hydrogen, the iron and perhaps the bichlorid of mercury." Now comes the question which Dr. Ohlmacher has stated, about the manufacture of this antitoxin. How long is it safe? Who can explain the death of the woman the other day, in a very short time after the use of the antitoxin? If Dr. Ohlmacher's statement is true, this antitoxin ought to be put in a refrigerator and not kept long, but carried to the place and used immediately. And nothing has been said as to whether these are the sequelæ or the consequences of diphtheria: pneumonia, albuminuria, bronchitis and various other conditions which have immediately followed the antitoxin treatment.

Dr. J. NORTH, Toledo—It has been said that figures lie. I believe there is a mistake in that. Figures do not lie, but figurers do lie. There has been a great deal quoted about the statistics of the past and the statistics of the present. I believe the statistics gathered during the last few months are the only ones of any value, because before then everything was reported as diphtheria, and now we know what is diphtheria and what is not diphtheria. Regarding the good results of antitoxin. Virchow, who was at first very skeptical about it, finally admitted the use of the antitoxin in his hospital in Berlin. After a time the supply of antitoxin was exhausted, while he was out of the city, and when he returned, about two weeks afterward, he found the mortality had increased to almost double what it was before; he went back to the use of the antitoxin, and the mortality went down to where it was before, when they used it. With such reports I think we can not go back on the figures. I have had no experience whatever in the use of antitoxin, because in Toledo we have had very little diphtheria since the antitoxin has come into use. But I believe in the use of it. I think the statistics justify it. Some one spoke of a woman who died from it, but for every one who dies from the antitoxin you can find a hundred graves marked diphtheria. And then, in connection with diphtheria we have the staphylococcus, which complicates the cases very much; and only recently we have an antitoxin for such cases. Where this antitoxin has been used, almost every case has recovered. Now, with the combined treatment of the diphtheritic antitoxin and the staphylococcus antitoxin, I think we will be able to save a much larger proportion of these cases. Because, statistics tell us, that where the Klebs-Löffler bacillus is found alone, we have much better results than when complicated, and if we have an antitoxin to counteract the other bacilli, we have something of very great value.

Dr. JOSEPH EICHBERG, of Cincinnati—No question can be discussed, except by those who have had experience; and they are almost unanimous in favor of the antitoxin treatment of diphtheria. It is not fair to judge of its success from its effect in cases which would certainly die under any treatment. On the other hand, we should not say that more mild cases are being cited for this plan of treatment than heretofore. Nor does it change the position because the gentlemen who have had recourse to this treatment have retained the local treatment. Even with all these measures of treatment, cases have succumbed. Nevertheless the antitoxin treatment will save many cases. Such beneficial results were cited by the gentleman from Akron. The same results have not been obtained by any other remedy. The change in the appearance of the throat in twenty-four hours is almost magical, and it would be difficult for one not familiar with the plan to believe it, if seeing were not believing. There is no stronger argument, in my mind, as to the efficacy of the treatment than the statement by Professor Virchow, of Berlin. On repeating the facts to the Pathological Society, Professor Virchow says we can not explain the action of the antitoxin on any approved therapeutic plan, but any physician is culpable who does not use it. I would like to know Dr. Murphy's way of gaining information as to the value of treatment in any disease, if not from the computation of statistics from many sources. In the epidemic at Akron, where I believe seven out of twenty-seven cases died before the introduction of the antitoxin treatment, only one case died afterward, and it had not received the treatment until some two weeks after the invasion. The longer we delay the treatment, after the appearance of local symptoms, the greater is the danger to the patient. As to its curative properties, there can be no doubt in the mind of any one who has properly employed it, though its prophylactic value has not been clearly established.

(To be continued.)

Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may be had at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 56 FIFTH AVENUE, CHICAGO, ILLINOIS.
W. H. LOWDERMILK & CO., WASHINGTON AGENT.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 56 Fifth Avenue, Chicago.

SATURDAY, JULY 27, 1895.

THE ACTION OF DIGITALIS ON THE HEART.

At the session of the Académie de Médecine held July 2, M. FRANCOIS-FRANCK reported a series of experiments in which he had studied the action of digitalis on the heart, and at the same time the effect of different digitalins.

On mammifera, administered in a therapeutic dose, digitalis produced uniform definite effects. It showed the beat of the accelerated heart; it regulated the beat of the arhythmic heart; and it greatly augmented the systolic power and the diastolic resistance.

The author held that these effects were developed equally on the two sides of the heart, contrary to the views of M. GERMAIN SEE, who thought that the action of digitalis was greater on the right heart, and contrary to the German physiologists who held that the drug's power was manifested on the left heart. In a toxic dose he found that digitalis produced first an excessive slowing of the heart movement, but a special arhythmic beat, which manifested itself by a dicrotic pulse. Afterward, the heart accelerates itself secondarily, becoming irregular; the contractions are precipitated by a sort of semi-tetanic ventricular movement interrupted by prolonged intermissions, finally causing death of the heart. In mammifera, as in cold-blooded animals, death is always produced in systole, and not in diastole, as has been affirmed.

The mechanism which produces these effects is described M. FRANCOIS-FRANCK as: 1, "the effects produced by the ventricles are not subordinate to a primary action on the auricles;" 2, "the action produced on the heart is not secondary to a primary

action on the contractile vessels of the aortic system, as the gradual ascension of aortic pressure does not produce the same effects as digitalis, as those persist even when the heart is separated from the aorta;" 3, "the abatement of velocity produced by digitalis resembles neither that which is produced by suspension of the activity of the accelerator nerves of the heart, nor those produced by excitation of the heart moderators." "It seems then," says FRANCOIS-FRANCK, "that the action of digitalis is first manifested on the cardiac muscular fiber."

In regard to digitalin, the author stated that the fatal dose of French chloroformic crystallized digitalin was 0.7 milligrams to the kilogram of animal weight. That of the amorphous digitalin is tenfold greater; and that of German digitoxin is three times less.

One gram of the infusion of the leaves of digitalis produces the same action as five or six grams of digitalin, although one can extract but one milligram of the alkaloid. "It then seems probable," says the author, "that the active principles mostly reside in the leaf."

The infusion of digitalis has been a favorite method of administration in this country, because it has long been known that the digitoxin was the most active principle of digitalis, and it was believed that there were certain principles in the leaf that were not extracted by any of the existing methods. FOUQUET¹ arranged the digitalins of commerce in two groups: 1, those insoluble in water and soluble in chloroform, *i. e.*, crystallized digitalin, amorphous digitalin and digitoxin; 2, German digitalin and digitalein.

The present paper of FRANCOIS-FRANCK will clear up some of the doubtful points in the physiologic chemistry of the action of digitalis.

THE GREATEST OF VIVISECTORS.

The late PROF. KARL LUDWIG is the subject of an earnest editorial in the London *Lancet*, based on a memoir by DR. MOSSO of Turin. The writer says that since the publication by MOLESCHOTT of his beautiful monograph on DONDERS, there has been given to the medical world no worthier *immortelle* to lay upon the tomb of a professional brother than MOSSO's tribute to LUDWIG, his great master in physiology.

The editor, having first considered the scientific achievements of LUDWIG, thus proceeds to comment upon the humane side of his character:

"But on passing from LUDWIG the experimental philosopher to LUDWIG the man and the citizen, PROFESSOR MOSSO has much to tell the world of the deepest interest. 'LUDWIG,' he says, 'the greatest of vivisectors, was President of the Leipzig Society for the Protection of Animals, and remained to the last,

¹ Bull, Gén de Thérap, Jan., 1892.

one of its most active members.' Germany owes it to him that her horses and beasts of burden are now humanely treated. To him is due that awakening of the true humanitarian spirit toward the brute creation that culminated in the 'Verband der Thierschutz-Vereine des Deutschen Reichs' (Union of German Societies for the Protection of Animals). It was mainly from her sense of the gentler attitude to be encouraged toward animals on the part of the rising generation, that Leipzig made him an honorary citizen on the fiftieth anniversary of his graduation in medicine. 'No physiologist,' continues PROFESSOR Mosso, 'has ever sought with greater frankness than he to impose just limits on vivisection. The gates of his institute were ever open to all who wished to assure themselves that he, in the midst of his experiments, knew how to spare suffering. The vivisector's art attained such perfection in his hands that, having to sacrifice an animal, he did not let it feel that it was even being tied. He would apply the muzzle and instantly proceed to the exhibition of ether or chloroform, which, in a few seconds, in a dog, for example, made it insensible. It is an error,' adds PROFESSOR Mosso wisely—'it is an error to believe that experiments can be performed on an animal which feels. The perturbation induced by pain in the functions of the organism is so profound as to render useless the experimenter's study. It was LUDWIG who uttered the celebrated *mot* that some physiologists, to study the nervous system, act like him who fires a pistol into a watch to see how the chronometer works. Suffering ought to be entirely eliminated from physiologic experiment, because the instruments we employ to-day are so delicate that they become unserviceable the moment the animal is agitated or moves.'"

The editorial of the *Lancet* closes with this eloquent peroration:

"Illustrative anecdotes without number might be multiplied to prove the real humanity of LUDWIG—of the man who was denounced on anti-vivisection platforms as the 'arch-fiend' of the 'Nine Circles,' and as the keeper of the worst 'torture den' in Europe. Well may the physiologist and the physician cry aloud, 'Humanity! what offenses are perpetrated in thy name!' PROFESSOR Mosso's masterly 'full-length' of a biologist, a teacher, and a philanthropic citizen, surpassed by none of his generation, ought to send a thrill of shame through the promoters of a mischievous propaganda which, mistaking sentimentality for sentiment, and morbid hyperesthesia for sound feeling, would have tied the hands of one of the most beneficent students of nature who ever devoted his life to the healing art."

Blank applications for membership in the ASSOCIATION at the JOURNAL office. Write for them.

DON'T NEGLECT YOUR SUMMER OUTING.

The *Medical Examiner* calls up the timely subject of the summer vacation for medical men. Our profession is quick to deal humanely with its overworked clients, as clergymen, brokers and weary housewives, and ship them off into the country or into the city, as the case may demand, but the physician is too frequently not so kind to himself. The *Examiner* calls up the case of the late DR. GOLDING-BIRD of London, who is reported as saying that he had worked himself into an early grave by economizing six weeks in the summer.

"The physician needs more active exercise and more sleep, too—fully seven hours—and as his sleep is often broken in upon at night, he should form the habit of sleeping at odd moments, even by day. The folly of incessant work is illustrated by the case of the brilliant DR. GOLDING-BIRD, who, a few months before his death, remarked to a medical friend, when his own great popularity was mentioned: 'You see me, at a little over 40, in full practice, making my several thousand pounds per annum. But I am to-day a wreck. I have a fatal disease of the heart, the result of anxiety and hard work. I can not live many months, and my parting advice to you is this: never mind at what loss, take your annual six weeks' holiday. It may delay your success, but it will insure its development. Otherwise you may find yourself at my age a prosperous practitioner, but a dying old man.'"

THE ANNUAL RECKONING.

The ASSOCIATION Treasurer announces that he is ready to send receipts for the annual subscriptions of members, who have not yet paid their yearly dues. The month of July should see the Treasurer's books well settled, but we understand that there are very many delinquents. The JOURNAL has been larger and better than ever before, and there is no valid reason why the annual dues should not be paid promptly. On the contrary, with the very material reduction of the advertising which is now taking place there is every reason why prompt payment should be made.

In response to certain statements made in the columns of some of our esteemed contemporaries, we think proper to inform them that immediately after the Baltimore meeting letters were addressed to every firm advertising medicinal preparations in the JOURNAL, informing them of the action of the ASSOCIATION, and requesting the publication of the formula. Several of them have responded by sending the name and amount of each ingredient in the compound, according to the letter of the ASSOCIATION resolution, some have asked for time to consult absent managers, and some have refused. Of the latter number one contract expired last week and has been

discontinued. Another expires this week, and the remainder will be dropped as fast as their contracts expire. There need be no apprehension that the ASSOCIATION instructions in the matter of advertising will be forgotten or passed over without action.

We once more take advantage of the occasion to urge upon the members the absolute necessity of strenuous efforts to increase the membership of the ASSOCIATION, not only to prevent regression, but to add more and more to the ever growing list. We very much wish to pass the 6,000 mark within the next three months. We are now issuing 5,700 copies every week, but as there are more than 100,000 physicians in the United States it is readily seen that the ASSOCIATION JOURNAL reaches comparatively few of them. In England no physician considers that he is in good standing unless he belongs to the British Medical Association. A similar *esprit du corps* in America would give us a membership of 60,000 at the very least. With such an organization there could be no question of the immense influence that might be wielded by the medical profession in America.

We have made gradual and steady increase for the last three years, but we must do more. Let us once more make a united effort to gather into the grand old ASSOCIATION every eligible medical brother in the United States of America. The doors are always open for the entrance of good men and they will be warmly welcomed by every man having the interest of the ASSOCIATION and of his profession at heart.

AN EXPIRING CRAZE.

The efforts made to bolster up the expiring KEELEY cure by special legislation last winter were in some few cases successful, to the extent of the passage of acts in its favor. As a sequel we have in a neighboring State a county resisting payment of bills of a gold cure establishment for the treatment of pauper drunkards, and it is probable that the constitutionality of at least one of these measures will be fairly tested in the courts. That a special proprietary secret method of treatment should be the recipient of State support, that the public funds should be drawn upon to pay for what is absolutely unknown, and is purposely kept so, lest its use should become extended, to the damage of its proprietor, or as one might naturally suspect, because it is feared that enlightenment as to its nature would damage public confidence in its virtue, seems a poor public policy, to say the least. Looking at it entirely from an extra-medical point of view, this would be the natural conclusion, and nothing but the most overwhelming evidence of its value, it would seem, ought to lead any one to support it. With the legal possibilities in the case we have nothing to do, but it would appear not at all improbable that a higher court

might find flaws in such legislation on constitutional grounds.

One of the most interesting features of the subject, however, is the zeal of the believers in the gold cure for its extension and continuance. Like the female homeopathic devotee, they make it a sort of a *cult*, and would apparently sacrifice anything for its propagation. Of course, this would be naturally encouraged by the management of the cures, but it is in its way a psychological phenomenon of interest. One noteworthy feature is that the enthusiasm is sometimes most marked in striking instances of the non-success of the treatment, as in the case of the late FELIX OLDBOY.

The non-success is revealing itself at the present time in various quarters and is becoming apparent to the laity as well as to the regular medical profession. The painstaking investigation of the REV. DR. BUCKLEY, though to some extent affected by the fact that some of the data obtained by him were evidently from strong partisans of the gold cure, only led him to the conclusion that there was nothing in it more efficacious for the drunkard than is found in the numerous temperance revivals which make no pretenses to secrecy, and which claim to act only through mental influence and the exercise of the will of the subject. DR. BUCKLEY'S study has a decided value as that of a conscientious investigator, who could not possibly be charged with any professional prejudice against the so-called cure, and yet who was compelled to reject its claims in spite of labored evidence in its favor.

As regards medical evidences of its failures, one may say that they are coming to be in the experience of every practicing physician. Out of fifty-eight patients treated in 1894 at DR. CROTHERS' inebriate asylum, at Hartford, twenty-six were KEELEY graduates and eleven more had been under other so-called gold cure treatment.

While we may consider inebriety, or perhaps we should say habitual drunkenness, in some cases and to some extent, a disease or the result of defective organization, the most natural conclusion one can deduce from the success of the gold cure craze, is that its successful treatment is more dependent upon moral and mental influence than upon medication. It is to this undoubtedly that should be credited all the permanent cures that date from the KEELEY treatment.

THE JOURNAL ITSELF.

An old and valued member of the ASSOCIATION, whose opinion is greatly esteemed by the editor, was emphatic in his statement that the JOURNAL of last week was the finest number ever produced by the office. The constant effort is that every number shall be better than its predecessors, and sometimes we think we have fairly succeeded. But what our friend

most commended was the plate in three colors printed in the JOURNAL office. He has a set of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION from the beginning, bound in uniform binding, and he said further that he was additionally proud of the JOURNAL now, because he as member of the ASSOCIATION is part owner of the great American medical weekly and its plant.

He should, he said, take an additional interest in the ASSOCIATION, and could see what had for years been foretold, had now come to pass, that the ASSOCIATION JOURNAL was second to none in America. This patriotic spirit now glowing brightly in the breasts of the American medical profession will bring organization, strength and power to our noble army of medical toilers, and a great reward. Let us redouble our efforts to increase the membership, by every honorable means, that we may not only become the greatest Association in the world in members, but first in quality of work done, and first in amount of knowledge promulgated for the welfare of humanity.

NEW INSTRUMENTS.

COMPACT POCKET CASE.

The attempt to make the smallest pocket case, on modern lines, has resulted, with the aid of Truax, Greene & Co., in a case as represented in the accompanying sketch.

The new instruments in the case are the angle tenotome, and the short aluminum probe.

The cutting edge of the tenotome being on the inside of the angle, is very advantageous in dividing all tendons, but especially the smaller and deeper seated ones. The case is of metal, and the instruments small and delicate. The racks and partitions are movable, but the whole case can be boiled *in situ* without injury. JOHN B. HAMILTON.

CORRESPONDENCE.

The Woodbridge Treatment of Typhoid Fever.

TOLEDO, OHIO, July 14, 1895.

To the Editor:—One extremely warm day I found upstairs in a one and a half story house a poorly nourished young unmarried woman, with a temperature of 105 degrees. The temperature of the air in the room was unbearable to me. I

had her removed to a room on the ground floor, and thought her trouble due to the intolerable heat to which she had been exposed almost constantly for several days. She soon became delirious which was followed in a few hours by a comatose condition which lasted three days.

The conditions surrounding the patient and the unusually rapid overpowering of the nervous system so masked the real disease that neither the physician who saw her in consultation nor myself diagnosed typhoid fever until the unconsciousness had passed away. Four other persons, two in the same house, and two in the house adjoining were taken sick at about the same time as my patient had been. These cases were diagnosed by their physicians as typhoid fever. One of them died in one week, and all of the others within two weeks from the time of taking sick. The disease in those cases was said to have been exceedingly virulent in character. My patient was removed to the suburbs, when all the conditions were favorable to the treatment of the disease. Of the few cases of typhoid fever which I had treated prior to that time none had died, and I felt comfortably confident that this patient would recover under what may be called the sulpho carbolate of zinc treatment. To my disappointment, however, she continued to grow worse until at the end of the second week of her sickness she was in the following condition:

Temperature 105 degrees, pulse 130, respiration 38. She was entirely unconscious, bowels moving unconsciously in bed. Urine drawn with catheter, tympanites very great, vomiting persistent and stercoraceous, hiccough present the great part of the time. An abscess had formed in external ear and had broken, without causing her to manifest pain. Bed sore over sacrum. Skin cold and clammy, but she would swallow liquids.

I regarded her case as being in the nature of a forlorn hope, but I ordered guaiacol m. v. rubbed over the distended abdomen every two hours, and ordered to be given by the mouth in emulsion, every fifteen minutes:

R. Hyd. chlor. mitis gr. 1-16
Menthol gr. 1-16
Guaiacol carbonate. gr. 4-16
Thymol gr. 5-16
Eucalyptol gr. 1-16.

I considered the patient's condition so desperate that I did not expect her to take many doses of the prescription.

After a few doses the vomiting and hiccough stopped, temperature fell, consciousness began to return, and in twenty-four hours the case presented an entirely different appearance. I dropped the calomel from the prescription after four or five hours, again introducing it after a day's rest. I tried giving larger doses of the other medicines at longer intervals, but the stomach did not bear the medicines given in that way so well. In a week the patient was sitting up and at the end of another week went to her home out of the city. She is now at work, and well.

I do not believe in ready-made prescriptions, but I most heartily concur in the opinion of my consultant who said "that it was a very creditable recovery." I do not care whether the credit is given me, or the prescription of Dr. Woodbridge, or whether it is said that the patient "must have had a strong constitution." I think it likely that a little more eucalyptol and a little less guaiacol would have done as well as the exact formula given by the Doctor, but I am sure that I did not attend to the details of treatment more faithfully while giving the second prescription than I had done while giving the zinc. I am equally sure that I did not stop the zinc until I was thoroughly convinced that the patient would die under that treatment. "Speak well of a bridge, etc." In the above case, I think the principle underlying Dr. Woodbridge's plan of treatment was such a bridge.

J. L. TRACY, M.D.

The Country Doctor.

EATON, ILL., July 18, 1895.

To the Editor:—In view of the restlessness that sometimes exists among country doctors, and their desire to remove to the cities; and in view of what has been said recently in the *JOURNAL* in regard to the city doctor, post-graduate schools and teachers, I desire to say a few words about the country doctor and his environments. In the first place, his field of operation is small and the possibility of his becoming famous is almost *nil*; but his usefulness in his locality is incalculable, and his living sure. He may not become rich in the common acceptation of the term, but he is generally—almost invariably in fact—in comparatively good circumstances. He is also an important member of society and his advice is sought for and generally appreciated, on all questions of general importance, or of public interest. He is the protector of the health of his community, and is always ready, and generally successful in preventing the spread of contagious diseases.

In times of epidemics his work is arduous, and he has many sleepless nights and weary days, yet he is usually cheerful, spreading sunshine among his patients wherever he goes, and is amply rewarded by the gladsome and appreciative smiles of his many patients and their friends.

He has no time for the blues and gives but little thought to the wolf which he knows full well is not at all liable to come to his door. His responsibilities are great, and none realize their weight more than he; but his almost superhuman efforts as a student of medicine and everything that pertains to his professional career and the welfare of his patients, gives him an assurance that he is doing all that any mortal, with like ability, and under similar circumstances could do, hence he has a clear conscience, is able to enjoy his three meals a day, and sleep well when he gets a chance.

He takes a post-graduate course occasionally, for he realizes that if he would keep in the front ranks he must avail himself of every opportunity for acquiring knowledge, and he knows full well that an occasional visit to a medical center will enlarge his knowledge in many ways, beside furnishing an opportunity to familiarize himself with the most recent methods of treating disease, and enable him to treat many difficult cases which would wend their way to the city, but for the fact that they realize that the progressive home physician can treat them quite as successfully and with much less inconvenience to themselves. The country doctor will never treat all the difficult cases he meets with; but because of his superior knowledge and his realization of the difficulties to be encountered in many hazardous operations, he will send his patient to a medical center where he may receive the benefit of that wide experience which can only be acquired in a populous community.

I believe as a general practitioner the country doctor is the peer of his city brother, but as a specialist he is not; he is nevertheless a wonderful specialist when we consider the innumerable lines of his work. He is a broad-minded and generally a well-posted man, not only in a professional way but in literature, science, art, and even in politics he is not always a novice. He is, in his community, an important factor; he is the common adviser of his clientele, the one man—if such there be—who knows it all; the Great Mogul, the one indispensable entity, who is appreciated and remunerated beyond his fellows, and should be the best contented man on earth, and the one man who, when he ends his earthly labors, should be entitled to an upper seat in the doctors' paradise in the great beyond.

Truly yours, C. BARLOW, M.D.

The City Doctor.

NEW YORK, July 23, 1895.

To the Editor:—What you wrote recently about the large polyclinics is true. The urban physician has usually a large hustle to keep things going. The subject of hospitals cutting off thousands of dollars of legitimate practice ought to

be more earnestly aired. In this, I am not a sinner for I do no hospital work. I once had charge of a small dispensary of the Medical Missionary Society, and while the work was among the very poor, some frauds would creep in.

Dr. David Webster, the associate of the late Dr. C. R. Agnew, once told me that he would rather examine a case in his office for a dollar, than for nothing in the dispensary. So having sent him cases that have paid his usual fee for examination, \$10, I have also sent him the dollar ones.

The profession has deliberately prostituted itself into a great machine for producing fraud by its immense hospital work. The real poor should be treated by the State, and the medical aid should be rendered by a system of State service similar to the Army, Navy and Marine-Hospital bodies.

Yours respectfully, JOHN A. CUTTER, M.D.

Sublimate Poisoning.

PHILADELPHIA, July 22, 1895.

To the Editor:—Under Philadelphia Notes in your issue of July 20, you record a case of recovery from 15 grains corrosive sublimate.

Some five or six years ago one of my patients, a young married woman, in a fit of jealousy, swallowed two tablets of corrosive sublimate, grs. 7.7 each, with suicidal intent. Fortunately I was promptly called, was in the house within twenty minutes, and by the use of emetics followed by egg albumen, succeeded in saving the patient.

There was no salivation, but a subacute gastritis lasting about ten days resulted.

Respectfully yours, E. W. HOLMES, M.D.

PUBLIC HEALTH.

State Board of Health of Pennsylvania.—At an annual meeting of this Board, held July 11, at Marietta, Dr. S. T. Davis, of Lancaster, who for three years has been the President of the Board, was succeeded by Dr. Pemberton Dudley, of Philadelphia.

Women Medical Inspectors.—Three women doctors have been appointed in the summer corps of medical inspectors by the New York City Board of Health. All of them are spinsters: Miss Mitchell, M.D., Miss Deane, M.D., and Miss Weiss, M.D. The other doctors of the body offered no objection to the selection of these three inspectors, all of whom are said to be fully qualified to perform the duties of their office. Their salary is \$100 a month, and the *Sun* has no doubt they will earn it by faithful service.

Water Supply of Cleveland.—The Ohio State Board of Health has refused the petition of the city of Cleveland to be allowed to discharge sewage from a new district into Lake Erie near the intake of the city water supply. Mr. Allen Hazen of Boston was employed by the Board as consulting engineer. Investigation showed that the water supply is already polluted and statistics revealed that the typhoid death rate for the past seven years has been higher in Cleveland than in any other large city of the State. Plans for extending the intake into the lake are under consideration; but Secretary Probst is of opinion that, while this may afford a temporary remedy, all the lake cities will eventually be compelled to resort to filtration for the purification of their water supplies. A better way would seem to be to prevent pollution by a proper disposal of sewage.

Board of Health of New York State.—Dr. Florence O'Donohue's term of office as a member of the State Board of Health ceased, and Governor Morton appointed Dr. Frederick W. Smith, of Syracuse as his successor. Dr. Smith is an alumnus of the New York University, in 1880. The Board

of Health appointed Dr. O'Donohue a short time ago a member of a committee to carry out the provisions of the Public Health law relating to tuberculosis in cattle. In the appointment of Dr. O'Donohue's successor it was understood in the Executive Chamber that Dr. O'Donohue would continue as tuberculosis commissioner at a salary of \$250 a month and necessary expenses. Both of these physicians reside at Syracuse. Dr. Smith has not any great amount of sanitary achievement to his credit thus far, but he is spoken of as an energetic and alert man.

Anti-Tetanic Serum.—Professor Vaillard is very sanguine that the preventive use of the serum of animals rendered immune against tetanus is likely to prove of signal service in the tropical regions where tetanus is so common after slight wounds as to be one of the most frequent causes of death. He also predicts a wide field of usefulness for the serum in preventing tetanus among new-born infants in some countries of Northern Europe, where trismus sometimes carries off 60 per cent.; also in military surgery and, generally, in the restricted area in which the specific bacillus of tetanus is indigenous; and, finally, in veterinary surgery where tetanus often follows wounds of the feet or castration. It is in the preventive field that it is most valuable; as a curative agent it is effective only in the rare cases in which the poison acts slowly; applied in the treatment of man or animals stricken with acute tetanus it is of no more avail than other remedies.

Diplomas for Disinfectors.—The government of the Grand Duchy of Mecklenburg-Schwerin by a decree dated May 29 has decided to grant a diploma for "Disinfectors of Apartments." The candidates will have to undergo a special examination before a medical commission at Rostock, and only those who pass will be allowed to call themselves "Licensed Disinfectors of Houses." They will have to swear always to faithfully observe the rules for disinfection and to execute carefully and conscientiously all sanitary works confided to them. In the exercise of their duties they will be placed under the surveillance of the Rector-Physikus and the local police.¹

Comparative Marriage and Birth Rates of Europe.—M. Cherrin has collected the following statistics concerning the percentages of marriages and births in the principal countries of Europe.² In 1,000 inhabitants of both sexes over 15 years of age the following percentages are married: Hungary, 91.6; Germany, 53.0 England and Wales, 52.6; Denmark, 52; Austria, 51.3; Italy, 50.1; Finland, 49.2; Holland, 49.0; France, 48.8; Belgium, 41.9; Greece, 41.6; Scotland, 40.9; Switzerland, 40.8; Ireland, 23.0. But the number of marriages is only one of the elements in the problem of increased population. The important thing is the fecundity of these unions. The following table shows this:

	Legitimate live births for 1,000 women (married) 15 to 50 years of age.	Illegitimate live births for 1,000 unmarried women 15 to 50 years of age.
Germany	270	26.5
Scotland	269	19.9
Belgium	265	19.8
Italy	251	24.6
England and Wales	250	12.1
Austria	250	44.4
Sweden	240	
Ireland	240	4.1
Switzerland	236	10.2
France	163	16.7

street cleaning under Mayor Strong, the *New York Medical Journal* indulges in the following remarks, which have a special pertinence to another large American city, where not only clean streets but some other problems of sanitary administration are just now attracting an unusual amount of attention: "It is the duty of the medical profession to take an active part in furthering all plans calculated to improve the public health, and we feel justified in directing attention to the sanitary importance of clean streets, and in asking members of the profession at large to do all in their power to aid the city authorities in their good work. The power of the profession to influence public opinion is enormous, and the power of public opinion to help or hurt public officers in their work is still greater. Public opinion is really the one irresistible force in our government. Backed by it, an officer can do almost anything; opposed by it, he can do nothing; while if it is indifferent in regard to some course decided upon by an officer, he may succeed in doing much, but his success will depend entirely upon his personal ability to work under a heavy strain."

A Typhoid Fever Panic.—The *Medical Press and Circular*, June 5, relates an incident of fever prevalence, in an isolated part of the western Highlands of Scotland, which created a decided panic. The following is a part of the narrative in the *Press*:

"A curious incident has lately been reported from Mingalay, a remote island off the northwest of Scotland. It is given on the authority of Dr. Ogilvie Grant, medical officer for Inverness-shire, to which county the island in question is attached for administrative purposes. Some time since a girl brought back the infection of enteric fever to Mingalay. After a while the rest of her family, six in number, contracted the disease. In the meantime a panic seized the neighbors, who one and all deserted the place. The father was then attacked and died, but no one would help to bury him. A priest, however, at length came to the rescue, put the body in a coffin and dragged it out of the house to a distance of ten yards. A similar scene occurred two days later upon the death of the mother. It appears that the district is too poor to pay for proper medical attendance for the poor. But surely, if a medical officer of health be provided, it should be possible to furnish a small staff to cope with the emergencies that are bound to arise from time to time in connection with infectious fevers."

Neglect of Vaccination in North Carolina.—The *Bulletin* of the North Carolina State Board of Health, for June, contains liberal selections from an address, on sanitary progress in that State, delivered by President Tucker at the recent meeting of the State Medical Society. The medical officers of both State Board and State Society note with regret a too general apathy in respect of the prevention of smallpox by the use of vaccination. Dr. Richard H. Lewis of Raleigh, Secretary of the State Board, has given much attention to the subject without being able to effect a change for the better. The remarks of Dr. Tucker on this subject were, in part, as follows:

"Let us for a moment consider the question of vaccination. For many years past the worthy Secretary of the Board of Health has reported to this Society an increased indifference on the part of the profession and the people to this great preventive measure, and in a recent session he announced from the floor of this Society that, in his belief, nothing short of a visitation of an epidemic of this dread disease, smallpox, in our borders will arouse the people to the sense of their danger and impress upon them the necessity for vaccination. We have no statistical data upon which to base an opinion, but a conservative estimate would leave more than half of our people, ages and classes considered, without the benefit of this great prophylaxis, and when we consider the increasing number of epidemics of smallpox occurring in the more populous Eastern States, the increased facilities for travel and the changed habits of our people with regard to travel, many thousands going and returning from the great centers of population, thereby subjecting themselves to the danger of contracting a disease which, once set on foot in our State, will grow into a conflagration

Sanitary Importance of Clean Streets.—Commenting upon the action of the New York City Board of Estimate and Apportionment, in authorizing an issue of bonds sufficient to meet the greatly increased expense of the more efficient

¹ La Semaine Medicale, No. 32, 1895.

² Les Nouveaux Remedes, No. 12, 1895.

more appalling, if possible, and more difficult of suppression than a prairie fire in mid-summer, we may well counsel together about matters of prevention. In the sparsely populated condition of our State it would be impracticable to enforce compulsory vaccination, the law would be cumbrous, expensive and difficult of execution; but we can and should secure the enactment of a law making it compulsory in our public schools; indeed, we might go a step farther, and make a certificate of vaccination a pre-requisite to entrance in any school whose doors are opened for public patronage, and we, as physicians, who are charged with the sacred duty of maintaining the health and promoting the well-being of the people, should resort more frequently to vaccination in our own private practice, remembering that the best 'starting point' is at the physician's own household; through these combined agencies, in a few years, we may hope to have the larger portion of our people brought under the influence of this great prophylactic measure, and thus aid our Board in the accomplishment of a work which has occasioned so much anxiety."

Mismanagement of New York's Water Supply.—New York is not the only city that has been called upon to suffer from corrupt trickery. It has recently come to light that a false scarcity of water has been purposely produced in order to favor the designs of contractors and their friends. The *Independent* refers to this trickery in its issue for July 11. It says:

"We have all been getting gradually wonted to this scanty supply, after the characteristically American way we have of submitting to, as inevitable, abominations which could be thrown off were we not too easy-going and unorganized. The trouble has been generally attributed to insufficient supply at the sources, which we have been induced to believe have been outpaced by the growth of population. But as one of the results of the uprising of last November there comes now the astonishing discovery that the trouble is of the opposite character, to-wit, closed gates, the conclusion from which is that although the Croton sources may not be so ample as desirable, it is uncertain whether they are not adequate to present needs, under a free flow, because that flow does not exist. How many gates are closed and virtually abandoned seems to be a matter of slow discovery and, at present, of conjecture, but some estimate the number as high as a thousand. Opinion is divided as to the cause. Some think the chief cause the neglect of employes to reopen gates which have been closed for convenience while working near them; others, that the mischief has been done in course of a deliberate plan to force the taxpayers to consent to construction of new aqueducts, which would mean large opportunity for stealings. However, the closed gates are ligatures, and the flow is suffering under stricture. How many gates are in this condition and how many are rusted out and spoiled, nobody appears to know. The narrative tells us that there is no trustworthy map anywhere by which to find either the location or the number of gates, and apparently the only way to find out is to search for them. When we reflect that New York underground, like New York aboveground, has developed without any consistent plan, and when we remember that its municipal operations have for many years been devoid of system and responsibility, managed only by jobbery and plunder, it is not hard to understand how this condition came about or to believe that it may be even worse than is suggested. Naturally, the underwriters are aroused after having long been uneasy. Our great fire has not come, but the concentration of values down-town is enormous, and only the requisite conditions are awaited. A great fire makes its own wind. The old suggestion of a supply comes from the inexhaustible bay comes up again. In connection with it the scheme, also old, for a system of roof pipes in the mercantile district is appropriate. Salt water is suitable for many purposes, and the cost of stand pipes and pumping will probably compare favorably with that of new aqueducts."

Health Reports.—The following health reports have been received by the Supervising Surgeon-General, Marine-Hospital Service:

SMALLPOX—FOREIGN.

Russia: Batoum, June 25 to July 2, 4 cases, 1 death; Moscow, June 22 to 29, 1 case; Odessa, June 22 to 29, 8 cases; St. Petersburg, June 15 to 22, 4 cases, 2 deaths.

Hungary: Buda-Pesth, June 17 to July 1, 7 cases and 2 deaths.

Holland: Rotterdam, June 30 to July 6, 6 cases.

Egypt: Cairo, June 10 to 17, 2 deaths.
 England: London, June 30 to July 6, 42 cases, 3 deaths;
 Manchester, June 22 to 29, 2 cases.
 India: Calcutta, June 1 to 3, 27 deaths.
 Ireland: Dublin, June 30 to July 6, 11 cases.
 Gibraltar: June 23 to 30, 1 case.
 China: Hong Kong, June 1 to 3, 1 death.
 Brazil: Rio de Janeiro, June 15 to 22, 21 deaths.
 Germany: Prague, June 22 to 29, 4 cases.
 Mexico: Nogales, June 30 to July 13, 12 cases.
 Scotland: Glasgow, June 30 to July 6, 1 death.
 Uruguay: Montevideo, June 8 to 15, 1 case.

SMALLPOX—UNITED STATES.

Louisiana: New Orleans, June 18 to 22, 7 deaths; July 6 to 13, 4 cases, 2 deaths.

Michigan: Smallpox reported, 13 at Battle Creek, Detroit and Olivet.

Missouri: St. Louis, July 6 to 13, 6 cases.

CHOLERA—FOREIGN.

India: Calcutta, June 1 to 3, 16 deaths.
 Japan: Hiogo, June 13 to 22, 39 cases, 26 deaths.
 Turkey in Asia: Adana, May 25 to June 1, 50 cases, 30 deaths; June 1 to 15, 550 cases, 300 deaths; Mersyna, May 28 to June 1, 3 cases, 1 death; June 1 to 15, 2 cases, 2 deaths; Tarsus, May 18 to June 1, 470 cases, 315 deaths; June 1 to 15, 750 cases, 530 deaths.

YELLOW FEVER—FOREIGN.

Brazil: Rio de Janeiro, June 15 to 22, 12 deaths.
 Cuba: Cienfuegos, July 7 to 14, 3 cases, 1 death.
 Mexico: Vera Cruz, July 4 to 11, 3 deaths.

CONSULATE GENERAL OF THE UNITED STATES OF AMERICA.
 RIO DE JANEIRO, June 25, 1895.

Sir:—I have the honor to remit report for week ended June 25, 1895:

There were 9 deaths from *accessio pernicioso*, a decrease of 3; 12 from yellow fever, a decrease of 4; 21 from smallpox, an increase of 12; 3 from enteric fever, a decrease of 2, and 1 from measles. From all causes there were 345 deaths, an increase of 29 over the foregoing week.

Cholera.—I think we may safely leave this disease out of account, as it appears to have entirely disappeared from the city; not even are the cases of diarrhea and enteritis any longer called cholericiform.

Yellow Fever.—This disease is declining gradually as it always does at this season of the year, and causes no alarm at present.

Smallpox.—This disease is slowly increasing as the winter advances. I have heard of no cases among the shipping, though I would advise additional caution and warn the shipmasters I see to protect their crews by vaccination. Good lymph can be obtained here from the Municipal Institution. On the whole, the health of the port may be considered good, the higher mortality being due to diseases of the air passages which are prevalent always during the fall and winter months.

Respectfully yours,
 R. CLEARY, M.D.,
 Sanitary Inspector, M.-H. S.
 NOGALES, ARIZ., July 15, 1895.

Dear Sir:—I have the honor to report one new case of smallpox in Nogales, Ariz., and three new cases in Nogales, Mexico.

I have received what I believe reliable information that yellow fever is prevalent in the following cities, viz.: Sonsonate and Santa Ana, Salvador; Champerico, Guatemala; Tapachula and Ocus, State of Chiapas, Mexico. All these cities being on the Pacific Coast, passengers pass through here from there via Guaymas frequently, and from them I have received this intelligence.

Very respectfully,
 W. F. CHENOWETH,
 Sanitary Inspector, M.-H. S.

NECROLOGY.

JACOB P. COWAN, M.D., of Ashland, Ohio, died July 8, aged 72 years. He was a graduate from the Starling Medical College in 1855. He had been prominent in political affairs in his section, having served as a member of the Ohio Legislature about forty years ago. He was also an ex-member of Congress from the Fourteenth District of his State.

EZRA GRAVES, M.D., of Amsterdam, New York, died July 1, aged 56 years. He was a graduate of the Medical Department of Buffalo University, in the year 1865. He was coro-

ner of Montgomery County for several years, beginning in 1880, and the city physician of Amsterdam in 1894. He was Secretary of the Northern Branch of the New York State Medical Association.

STEPHEN E. FULLER, M.D.—The following resolution was adopted by the Kings County Medical Association at its regular meeting June 11, 1895:

WHEREAS, Dr. Stephen Edward Fuller, an old and highly esteemed member of this Association, has been removed from our membership by death;

Resolved, That this Association, while bowing to the inevitable and mourning its own great loss, tender to the widow and family our sincere and heartfelt sympathy in their affliction.

Geo. A. OSTRANDER, M.D., } Committee.
Thos. M. ROCHESTER, M.D., }

PROF. FRANZ VON RIED, at Jena, Germany, aged 85. He was professor of surgery in the University of Jena from 1846 to 1884, when he retired.

JAMES CALEB JACKSON, M.D., who, nearly forty years ago, founded the Jackson Sanitarium, at Dansville, N. Y., died in New York City, July 11, in his eighty-fifth year. He was formerly an editor of the *Liberty Press*, of Utica, and was a co-worker with Gerrit Smith, Garrison and other antislavery leaders. He was primarily a water curist and vegetarian, but in later years he was less of an extremist.

WILLIAM S. HOUSINGER, M.D., of Chazy, N. Y., July 15, aged 74.—G. M. Thompson, M.D., of Boston, Mass., July 13, aged 82.—George H. Saltsman, M.D., Alliance, Ohio, July 12, aged 76.—George K. Smith, M.D., of New York, July 15, aged 67.—A. W. Crawford, M.D., of Emlenton, Pa., July 14, aged 81.—Edward Loomis, M.D., of Dodgeville, N. Y., July 7, aged 89.—G. W. Griggs, M.D., of Evant, Texas, July 20, aged 76.—J. W. Morris, M.D., of Leavenworth, Kan., July 20, aged 73.—J. W. Christopher, M.D., of Texarkana, July 17, aged 70.—S. R. Mitchell, M. D., of Hampton, Iowa, July 8, aged 69.—N. S. Halterman, M. D., of Glenwood, Minn., July 18.—James C. Jackson, M.D., of Le Roy, N. Y., July 10, aged 84.—L. D. Putnam, M. D., of Grand Rapids, Mich., July 22, aged 72.

BOOK NOTICES.

System of Surgery. Edited by FREDERICK S. DENNIS, M.D., Professor of the Principles and Practice of Surgery Bellevue Hospital Medical College, etc., etc., assisted by JOHN S. BILLINGS, M.D., LL.D., Deputy Surgeon-General U. S. A. Vol. II. Profusely illustrated. Cl., 8vo., pp. 918. Philadelphia; Lea Brothers & Co. 1895.

We have already recorded our favorable opinion of this excellent system, as set forth in the first volume, and we are pleased to notice that the second volume fully merits the warm praise given the first.

The contributors to this volume are Dr. Frederick S. Dennis, W. H. Forwood, George R. Fowler, Frederick H. Gerrish, Virgil P. Gibney, William W. Keen, Roswell Park, John B. Roberts, Nicholas Senn, Lewis A. Stimpson and Henry R. Wharton.

The topics discussed in the volume are Minor, Plastic and Military Surgery, Diseases of the Bones, Orthopedic Surgery, Aneurysm, Surgery of the Arteries, Veins and Lymphatics, Diseases and Injuries of the Head, Surgery of the Spine, and Surgery of the Nerves. The "System" so far as it has progressed, is a credit to American surgery.

Early Scoliosis or Curable Curvatures of the Spine. By PERCY G. LEWIS, M.D., M.R.C.S., etc. etc. 16 mo., pp. 49. Price 2s 6d. London: John Bale & Sons. 1895.

This little book is the result of the author's study of the cases which came under his notice at the Victoria Hospital, St. Andrews' Convalescent Hospital and in private practice. One of the principal points made by the author is on the effect of the twisting of the spine owing to weakness or atrophy of

certain muscles, and as the muscles are weak, he considers that "the practice of gymnastics properly carried out, is the natural cure of scoliosis." The illustrations showing the method of applying gymnastic exercises are well executed and instructive. Every practical orthopedist will agree that there are many cases of early scoliosis that may be cured by gymnastic training.

The Amateur Sportsman. New York: Published by M. T. Richardson Co.

The July number of this publication contains a great amount of interesting matter relating to all phases of sport. The disciples of Izaak Walton and the Nimrods of the medical profession will take pleasure in the perusal of its pages.

MISCELLANY.

Disinfection of Tubercle-infected Houses.—Delepine and Ransome (*British Medical Journal*, Feb. 16, 1895) reported that the disinfection of apartments contaminated by the tuberculous could not be accomplished by the usual means of fumigation. Sulphurous acid is insufficient. The only efficacious method according to these authors is the application of a solution of chlorinated lime on the walls of the chambers. Sublimite has not proved efficacious. Exposure to sunlight is an important factor, and wherever possible the sunlight should be freely admitted for some weeks.

"The Medical Corpse of the Navy."—An odd misprinting of a paragraph in one of our most serious cotemporaries makes it perpetrate a sly dig at the medical branch of the United States Navy. The paragraph is:

"A number of deaths and retirements have made twelve vacancies in the medical *corpse* of the Navy, and the singular fact that these places are difficult to fill still exists."

Although the Naval surgeon's position does not compare favorably, in the minds of our profession, with that of the Army or Marine-Hospital surgeon, it must be said that the "corpse" is a lively one.

A New Biographical Sketch.—Oliver W. Nixon, M.D., is the author of a book entitled "How Marcus Whitman Saved Oregon," from the press of the Star Publishing Company of Chicago. A review of the book has appeared in the *New York Herald*, written in enthusiastic terms by Rev. George Hepworth. He says: "It is refreshing, like a southeast wind in August. It is stimulating, like some newly discovered tonic. I even went so far as to forget all about Whitman himself, in the interest of whose memory it is written, and gave myself with delight to the pictures of life on the plains and the devil-may-care ventures and adventures of the rugged fellows who can not live anywhere near the borders of civilization. When I finished this volume I felt as though a sort of blizzard had blown through me, and, I assure you, it was not an unpleasant sensation. The West is getting tame, but in the '40s, oh, in the '40s it was worth visiting. And this volume carries you back to those old times, with many a racy incident and many a deed of prowess. I have spent some pleasant hours with it."

Electricity in the Treatment of the Vomiting of Pregnancy.—Larat and Gautier, *Revue de Thérap. Méd. Chirurgicale*, VIII, p. 242, 1895, recommend galvanic electrization as the best remedy in the vomiting of pregnancy. The method is important; the positive pole should be applied under the clavicle between the insertion of the two tendons of the sterno-cleido-mastoid muscle; this positive electrode should be about the size of a silver half dollar, covered with a piece of wet chamois skin. The negative electrode should be placed over the epigastric pit. The current may be feeble; 8 to 10 milliampères are nearly always sufficient, but the precaution should be taken

to open and close the current slowly. The sittings should last from a quarter to half an hour, and repeated several times a day in case of obstinate vomiting. From twenty-four to forty-eight hours are required to effect a cure or marked relief. Ribes has also obtained equally good results by the use of electricity in the vomiting of pregnancy.—*Revue des Sciences Medicales*, 15 July, 1895.

Cæsarean Section, Symphyseotomy and Version in the same Female in Six Years.—The *British Medical Journal* quotes Chrobak concerning a case prolific in obstetric surgery. Chrobak has communicated to the *Centrablatt für Gynäkologie* his notes of a case of deformed pelvis, for whose relief Breisky had performed Cæsarean section in 1888, Chrobak himself delivering after symphyseotomy in 1891. The patient was recommended to see him from time to time, but she never presented herself till the autumn of 1894, when she was in labor. Circumstances led Chrobak to rely on turning alone; the child died during delivery. Version and extraction proved easy; the maternal soft parts were not damaged. The Cæsarean cicatrix in the uterus was found to have become considerably stretched; it was rigid and felt like a tough pad of muscular tissue. The symphysis pubis felt perfectly firm; the bones were united by a fibrous bridge not a third of an inch broad. The bones had not been sutured. The symphysis was not damaged during this third labor. The patient can now walk with ease. On rotation of the femur, slight mobility of the symphysis is noted.

A Chinese Doctor with an American Degree.—Miss Dr. Hu King Eng, the first of her race to acquire an American diploma in order to practice medicine in China, and the second woman of her race to take an occidental medical degree, is now on her way across the Pacific to her native land to inaugurate there a new era in woman's work among women. She is Dr. Hu King Eng, a charming, modest little woman, characteristically Celestial in every way, despite her nine years' residence in the United States. She has never discarded her quaint, rich native dress, and loves her own land best. She received her doctor's degree in Philadelphia a year ago, has spent the past twelve months in taking a post-graduate course and in obtaining actual experience in her profession, and a week ago she sailed from San Francisco for Foo Chow, where she will take up her life work as physician and missionary at the Woman's Hospital, an institution supported by the Woman's Foreign Missionary Society. While she is a pure-blooded Chinese, and proud of the fact, Dr. Hu King Eng was never a heathen, her family having been Christians for two generations. Her grandfather was one of the first natives converted in Foo Chow, and her father one of the first Christian ministers ordained in China. She has a brother in the Methodist ministry and a sister a teacher in a Methodist school in China.

Russian Meats for Export.—In the *U. S. Consular Reports*, for June, 1895, Consul-General Karel makes the following supplementary report on foreign markets for Russian cattle and meat. He stated in a former report that a commission had been appointed to work out a project for the development of cattle and meat exports and that said commission was divided into four categories. Since then, one branch of the commission has held a meeting and recommended the following measures:

1. To avoid the bringing of contagious cattle diseases from the northern Caucasus into the interior governments, it is ordered that sick cattle shall be killed wherever found.
2. The quarantine districts to comprise as small territories as possible.
3. To suspend the quarantine measures regarding the transportation of wool, because it has been established that wool does not spread contagion.
4. For the export of meat to England, to build special fast

boats, which will carry no other freights that would taint the meats. These boats must sail under the Russian flag, and until they are built, an agreement is to be entered into with the Company of Sea Communications, to arrange its boats for carrying the meats.

5. To establish special agencies in England for the sale of Russian meats.

6. To build at Libau, the principal seaport for exporting meats, large ice houses and other arrangements to keep the meats in good condition.

7. Cattle to be transported on the Russian railways with speed.

The Last Contribution of E. R. Palmer, M.D.—The following is an item in the *American Practitioner and News*, June 29, written by the late Dr. Palmer, of Louisville. A few hours after receiving the journal containing the item, the telegraph flashed to us the sad information that the bright career of its writer had suddenly been cut short, and that, too, through the instrumentality of the favorite wheel, of which he wrote so jocosely in the paragraph here repeated:

"A Convention Episode.—At a recent meeting of the American Genito-Urinary Association at Niagara Falls, two staid married members from the City of Brotherly Love, by their manner and conversation gave the writer a mild sensation on the afternoon of the last day of the meeting. They were standing on the balcony of the Clifton House in a state of nervous expectation, when the following conversation took place: "Have you heard anything from them?" asked one. "No," said the other; "and they were to come down from Buffalo on this afternoon's train, sure." "Wonder if the train is in yet?" said No. 1. "Yes, half an hour ago," said the hotel porter standing by. "Well," continued No. 1, "it's plagued strange. They ought to be here at the hotel by this time, sure. One thing is certain, if they don't come I sha'n't stay the several extra days I had intended to spend here." "Nor I, either," said No. 2. To say that I was worked up, inflamed with a burning desire to see these charmers who were coming down, and that, too, right to the convention headquarters, is putting it mildly, and so, as a moment later, one of my friends exclaimed with delight, "Ah! here they come!" I quite naturally looked quickly in the direction of Suspension Bridge, only to see two messenger boys each trundling a *bicycle*. What a craze bicyclocomania is indeed!
E. R. P."

Forward Dislocation of the Fifth Cervical Vertebra.—(Ghyselink *Arch. Méd. Belges*, 1894, August.) Although the post-mortem showed a complete dislocation forward, together with a revolution of the vertebra on its transverse axis, so that the upper surface was directed forward, the vertebra itself was in front of the sixth cervical, and the spinal cord was, as it were guillotined, yet during life the differential diagnosis could not be made between fracture and dislocation. The patient, a soldier, age 23, was on duty as hostler. A fractious horse threw him under the crib, where he was found. His countenance was pallid; skin cold; legs, abdomen and lower half of thorax paralyzed; arms paretic, their strength, particularly the right hand, almost lost. Sense of feeling absent from below as high as the third intercostal space, markedly diminished in the arms, but normal on the head. The patient had severe pain in the neck. The skin was uninjured; there was a slight depression at the location of the fifth vertebra. Great pain on pressure over the first five spinous processes. Crepitus absent. The patient could voluntarily make slight motions of the neck. Respiration shallow, 30 to the minute, diaphragmatic. Palate and pharynx unaffected. Nothing abnormal could be felt in the pharynx. Retention of urine, moderate priapism, patella reflex wanting. Temperature in the axilla 36 degrees C. Skin everywhere painful, especially when touched. Patient anxious: Treatment consisted of the application of leeches to the neck, stimulants, injections of ether. At night it was necessary to use morphin. On the following day, hands and forearms were completely paralyzed, the latter elevated to the second intercostal space. Rectum paralyzed. Severe pains shooting from the neck. Gradually tympanites came on, coma and death on the fourth day.—*Centrablatt für Chirurgie*, No. v, Feb. 2, 1895.

Alcoholism in France.—France is just now considerably exercised over the question of alcoholism. Societies are being formed on all sides under the supervision of the "National League against Alcoholism." One of the largest of these promises to be the "Society against the Use of Alcoholic Drinks," started in Paris under the Presidency of Dr. Legrain, Physician-in-Chief to the insane asylums of the Seine. In a manifesto, which is to be scattered broadcast over France, the founders of the new society declare that "the time has come for all good citizens to enter on a campaign against a scourge which dishonors and ruins us." They add that they propose to propagate a knowledge of this evil in all walks of life, to agitate against it, to give an example in themselves in temperance by abstaining from the use of alcoholic drinks, to teach the principles of temperance in schools, and to organize school children into temperance societies. The dues are to be 1 franc, which is only to be collected from those over 16 years of age. They have also decided to distribute cards on one side of which is printed—"1. I promise to abstain entirely from brandy and liqueurs, save on a physician's prescription. 2. To make only a moderate use of wine, beer or cider." On the other side is the following: "The strength of a nation resides in the intellectual, moral and physical vigor of its children. Alcoholism enfeebles a nation and leads it to ruin." "To be temperate is to be a patriot." "Do not enter saloons except in cases of absolute necessity." The need for such societies seems to be urgent, judging from the following figures:

Quantities of pure alcohol consumed in France:

	Absinthe, Bitters, etc. Hectoliters.	Other Spirits. Hect.	Total. Hect.
1881	25,904	64,081	89,985
1882	33,385	84,348	118,183
1883	38,497	94,998	133,405
1884	50,235	107,548	159,783
1885	57,732	106,078	163,810
1886	65,268	104,673	169,941
1887	74,178	110,436	184,614
1888	81,342	108,954	190,296
1889	90,428	113,708	204,208
1890	105,258	122,462	227,720
1891	110,598	127,327	237,920
1892	129,670	128,773	258,443

Hospital Notes.

HOSPITALS MUST BE PROVIDED WITH FIRE ESCAPES.—New York has the advantage of some new laws for the greater protection of the inmates of hospitals, asylums, etc. The district attorneys of the various counties have received from the Secretary of the State Commission in Lunacy a letter in which attention is called to chapter 381 of the laws of 1895. This enactment provides for the erection of suitable fire escapes on all hospital buildings used for general hospital purposes, or hospitals or asylums for the insane, or any hospital buildings which are more than two stories high. The letter in question charges the district attorney with a strict enforcement of this law, which, however, excepts hospitals and asylums maintained by the State, city or county. The law becomes operative on Oct. 1, 1895. A year is given in which to comply, but after that time the fire escapes may be erected by the authorities and the cost charged against the hospital or asylum.

ERIE COUNTY HOSPITAL.—Considerable warmth of feeling has materialized in Buffalo, N. Y., between the staff of the Erie County Hospital and a Committee on Management who are appointed by the Board of Supervisors. A delectable little farce by the faction held in power by the political anthropophagi of that city is the result. This committee, with a Holman-like propensity to reduce all expenses regardless of public safety, has rendered itself a stumbling block to the success of the hospital in question, and smarting under

the publication of an article in the Buffalo Times which called attention to the faulty hospital system, held a meeting and recommended the dismissal of the hospital staff which consists of some of the best known medical men in Buffalo among others, Drs. W. S. Tremaine, Herman Hayd and John H. Prior. Three days later the committee experienced change of heart, reconsidered their hasty action and the staff still remains.—A site has been purchased by the Hospital Association of Evanston, Ill., for the purpose of erecting a hospital in that city.—Plans have been prepared to enlarge the hospital at Rutland, Vt.—The contract for the new Woods Run, Pa., hospital has been let. The cost of the building will be \$12,000.—The Southern Pacific Railroad will build a railroad hospital in Oakland, Cal.—The Niagara Falls Memorial Hospital to be located at Niagara Falls, N. Y., was incorporated July 18.

An Acute Coryza in Winter.—The *Chemist and Druggist* gives us the following: "Little boy (with bad cold in the head): "Water is runnin' out of my nose all the time." Mamma: "That's because you went out in the cold with no hat on." Little boy: "I didn't know it was cold enough to burst my pipes."

THE PUBLIC SERVICES.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from July 13, 1895, to July 19, 1895.

- Col. CHARLES T. ALEXANDER, Asst. Surgeon-General, is granted leave of absence for two months, to take effect on or about July 13, 1895.
- Capt. WILLIAM H. CORBUSIER, Asst. Surgeon, will, in addition to his present duties, take charge of the Medical Supply Depot in New York City, during the absence on leave of Col. ALEXANDER.
- Capt. ADRIAN S. POLHEMUS, Asst. Surgeon, is granted leave of absence for two months, to take effect after his return to his proper station (Ft. Douglas, Utah), and at such time thereafter as his services can be spared by his post commander.
- Capt. JULIAN M. CABELL, Asst. Surgeon, is granted leave of absence for four months, on surgeon's certificate of disability.

Marine-Hospital Changes. Official list of changes of stations and duties of medical officers of the U. S. Marine-Hospital Service, for the fifteen days ended July 15, 1895.

- Surgeon P. H. BAILLIACHE, to assume command of Camp Low Quarantine, July 5, 1895.
- Surgeon W. H. H. HUTTON, to report at Bureau for temporary duty, July 12, 1895.
- Surgeon W. H. WHEELER, relieved from command of Camp Low Quarantine, July 5, 1895.
- P. A. Surgeon C. E. BANKS, to proceed to Detroit, Mich., on special temporary duty, July 5, 1895.
- P. A. Surgeon H. T. GOODWIN, granted leave of absence for thirty days, July 12, 1895.
- P. A. Surgeon G. T. VAUGHAN, granted leave of absence for seven days July 6, 1895.
- P. A. Surgeon J. B. STONER, to proceed to Detroit, Mich., for temporary duty, July 12, 1895.
- P. A. Surgeon J. M. EAGER, to proceed to Southport, N. C., and assume command of quarantine station, July 6, 1895.
- Asst. Surgeon W. J. S. STEWART, granted leave of absence for nine days, July 5, 1895.
- Asst. Surgeon H. W. WICKES, granted leave of absence for twenty-three days, July 5, 1895.

LETTERS RECEIVED.

ADDRESSES.

THE NECESSITIES OF A MODERN MEDICAL COLLEGE.

President's Address read at the Meeting of the American Medical College Association, Baltimore, May, 1895.

BY E. FLETCHER INGALS, A.M., M.D.

PROFESSOR OF LARYNGOLOGY AND DISEASES OF THE CHEST, RUSH MEDICAL COLLEGE, CHICAGO.

In the early history of this country, and as late as fifty or perhaps even twenty-five years ago, large tracts of sparsely settled portions of the United States presented conditions in which it was impossible for the thoroughly educated medical man to obtain a just recompense for the time and money necessarily expended in acquiring his medical education, yet these communities required the services of physicians, and it therefore happened that persons with very slight qualifications took up the practice of physic and endeavored to supply the demands of the community that was unable to obtain anything better.

With increase in population, wealth and civilization the people became more discriminating in their choice of doctors, the communication with distant points was more rapid, the advent of railroads made it easier to secure competent medical men, and consequently the poorly qualified doctors have gradually decreased until at present there are few places in the United States where the citizens do not demand skillful aid for the sick. Fifty years ago there were many thoroughly qualified physicians in the country, and the professors in medical colleges were generally men of excellent attainments, but new and ambitious medical colleges began to confer degrees on students with but little preliminary education, and who had attended but two short courses of medical lectures, with little or no laboratory or clinical instruction, which necessarily gave a low rank to the profession as a whole. It was realized by many, even at that time, that the product of such methods of education was not what it should be, but the necessities of the sparsely settled communities seemed to warrant the course that was adopted, and there can be no doubt that the men thus licensed to practice medicine were far superior to many others who without any qualifications were practicing in various parts of the country. From these conditions it can be readily understood that the medical college of fifty or even thirty years ago was not necessarily a very pretentious institution. A few small rooms over a store, or in an humble improvised building; or in the more pretentious colleges a lecture room arranged in the form of an amphitheater for a hundred or more students, with a small chemic laboratory, an articulated skeleton and a few anatomic plates constituted the whole equipment that was thought necessary for teaching medicine. With the changed conditions that have come about during the last quarter of a century, the col-

lege that starts to-day with the equipment that was satisfactory fifty or twenty-five years ago, is held in derision by the profession and secures for its students only the poorest of the low grade men who hope to acquire some dignity through their medical title. Within the past few years medical men have felt more keenly the necessity for proper equipment, and the great body of the profession has risen to a plane where it is ready to support the colleges that require much better qualifications of their students before they can go out with a diploma entitling them to the confidence of the public.

The few back rooms over a store which were adequate fifty years ago to train the prospective doctor; the single amphitheater and little chemic laboratory are no longer sufficient to furnish the accommodations necessary for the better educated men who are seeking a knowledge of the healing art.

In my effort to ascertain what the proper equipment of a medical college should be, I have not relied wholly upon my own opinions, but have availed myself of the ripe experience of others so far as practicable, and I have endeavored to present a consensus of their views.

To-day it is realized that a first-class medical college must have a large and commodious building with beautiful lecture rooms and ample laboratories. The fully equipped medical college of to-day should have two or three amphitheaters, one of which should be large enough to seat the four classes and allow room for a few visitors. The others should be large enough to seat at least two of the classes, since there are many times during the course when it is desirable to bring together the students of the various years. In connection with these, there should be a number of smaller rooms for clinical purposes or demonstrations. Instead of the single skeleton which was used a few years ago by the professor of anatomy, the well-equipped colleges now furnish a large number of skeletons so that each student may be able to study every bone from the specimen in his hand, therefore an osteologic room has to be provided capable of seating, about tables, half of the first or second year classes, with skeletons sufficient in number to provide one to every two students. A well-lighted dissecting room capable of accommodating at least half of the first or second year classes must also be provided, and it is needless to add that ample material is absolutely necessary. The little chemic laboratory which in former years served for the professor to arrange a few experiments, that would now be thought inadequate in the teaching of a grammar school, has given place to a large, well-equipped laboratory capable of accommodating at least half of the first or second year classes. Histologic and pathologic laboratories capable of accommodating at least one-fourth of either of these classes must also be provided, and a bacteriologic laboratory of similar size has come to

be a necessity. Even larger rooms than these would better serve the convenience of the teachers, but they are not necessary if the class is properly divided, and the teacher will accommodate himself to the various sections. With only four years at our disposal, with the vast field to be covered, it is impossible to make skilled specialists of our students, or even to complete their general education; but it is necessary that every one should be well grounded in the rudiments of medical science and taught how to study, and how to utilize his information in general practice for the best interests of his patients. The best medical colleges now realize the necessity of manual training by which their students are taught the practical use of the test tube, the sterilizer and the incubator, and by which they acquire facility with the microscope, the ophthalmoscope, the laryngoscope and whereby they individually learn the proper methods of applying bandages and splints; indeed, training whereby they may learn every mechanical process with which the fully equipped physician must be familiar. For this work additional rooms are needed, each about half the size of the laboratories already referred to.

The recitation system adopted for a considerable part of the work by many colleges is a great improvement upon the old plan of having the class listen to lectures, or read medicine. Where this system has been tried its value is more apparent each year in the better qualified classes that are turned out. It is found that this training of the class which requires them to learn the precepts of some good text-book, even though the instructors may be comparatively young men, produces much better results than when the whole class assembles in a large room to hear even the most eloquent of lectures. It seems to me that the best results are obtained by a combination of recitations with didactic and clinical lectures. The first year about three-fourths of the work should be done in laboratories and class room, the class being divided into small sections. These sections are assigned lessons which they recite to instructors, but about eight or ten times a week they assemble to hear didactic lectures from the professors. In cities of sufficient size to support medical colleges, there are always located a number of ambitious young men fully competent to give the class room instruction when a suitable text-book is provided. These instructors supplement the labors of the regular professors, and in many departments may be called upon to do about two-thirds of the work. This practice gives young men experience and enables them to demonstrate their capacity for teaching and later may become of great value to the college, when its trustees are called upon to fill vacancies in the regular faculty.

In such a course the professor confines himself to the consideration of the more important subjects of his particular department, which are thus impressed upon the class by his individuality and personal experience. At the beginning of the term he should lay out his entire course, assigning beforehand the lessons for each day. This schedule should be placed in the hands of his instructors so as to form a harmonious course. The recitations should embrace not only those subjects which have been assigned from the text-book, but also all those which the professor has considered in his didactic lectures. The necessity for clinical teaching has been so repeatedly impressed, not only upon the teaching corps in our colleges, but also upon physicians and students, that every college

does its utmost to furnish suitable clinics, and it is a matter of great importance to this Association to decide what constitutes proper clinical facilities for medical teaching. The advantages that were considered ample until recently can not now be accepted; every college must, therefore, be provided with dispensary rooms and hospital accommodations. I am familiar with the fact that fifty years ago a first-class medical college could be conducted with very little clinical material, but it does not seem practicable to give the instruction requisite at the present time with less than four or five thousand out-door patients annually, and hospital facilities of less than seventy-five to one hundred beds. Where there are few patients some slight advantage may be derived from the more careful study of each case by the students, but unless there is sufficient variety the clinical experience which the student obtains is necessarily limited; therefore, the larger the clinical material at the command of a college, other things being equal, the better will be the instruction that is given to its students. I am aware that these statements may be questioned by professors in some schools where clinical material is scant, but the experience of teachers, both in this country and abroad, will support my views. Without in any way desiring to limit the usefulness of the schools in small cities, I must still maintain that clinical experience is of the greatest possible importance to advanced students. The argument that good physicians were made fifty years ago when clinical advantages were very small is not apposite to the case, when we consider the great advancement in medical science and in the methods of training that have been made within a quarter of a century. I do not desire to discourage professors in small schools from doing good thorough work in training medical men, for I believe there is a field that could be well occupied by colleges, even where adequate clinical advantages can not be obtained, if they would confine themselves to what might be considered the junior department of medical teaching. They could by recitations and didactic lectures ground their students thoroughly in the fundamental principles of medicine; they could teach many of the things that must be learned in the laboratory; indeed, they could fit their students thoroughly to enter the third year of the most advanced medical colleges. In this way they might do a laudable and important work for some of the young men in their vicinity who desire a medical education.

In addition to the requisites that have already been mentioned for a first-class modern medical college, a gymnasium for the cultivation of the physical strength and health would undoubtedly be advantageous in aiding the highest mental training. It would also be very desirable if a large examination hall could be added to each of the medical colleges, where the progress of the student might from time to time be ascertained, that he might the more efficiently apply his subsequent work, and where final examinations could be held under the most favorable conditions for preventing cheating by incompetent students. I wish to urge upon teachers of medicine throughout the country the importance of several review examinations during the course. I am fully convinced, by experience, that such examinations every five or six weeks impress upon the students many things that would otherwise be lost, and as a result such students are infinitely better qualified at

the close of the term than they would be otherwise. I believe these review examinations would be found most beneficial in all departments, not only in showing the student in what he was lacking and upon what he must put the hardest work, but also in giving the professor a better knowledge of his qualifications when he comes for the term or final examination.

The plan I adopt has given much satisfaction. In this plan students are strictly marked on every recitation and an absence counts zero against them. At the close of the term the average obtained in the recitations counts one-third, the average of the review examinations counts one-third and the mark obtained on the final examination counts one-third in establishing the grade. This I believe is most equitable to the students, and enables the professor to estimate correctly whether the student is qualified to pass the term or final examination, providing due care is always taken, as it should be, to secure an honest examination.

Within the past few years, I have had frequent occasion to consider the cost of a thoroughly equipped medical college. From these estimates and from the advice I have obtained from others, I have to submit the following figures as a fair estimate of the cost of a medical college properly equipped for teaching medicine in this country at this time.

The buildings for a medical college complete, containing the amphitheatres, clinical rooms, laboratories, and recitation rooms that I have already mentioned (excepting the gymnasium and examination hall) would at this time in most places cost for a total class of 200, from \$75,000 to \$125,000, if all under one roof; or for a total class of 500 about \$150,000 to \$200,000.

The price of land would necessarily vary, but in any city capable of furnishing proper clinical advantages it would probably be between \$30,000 and \$50,000. The fitting up of a chemist laboratory suitable for a total of 200 students in all its classes would be about \$3,000 or for one of 500 students would be about \$5,000. The fitting up of the histologic and pathologic laboratories would be about \$3,000 for the smaller class, or about \$5,000 for the larger class. The fitting of a bacteriologic laboratory would be about \$3,000 for the smaller class, or about \$5,000 for the larger class; making a total of \$114,000 to \$184,000 for the smaller, or \$195,000 to \$265,000 for the larger school.

The cost of maintenance of all of these laboratories for the smaller classes would be about \$4,000 and for the larger class, about \$6,000, exclusive of salaries to the professor or director. The running expenses of the college as a whole, comprising the maintenance of the laboratories would be for the smaller class about \$20,000 and for the larger, about \$35,000 per annum.

In addition to these expenses, small fixed salaries should be provided, as far as possible, for the young men occupying the positions of instructors, demonstrators, etc. For the professors of what might be termed the non-practical departments, such as chemistry, physiology, anatomy and materia medica, salaries should be allowed adequate to enable them to give a large portion of their time exclusively to their duties as teachers. For the professors occupying the practical departments, it is not so essential that similar salaries should be provided, as there is always more or less indirect return for their services;

yet, it can not be questioned that in most cases the best work is accomplished where proper remuneration is received. It is probable that the expense of maintaining the college and paying the professors suitable salaries would not fall short of \$45,000 for the smaller or \$75,000 for the larger annually. In this connection, I will not attempt to estimate the cost of construction and maintenance of dispensaries and hospitals for the accommodation of patients that must be used in the clinical demonstrations, for these can generally, and should always be secured from charitable persons or the public in return for the services of the physicians to the indigent sick. I may state briefly, however, that the original cost of these would be much greater than that of the college buildings and the running expenses would be correspondingly large.

If the colleges were required to bear these expenses, not one of them could afford the other necessary equipment. In consideration of the question, How the money should be obtained for the necessary expenses of a medical college, I know that I reflect the opinion of the profession when I state that such institutions should be amply and liberally endowed; and no opportunity should be lost to impress upon the laity the peculiar beneficence of charitable bequests to this end and the advantages to be obtained by individuals, families and the community at large from a thoroughly educated medical profession. Until the time when our schools shall be endowed they must depend upon the income from the students for their running expenses.

In this connection I wish to suggest that a professional education should be paid for, and that the average fees charged to-day in the medical colleges throughout the country, are only about 50 per cent. of what they should be to provide the money necessary for furnishing the most complete equipment, and giving the best practical instruction to students; but I do not wish to be understood as advocating uniform prices by all colleges. I believe, however, that if all the colleges in the country would raise their fees 25 or 50 per cent. as might be agreed upon, it would enable them to furnish much better facilities than are now enjoyed by medical students, and the students themselves would be correspondingly benefited.

Administration: As most of the medical colleges in this country are supported and owned by their respective faculties, it has been the custom for their management to be left entirely with these bodies, but since a few of the colleges have received endowments, or have become connected with universities, the question has arisen as to the best plan to be adopted in their administration.

It is urged by some that as the faculty know more of the needs of students than others, the management should be left entirely with them. It is urged again that under such an administration, it is very difficult and sometimes impossible to correct evils that are liable to creep in, because of the relations of members of the faculty to each other. For example, a good professor may be appointed, but in the course of time, growth of intemperate habits or something else may occur to render his further connection with the institution undesirable. In the meantime, he has formed personal relations with the other professors, which prevent them from taking any active part in his removal, consequently he remains, much to the

detriment of the school. In such a case, were the administration in the hands of a board of trustees, it would be a comparatively easy matter to make the necessary change. So long as medical colleges are supported by the individual efforts of the faculty, so long, they must almost of necessity, remain under the control of this body; but when they pass into possession of a university or college, whether as an endowed institution or a State school, the administration will necessarily change. It has been frequently urged, that if our colleges were under the charge of boards of trustees distinct from the faculties, it would be much easier to secure bequests for their endowment. This seems to be a true statement, but the experience of four or five colleges shows that it can not be accepted as an invariable rule.

Many instances might be cited where the faculty control has permitted abuses which the personal relations of the professors has rendered them unable to correct; yet, on the whole I think it must be conceded that the faculty control in the case of an institution that must in some way be supported by its members is the best plan. Under other circumstances the board of regents or trustees of the university, must assume in great part the administration, and the responsibility for the conduct of the college; but even then to what extent the administration should be left in the hands of the trustees or of the faculty is an open question, upon both sides of which many arguments may be made.

Certain institutions assume the whole control of all their departments, allowing the faculty little or no voice in management; others give the faculty greater or less privileges in the general and financial management of the school.

It appears to me the better plan would be, in State schools or in endowed institutions having medical departments, for the board of regents or trustees to have control of the financial management, aided by the advice of a committee from the faculty; while the general management of the school, as to its curriculum, time and duration of terms, discipline, etc., could better be left mainly to the faculty.

In the appointment of professors or instructors, the faculty should have the nominating power but only the trustees should appoint. In the discharge of professors, for incompetence or other cause, the trustees alone should act in accordance with the contract made at the time the professor was engaged, and such information as they might desire from the faculty.

In the general management of the school, I believe it would be well for the faculty as a whole, including not only the regular professors but all the assistants, to consider all matters of importance, but the final action upon these should be left to a limited number of the more experienced members of the faculty who should be an executive committee, with power to act, with the consent of the board of trustees or regents.

Although many good arguments may be advanced for absolute control by the board of regents or trustees of any department under its care, yet I feel satisfied that either a nominating or a vetoing power should be left in the hands of the faculty, or the executive committee of the faculty, in order to promote harmony and the best interests of the institution.

The American Medical College Association has already done much to advance the cause of medical

education in this country. If our action is wise, we may in the future, shape the course of the better medical colleges, and is so doing we will sooner or later compel those of lower grade to fall into line, if they wish to receive the support of the profession.

It would be unwise for this Association to take any receding step in the requirements laid down for graduation, and when we consider the effect which increased requirements have had upon the colleges adopting them, there is certainly no reason why any individual member of this Association should wish to take a lower grade than that which we have adopted. The judgment of the profession in this matter is shown in the fact that every advance by a college in the way of requirements of students has been followed by an increase in the size of its classes.

I feel that we have already accomplished all that is necessary, at least for some years to come, as to the duration of the course of study before graduation, although it is of the utmost importance to fix upon the minimum amount of work to be done in this time, and to lay out, as your committee has attempted to do, a suitable curriculum.

Much remains to be done in fixing a high standard of preliminary education. The work of your committee in framing a curriculum that may be adopted by the various members of this Association, I hope will receive your cordial support, at least in so far that its general features may be adopted, in order that uniformity and excellent courses may be secured in all colleges, that desire recognition as first class institutions. The difficulties in the way of deciding upon the preliminary education to be required are many, and I feel that great wisdom is necessary in this body in order to solve the question.

The time has passed with the colleges in this Association, when ignorant young men will be encouraged to study medicine, for their fees, and when schools will maintain scant requirements for the sake of attracting incompetent students to their classes.

In the former Association of Medical Colleges an attempt was made to regulate the fee which should be charged by each; this, I do not believe is wise and I hope the subject may not come up to disturb our councils; or if it does, that no attempt will be made to do more than change the fees by a certain percentage. I believe that the colleges should be left to compete with each other solely upon the merits of their instruction. If a certain body of men choose to give their services gratuitously and to pay from their own pockets the expense of running a medical college, it does not seem to be the affair of any one else, provided others are treated with common courtesy and all adhere strictly to the high requirements adopted by this Association.

In closing, I wish to thank this Association for the honor it has conferred through me upon the college which I represent. I am led to believe that this honor was not a personal matter, either to myself or the college, but that it was an expression of appreciation for the stand this institution has taken upon advanced medical education. My colleagues are firmly opposed to any retrograde step, and I can assure you of their support in a policy of steady and constant improvement, in preliminary requirements of students, and in the methods of medical education.

THE NU SIGMA NU FRATERNITY—ITS MISSION IN THE MEDICAL PROFESSION.

Delivered by the President, at the Thirteenth Biennial Convention of Grand Council at Minneapolis, Minn., June 3, 4 and 5, 1895.

BY JOHN L. IRWIN, PH. C., M.D.
DETROIT, MICH.

Next in organization and domain to that great institution whose power and influence are felt in every hamlet, on every shore, by every river of the habitable globe—the stupendous brotherhood of Masonry—is the secret order confined to the medical profession, the largest medical organization of its kind extant, the Grand Council of which, convening biennially, holds its thirteenth convention to-day with the University of Minnesota Chapter and fraters in the city of Minneapolis, to enact its laws as a central governing body having chapters in the leading medical universities.

Laying claim to an origin at least coeval with the ancient Egyptian priesthood, and deriving its authority from an antiquity that was hoary when Christianity was born, it has nevertheless adapted itself to the needs of modern medicine; and at the close of this, the civilized nineteenth century, it was never so numerous or powerful as it is to-day in this country.

The question of this hour is, What is the Nu Sigma Nu? What its mission in the medical profession?

As man first became civilized on the banks of the Nile, we naturally look there for the first evidences of the existence of a knowledge of medicine. We find that the traditions of the ancients, outside of Egypt, refer the origin of their connection with medicine to that country. Some hold, however, that the Assyrians and even the Phœnicians, at an equally early date, had made medical progress. Ancient traditions tell us that Chiron brought medical knowledge from Egypt to Greece, and became the first Greek physician. His pupil was Æsculapius, about whose history there is some doubt and uncertainty, but he is believed to have lived about 1500 B.C., and whose eminence as a physician caused him upon his death to be deified, and he became the Greek god of medicine, under whose auspices all further researches were made.

The sons of Æsculapius became physicians, and two of them were surgeons in the army of Greece. History tells us that during the Trojan war, a son of Æsculapius, having received a serious wound, was being carried from the battle-field to the ships by Nestor, who is recorded as having exclaimed:

“A wise physician, skilled our wounds to heal,
Is more than armies in the public weal!”

The descendants of Æsculapius, continuing the practice of medicine, gave rise to an order of priests devoted to the service of the god of medicine, who were called Æsculapidae. Aristotle, the greatest philosopher of all antiquity, was a member; and Hippocrates was eighteenth in the line of descent. Thus arose the ancient order of the Æsculapidae, which came to view in the new world as the Nu Sigma Nu Fraternity, in the establishing of the Alpha Chapter by prominent members of the medical faculty and others at the University of Michigan, Ann Arbor, many years ago. The ancient order, as originally founded in the mysteries of religion and science in Greece, was revived at Ann Arbor, with its rituals and ceremonies.

The ritual, as then accepted, has since been entirely revised—made to meet the present wants of medicine; and was accepted at the convention held by our order during the World's Fair in Chicago in 1893.

Though scoffers challenge its lineage with the medical order of the ancients; and deny its ancestry as far back as Herophilus, the present usefulness of the Nu Sigma Nu Fraternity and its service to the medical profession can not be denied. Its widening influence is its own excuse for existence. It serves the needs of the true physician, appeals to his tastes and to his sense of solemn and obligatory pledges with a largeness and freedom which can not be overlooked by one who fairly and broadly studies medical phenomena.

Medicine has ever been considered the most noble of arts. The essentials for a competent knowledge of medicine were early laid down in the tenets of our order. Only pure souls could enter the temple of ancient medicine.

It is our duty to assist one another in the attainment of all knowledge pertaining to our profession; to be good citizens and conscientious physicians—avoiding contention and strife. To ask nothing but what is right—submit to nothing that is wrong.

We are taught that to be true physicians and loyal fraters we must practice brotherly love, ambition, temperance, honesty, purity, justice and charity. The best principles and character are required of true and loyal members. Our ancient brothers found knowledge and wisdom less common than do we of modern times—but the character and principles inherent to just and good men are found alike in all times.

Our members are obligated to employ their hands only in good work. Our order teaches us that a life of integrity is better than the most famous or successful career lacking that element.

The highest compact we can make with our fellows is: “Let there be truth between us forevermore.” We know that noble persons meet on the grounds of sincerity and uprightness.

We are told that physicians take each other's measure when they meet for the first time; and when they meet one upon whom the degree of this order has been conferred, he should need no auxiliaries to his personal presence. His aims should be generous and universal. A scholar may be a well-bred man, or he may not, but a true physician must be. Manners have been somewhat generally defined to be a contrivance of wise men to keep fools at a distance. Emerson says: “Society is very swift in its instincts; and if you do not belong to it, resists and sneers at you, or quietly drops you.”

The Nu Sigma Nu presents truth in a certain form. All along our pathway as true physicians, our ritual is useful to us. Most of the true physician's deeds are not recorded, his best acts are seldom chronicled. The true member of our order is he whose actions are the best; and he will live the longest with us. No true physician ever lived without influence somewhere.

Our living principle is the recognition that we are a medical brotherhood. Improvement, diligence and duty are our watchwords. We know that good sense, industry, good principles and a good heart will make a well-constituted mind achieve success in any calling.

We are an association of physicians having common rights and privileges; but we are more—we must have ever with us the symbols of divine presence.

The pot of incense is always found burning at our altar. The Nu Sigma Nu Fraternity seeks to make medical men true physicians—the world makes the so-called “successful practitioners of medicine.”

It is said that on all the shores of all the seas there are not two grains of sand formed alike—our order takes the best material from the ranks of the medical students and practicing physicians, and offers them our standard. What air is to the lungs, blood is to the heart, light is to the eye, liberty is to the heart of man—the beautiful precepts of our ritual are to the true physician.

“He only is rich who owns the day.” The true physician’s time is not his own.

Melody in music is produced because the different sound waves reach the ear at the same time. If sound, whether high or low, loud or soft, were to travel at different rates, confusion and not melody would be the result. The tenets of our order teach us as members to work hand in hand, to achieve the greatest good for the greatest number.

The order of Nu Sigma Nu is not a pastime—a mere diversion—it is an ever living principle. Our ritual exemplifies important truths, one of which is that of a medical brotherhood. It teaches us that there is a purpose in our being; and this purpose we are to apply to the duties of our profession. Emerson says: “The crowning fortune of a man is to be born with a bias to some pursuit which finds him in employment and happiness.” Candidates for the degree of Nu Sigma Nu are selected as to their fitness and natural talent for the work of our profession; and as the disciples of our ancient Grand Master they must show a bias to their chosen calling, which is of all callings the most humane and honorable.

The requirements for admission into our order are those which are possessed by the true physician of nature. We believe the true physician is he who best studies nature and her laws. We know that if we are what nature intended us to be we shall succeed—if we are anything else we shall be worse than nothing.

Our ritual tell us it is our duty to stand well in the front rank among the progressive physicians of the day. It bids us never to desert our true sphere; our own line of talent. Candidates for our degree must study their aptitudes—to see if naturally bent to medicine as a calling. There is hardly any person who is not qualified to shine in some profession, and it is far better to be at the head of an inferior calling than at the foot of one which the world calls respectable. Although some men, and men of sagacity, deny the doctrine of natural tendencies, and hold that any one by dint of energy may become what he chooses, yet it would seem that while the natural bent may be hard to discern, still—as the boy is father to the man—he generally gives some indication of what sort of man he is likely to become. The fact that one has an original bias, a fondness and predilection for a certain pursuit, is the best possible guaranty that he will follow it faithfully; hence our ritual causes us to select candidates for our degree, whether they come from among the medical students or medical practitioners, by the standard of natural aptitudes, as well as the moral and intellectual conduct required by our order.

Our ritual teaches that it is not the calling or station in life which gives dignity or nobility to the

man; but the man who dignifies the station or calling. An humble avocation may be ennobled by the manner in which its duties are discharged; and one may challenge the respect of all whose good opinion is worth having.

Nothing can be achieved without tenacity of purpose. Fraters who are just entering their medical career should remember that the greatest weakness of our young men is fickleness, and where one of them perseveres in a calling which he ought to abandon, a dozen abandon their callings who ought to stick to them. The better the profession the more likely they are to do this, for all kinds of business which are surest in the end—which pay best in the long run—are slowest in the beginning to yield a return.

After a young man has adopted a profession, he should be slow to believe himself to have made a wrong choice, especially after he has acquired much valuable experience; and should try another only after repeated failures in the most desperate attempts to succeed. When we reflect that the man remains the same whatever his avocation—that a mere change of calling will neither add to his strength of mind nor diminish its weakness, we may conclude that in many cases what he is in one vocation he would be substantially in any other, and that he might gain little or nothing by the change. In hours of despondency, or when smarting under some disappointment, a young man is apt to fancy that in some other calling he might have been more nearly successful. It is so easy, while regarding it at a distance, to look at its bright side only, shutting the eyes to what is ugly or disagreeable, that it is not strange that men abandon their professions for others for which they are perhaps less fitted.

Our purpose carries a moral truth with every professional obligation. It says that to be true and loyal members of our order we must carry justice, fair dealing and truth into our consulting room. We must be noble, just and true in the presence of our patients.

Our ritual insists that our professional work will be all that the true physician could desire—not less preaching, but more practice. It is true that our organization is a secret one, but as members we are not bound by obligation to any unworthy member—we are not bound to each other whether we are right or wrong. The pin or badge we wear upon our breasts is not an index to the life behind it, but it should be.

We are taught not to despise the man of only ordinary intellect. There is, perhaps, no mistake of our young men more common than that of supposing that in the pursuits of life extraordinary talents are necessary to one who would achieve more than ordinary success. The average man can not believe that those persons who have made themselves a place in history by connection with striking events, whose influence has been felt through ages in changing the destiny of nations, have been men of ordinary intellectual caliber. Men who can do the little things well are they who go to the front.

Our ritual disapproves of all things unprofessional. Its shining light is character. A French writer on agriculture observes that it is impossible, profitably, to improve land by trying favorably to change its natural character—as by bringing sand to clay, or clay to sand. The only true method is to adapt the cultivation to the nature of the soil; so with the moral and intellectual qualities required to make true phy-

sicians. Exhortation or self-determination may do much to stimulate and prick a man on in a wrong career against his natural bent, but when the crisis comes this artificial character thus laboriously induced will break down, failing at the very time it is most wanted.

Persons who have been at pains to collect statistics in mercantile pursuits in our large cities have found that only three out of a hundred merchants are successful, all the others becoming bankrupt or retiring in disgust. Why is this? Is it not because they have gone into business without business aptitude? The ritual of the Nu Sigma Nu requires of all candidates the moral and intellectual essentials with which to achieve success, not as *medical practitioners*, but as *true physicians*. We know that successful medical practitioners so-called are not always true physicians.

The bane of the medical profession is the tendency of members to prey upon one another. Our ritual condemns this. It teaches us to practice its precepts in the quiet of our consulting room, and at the bedside of our patients as well. It respects honest convictions, but it directs us to give allegiance to no sect, school or 'pathy in medicine. We are to make use of the teachings of accumulated experience, and avail ourselves fully of every aid offered to us by advancing medical science. We are to be true physicians in a broad and liberal sense, and are to practice anything wherever found, which will contribute to an honest effort to heal the sick and prolong life. We are to be rational in our methods, and to assist nature in *her* efforts to cure disease.

We are taught to go forward in our methods of practice, keeping pace with the advancement of medical science, because we know that the medicine of yesterday is not the medicine of to-day; and that of to-day will tomorrow represent the historic and dead past.

"We believe that the laws of nature are not things evolved by any speculative method; but we must discover them in the facts. Before we accept them as methods of practice we have to try them by repeated observation and experiment. In proportion only as they hold good under constantly increasing change of conditions, in a constantly increasing number of cases, and in the greater delicacy in the means of observation, does our confidence in their trustworthiness arise."

What is most needed, in the medical profession of to-day is not schools, sects, or 'pathies, but the elevation of character and intellect, and the improvement of the conduct of the medical adviser. To this task the moral agencies of our profession must apply themselves; ethical considerations must enter into all phases of professional work. As members of the Nu Sigma Nu, it is our duty to carry the grand principles of our ritual into every detail of our daily labors—honesty, truth and commiseration should ever be present in our relations with our patients. It is said that cheerfulness and repose are the badge of the gentleman. Our ritual requires a candidate to be a true gentleman ere he receives the degree and badge of Nu Sigma Nu.

Our duties as members do not interfere with the exalted duties we owe to God, our country, our family or ourselves. Who of our members will ever forget his initiatory ceremony? Our institution elevates the character of the physician by placing before

him incentives to goodness—keeping in view the great Golden Rule for our maxim. Our ritual teaches elevating and inspiring ideas of higher life and stricter duty, and if our beautiful precepts were practiced, not only by all our members, but by all the members of the medical profession everywhere, humanity would proclaim the goodness of our plans, the utility of our triumphs.

Fear of disease and dread of death cause mankind everywhere to employ physicians—wherever sick and suffering mankind is it turns to us for relief. This reliance of humanity on our profession to heal its wounds and cure its diseases, naturally brings us in contact on the one side with mankind's greatest, most vital interests, and on the other with the great science and glorious art of medicine, and gives us power in our legitimate sphere almost like that of the monarch. We are intrusted with secrets that would be confided to no other person; and are as honorary members and guardians to every family we attend. No other men can do the good that can be done by true physicians; others may have the will, but they have not the power and opportunity.

Ours is a calling capable of developing all the good qualities of one's heart, hand and brain. Our ritual would have us keep our lamps trimmed and our oil ready, to do the greatest possible good for all who trust to our skill for relief, that we may be in very truth called true and good physicians.

Wordsworth says: "Blend not your pleasure or your pride with sorrow to the meanest thing that feels." Our ritual bids our undergraduate member treat with kindness, consideration and courtesy all his fellow classmates—the one who wears the faded coat alike with the wealthy and more fortunate. It insists that the one who wears our golden badge should be one to whom the world can point with esteem and honor; and whose conduct in his profession is such as to be truly worthy of such recognition. Such, then, being the mission and effects of our organization, can any one doubt there is an excuse for our being? Has not the medical profession given us a hearty welcome? The answer is found in the fact that some of the brightest minds in the medical world to-day are members of Nu Sigma Nu. In the leading medical faculties everywhere are found our fraters; our badge is being worn by some of the brightest students in our leading medical universities. Let the good work go onward until we have a chapter in every leading medical university and center of the world.

As the gem can not be polished without friction, neither can the physician be perfected without trials. Troubles give sinew and tone to life; fortitude and courage to the true physician. That would be a dull sea and the sailor would never become skilled, where there was nothing to disturb the surface of the ocean. What though things look a little dark, the lane will have a turning, and night will end in broad day. Trouble will disappear before the ever-cheerful heart, as the mist before the brightness of the sun's darting rays.

Let the trials of life come fiercely, if God thus wills—it may be for the best. Gold from half-heated crucibles with dross is found. Each one of us in this life is feeding fuel to his own future, each one tending the crucible in which his own destiny is being molded. If sin and wrong are mingled therein, not thereout can come the elixir of life, but only poison-

ous drugs of suffering and death. Could we but teach the people that not alone in steaming crucibles from precious herbs, but from out the pure air, the glad sunshine, the sweet waters from rivulet and fountain, simple food and temperate habits, an upright walk before God and man, a good conscience—that from these is distilled the real elixir of health, happiness and life—could teach the people such simple truths, we, as physicians, would find our work less arduous; but it is perhaps one of the impossible things.

In vile indulgence every known law of health is defied, and the drunkard and the glutton and the licentious expect to find in some pill or powder that health for both body and mind which can best be found in the God-given medicines of pure principles and a virtuous life, in which alone are distilled the elixirs of the other life which is immortal.

Every institution is an outgrowth of the condition of humanity. Our institution supplies a long-felt want in the medical profession. Our great principles hang, as clusters of fruit, our ritual being the great trunk, whose leaflets permeate the medical profession, and whose attributes do so much to make the true physician. No association ever had a more noble mission than has ours to-day.

The ritual of Nu Sigma Nu, incorporated with the elements of the Christian code, is the unerring rule by which the conduct of its members is tried, laying the broad foundation of that sentiment which bids us to do unto others as we would that others should do unto us. Our institution receives each successful candidate as a brother, and asks him to cultivate the true fraternal relations designed by Providence.

As physicians we know that the greatness of benefits enjoyed by humanity come, not through mighty deeds of valor, but through little acts of kindness. Our profession is not yet perfect; much remains to be done. There is yet much work to be accomplished.

In all lands and among all classes of people, the maternal love is regarded as the most touching of human sentiments. We, as physicians and students of medicine, love our Alma Mater, the institution at which were fostered the higher powers of our intellects and hearts. We love to recall in sweetest memory the events of our college life; but as we grow old in our chosen calling and time will have recorded the flight of years, I verily believe, even more proudly than now, shall we refer to our connection with this great organization.

It is now many years since were revived at the Athens of Michigan the ancient tenets of our institution. I received the degree of Nu Sigma Nu while a medical undergraduate at Ann Arbor. For the past five years I have held positions of responsibility in our Grand Council, and I have observed in that short time the marvelous growth of our order, chapters and members having multiplied until to-day we are represented in almost every part of the civilized world. The work will go onward and upward, until our mission as a fraternity, the elevation of the moral and intellectual standing of medical practitioners in all lands has been accomplished.

I think I ought not to let this occasion pass without addressing some remarks to the memory of those who, having entered into rest, are joined to our Omega Chapter. Their going from among us has seemed like the golden departure of the setting sun. It belongs to the amenities of our profession, to the respect, the esteem, the love and attachment that we have for

one another, that the opportunity is given at this time of testifying to their eminent worth, and above all to their loyalty and devotion to the precepts of our ritual.

It remains for our younger members, stimulated by their high attainments, to lend their energies in the direction of the best thought, the best study and the best learning, that they may become qualified to fill the places and follow the footsteps of our departed fraters; and it becomes us all, touched by the loss of our brothers, to soften the asperities of our chosen calling, making our friendship for one another more calm, constant and cordial; that we may, when life is over, leave behind us a memory which, like a sweet perfume, will make pleasant through all time the places in which we have moved.

In conclusion I wish to say: in accepting, two years ago, at our World's Fair convention in Chicago, the exalted position of your Grand President, to which my fraters called me, my first thought was that while I must yield to their wishes to discharge the responsible duties of this, the highest honor in their gift to bestow, yet to none did I yield the measure of my appreciation of the high honor so liberally conferred. Not to my own fitness or worthiness, but to the high regard in which I have ever held this exalted station, did I trust in some slight way to prove a worthy successor to my brilliant predecessors who have, with unsullied honor and unerring devotion, fulfilled the best hopes of our fraters who raised them to the honored position I to-day relinquish.

They need no words of favorable mention from my lips. For the work they did—noble, humane—they live forever in our fraternity's history. Their faithful services and loyalty to our order are written in letters of living light in the hearts of a grateful brotherhood.

I leave the work with you, my brothers, and believe that my successor and his new staff of grand officers will carry our noble order onward and upward in its march of triumph toward a higher and better life.

"The sweetest lives are those to duty wed,
Whose deeds both great and small
Are close-knit strands of an unbroken thread,
While love ennobles all.
The world may sound no trumpets, ring no bells.
The Book of Life the shining record tells."

230 Third Avenue, Detroit, Mich.

ORIGINAL ARTICLES.

AN ORIGINAL OSTEO-PLASTIC OPERATION FOR THE REMOVAL OF LARGE VASCULAR TUMORS GROWING IN THE VAULT OF THE PHARYNX, ANTRUM OF HIGHMORE, SPHENO-MAXIL- LARY AND PTERYGO-MAX- ILLARY FISSURES.

Read in the Section on Surgery and Anatomy, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY JOHN A. WYETH, M.D.

NEW YORK.

Mr. Charles Bull came under my notice early in December, 1894, with the following history: In December, 1892, the patient, a student, then 18 years of age, began to complain of some difficulty in breathing through the nose. In March, 1893, he began to suffer from severe pains in his head, was very nerv-

ous, could not sleep, began to lose his appetite, and had to discontinue his studies. In June of that year he was examined by a specialist, a well-known rhinologist, who discovered a growth in the naso-pharynx and pronounced it a naso-pharyngeal polypus. From June 30 to Nov. 18, 1893, treatment was discontinued, as the young man went on a sailing voyage. On November 21 he again visited the specialist. By this time the tumor had grown considerably, and by December 14 the patient was suffering intense pain in the head, complaining that it was a pressure on the brain which caused him great agony. On June 12, 1894, the growth was removed by Dr. R. P. Lincoln with the galvano-cautery, and the patient was immediately relieved. Ten days after this operation he was able to go out of doors, and went regularly to receive special treatment, which consisted in the application of the galvano-cautery to the base of the tumor which had been removed.

In July, 1894, the left cheek began to swell and protrude and the left eye to be more prominent than usual and in the middle of November he began to break down rapidly; became restless, nervous, could not sleep, and suffered from great exhaustion after each application of the galvano-cautery. About this time he was examined as to the condition of his left eye by Dr. J. B. Emerson and Dr. Henry D. Noyes, of New York. The pain was so great that he began to take codeia for its relief. He was now suffering considerably from loss of memory and seemed completely indifferent to every one and everything about him, talked incoherently at times and was evidently fast giving way under loss of sleep, lack of nourishment and the anemia from hemorrhages which had occurred on several occasions. The last operation by the galvano-cautery was made on Dec. 8, 1894. A day or two after this he came under my care. His condition then was not at all satisfactory for a formidable surgical procedure. He was pale, waxy, evidently very anemic, and suffered from double vision; the left eye was wide open and could be closed only with great difficulty; it was protruded and pressed inward, resting partly upon the nose. The left cheek was swollen as if it were occupied by a tumor as large as a hen's egg, and the tissues which occupied the pterygo-maxillary and zygomatic fossæ were pushed outward.

It was evident to me that he was suffering from a tumor which, beginning in the naso-pharynx, had grown into the antrum of Highmore, breaking through the posterior inner wall of this cavity and into the speno-maxillary fissure and the zygomatic fossa far enough to press upon the blood vessels of the eyeball and produce the venous congestion of the cheek and side of the face.

Considering every point of the case, it seemed to me that nothing was left but to try the hazard of a very formidable operation. A careful study of all the methods usually employed to reach these tumors, convinced me that none of them would suffice for the conditions with which I had to deal in this case. I therefore determined upon the following procedure, which is original and I believe, novel. On account of the vascularity of the parts involved and the hemorrhage which must inevitably occur, and also on account of his anemic condition, the first step was to insert a pipette into the median cephalic vein at the elbow and have ready a good quantity of normal salt solution to fill the blood vessels whenever it might

become necessary as the operation progressed. The anesthetic used was chloroform, which was preceded by a hypodermic injection of one-eighth of a grain of morphin, half an hour before the operation, followed by another hypodermic of one-sixteenth of a grain of morphin, ten minutes before the anesthesia. There were present, in addition to Dr. J. A. Bodine, my assistant, and my private hospital staff, Professors Henry D. Noyes, J. B. Emerson, Robert C. Myles, R. H. M. Dawbarn, Dr. Rufus P. Lincoln, of New York City and others.

The operation occurred on December 12. An incision was made beginning along the temporal arch two inches back of the outer angle of the orbit, following the temporal arch to the edge of the orbital cavity, along the frontal process of the malar bone, curving parallel with, and one-eighth of an inch from, the orbital margin, until the point of the knife reached the infra-orbital foramen; then downward to the level of the ala nasæ and outward through the cheek until the point of the knife neared the opening of Steno's duct. This incision was down to the bone from the point of beginning to the lower part of the superior maxilla, where the antrum of Highmore rests upon the alveolar process of the upper maxilla opposite the first molar tooth. Hemorrhage was carefully stopped throughout the entire incision by pressure and by ligating with catgut the larger vessels which were divided, but the soft tissues were in no way dissected up from the bone, except when it became necessary to enter the orbital cavity in its outer half, where the tissues were carefully dissected away from the bone and the eye displaced to the right, (taking care not to press or injure this organ,) until the anterior commissure of the speno-maxillary fissure came into view. I then hurriedly passed in this a key-hole saw with the teeth turned upward, and rapidly sawed through the junction of the malar with the frontal bone. The saw was then turned over with the teeth directed downward and beginning at the same point, I rapidly sawed through the floor of the orbital cavity, traversing the infra-orbital foramen until I had sawed through the antrum of Highmore at the level of the alveolar process of the upper maxilla. A hook was then placed in the outer angle of the orbit and a quick sharp jerk fractured the zygomatic process of the temporal bone, displacing the side of the face; completely exposing the antrum of Highmore, the zygomatic fossa and the pterygoid and speno-maxillary fissures. The hemorrhage was tremendous, but was easily controlled by rapidly packing sponges into the wound and making firm compression. So great and so sudden was the hemorrhage that the pulse jumped from about 80 or 85 up to 140, and the patient seemed about to expire in collapse. At this juncture the faucet was turned on and one pint of the saline solution, already prepared and kept so hot that the hand could scarcely be borne in it with comfort (temp. 110° to 120° F), allowed to run into the vein immediately. Under the pressure of this solution the heart immediately rallied and came down to 85 beats to the minute. The tumor was again exposed and with a periosteal elevator lifted out of the antrum of Highmore and its attachments to the pterygoid process of the sphenoid bone were severed. By opening the patient's mouth which action depressed the coronoid process of the inferior maxilla, the pterygo-maxillary fissure and the zygomatic fossa

were well exposed. The whole antrum was well packed with a long wick of iodoform gauze, which was allowed to project at the anterior inferior angle of the wound, from which it was drawn on the third day after the operation. The bone which had been temporarily displaced with the soft parts adherent, was then brought back into position and held there by stitching the soft parts along the line of incision. A bandage and compression were applied in order to maintain approximation. No sutures were inserted in the bones. The patient made an uninterrupted recovery. He is now entirely well and was to have been present at this meeting to be exhibited, but for an unfortunate accident which occurred to him a week ago; he having been by accident struck upon the glass of his spectacles, driving several particles into the conjunctiva and globe, inflicting a very painful and dangerous wound of the right eye. The bones have all united in their normal position; he has perfect use of the eye and, although the filaments of the facial nerve were divided, he still has motion of the orbicularis palpebrarum muscle. Disfigurement from the scar is insignificant.

Beside the novelty of this procedure, there are three important points which I desire to bring out. First of all, is the character of the anesthetic, morphin being almost entirely relied upon. The amount of chloroform taken was only 2 drachms in one hour and forty minutes of narcosis. I have done a number of major operations with this combination of morphin and chloroform, or morphin and ether, in operations about the respiratory tract, and in one instance in removal of the larynx I used nothing but morphin and obtained complete narcosis and anesthesia, the operation lasting an hour and thirty-two minutes, without a drop of chloroform or ether, the patient remaining perfectly quiescent during the operation, suffering no shock, and with no memory of it.

The second important point is the value of transfusion with a salt solution (one teaspoonful to a pint), to prevent collapse and shock under great and sudden loss of blood. During this operation, five pints in all were allowed to run into the veins, and the blood became so thin that practically salt water ran from out the vessels in the line of the incision, showing the red corpuscles were almost exhausted, and yet we were able to make the patient's pulse drop from 130 and 140, the rapid pulse of collapse, to 80 or 90 beats per minute, full and strong, showing that the heart had plenty of volume to act upon and so did well. Prof. R. H. M. Dawbarn, who has done so much to establish this method of transfusion, attended to this feature of the operation for me and rendered, in other ways, most efficient help.

Finally, the persistence of motion in the orbicular muscle of the lids after division of the branches of the seventh nerve.

For the following study of the nervous distribution of the orbicularis palpebrarum I am indebted to Dr. J. A. Bodine, of the New York Polyclinic.

The orbicular portion of the muscle is supplied solely by the facial nerve. This portion, however, is not necessary to the act of closing the eye. In fact, the palpebral portion is quite distinct from the orbicular, and its action is habitually involuntary. It receives nerve impulse from the sympathetic plexus around the cavernous sinus. In addition to the nerve fibers from the seventh, the upper lid may and does get motor impulse thus; the ophthalmic or first divi-

sion of the fifth receives fibers from the fourth and third, and frequently from the sixth, prior to its division into nasal, frontal and lacrymal. Some or all of these motor fibers may go with the lacrymal branch of the ophthalmic. After the lacrymal supplies the tear gland, it sends fibers to the upper lid. (Gray, page 760.)

Again, the lacrymal not infrequently arises by two filaments, one from the ophthalmic and one from the sixth nerve, thus the upper lid would get motor impulse from the abducens (sixth).

Again, if the ophthalmic has received motor fibers from the fourth, third and sixth as already stated, the supraorbital branch of the frontal nerve which goes partly to the upper lid would carry motor influence, and from this same (frontal) nerve the lower lid could be supplied through the infra-trochlear.

Of course the act of lifting the lid depends upon the levator palpebræ supplied by the third nerve.

ERASION, EXCISION AND AMPUTATION IN JOINT DISEASE.

Read in the Section on Surgery and Anatomy at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, May 7-10, 1895.

BY DE FOREST WILLARD, M.D.

CLINICAL PROFESSOR ORTHOPEDIC SURGERY, UNIVERSITY OF PENNSYLVANIA; SUROEON PRESBYTERIAN HOSPITAL PHILADELPHIA, ETC.

From failure of early diagnosis, from lack of early treatment, and from the neglect of early protection and fixation of inflamed joint surfaces, or on account of the intensity of the tubercular process, a large number of cases of tubercular joint disease still require operative procedures for the safety of the limb or the life of the affected individual. Fortunately, owing to a better appreciation of the conditions, these cases are becoming rare; it being more generally recognized that destructive results are preventable by early treatment; that is, by long-continued protection secured by rest and by effective mechanical devices. Proper management of these cases will result in the saving of a large number of these joints, even if the tubercular bacillus has secured a foothold in the osseous structures adjacent to the joint itself.

Much will depend upon the joint invaded; but the same principles of treatment will apply to all. The treatment may be summed up in the one word *rest*. This condition may be induced either by fixation, by extension, or by both. As a result, however, of the causes first enumerated many joints become so thoroughly implicated by the tubercular process that removal of the offending and dangerous foci becomes imperative.

Erasion (improperly termed arthrectomy) aims to remove by gouge and spoon and scissors the diseased hard and soft parts only; excision or resection goes a step further and takes away not only the implicated structures, but also an outlying area of bone; it is, therefore, still more radical, and aims to keep well outside of the disease. Amputation sacrifices a large portion of healthy tissue lying on the distal side of the diseased joint and is therefore still more mutilatory.

The proper application of these several operations to individual cases, therefore, demands a discriminating and judicious consideration. The decision will vary with the joint involved, the extent and character of the disease, the age and condition of the patient, the dangers of systemic infection, the risk to life,

and the ultimate results to be obtained as regards locomotion.

As *erosion* is the least mutilating and is both theoretically and clinically so effective an operation, it has steadily grown in favor, especially as it renders possible the continuance of function in a considerable proportion of cases. It is also, as a rule, a less severe procedure; while it leaves excision and amputation, the two more radical operations, still in reserve. Even should the more serious operation follow, the loss of time especially in children, will be more than compensated for by the increased growth of the limb.

WRIST AND ANKLE.

Erosion.—The ankle, wrist, tarsus and carpus may be considered in a single group, as the course of the disease in these joints is closely allied. The complicated character of the articulations involved makes extensive infection of the area very probable, and conservatism is almost universally recognized as the proper course of procedure.

The exclusion of all operative methods, as advocated by some authors, is unwise, and radicalism as to early amputation is equally wrong. A large number of these cases can be saved, and a useful walking member with movable joint can be obtained by the proper application of simple *erosion*; that is, the removal of diseased structures only and the continuance of proper mechanical appliances. Subsequent progression depends largely upon the situation of the foci. In an extra-articular osteitis that has involved cancellous tissue chiefly, the chances of securing good results by *erosion* without joint infection are excellent. By thorough removal and subsequent injection of anti-bacillary substances, arrest of the tubercular process is common. I have frequently secured excellent results by repeated gougings of small areas as they appeared, and the joint surfaces have entirely escaped contagion.

In young cases, where time is not a very serious matter to the patient compared to the benefit to be obtained, these repeated operations are most helpful, as excellent movable joints are thereby secured. In more serious cases, the disease will involve the tarsal or carpal articulations, and extensive removals may become necessary; yet, in many even of these cases the disease can be eradicated without loss of limb.

For these reasons, conservatism, even though carried to an extreme degree, is desirable, save in those cases where the tubercular process is intense and the resistive power slight; in the latter cases, amputation should be thoughtfully considered. In *erosion*, knife, scissors and gouge are to be employed until apparently normal bone is reached. Whenever it is possible to avoid the osseous structures underlying the cartilage the operation should be arrested, since cartilage is almost certain to die and implicate the adjoining articulation. It is impossible to be certain when all the invaded soil is removed; but fortunately, nature is able to overcome a moderate number of bacilli, and it is not well to open and invade any unnecessary articulation. When in close proximity to an articulation a certain number of cells, even though left behind will be destroyed by phagocytic action, or a second operation may be undertaken.

Portions of the tarsus and carpus which are liable to infection and can not be reached through the wound may be helpfully influenced by cataphoresis;

that is by driving iodoform into the tissues by the positive pole of a battery, using a current of about 5 milliampères. By this method, or by hypodermic injections of iodoform in the region of the joint, the progress of the disease can often be arrested.

The incisions for *erosion* will vary with the site of the infected area, but for large removals I prefer the long lateral cuts as in excision.

The only guide as to the limit of removal is the extent of the disease. In children, the epiphyseal line should be avoided if possible. Unfortunately, however, in cases which demand excision, avoidance of this line is seldom feasible. The removal of the end of the tibia and fibula, together with the astragalus, necessarily shortens the leg very seriously, and ordinarily results in a stiff joint. In a large number of cases it is doubtful whether the patient is as comfortable as he would be with an artificial limb; practically nothing can be gained in growth if the lower epiphysis is removed.

In the carpus after operation, thorough fixation should be enforced by plaster-of-Paris, or other fixed dressing, which will prevent motion and relieve the resulting inflammation. Drainage, cleansing and local injections of sterilized iodoform oil (10 per cent.) are essential in the after-treatment.

At the ankle and tarsus, the inflamed parts must be absolutely protected from the weight of the body; not for an instant should a step be taken upon the diseased member. Crutches should be used, both before and after operation.

Thorough drainage is necessary and demands the most careful attention to prevent subsequent contamination which will increase the suppurative process. The great fault in such cases on the part of the surgeon lies in his failing to continue asepsis. A wound can escape contamination for weeks and even months, but only by the most scrupulous attention to the laws of cleanliness. I have seen chronic sinuses kept sweet for eighteen months, but it demands "eternal vigilance."

At the wrist the lateral incisions will frequently give good exposure, with the least injury to important structures.

For reaching the tarsus and carpus the only rule to follow is to avoid vessels, nerves and tendons as much as possible and yet secure thorough removal. Many surgeons employ one or two long dorsal longitudinal incisions with transverse cuts if necessary. If tendons or nerves are cut during the operation they should at once be sutured with sterilized silk or catgut chromicized. If one incision only is used at the wrist, it should extend from the middle of the first metacarpal well upward upon the radius. As tendons are divided the ends should be grasped with forceps, marked in pairs.

Excision.—A formal excision is desirable in more advanced cases where the process has advanced to large destruction of bone tissue, surrounding one or more of the articulations, where the general health presents evidences of succumbing to the disease, yet where there is reasonable hope of saving the limb from amputation.

The ankle or wrist joints are first involved ordinarily, although the tarsus and carpus may be primarily the seat. In the latter case, amputation is the more common, especially in tubercle-saturated patients.

In operating upon the ankle, the line of incision

will vary with the exigencies of the case, but I have found that very satisfactory exposure can be made without injuring the vessels, nerves and tendons by two long, lateral, curvilinear incisions, which can be extended as desired by cross cuts when both the astragalus and malleoli demand removal. The peroneal tendons are difficult to hold aside, but can frequently be saved by using a retractor, or by carrying around them a thread of silk, which is less in the way of the operator. If divided, they should be sutured with silk or chromicized catgut. In the tarsus, I rarely make a cross dorsal cut (although the tendons can be sutured), as I am able to make a satisfactory atypical excision through long lateral incisions. I have never employed an osteoplastic operation, even when the os calcis had to be removed.

The most useful saw for joint-work is a key-hole saw made on the principle of Adams' blade, but with a longer cutting face. This can be easily managed and can be manipulated without injury to the surrounding parts. A strong, S-shaped bone retractor is also useful for lifting out the tissues and protecting them. A strong blunt knife is also of advantage in making the dissection.

Amputation is often necessary in extensive destruction of joints and especially in adults.

KNEE.

In children under 12 years of age it is exceedingly important to preserve the epiphyseal line in order to secure growth for as long a period as possible. Erasion is, therefore, preferable to excision in all cases where it can be done effectually. The incision varies with different operators; I do not deem it of any special importance. My preference is the horse-shoe flap with the convexity downward, as stitching of the tendo-patella can be more easily accomplished than suturing of the sawed patella when the straight incision is employed, and better drainage can be secured than when the convexity of the flap is upward; moreover, it gives excellent exposure of the articular surfaces and thorough examination can be made. In some cases lateral incisions alone are sufficient to permit removal when the foci of disease are few. The spoon, gouge, knife and scissors should be thoroughly employed until all the diseased hard and soft tissues are removed; the hollow-handled flushing spoon being particularly useful to carry away the *débris*. Diseased synovial membrane throughout the bursa should be thoroughly removed even though patient search is required. Boiling water may be freely used to destroy the remaining bacilli, or the cavity can be filled with an alcoholic solution of acetanilid or a sterilized glycerin emulsion of iodoform.

In a few cases it will be possible to close the wound without drainage, but where purulent infection is decided, it would be better to drain with rubber tubing for at least a week.

In cases over 12 years of age, and in adults where the destructive process is not too extended, a formal excision is usually preferable, although erasion can sometimes be profitably employed, particularly where infection seems moderate. In the latter case, lateral incisions with scraping and drainage are rarely sufficient.

As to the incision, the same rule applies as in erasion. In an adult, particularly, the incision should extend well above the diseased bone, and all the foci should be gouged unstintingly. A butcher saw with reversed blade to saw from within outward,

with proper protection of the parts beneath, is an excellent instrument. Occasionally, the key-hole saw answers nicely, but the angle of removal can not be so accurately determined as with a larger instrument. It is very important for the surgeon to train his eye to make the section at such an angle as to bring the tibia in good line with the femur without a second cutting. As a rule, the popliteal tissue will yield sufficiently to permit the straight position; but if there is still interference the contracted tendons can be divided.

The patella need seldom be removed unless diseased, as it is of service if the tendon is stitched *in situ*.

Amputation.—In children, the cases demanding primary amputation will be few; but occasionally the destruction of bone and joint by saturation is so extensive that removal is the only operation promising hope of life. In adults, the removal of the limb may frequently offer the best hope of life and of usefulness.

As to suturing of the bone, I prefer to trust to external appliances. If plaster-of-Paris is properly applied, good results can be secured, but a bracketed splint for adults is sometimes useful. A plaster cast can be freely opened on either side and the anterior and posterior halves can be removed for dressing, while the limb can still be held in good position without disturbance of the parts.

With thorough asepsis, dressings are infrequently required, and in children there is less disturbance and pain. Drainage tubes should be removed early. After healing, an apparatus should be worn until all tendency to deformity has disappeared.

HIP.

The question of erasion at this joint is one which depends largely upon the amount of disease, the age of the patient, the amount of suppuration, etc. It certainly is an operation far less successful in this joint than at the knee, ankle or wrist.

In cases demanding early opening the pains are often severe and nothing short of complete excision of the upper end of the bone is advisable. In a few cases, however, where the exploratory incision demonstrates fairly good joint surfaces, the foci of disease may be removed by gouge, and the loss of bone substance and consequent shortening so frequently found in excision in young children may be avoided.

In osteomyelitic cases this puncturing of the bone with subsequent drainage is useful.

The disadvantage of erasion lies in the fact that it is almost impossible to decide as to the limit of the disease, and the continuation of the process ultimately demands excision; the latter operation is therefore the one employed by the majority of surgeons, as its results are beneficial in shortening the time of suppuration, and a fairly good walking member is secured.

I realize thoroughly that operative interference tends to disseminate the tubercle bacilli and, if undertaken, the extirpation should be thorough; hence the desirability, as already stated, of complete removal.

The two most practical routes by which the joint is to be reached are the anterior and lateral incisions; the anterior incision is the most suitable for exploration and where sinuses have already formed in this region. This incision is made so as to interfere as little as possible with the muscular tissue, the cut being begun just below the anterior spinous process

and extending downward as far as necessary, the object being to enter the joint between the sartorius and rectus on the one side and the tensor vaginæ and glutei on the other. By this route, both muscles and blood vessels are uninjured. When the neck of the bone is reached the capsule can be divided, exploration of the head, neck and rim of the acetabulum can be made, and the amount of the diseased bone decided upon. A strong blunt knife assists greatly in the process of clearing the bone, and the neck can be divided without injury to the surrounding tissue, with a narrow key-hole saw, guided and guarded by the finger.

The head of the bone is often with difficulty released from the socket. This may be accomplished before section of the neck by manipulation of the femur and the use of a blunt knife or, as I usually prefer, after section of the neck by grasping the fragment with strong lion-jaw forceps. The ligamentum teres, if intact, must be severed. I have found a flexible knife, which can be made to conform to the acetabulum, useful in dividing this structure. All the diseased structure should be removed from the acetabulum and the surrounding area with thorough flushing, and with perfect asepsis the wound may sometimes be closed and perfect union secured. The joint should be filled with iodoform oil. In bad cases both gauze and rubber drainage should be employed for the first few days, the gauze being removed at the first dressing, and the rubber tubing as rapidly as possible.

When the suppurative process is severe, a posterior opening may be made and thorough drainage instituted. This method is most useful in the cases already described, or where the head of the bone has become separated and lies as a sequestrum.

In old or largely suppurative cases the lateral incision over the trochanter is desirable, as it gives a larger exposure of the joint, and when the trochanter is to be removed it is decidedly better. Whenever it is possible to strip off the trochanteric attachments of muscles in a comparatively healthy bone, this method should be employed, as subsequent motion is thereby improved. As the femur is often extremely fragile in these cases where the osteitis has extended throughout the entire shaft, great care should be taken not to fracture the limb, especially in making rotatory movements.

If the disease seems to have a definite limitation it will be better for subsequent locomotion to leave the trochanter, even if the drainage is somewhat interfered with by its retention. In these cases the drainage may be supplemented by a posterior opening, which often compensates for lost lateral space.

The power to steady the femur upon the pelvis is so important in locomotion that the retention of all possible muscles is essential, consequently I retain the trochanter whenever it is safely possible. I can show cases of excision when the femoral head and neck have been removed through an anterior incision, that can stand upon the toes of one foot without assistance and flex the thigh upon the pelvis beyond a right angle, can abduct and adduct the limb and have no deformity but shortening, a result which is a great improvement upon the condition attained after excision of the trochanter.

The majority of hip excisions, however, leave the patient a cripple for life, which readily accounts for the persistence with which many surgeons adhere to

the conservative methods of treatment, and as an ankylosed limb in fair position is usually more serviceable for locomotion than an excised joint, the resection should not be undertaken until it is certain that suppuration will occur or that danger to life will ensue by delay.

The results to be feared are the exhaustion from long drainage, amyloid degenerations and general tuberculosis. While excision aims to remove the dangerous tubercular foci, yet the operation sometimes rapidly disseminates the disease. In a child with a bad antecedent history, an excision should be performed earlier than in a healthy child. Long continued, or very profuse suppuration also calls for surgical interference to avoid waxy degenerations. When in doubt, an exploratory incision is advisable, especially if suppuration is present.

In general, a case which is progressing unfavorably in spite of good mechanical treatment, with evidences of systemic infection, demands interference. Acetabular disease, when manifested by suppuration within the pelvis, is best arrested by thorough removal and drainage. Amputation is usually reserved for adult cases with old and suppurative sinuses and marked caries.

ELBOW.

In this region, erosion is decidedly the best operation for young children: by careful gouging of the diseased areas a very fair member can be secured. Whenever possible, the attachment of the biceps and triceps should be left intact. When the entire bone must be removed the retention of the periosteum, (if healthy) at the points of muscle insertion is advantageous. Quite frequently the cancellous tissue of the olecranon can be gouged without disturbing the insertion of the triceps.

The incision for erosion may be lateral, but a focus in the ulnar is rapidly reached by a cut made directly over the olecranon. For formal excision, a posterior long incision directly over the olecranon, or two lateral posterior ones with cross cut, will give good exposure and save also the ulnar nerve.

The head of the radius is liable to disease, but section of the neck will often permit retention of the biceps. I have not found much difficulty in drainage, even when I have sawed through the olecranon and left it *in situ*. For excision, the narrow saw and rongeur forceps are the most useful instruments in addition to the gouge and curette. Care must be taken to remove every particle of diseased tissue, whether excision or erosion is employed, and the parts should be flooded with bichlorid and afterward with iodoform oil and other antibacillary substances.

Drainage tubes should not be retained too long. Plaster-of-Paris makes the best subsequent dressing, as the cast can be made thick at the bend of the elbow by longitudinal reverses, thus giving strength to the dressing when the windows are cut. Amputation is seldom required except in adults or in the worst class of cases.

SHOULDER.

The rarity of tubercular disease at this joint makes it difficult to speak with certainty as to definite results. My personal experience has been so limited that I can not speak from that standpoint, but my opinion is that erosion is decidedly the best operation for this region, and that it should be done as early as possible, as soon as the presence of pus is determined,

The incision should be made so as to avoid as much as possible, interference with subsequent muscular action, and the vessels and nerves should be left unmolested. I have never seen an amputation for this condition.

CONCLUSIONS.

1. When operative measures are demanded, erosion is the preferable procedure, as it gives less subsequent deformity and results in better locomotion. This operation is especially applicable at the ankle, wrist and shoulder, frequently at the knee and elbow; rarely at the hip.

2. Excision is most useful at the hip. It is also largely employed at the knee and elbow; more rarely at the other articulations.

3. Amputation should be employed in rapid and extensive degenerations at the ankle, knee, wrist, elbow, and in old hip cases which have relapsed after excision.

4. In children, the less mutilatory operation should be first employed, even though repetition is required; but in adults, temporary operations are seldom advisable.

5. The necessity for operative treatment in joint diseases arises from neglect of proper mechanical measures. Protection and fixation of the joint in the early stages of tubercular invasion will nearly always result in a cure with movable joint and good function. These measures together with antibacillary injections and cataphoretic in-driving of iodoform are steadily decreasing the number of cases demanding operation. Motion and traumatism are the chief causes of inflammatory complications in tubercular ostitis, and often result in such an amount of sup-puration and loss of bone as to demand removal of the diseased tissues.

EXSECTION OF THE KNEE-JOINT,

WITH REPORT OF A CASE OF COMPLETE DISLOCATION OF THE KNEE, OF NINE YEARS' STANDING, AND WITH SPECIAL REFERENCE TO METHODS OF FIXATION.

Read in the Section on Surgery and Anatomy, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY S. F. FORBES, M.D.

AUTHOR OF "NEW AMPUTATION THROUGH THE FOOT;" LATE PRESIDENT OF THE OHIO STATE MEDICAL SOCIETY, ETC.
TOLEDO, OHIO.

Early in May, 1894, Maggie D., a wholesome young girl of German parentage, came under my care for a slight malarial trouble. In the course of the attendance, which was only three or four days, I discovered that the girl was severely crippled in her left leg; She was otherwise a healthy, robust, well-formed young woman, of 21 years of age; but she was utterly unable to move a step, even about the house, from chair to chair, without the aid of a crutch, which she kept constantly at her side. In attempts at locomotion, or standing, with this leg, the toes of the foot only touched the ground, and the body sank down a foot or more, and gave the appearance as if falling.

Her story was, that nine years before, when 12 years of age, while running on the frozen ground, her left foot fastened in a hole and she was thrown down and suffered a severe injury of the left knee. She was conveyed to the house and left to lie on a couch for a week or two. Then a physician saw her, and after a short and imperfect examination gave the opinion that it was a strain of the joint which would be well

in due time. But from that time on, for over nine years, she had not been able to walk a step on that leg.

Examination at once revealed a complete dislocation of the knee in the antero-posterior direction, the head of the tibia being thrown into the popliteal space, and the condyles of the femur down upon the front of the tibia. The leg was bent at an angle of nearly 45 degrees from the line of the thigh; the whole limb was shrunken and poorly developed from its nine years of enforced idleness. There was slight motion at the knee and the shortening from the anterior superior spinous process of the ilium to the internal malleolus in a straight line was five and one-half inches. Part of this, perhaps one inch, was in consequence of the angle at the knee. Her gait in walking with the crutch was, slow, jerking and exceedingly ungraceful. The young woman was keenly alive to her crippled condition, and the fear that she was to go through life in this deformed state caused her almost constant anxiety and unhappiness. When, therefore, an operation was mentioned, looking to her improvement she gladly assented. Near the end of the month (May) she entered the Toledo Hospital, and was made ready for exsection of the bones composing the knee.

Complete dislocation of the knee of nine years' standing. Unable to walk without a crutch, or use the limb during that time.

In considering the methods to be used in the conduct of this case, I resolved not to employ for fixation the steel drills, as advised and used by Wyeth, nor the bone or ivory pegs used by others, nor indeed but little, if any, of the so-called internal or direct methods of fixation. Such methods are in some cases painful and irksome, and in all cases not more effective than external supports. I could not then see, and can not now, how the bones, in exsection of the knee, differ, or should receive different methods of treatment from those in transverse compound fractures of the femur. Neither did it appear that the excessive and cumbersome bandages including the pelvis, generally used heretofore in these cases, were either necessary or advantageous.

Briefly, the operation and after-dressing were as follows: the patient being anesthetized and the limb having been prepared, an incision was carried across the knee from condyle to condyle, and an upper and lower cuff dissected back a sufficient distance. All of the structures in front and under the condyles, in-

cluding the patella and some extraneous osseous material, were removed down to the tibia. The condyles were carefully bared, pushed out of the wound, and one and three-eighth inches removed by the saw. The leg was now well flexed on the thigh, the head of the tibia cleaned and pushed out of the same wound, and three-eighths of an inch of the articular surface of this bone removed. On straightening the leg now, the bones came together fairly well, but the leg was so nearly cut off and was so loose and unsteady that I confess to having had a temporary weakness come over me, and decided to use some internal fixation. Hence, six chromicized catgut ligatures, three on a side, and one silver ligature in front, were applied to the divided bones. The hemorrhage was trifling, and when completely arrested, a few strands of catgut were left in the wound for drainage, the periosteum was drawn down and carefully stitched with catgut, the external flaps treated in a similar way, and the line of the wound sealed with iodoform collodion, the drainage strands only protruding. Two layers of sublimate gauze were next applied, covering the entire foot and leg, reaching well up on the groin. An envelope of absorbent cotton was wrapped evenly around the limb, extending above and below the wound a few inches. The whole limb was now

Ten months after operation (exsection of knee joint); has good use of the limb; walks long distances without crutch or cane.

neatly and carefully wrapped in a well-filled flannel bandage, and a plaster-of-Paris bandage applied from the toes to the groin. During the application of this latter envelope, strips or splints of wood (ash), five-eighths of an inch wide and one-eighth of an inch thick, were inserted as the binding went on, reinforcing, so to speak, the plaster, and giving an instant steadiness to the limb. These strips were four in number, two under and one on either side of the limb, extended from the ankle to the body, and were permanently embedded in the plaster envelope.

The patient made a good recovery from the anesthetic and operation, and from the hour of her returning consciousness until the present, has repeatedly stated that she never felt the slightest motion of the bones upon one another. So far as her feelings and sensations were concerned, as well as from all other indications by which the surgeon might judge, the fixation was instant, complete and permanent.

The further progress of the case was uneventful. About thirty-six hours after the operation some reac-

tionary fever began. The pulse rose to 120 and the temperature to 104 in the course of a few hours. Pain and restlessness occurred to such a degree that a hypodermic of $\frac{1}{4}$ grain morphia was given with much relief, and in a few days a nearly normal condition of the system returned, and continued until the patient was discharged cured.

About three weeks after the operation the bandage over the outside of the knee became stained from some internal discharge, and a trap was cut through the plaster down to the wound, when it was found that a thin edge of the upper border of the lower cuff about one-quarter of an inch wide and three inches long across the limb had died, and was being cast off. The parts were cleaned and absorbent cotton pushed in around the wound, which was covered by iodoform gauze, and this dressing repeated two or three times daily, thereby keeping the wound and adjacent parts perfectly clean. In about one week the slough became loose enough to be, and was removed, leaving a perfectly clean wound one-quarter of an inch wide, two and one-half inches long across the limb, and one-half inch deep. In the bottom of the wound the silver wire lay loose, but partly covered by the granulations, and as it was serving no purpose I divided it and took it away. No bone could either be seen or felt in the wound, which was re-stitched with catgut and made quite tight, covered with gauze and bandaged. In about two weeks more the wound was healed, and in seven weeks from the day of the operation the plaster and all coverings were removed from the limb, which was fully healed and appeared quite strong. The patient was now allowed to go about the ward, and in pleasant weather out of doors a little, on her crutches, wearing only a bandage and some slight support around the knee. Within three weeks thereafter the limb had acquired sufficient strength for her to stand upon that leg, and make some little attempts at walking with it. She was discharged from the hospital and from all surgical care and attendance ten weeks after the operation, with a straight limb and one which was already serving her somewhat in walking.

The progress in usefulness and strength in the limb has steadily continued, and now at this writing, ten months after the operation, she walks without crutch or cane, getting on street cars in crowded streets, and walking miles even, without pain or fatigue. In fact, she is acting as a house girl in a private family, and is upon her feet more or less all day. Her gait has also become quite normal, and when walking at a moderate pace, no halt or limp is noticeable.

She wears under the shoe of the affected limb an iron support of just two inches, and uses the limb with a freedom and confidence quite surprising, considering the short time which has passed since the operation.

Two points of practical value are sought to be proved in the report of this case. The first is, that in exsection of the knee joint all internal or direct fixation, especially of unabsorbable material, is unnecessary, and sometimes undoubtedly interferes with the healing process; and that external support by means of the plaster bandage, strengthened by wooden strips, gives instant and permanent fixation. There are two purposes, however, which chromicized gut serves in these cases, namely: these ligatures aid somewhat to keep the bones steady in the handling

which takes place during the dressing of the limb, and also they prevent the crowding in of the soft structures between the ends of the bones. For these purposes, but not for any purpose of lengthy fixation, a few heavy strands of gut may very properly be used. But all such measures as steel drills, ivory pegs, or other similar methods, should be abandoned; for they, as before stated, are often painful and irritating, literally as a thorn in the flesh, and do not serve the desired purpose as well as the method here described.

The second point in connection with this case is, that the practice of extending the bandage up onto the pelvis, while it is irksome and painful to the patient, is not necessary to secure entirely satisfactory results. Many times during the progress of the case I found my patient, on arriving at her bedside, in a half-sitting position, engaged in reading or light needlework, and insisting that this position she knew did not affect the bones of her leg. The partial, even quite limited use of the hip joint, affords much relief to the tedium of the weeks which must pass during the process of bony union. In conclusion, the opinion is here expressed, that by the employment of the methods of fixation and bandaging here described, operators will secure not only the best surgical results attainable in these cases, but they will also receive the grateful appreciation of their patients for rendering their condition as painless and comfortable as possible during the period of repair and convalescence.

FLAT-FOOT—ITS CORRECTION AND COMPARATIVE STUDY WITH THE FOOT OF THE ORANG, CHIMPANZEE, GORILLA AND BABOON.

(ILLUSTRATED BY PHOTOGRAPHS.)

Read in the Section on Surgery and Anatomy, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY B. MERRILL RICKETTS, PH. B., M.D.
CINCINNATI, OHIO.

Of all misfortunes in the way of orthopedic deformities, I believe there can be none worse than aggravated forms of flat-foot. The patients must not only suffer the humiliation of being deformed, but must suffer pain in many instances to the degree of absolute helplessness, and of but little use, unless it be to the instrument makers. They have usually experienced all kinds of treatment, both medical and surgical, have taken all the rheumatic remedies and applied the greater number of patent nostrums for the relief of soreness. When once the deformity becomes painful, either from trauma or the natural consequences of such a deformity, there seems to be no means of relief, especially for that class in which flat-foot is most commonly found. That the cause of flat-foot is primarily rachitic, I am not quite sure, as I believe that there is as great variance in the shape of the feet as there is in any other part of the anatomy. We have differently shaped hands, and why not differently shaped feet? The measurements of the hands vary materially with individuals; sometimes they vary in the same individual. Just so do the feet vary, and especially the arch of the foot; some are higher, while others are lower than the average. If a foot with a low arch should be subjected to an injury in such a way as to diminish the height of that arch, it is to be suspected that the

patient will suffer more or less inconvenience from the changes.

I do not wish to be understood as challenging the theory, which many investigators have set forth and advocated, viz., that flat-foot is usually due to a rachitic condition. I believe that rickets is responsible for a large percentage of flat-foot.

When we take into consideration the bony structure of the foot of man's nearest allies, I do not believe it is safe to say that all flat-foot is of rachitic origin, especially while the effects of trauma are so well known. Man being the only true biped, it is interesting to study the most conspicuous differences between him and his nearest relations, those which but occasionally become erect; though the erect position has caused the foot to become flat and the great toe shortened, and otherwise modified, through the influences to which the loss of power of prehension can be attributed, there is an arch in the foot of man that does not exist in that of his allies. This, however, is not the case in all bipeds, for there are

1. Orang.

still certain savages that retain the power of prehension, as shown in their ability to climb trees. Some apes are now undergoing this evolutionary change. Baboons are to be found among the hills and rocky districts only climbing trees from necessity. In them, we find a foot that is flat to the highest degree. The gorilla runs in a sidling manner and rests on its hands and feet. This, perhaps, is due to the excessive flatness of its foot, the ends of the toes being bent under to take the place of the arch. Some of the hylobates can walk or run upright. The construction of the hands of the quadrumana is of the same pattern as those of man, but not so symmetrical or well adapted for diversified use. Some of the monkeys, the chimpanzee and the orang-outang, walk on the margins of the palms or on the backs of their bent fingers.

This is perhaps due to the great length of the hand, a condition necessary for climbing. However, the greatest climbing monkeys in the world are the

American atales and the Asiatic hylobates, which have rudimentary thumbs, the fingers being converted into hook-like appendages. There came a time when a difference in the construction of the hands and feet was necessary, perhaps due to the manner of procuring substance, on the ground and not in trees; quadrupedal or bipedal. The mastoid process, which is found in the human skull, is the

dren are born with flat-foot, and that the arch is developed as the child reaches adult life. Accidents, together with a rachitic constitution, are, I believe, invariably responsible for the arch not reaching its highest degree. The manner in which the foot is dressed, no doubt, has something to do with increas-

2. Orang.

4. Orang.

3. Orang.

5. Orang.

result of the erect position of man, and they are almost rudimentary in the next nearest relative, the gorilla. They do not exist at all in the baboon, chimpanzee or orang.

A careful study of the accompanying photographs will, I think, add much to our knowledge of this abnormal condition in man. It is a fact that all chil-

ing the degree of the arch, for in all savages who have not worn shoes we find flat-foot to a greater or lesser degree. This is so with the Samoans, Dahomeys and several other tribes of the South Pacific, as observed by myself. It does seem, however, that the arch of the foot is increased with the degree of

civilization. We need not, then, be surprised to find that the arch of the foot will not tolerate the excessive endurance so often imposed upon it, and when this arch has reached its degree of endurance neither should we be surprised in not being able to devise some mechanical means that will answer every purpose intended for a high arch. It has been my observation that the fastest runners have the highest

lieve it makes any difference what the cause is in these most aggravated cases; there the remedy would be the same, whether congenital or traumatic. I believe that many of the milder ones are benefited by some one of the many appliances. Since the introduction of clean surgery, much more has been hoped for, and it now remains for us to determine which of

arch. This, perhaps, may have some bearing upon the subject.

This abnormal condition, flat-foot, naturally falls within the domain of orthopedic surgery, and it is only in the most simple cases that any kind of appliance gives any benefit whatever, it being seldom claimed that the benefit is permanent. I do not be-

lieve it makes any difference what the cause is in these most aggravated cases; there the remedy would be the same, whether congenital or traumatic. I believe that many of the milder ones are benefited by some one of the many appliances. Since the introduction of clean surgery, much more has been hoped for, and it now remains for us to determine which of the surgical operations is to be adopted for the correction of the deformity in those cases which have made the subject helpless and practically an invalid with great suffering. Surely the various tarsotomies have been found wanting, also the various operations upon the tissues of the plantar regions. This being the

case, it seems that for the present there is but one of three things to do: 1, to shorten the foot by dropping down the posterior part of the os calcis, thereby raising the arch, as suggested by Gleich, of Vienna; 2, supramalleolar osteotomy (Trendelenburg); 3, amputation of the foot and its substitution by an artificial one. Whatever operation should prove the

ators we find Willy Meyer, Royal Whitman, Bernard, Roth and T. S. Ellis. In our own country it appears that Meyer was the first to operate, surely the first to operate in the way suggested by Trendelenburg, of Bonne (supramalleolar osteotomy), although he had operated twice in cases of flat-foot, as the result of Pott's fracture, before operating for simple flat-foot according to Trendelenburg.

For my own part, after finding all appliances useless, giving the more aggravated forms no relief

most desirable, to Golding-Bird, Davy, Ogston, Stokes, Wienlicker, Hare, Phelps and Trendelenburg belong the credit of having been the first to substitute the various surgical appliances with a direct surgical operation. The first of these seems to have been in 1878, only fifteen years ago. Among the later oper-

whatever, if anything increasing the amount of pain, I have decided that Trendelenburg's operation is the most rational so far presented. In consequence thereof, I operated upon a mulatto, female, age 38, weighing about one hundred and fifty pounds. Although there was a predisposition to flat-foot, she had no inconvenience at all until at the age of 28, when through a misstep in going down stairs she

broke down the arch of the foot, since which time she has been a great sufferer, not being able to attend to household duties for several months at a time. The patient had been subjected to various kinds of appliances, having had the foot in plaster for several weeks on several occasions. It was not long until she began to have pain in the left foot, the result of overwork. Between the two it was necessary for her to use crutches in getting about the house. I was consulted on November 7, when I advised one of the various operations suggested for the relief of such deformities. It was at this time that one of our most prominent instrument makers declared that he could relieve her trouble. I was perfectly willing that he should be given an opportunity to apply his skill and so permitted him. At the end of six weeks her suffering was unbearable, and she was

wound was closed with silkworm gut. Time, fourteen minutes. The right fibula was divided in the same manner, in a corresponding locality. Silkworm gut used for sutures. Time of operation, eleven minutes. I then proceeded to divide the right tibia. After making my incision it was found, upon removing the rubber bandage which had been used upon the other leg, that the posterior tibial artery had been injured. I was at a loss to know where the hemorrhage came from, but I soon determined that the artery was in an abnormal position, running along the tibia upon its inner and anterior surface. The branch divided was about the size of an ordinary pin, but the hemorrhage was quite severe, necessitating the ligation of the posterior tibial. The hemorrhage once checked, the bone was divided and the operation completed within sixteen minutes. Silkworm

16. Before operation.

K. T., age 33, 150 pounds. Both feet inclined to flat foot. Broke down arch of right foot at age of 23. Disabled four out of ten years. All appliances failed. On Dec. 19, 1893, supra-malleolar osteotomy both legs. Left fibula 12 minutes, left tibia 14 minutes, right fibula 11 minutes, right tibia 16 minutes. Fenestrated plaster-of-Paris cases. Complete recovery with double bow-legs. (Trendelenburg's operation.)

anxious that I take the matter in hand and give her relief in some way. Consequently on Dec. 19, 1893, I made a supramalleolar osteotomy on each lower leg, while the patient was under the influence of chloroform. An incision one inch long, directly down upon the left fibula, two inches from the lower end, was made, the periosteum divided and the bone severed with a chisel, subperiosteal. The wound was closed with silkworm gut. Time of operation, twelve minutes. An incision was then made upon the inner surface of the tibia, in the same manner, and the bone likewise divided at a point corresponding to the division in the fibula. This was also periosteal. The

17. Fifteen months after operation.

gut was used throughout, a small piece being drawn through for drainage in each wound.

After the incisions had been dressed and the legs banded with cheese-cloth, plaster-of-Paris was applied by my assistants, Drs. J. V. Ricketts, H. V. Sparger and O. S. Mills, while I held the foot in an extreme adducted position. The left leg was first applied, so I was able to place the right foot in position before its plaster cast became hardened. These casts were removed at the end of fourteen days, and three of the wounds found to have united primarily. The legs were adducted to a greater degree and new plaster dressings applied. The left, however, was more adducted than the right, because it was the more troublesome of the two. In fact, the right foot had caused but little trouble, aside from its being overworked. The wound which had not healed primarily

was upon the left tibia. There was more or less trouble for several weeks when a small spicule of bone was removed. After this time the union was perfect, and the patient has since been able to go about her household duties without pain or discomfort in any way whatever. She is absolutely free from pain, and I might say entirely cured. She has gained considerable flesh, weighing perhaps thirty pounds more than at the time, still she does not complain, but says she has not felt as comfortable and as free from pain since the day of her injury, eleven years ago. Thus, this case illustrates that the end has justified the means, and I look upon it as one of the most gratifying results that could be obtained in a deformity of this kind.

I am free to admit that I look upon supramalleolar osteotomy as the most rational means of treating

18. After operation.

flat-foot that can not be managed with the ordinary appliances. I believe that if the operation is done aseptically it offers more than any appliance, and should be substituted for them without any great hesitancy. The division of the os calcis, as suggested by Gleich, does not, I believe, offer the same advantages. It is not so rational. If either the operation of Trendelenburg or Gleich should prove fruitless, and the patient continue to be an invalid, I believe it is our right to make an amputation of one or both feet and substitute them with artificial ones. There are many deformities that are attended with more suffering and pain, loss of time and humiliation than the wearing of one or two of the most ingeniously constructed artificial feet.

In conclusion I would say:

1. That flat-foot is principally due to one of three

causes: (a), failure of the tarsus to become arched; (b), rickets; (c), trauma.

2. That it becomes aggravated with age.

3. That all bipeds are born flat-footed—the arch being an after-consideration.

4. That the highest arches are found in the fleetest runners.

5. That the barefooted races do not have any very perceptible arch or inconvenience.

6. That man's nearest allies, the chimpanzee, gorilla, orang and baboon, have but little indication of an arch. On the other hand, the tarsus in the chimpanzee, his nearest ally, lies upon the plane, while the posterior under surface of the os calcis does not touch the plane to any degree whatever. In the gorilla, however, the posterior part of the os calcis, together with the tips of the toes support the body—the tarsus not touching the plane. This is the case with the orang.

19. Before operation.

7. That the construction of the hands and feet of the quadrumana are of the same pattern as those of man, but are not so symmetrical or so well adapted for diversified use.

8. That the manner of dressing the foot in early life is a prominent factor in causing pain and discomfort in feet that are disposed to flatness.¹

9. That the degree of the arch of the foot increases with civilization.

10. That but little benefit can be derived from any kind of an appliance, except in the lesser degrees of deformity.

11. That the aggravated forms of flat-foot should be subjected to the operation of Trendelenburg or Gleich, regardless of what the cause may be.

¹ In this connection, I will say that the French Academy of Science has expressed its belief that the small toe in man is becoming rudimentary as the result of the wearing apparel of the feet.

12. That so far as can be determined by observation, the relief given by the Trendelenburg operation has been absolute.

13. All things being equal from a cosmetic point of view, the operation of Gleich (dropping the posterior half of the os calcis) would be the most desirable.

20. Von Meyer's triangle on normal foot.

21. Von Meyer's triangle on an abnormal foot.

22. Shows position of post. portion of os calcis after being divided. Gleich's operation.

23. Lesser degree of lowering post. portion of os calcis. Gleich's operation.

24. Extreme degree of lowering post. portion of os calcis. Gleich's operation.

ble. Nothing but time and the making of a number of operations by each method will determine their relative merits.

14. That in all cases of Pott's fracture, where flat-

foot has previously existed, a cure has always resulted.

15. If the osteotomies are made subperiosteal and aseptically, without complications, no serious results should follow.

16. That the first plaster-of-Paris dressing which has been fenestrated and reinforced by small ribs of steel, should be removed at the end of the tenth or twelfth day, and a new one adjusted to make sure that adduction is of the proper degree.

25. Shows how the astragalus is displaced to the inner side of the foot.

26. Shows the situation of the astragalus point lying outside the small von Meyer's triangle.

27. Shows the foot after the removal of the wedge-shaped piece of bone.

28. Shows the foot adducted and the astragalus point on the inside of von Meyer's triangle.

17. That my own experience would lead me to operate unhesitatingly upon any flat-foot causing incapacity by pain or deformity, which could not be relieved by any mechanical devices.

18. That the operation in the case just reported has resulted in all that could be asked for—making a producer out of a consumer.

ON CRYPTOGENIC CYSTITIS AND PYELITIS.

Read in the Section on Surgery and Anatomy, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY CARL POSNER, M.D.

PROFESSOR OF GENITO-URINARY DISEASES UNIVERSITY OF BERLIN.

The time is gone when the ever usable and available "catching cold" might serve as an explanation for suppurations and catarrhs of the mucous membranes. We know now that while it may produce a degree of predisposition of the tissues, the real awakening of the affections in question must proceed from precisely definable poisons. These, in the vast majority of cases, are connected with microorganisms or are produced by them.

Thus "vesical catarrh from cold," which formerly was so frequently diagnosed, has disappeared from our field of vision; in like manner, purulent inflammation of the pelvis of the kidney must be attributed to pyogenic presences—bacteria or the products of their metamorphosis—impinging upon the mucous membrane. Their presence is an absolute *sine qua non*, without which any disturbances such as stones, foreign bodies, stasis, etc., can not produce this definite effect.

How do these pyogenic elements enter the urinary passages? As regards the bladder, it is now the habit to think exclusively of infection from without. Bacteria can readily be carried into the bladder from the urethra by instruments, with ease. L. Lewin's and H. Goldschmidt's experiments have demonstrated the process by which they can certainly occasionally ascend to the pelvis of the kidney.

But this simplest of explanations does not always apply. Cases are not at all rare in which cystitis appears, though they have never been catheterized, and with equal frequency pyelitis obtains without ever having been preceded by cystitis. In the latter, post-mortem examination often enough shows an absolutely intact condition of the bladder with severe suppuration of the kidney.

The deduction is inevitable that in such cases the pus producers have immigrated from the circulation. The kidneys serve as drains for the body; any presence of microorganisms causing fluid poisons, must lead to their elimination by the kidneys, and attention has often enough been attracted to the danger to which the kidneys are exposed by the presence of purulent foci in the organism. Pyelitis has frequently appeared after abscesses and furunculoses. But in the majority of instances no heed has been taken of the fact that the healthy body continually harbors immense numbers of pus producers which relatively slight causes can send into the blood and the kidneys. So the intestinal bacteria, preëminently among them the bacterium coli, are entirely innocuous parasites as long as they inhabit their normal domiciles; but as soon as they migrate into other tissues, they act as most energetic pus provokers.

Brunner's declaration regarding strumitis must be designated a most important general law and a very significant one for general pathology. The participation of the urinary passage herein might perhaps have been deduced from the circumstance that of all the bacteria which have been proved to be provokers of cystitis and pyelitis the bacterium coli plays a most important part.

Numerous experiments made by me conjointly with Dr. Arthur Lewin have shown that upon completely

tying off the rectum, eighteen to twenty-four hours suffice to produce an inundation of the entire body with bacterium coli. When we injected the easily discernible bacillus prodigiosus into the rectum of animals and ligated it at once and allowed the same time to elapse, we found this readily recognizable organism in all the organs of the body and especially in the kidneys and urine.

This, which refers to microorganisms, as easily applies to fluids. It has long been known that drugs and poisons of most widely different kinds such as iodine, bromine, carbolic acid, corrosive sublimate, quinine, morphine, etc., are as quickly absorbed by the proctodeum as when they are applied subcutaneously. I made a series of experiments with the assistance of Mr. Fanadic, to elicit a closer knowledge of the manner of this absorption, by injections of solutions of coloring matters into the rectum. Aside from other results, precisely the same facts obtained, viz., that twelve to fifteen minutes after an injection into the rectum (for example of indigo-carmin) it could be found in the kidneys and urine.

No one who witnessed these experiments can escape the conviction that they point to a cause for the development of such renal and vesical affections as hitherto have been obscure. As yet, far too little attention has been given to the dependence of these organs upon the intestine. And still, observation of diseases of the urinary apparatus indicates often enough that their origin should be sought for in digestive disturbances.

The future will teach in how far purulent diseases require consideration in this connection. I believe, as has been elsewhere suggested, that chronic forms of nephritis in their narrower sense, will find their explanation herein.

It may suffice, for the present, to invite attention to the conditions under which those many cystites and pyelites, formerly designated as "cryptogenic" may originate. Then, accepting that the bacterium coli can provoke such diseases, the conclusion is inevitable that intestinal affections which can cause them to penetrate the circulation, merit special consideration.

SOCIETY PROCEEDINGS.

Cleveland Medical Society.

Quarterly Meeting, June 28, 1895.

THE PRESIDENT, DR. WIRT, in the chair.

Meeting called to order at 8 o'clock P.M. Reading of the minutes of last meeting. Nominations for membership.

The application of Dr. J. H. ROGERS, of Louisville, Ohio, has been approved by the Censors. On motion of Dr. Humiston, the Secretary was instructed to cast the ballot for Dr. Rogers as a member of the society.

PROGRAM OF THE EVENING.

DR. WIRT—At this quarterly meeting we dispense with the report of cases and exhibition of specimens. We now come to the program of the evening. You have all no doubt read in Dr. Wood's text-book on "Therapeutics," his classic description of the experiment upon himself in the use of Indian hemp. In this most perfect description, the Doctor relates that he lost all appreciation of the relations of time, space and surroundings. The Doctor has the happy faculty of hypnotizing his audience, and although the effect is not identical with that of Indian hemp, yet you do lose all appreciation of time, space and surroundings.

It has been my happy privilege to bring about, in a measure, the possibility of this condition for you. I therefore take great pleasure in introducing to you the speaker of the evening, DR. H. C. WOOD, of Philadelphia.

THERAPEUTICS OF HEART DISEASE.

Dr. Wood said:—Gentlemen of the Cleveland Medical Society; if any unfortunate skipper ever took with him a load of coal to Newcastle, before he had time to unload his cargo he probably felt very much as I do to-night coming before you, for I am not at all sure that I know as much about the subject that I am to speak of as many of you do. And I am very sorry that I was not prepared with a series of thorough doses of Indian hemp that I might hypnotize you into comfort and peace during the administration of the nauseous dose that I am about to give you.

I want to talk to you, nevertheless, concerning a disease which, as you know, is everywhere prevalent throughout the civilized world. And I propose first to carry you back to the days of my childhood, and one of my first patients (an old lady probably 85 years of age, who had many a time sat upon the lap of Washington) who was redolent with the memories of Physic and of others of the older day medical men of Philadelphia; and who taught me this great lesson: that it is possible, with a very small amount of valvular integrity, to pass through a long life of labor and usefulness.

Now when we come to look at the why of this thing we can go back to our early childhood days, and remember how in the frosty mornings we crawled out of bed and ran to the old pump under which we washed ourselves. We had to redouble our strokes in order to keep warm. And this is what the heart does; and it is what we call compensatory hypertrophy. Almost all your practical skill in treating a disease of the heart must rest upon practical skill in deciding, not whether this valve is diseased, or whether that valve is diseased, but whether the increased power of the heart has or has not kept pace with the increased work required of the heart.

And here I want to say a word in regard to this question of diagnosis. There are some who think that when the aortic valve is diseased, you should never give heart tonics or heart stimulants; that digitalis is not indicated. Not so, gentlemen. The aortic valve is no different in its functions and its relations to drugs than the mitral valve. It so chances that the mitral disease is commonly produced rapidly during youth, and the aortic disease comes on slowly during age, and in the one case the heart is more prone to be unable to adjust itself to the new conditions, and you get cardiac weakness.

It is not a question whether this valve be diseased or whether that valve be diseased, but it is a question of the relation between the work and power.

We want, then, always in every case of heart disease, from the very beginning to guard against this failure of development of compensatory hypertrophy; but before taking up the subject of drugs and their uses in failing heart, let me say a word to you in regard to the effects of failure of heart power. Where does the strain come, or where is the lack apparent? When the heart fails the blood fails to be in the aorta and its tributary vessels; and when the aorta fails and its tributaries are empty the veins are full, and consequently you may take for a sign of failing heart that there is over-venous repletion of the skin, congestion of the lungs and liver and edema of the extremities.

Now I want to call attention to this fact, that it is the liver among all organs, next to the lung at least, that feels this excess of blood in the venous system. Engorgement of the portal circulation is present almost always in every case of heart disease. It is largely for this reason that mercurials are of the value that they are in heart disease. And if I have had any special success in the treatment of this class of cases, it is because I have recognized the value of mercurials. Mercurial purges and corrosive sublimate given in long-continued small doses are of the greatest importance. The fiftieth of a grain or the sixtieth or even the one hundredth of a grain of corrosive sublimate, given with the tincture of the chlorid of iron will sometimes effect almost a revolution, aiding your true heart tonics in the most remarkable manner; aiding, so to speak in the digestion and absorption of the medicine.

I want here also to force upon your attention the necessity of cardiac rest. There has grown up a wide school of therapeutists in Germany who teach that we are to cure heart disease by cardiac gymnastics, climbing mountains, etc. Gentlemen, the heart is an organ that never rests under any circumstances, and do you believe it is common-sense teaching that you can take an organ that has had no rest and is exhausted, and build it up by piling on to the load which nature has put upon it? Not so. Did you ever notice the difference between what we call a fat American or Englishman and a fat German of the better class. The American or Englishman could walk eighteen hours through the snow,

climbing mountains. His paunch might be larger than necessary for anybody to carry, but his arms and legs are iron. But take the fat German, he is usually all fat and beer. In the German mountain cures it is not the extra work put upon the heart that cures, but it is the extra work put upon the muscles of the body that cures. Such cases are not instances of genuine failing heart.

Another set of cases are cured by the mountain treatment. These are the cases with a heart working irregularly because the blood is loaded with uric acid derivatives or uric acid-like compounds.

But you take a spare American with bad heart and you put him up the mountains, and you ought to put the lid on the coffin so he could carry it up and bury himself.

Leaving these means, which seems to me of great practical importance, I come to ask your attention to the drugs we have to use in cases of failing heart. I have studied adonidin cactus, convallaria and other of the newer remedies, and I do not think they have real value. I have never seen, myself, any good result obtained from any cardiac drug whatever that could not be obtained from nitro-glycerin, strophanthus and digitalis; and I never had any satisfaction whatever in the treatment of real downright heart trouble with any other cardiac drugs than these three.

First nitroglycerin. Nitroglycerin lays itself aside from the two other cardiacs or cardiac drugs, in the fact that it dilates the arterioles, and lowers arterial pressure. More than that; nitroglycerin probably has a powerful momentary stimulant influence on the heart muscle; but if one passes over in the slightest degree the dose, the stimulant action passes immediately into one of immense depression; kill the animal with nitroglycerin and its heart is relaxed as a wet paper bag; kill the animal with strophanthus or digitalis and its heart is spasmodically contracted.

Then, again, remember that nitroglycerin, like prussic acid, acts only for a few minutes. The profession has been giving prussic acid for years three or four times a day. Now, it is a well-known fact that if a man takes a fatal dose of the acid and survives thirty minutes he almost invariably gets well. All symptoms are usually gone in twenty minutes. A fatal dose may show no influence after twenty minutes. How much influence will there be in two hours, from a dose that at no time has caused any demonstrable effect? Now, it is very nearly so with nitroglycerin; and therefore if you are going to use nitroglycerin at all, use it small doses and at very short intervals. It is only valuable as a momentary pick-me-up, to the heart. It is only useful in the crisis of the attack, and is especially efficient if the attack takes the form of angina pectoris. How it acts I do not know. It is very possible it may be by relaxing spasm, rather than by stimulating the heart.

And now let me call your attention to strophanthus. Strophanthus is a drug which is used in the chase. I believe it is true that every drug used in the chase of animals by savage peoples is one that acts either upon the nerve or muscle, the reason being that the man who chases an animal wants to get him, and wants to use something that will stop him from running away. Strophanthus is a muscle poison. It only acts upon the heart as it acts upon the other muscles, but it so happens that in man the heart muscle is more susceptible to its influence than are the voluntary muscles; and so in human medicine we are able to get a stimulant effect on the heart before we get it on the other muscles. It is a drug, therefore, that acts directly as a stimulant to the heart muscle. But there is no reason to think that, like digitalis, it acts further as a tonic than as a stimulant. Then, again, the muscle of the arteries is acted upon by strophanthus and so it contracts the arteries. It increases arterial pressure, it empties the veins and fills the arteries. It differs, further, in its action from digitalis in being more distinctly diuretic; it is much more prompt than digitalis, acting at once; it is much less permanent than digitalis.

Let us now study digitalis, which, always in proper doses elevates the arterial pressure. How? It does it in the first place by contracting the arterioles. It narrows the blood paths, it lessens the amount of blood space to be filled. It does this in a two-fold way: by stimulating the vasomotor center in the medulla; by acting on the arterioles themselves. Take a terrapin; cut out its nervous system, leave its heart intact; or cut out its heart, then put your fluid under pressure into the arterial system and have it come out from the vena cava. Add a little digitalis and it almost arrests the flow. It contracts the capillaries directly. But it acts upon the heart more powerfully. Every one knows the full strong beat you get from the drug. Especially do

not forget that it stimulates the pneumogastric nerves as well as the heart muscle. It lengthens the interval between the beats. When that beat comes it is a great mighty throb of blood. But digitalis is more than a stimulant to the heart. You take a heart which is beating one hundred and ten to one hundred and twenty times a minute. The veins are everywhere full, the aorta is empty. The diastole has not been long enough for the heart to expand and receive the blood. The heart is continually irritated by impulses coming up from every part of the body crying, Give us more blood. You give that heart, digitalis. You quiet it, you take off its nervousness, you get the long diastole, you get the powerful systole; so there comes a great wave of blood through the arteries. In the failing heart the coronary artery gets little or no blood. At the very time when the heart is being overworked and overworried it is starving. But when the great wave of digitalis action comes, it swells out the aorta, it fills the coronary artery, it goes into every part of the heart, it brings sustenance and food. The old effete material that has been clogging the heart walls is also squeezed out by the powerful contraction of the muscle. Thus digitalis acts as a heart tonic, but it does more than this.

Gaskell has proved that there are two functions or stages in the heart life. What is true of the heart life is true, I believe, of every portion of the human body. A period of functional activity and structural down-tear, alternating with a period of functional rest and structural upbuilding. During diastole of the heart there is no functional activity; relaxation. During systole there is functional activity. During systole this functional activity is accompanied by destruction of tissue. During the period of diastole, or of functional rest, every force in the heart is given to repairing the ravages of function, and there is restoration and upbuilding.

Now, it is the pneumogastric nerve that occasions the inhibition or stopping of functional activity in order that the structure of the heart, which has been worn, may be up-built. My own belief is that every portion of the human body has behind it this principle. The spinal cord has its inhibitory centers. Every nerve cell has above it a higher nerve cell that inhibits it. However this may be, during diastole the pneumogastric grasps the heart firmly and says to it, Let the workmen build up the ravages in the walls.

Digitalis has the power of stimulating to a point of intense activity the pneumogastric nerve. Expose a frog's heart, give it digitalis, and you will see the strange fight for mastery between the irritated pneumogastric nerve, and the irritated heart muscle. Sometimes the digitalis arrests the frog's heart in diastole. It never does this after section of the pneumogastric nerve. It is when the pneumogastric nerve gets victory over systole, that there is arrest in dilatation. Now, don't you see how digitalis acts in failing heart? Not simply as a stimulant but also as a tonic. It brings food to the heart at the time of its starvation and overwork; it squeezes out of the heart muscle the effete matters which have been lying there; especially does it stimulate the pneumogastric nerve, the trophic nerve of the heart, enabling it not only to quiet the heart into long diastoles, but to hasten during these periods the up-building of the heart structure.

Every now and then in our hospitals we see a case of heart disease in a poor man who has had no rest and no medical treatment; the heart seems hopelessly feeble, but a short course of digitalis brings not only immediate relief but seems to lift the whole man up to a higher plane. It is because the digitalis has really helped the trophic nerve to use the food which has been given to the heart by the use of digitalis to the restoration of the structure which was almost destroyed.

Before applying these considerations to individual cases, let me say a word or two about the preparations of digitalis. It does not make any difference which preparation, provided it has been made from a good drug. I speak now of the official preparations of digitalis. Digitalin is always a doubtful theme. Of two specimens one will be soluble, one insoluble; one is called the French, the other German. Digitalin is not of the nature of the active principle. It is a mere extract of digitalis more or less purified. There is a wide-spread belief that the infusion of digitalis is better than the tincture. Not so, gentlemen. The reason of the belief is that proportionate doses are not used. Commonly, digitalis tincture is given in 5 to 10 drop doses, the infusion from a teaspoonful to a dessertspoonful, which is equivalent to about 20 to 40 drops of the tincture. Results are obtained from the infusion because it is given in larger doses.

Sometimes you will find a stomach that the infusion will agree with better than the tincture. Sometimes one that the tincture agrees with better than the infusion. Practically, there is no difference. Again, the tincture of digitalis lends itself fairly well to hypodermatic medication; infusion you can not use.

I do not propose to occupy your attention at all with discussing the ordinary use of digitalis in heart disease. Only to call your attention to certain points. First let me say a word in regard to its employment in acute endocarditis, acute heart disease. Early in the case, digitalis is very rarely indicated. It is more apt to do harm than good. The heart is already in a state of irritation. There are some cases of endocarditis—septic or malignant endocarditis—in which it does not make much difference what you give. But in ordinary rheumatic endocarditis, digitalis does harm. The heart is not weak but over-irritated. Usually tincture of aconite and similar drugs are what you want to try. But when the storm has gone by, the only salvation for the stricken child is the up-building of that heart into a great powerful organ that shall enable it to overcome the leak that has been left in the valve. There is no power to repair that valve. There is no rag that we can push or stick into that broken space. There must be increase of power, and so under these circumstances, so soon as the acute disease has passed by, it is absolutely important to begin the use of digitalis in small doses continually, given with great watchfulness. Recollect here, as in other cases, that when you give digitalis you give a drug which has a persistent influence. The moment you get the slightest effect that moment you stop the drug, for you know that effect will last hours, perchance days.

Passing by the ordinary use of digitalis, let me call your attention to its administration in large doses. And here I beg of you not to misunderstand me; I do not mean to say that the doses of digitalis I am going to speak of are to be used in the ordinary cases of heart disease. But there come times in the life of almost every case of heart disease when the heart fails to respond at all to the moderate dose of digitalis, and when the large dose of digitalis will have a most pronounced and beneficial effect upon it.

A case happened to me two or three months ago. I was sent for by Dr. S. to see a case in consultation. The man, 76 years of age, had one pleura two-thirds full of water. His pulse was, as far as one could count it, 160 to 170 a minute. It was a mere broken confused jumble of pulse beats. The man had been sick eight weeks without conscious sleep; sitting up struggling for breath.

"Doctor," said the physician in charge, "I sent for you to back me up in tapping this pleura."

"I don't think that pleura ought to be tapped. However, I will back you up in doing it, provided you tell the wife of the man that he is liable to die during the operation." This was done and the wife said, "Then he had better die without operative procedure."

"Now," I said, "let me try digitalis. Give that man 40 drops of digitalis now (6 o'clock), give him 40 drops at 8 o'clock, 40 at 10 o'clock, and then hold off."

I went there the next morning. The old man had slept soundly the whole night. Had begun to urinate freely (had had nearly complete suppression), and his pulse was down below 100, perfectly regular. The result was that the man came down to see me in my office not many weeks afterward, and has been going about apparently in good health ever since; of course with a diseased heart.

There are cases in which you have to keep these doses of digitalis up. There is a certain large graveyard in the suburbs of our city. Years ago when I had worked out these thoughts to my satisfaction, I was sent for by an old German doctor, to take charge of a patient whose window overlooked this graveyard, while he went on his vacation. The lady was sitting up in bed or on a chair in perpetual horrible orthopnea. This old German was a very plain-spoken man. I asked if I might try the use of very large amounts of digitalis. The doctor explained my wish to the patient, saying: "All right, Sarah, what the devil is the use of your sitting there for weeks? This young doctor says he will either put you in the graveyard or get you down stairs. You had better be in the graveyard than as you are, so you had better let him try."

She said: "Very well. I would a good deal rather be in the graveyard."

I gave her about 2 teaspoonfuls of tincture of digitalis a day. She was down stairs in two or three weeks.

Not long after that I had another case. A banker somewhere from the West. He had been taken acutely ill, or

rather chronic disease blossomed out in full while he was attending to some business in the East. He had been under homeopathic care for three or four weeks in perpetual orthopnea. I put him on enormous doses of digitalis, and the result was that in one or two weeks he was able to go home.

Now, gentlemen I mention these cases to you, not simply as examples of the results that can be obtained by large doses of digitalis, but to point out to you a further lesson.

The ending of the first old gentleman has not come yet. But it so happened one day in the course of some months after, the woman whom I put upon the digitalis had been going about attending to her household duties and she went to market. Returning with a light basket in her hand she fell dead over her own lintel. And the banker from the West went back to his office and gathered together the gold, but it so happened one day that as he was reaching forward to put his clutch upon the yellow coin he fell dead across his counter.

Some would say it was the digitalis killed them. But such is not the truth. It is not digitalis that arrests that heart. It is the power of digitalis to quiet the nervous condition of the heart; to feed up the heart as far as may be, to keep it going as long as it can, until at last there comes a time when there is not one grain of power left in the heart. When the power had all gone out of the banker's heart it ceased. That is the effect of digitalis. When you venture to give these large doses of digitalis in the treatment of cases of heart failure, tell the patient, or at least the friends of the patient, that this thing will come. Remember, the patient will live longer than if left to himself. It is better to live months of comfort, and perhaps a year or two, and then drop dead in the harness, than to struggle in agony for a shorter period.

A few words in regard to the so-called cumulative action of digitalis. Digitalis may be given through a length of time and suddenly there comes an explosion of its action. I remember a case of pleurisy I had. I was using digitalis to stimulate the kidneys and get out the fluid. I went there on on Sunday; the pulse, which had shown no effect of digitalis, had fallen from 106 to 80. I stopped the digitalis. Monday the pulse was 70; Tuesday the pulse was 60; Wednesday the pulse was 40; Thursday the pulse was lower still, and I began to wonder what the pulse would be on Saturday. But when the pulse got down somewhere between 30 and 40 there it stopped, stayed so three or four days, and then came up.

I have never yet seen but one case hurt by the use of digitalis, and that was a case of mistaken diagnosis. A lady had been under the care of two or three of the best doctors in Philadelphia; was supposed to be dying. I was sent for and she was placed under my care, as her husband did not believe in consultations. She got worse. I kept on with the digitalis until it suddenly occurred to me, This is a case of digitalis poisoning. I stopped the digitalis and she began at once to come up. I never told my secret and she thinks I am a great doctor. There was no true heart failure; only neurasthenia, from gastric catarrh.

This cumulative influence comes on at certain times: first place, when the drug fails to act upon the kidneys; second place, when it is already in the body. You have a case of dropsy; you tap; reduce the pressure. Instantly the blood vessels take up the serum; that serum is loaded with digitalis. Then comes digitalis poisoning. It is not the drug that is in the body, but the drug that is in the blood that affects the heart.

A practical induction is: When you expect to tap a man suffering from heart disease or from any form of dropsy in which you have been giving digitalis, cease your digitalis for a length of time before you tap him.

Years ago I noted one class of seemingly incomprehensible cases. Cases of mitral valve insufficiency; in which the heart seemed to be in the last stage of weakness; cases where I said to myself, This man will be picked right up by digitalis, but when I gave the digitalis there came increased heart dullness, and an anginous horror that instantly demanded the withdrawal of the drug. I was sure that I was right in my diagnosis that the heart was weak and failing. I was sure that I was right in my physiology that digitalis was a heart tonic and stimulant. But when I put the two things together they did not work. The cases always went from bad to worse. At length I worked out the problem. The cases were, all of them, cases of mitral insufficiency, and they were really cases of exceedingly weakened auricle; an auricle that was toned down and thinned out until it was little more than the thickness of paper. Now, under the influence of digitalis there came back a reflex wave through

the mitral valve and that met the blood pouring in from the pulmonary veins. The thin, paper-like auricle could not stand the double pressure. It could not stand the strain of the blood pouring in and the blood pushing back through the insufficient mitral valve by strengthened systole. Whenever this condition exists nothing can be done. It is the shadow of death, and death very near at hand.

Digitalis has been much used in treatment of aneurysm. Gentlemen, it is death to aneurysm. . . . The reason surgeons have not killed more cases of aneurysm is because they do not use digitalis in large enough doses to have any effect. Digitalis is the most dangerous drug known in aneurysm. You give a certain amount of strychnin, or a certain amount of atropin and get, let us suppose, 20 per cent. of increase of arterial pressure; but the pulse wave is small. Digitalis puts up the arterial pressure 20 per cent. but it does more than this. It makes a long diastole. It makes a great wave of blood; not a little tiny thread, but a great mass of blood rushing with full force down the arteries, coming into the chamber enlarged by atheromatous degeneration, stretching and tearing everything before it. It is the immense distension due to the large blood wave, under the influence of digitalis, which makes the drug especially dangerous. This is not merely theory. Some years ago a man was picked up in the street and brought into the hospital. He had a pulse you could scarcely feel; temperature 4 or 5 degrees below normal. I ordered digitalis to be freely given. At my visit the next day the man was sitting up enjoying himself, talking and laughing. I put my hand on his pulse and I got the tremendous big strokes of digitalis. As I was directing that the digitalis should be stopped, the man sprang with a great cry up into the air; there came a crimson flood from the mouth and nose, and the man dropped back dead. That man had an aortic aneurysm; we had ruptured it with our digitalis. At the autopsy the aneurysm was found torn right across. And, therefore, gentlemen, when you have an aneurysm to deal with, don't use digitalis.

Let me speak of the contrast between digitalis and veratrum viride in the treatment of pneumonia. You have a case of pneumonia in the first stage. You give veratrum and you lower the heart action. More than that, you open out every blood vessel in the body. Here is the blood in that lung in excess. You can put the whole of the blood of the man in the abdominal vessels. You take away the blood from the lungs; and put the whole body upon one plane of dilated arterioles, so to speak. That is what veratrum viride does in the beginning of pneumonia.

If you have a lung in a man in which the general system is adynamic, you can get at the same result in a different way. You have general relaxation. Now you give ergot freely which contracts the blood vessels. Bring about the same result by contracting the blood vessels in the lung and the whole body.

Digitalis comes into use in pneumonia in an entirely different stage. How does that man die in advanced pneumonia? Very often from paralysis, exhaustion or arrest of power of the right heart. What is the reason? Because the right heart, heated almost to death by the fever, has to force blood through paths narrowed by the pressure of the exudation upon them. You give digitalis; it stimulates that right heart. It does not cure the pneumonia, but it keeps the right heart up to its work, and by and by the pneumonia subsides.

In answer to a query, Dr. Wood further said: in regard to this question your President has put to me about the use of alcohol in etherization. Some years ago there was reported a case wherein a woman had cardiac failure from etherization, and brandy was given her. Six or eight hours after the etherization she died of heart failure. Is not this wonderful? This woman had a pint and a half of brandy; that, not the ether, was the cause of death.

What is the difference between ether and alcohol? Only a little water; physiologically there is no difference. Then, again, you might as well give ether as alcohol to a failing heart. This is not mere theory. Test it on the animal. As you give alcohol, less ether is required.

By no dose of alcohol . . . can you bring up the arterial pressure of the animal poisoned by ether. You might as well give hypodermic injections of ether in the failing heart of etherization. Here I see some of you smile; there are surgeons fatuous enough to do even this thing. Gentlemen, does it make any difference to the heart whether a drug which is in the blood has been picked up in the left leg or the right leg, in the lung or in the buttock? Is the heart a sentient being that it can tell where the blood got the ether? Why not crowd the ether on the sponge and give

it to the man by the mouth. Sometimes these hypodermic injections do seem to arouse the patient. It is because they are a local irritant and reflexly excite the heart, the same as holding ammonia to the nostrils. But just so far as the ether is absorbed just so far it aids in overcoming the heart.

The only drugs which, in these failing insufficient hearts, I have found to be of value are strychnin, cocain and digitalis. Digitalis should be given hypodermically. More than this; I have found in the lower animals that the lowered pressure under chloroform or ether is brought up wholly by digitalis injected into the veins. More than this; I have found that digitalis given before the anesthetic has a remarkable power in steadying the heart. Whenever you have any reason in any case to especially fear cardiac depression from the use of the anesthetic, precede the anesthetic by your digitalis. And precede it long enough so that the heart shall be under the influence of that digitalis when the anesthetic is given.

And with digitalis always use strychnin in the accidents of anesthesia. It affects the respiratory function probably more than it does the cardiac function, but it certainly has some power in backing up the action of digitalis on the heart.

And then there is another drug which is of equal value with strychnin, and which can be associated with strychnin; and that is cocain. It acts upon the respiration and circulation about as strychnin. In the chloralized dog you can raise the respiration by as large doses of strychnin as can be given without producing convulsion, and then by giving cocain get a further increase of the respiration. You will find in cases of adynamic, advanced pneumonias, where you want to sustain the respiration, as well as the circulation, that the combination of strychnin and cocain is of especial value.

British Orthopedic Society.

First Provincial Meeting of this Society held at Liverpool, May 24, 1895.

After lunching together at the Adelphi Hotel, the members visited the new Royal Infirmary, the Children's Infirmary, and the Southern Hospital, at the invitation of the several staffs. They were then entertained at dinner by Mr. Robert Jones, after which they adjourned to the Medical Institution where the ordinary meeting was held.

A large number of living cases were exhibited, representing torticollis, talipes treated by tarsectomy, wrenching, tenotomy, etc., also numerous other cases of knee, hip, and joint diseases; several casts and stereoscopic slides were on view, the latter shown by Messrs. Robert Jones and Thelwall Thomas, being most instructive as showing the advantage of stereoscopic photography in the demonstration of orthopedic measures.

MR. ROBERT JONES was elected to the chair. Several candidates were balloted for and elected.

MR. TUBBY, of London, read notes of a case of talipes equino-varus, drawing attention to the rotation inward of the lower end of the tibia and fibula which complicated these cases. He had performed osteotomy of the lower end of the tibia, the limb being afterward put up in plaster with a satisfactory result.

MR. ROBERT JONES agreed with Mr. Tubby that the rotation was due to an alteration in the shape of the tibia and fibula and he had for years successfully treated it by osteoclasm above the ankle joint and in this way, by inversion at once corrected the deformity. A comparison of the position of the patella with the great toe was evidence that the deformity was below the knee.

MR. MURRAY of Liverpool, considered that the fault lay not in the tibia, but above the knee.

MR. LUKE FREER of Birmingham, held that the inversion was general, the knee and hip being equally involved and secondary in origin to the foot inversion; he had always met the difficulty by passive manipulations and occasionally instrumental aid, by which the knee and hip were rotated outward, as it were, simultaneously with the daily after-treatment of the talipes itself.

MR. FREER showed photographs of a case of extreme rachitic genua valga; the girl had worn instruments for four years with little benefit and when 8 years of age, he had performed a double MacEwen with the best results, continu-

ing retentive apparatus, however, for two years after, to prevent relapse. A week ago she had turned up again after a lapse of eight years, with most pronounced genua vara, evidently due to rachitis adolescentium. He emphasized the necessity of mechanical control after osteotomy and the fallacy of very early operation.

MR. MURRAY thought the case would be best treated by another osteotomy.

DISCUSSION ON THE TREATMENT OF INTRACTABLE TALIPES EQUINO-VARUS.

MR. ROBERT JONES opened the discussion. He maintained that it was always an avoidable condition, and that the relapses so often alluded to were generally due to carelessness on the part of the patient's friends, and sometimes on the part of the practitioner. The relapses frequently occurred because the surgeon did not recognize their causes; these were: *a*, insufficient correction of deformity; *b*, superincumbent body weight on outer side of tarsus; *c*, slack and lengthened state of muscles opposed to the deformity. Frequently surgeons were content to merely twist the foot until they were able to get it comfortably into the straight position, and yet so soon as the little patient put his limb to the ground, one could see that the flexor muscles of the foot had not recovered their powers and the result was that the whole body weight fell on the outer side of the tarsus. The foot is not cured until the patient can voluntarily place it in the position of valgus, and he should not be allowed to walk until the foot is so far recovered that each step he takes tends to improve the position of the foot; in other words, until the act of walking becomes a beneficial factor in the correction of the deformity. It was impossible to lay too much stress upon the influence in the maintenance of deformity, or its recurrence, exercised by the overstretched muscles on the convex side of the deformity. In proof of this, Mr. Jones instanced his treatment in infantile paralysis, where contraction had existed for some years, and their influence upon the lengthened opponent muscles. After discussing the anatomy of inveterate club-foot, Mr. Jones traversed Phelps' statement that the bony deformity in intractable cases did not by any means keep pace with the deformity of soft structures. He maintained that it was impossible for the foot of a growing child to remain twisted without corresponding bone changes and he drew attention to the osseous deformity in lateral curvature in knock-knee. In discussing the methods of treatment, including that of manual correction, subcutaneous division of deep structures and tendons, forcible wrenching, tarsoclasis, open incision, linear osteotomy, removal of astragalus or cuboid tarsectomy and Pirogoff's operation, he found it difficult to criticize all the methods, and he wished to insist upon a very often forgotten fact that the goal might be reached successfully by different routes. Some surgeons, like Wolff, of Berlin, were able to show extremely satisfactory results where the hand alone was used, and this in extremely intractable cases. Phelps had described uncommonly good results by means of his open incision and Mr. Jones had personally seen some very useful feet after Lund's excision of the astragalus. That evening Mr. Murray had shown what could be done in suitable cases, by well performed tarsectomy. After describing Phelps' operation, Mr. Jones argued that it had more effect on the varus deformity than on the equinus, and the cases he had seen after the operation seemed rather deficient in the power of putting the heel to the ground.

Phelps' argument for open incision seemed founded on the ground that it was indiscreet to work in the dark, but at the same time it was noticeable that he had very considerably modified the length of his incision, so that it became almost essential by reason of the small incision now made, to introduce out of sight the tenotome for the division of some of the deep structures. Mr. Jones had performed Lund's operation on six cases and wedge-shaped tarsectomy thirteen times, but although his results were fairly satisfactory, he had discarded the operative treatment for that of forcible wrenching. He felt the difficulty in that inevitable percentage of failure after incision of a wedge to make up the deficiency by subsequent methods, as the foot became so firmly ankylosed and resisting. He maintained that operations such as those described should only be done by surgeons of experience under strictly antiseptic precautions; that the foot should be over-corrected at the time of operation and that the appliances should be worn for a considerable time afterward. He felt certain that all cases of club-foot could be successfully treated by Thomas' wrench, and that the failures which had been reported were due to the

fact that surgeons often did not learn its method of application. He then described in detail the mode of twisting by means of that instrument. He always divided the tendo-Achilles before proceeding to further treatment, as its contraction often had to do with the varus deformity as well as that of the equinus. He rarely found it necessary to divide any other tendons. Occasionally several wrenchings were preferable to forcing the foot into position at once. After each wrenching the foot became quite capable of being molded into any position. In the after treatment he preferred the application of a cheap iron shoe to the plaster appliances now commonly in use and he described the simple device of adding an iron flapper on the outer edge of the boot in order to complete the eversion of the foot during walking. The rotation inward of the leg he corrected last of all by osteoclasm. This internal rotation could always be avoided if one began treatment early by twisting in their long axes the tibia and fibula outward, grasping the lower end with the right hand and the upper end with the left. The cases he had shown that evening, all of them of a very extreme character, were sufficient proof of the efficacy of this method of treatment; a method which, while leaving intact, and training to a proper shape, the tarsal bones, left a pliable foot as the result. There was very little pain attached to the method. Treatment had only to be continued for a few months and there was absolutely no risk involved. This could not be said of the cutting operations with the inevitable percentage of mortality. Surgeons were too accustomed to be shown only the successful cases of tarsectomy, but in private and hospital practice he had frequently come across some of the dire disasters.

MR. TUBBY thought that in the normal state the action of the extensor and flexor muscles was not alternate and distinct, but that the muscles acted in concert. There was a wide field for observers for investigating the condition of the equilibrium of muscles; he never found tarsectomy necessary but had seen some very bad results from it. Cases were sent out too early and relapses occurred not seen by the surgeon; he considered the wrench a very satisfactory instrument in intractable cases, the ligaments in youth being elastic; he was opposed to Phelps' operation; excessive division of vessels favors gangrene of the parts. The operation appeared very pretty on the table and very ugly afterward.

MR. MURRAY said that in the treatment of congenital talipes equino-varus, all were agreed that the equinus part of the deformity should be dealt with by division of the tendo Achilles, but all were not agreed as to the treatment of the varus. He stated his objections to Phelps' operation and also to wrenching. The wrenching was painful and had to be often repeated, an important matter with poor patients from a distance. Of the several operations practiced, he personally preferred the removal of a wedge-shaped piece from the outer side of the foot, irrespective of bones or joints, and was well satisfied with the results he had obtained. He had performed the operation forty-two times in thirty-four patients. The dangers from the operation were practically nil, and much time and expense were saved, as the patients walked well without instrumental support in less than three months.

MR. LUKE FREER was of opinion that the very few cases of intractable club-foot with which surgeons engaged in orthopedic practice had to deal were, as the chairman had observed, a reflection on the patient's friends or more often on the practitioner. Severe relapsed cases treated by tenotomy and daily manipulative after-treatment would usually be well, with pliable feet, under three months, and he showed several photographs of cases so treated; he was in favor of the wrench rather than tarsectomy in cases where the hand was not sufficient; he agreed with the use of simple retentive apparatus easily removable for manipulation. Of all the cases of tarsectomy he had seen, he could not call any one really satisfactory; the best were "stumpy."

MR. NEWBOLT, of Liverpool, said that osteoclasm should be done through the tibia and fibula, not through the femur.

MR. ROBERT JONES, in reply, referred to the length of time in treatment, which was slight after the first wrenching; no relapse occurred if the child was not allowed to walk before the weight was borne on the inner side of the tarsus, instead of the outer. The chief advantage of his method was safety. Private patients would invariably prefer a non-cutting operation. There would be very few intractable cases of club-foot if medical men would learn how to deal with them sufficiently early.

The next meeting will be held during the British Medical week in London, in July.

The Ohio State Medical Society.

Annual Meeting held at Columbus, May 15, 16 and 17, 1895.

(Continued from page 162.)

FIRST DAY—AFTERNOON SESSION.

DR. EDMUND C. BRUSH, of Zanesville, Ohio, read a paper on

FRACTURES OF THE SKULL.

The paper was a supplementary report of nine cases. The former cases, ten in number, had been treated by immediate operation, by a secondary operation and on the expectant plan. The deductions pointed clearly to the propriety of immediate operation, provided any depression could be detected.

In the supplementary report, the cases present many different phases of fractures of the skull and the results therefrom. All of those operated upon recovered, and in each case the operation was performed without delay and without any regard to the symptoms, good or bad, present. The one idea was to remove all pieces of bone that impinged upon the brain, whether the brain resented the pressure or not. Due attention was given, to the physical condition, so far as it was influenced by shock. The idea that "in children the toleration of the brain to pressure is such as to justify delay in elevation of the fragments unless alarming symptoms supervene," is probably true, but what is to be gained by waiting? Prompt action will probably prevent alarming symptoms and dangerous secondary complications. In the operations reported, the trephine was not used. With an elevator and a pair of sequester forceps much can be accomplished. This is not said in the way of depreciation of the trephine. It is an instrument of untold value. The anesthetic used was the A. C. E. mixture.

There is no need of repeating text-book literature on rules and methods for operations on the skull. How to prepare the patient for the operation, how to operate, and how to treat the cases after operation, are familiar matters to all. There is, however, a new idea being advanced or experimented with. Perhaps it might be well to say that an old idea is being revived in a new form. To find some hard substance to replace the bone removed has been a source of much thought in the past and it is likely that the near future will solve the problem. This may be Senn's decalcified ox-bone. It may be disinfected celluloid plates, or it may be the removed pieces of skull or even transplanted pieces of skull.

In looking over the literature on the subject under consideration, I was forcibly struck with the following found in "Bell's Surgery," 3rd volume, edition of 1796—nearly one hundred years ago!

"In the management of fractures of the skull attended with depression, the indications are:

"1. To discover as exactly as possible the site, the course, and the full extent of the fracture.

"2. To obviate the effects of the injury done to the brain by elevating or removing all the depressed parts of the bone.

"3. To endeavor to complete the cure by application of proper dressings and attention to the after-treatment."

DR. JUDSON DALAND, of Philadelphia, Pa., read the following paper:

THE PATHOLOGY, DIAGNOSIS AND TREATMENT OF MALARIA.

(Illustrated by lantern slides). After presenting a number of views of normal blood and of malarial blood, giving a short description of each, Dr. Daland said: You may ask of what practical value is all this study? This organism is always present when a patient is suffering from malaria, and therefore may justly claim the position of acting as the cause of this disease. It is important because by the study of this organism one may determine if the treatment employed is successful. It is perfectly manifest that so long as this organism is present the disease still exists. Very constantly the question as to the diagnosis of malaria arises. And the differential diagnosis between malarial and other diseases that produce the characteristic symptoms of chill, fever and sweat are constantly before us. The cases of gall stone associated with intermittent fever are more readily recognized as such, and not treated for months as intermittent malarial fever. Tuberculosis with intermittent fever is also more quickly diagnosed. When the examinations are properly made, the absence of the parasite proves the absence of malaria, as well as its presence proves the presence of malaria. Hepatic abscess or anything which produces intermittent fever, which may at times be suspected to be malarial, can be clearly separated by this important sign. As soon as we can know certainly an individ-

ual is suffering or not from malaria, our course of action is plain.

Passing from a discussion of its enormous diagnostic value, let us think for a moment regarding the influence of this body upon the blood, and the impression that is created in our mind by a study of this organism while the patient is under treatment. In the first place, it is important that the patient shall not receive quinin when you are experimenting with this organism. This alkaloid not only changes the organism but has an absolutely destructive effect upon it. It is the hope of every physician present that we may multiply these remedies very rapidly.

The study of the effect of a paroxysm upon the blood mass will give us valuable indications regarding the treatment. If one takes a patient suffering from intermittent fever and examines the blood, one usually discovers that the mass of corpuscles has been reduced from 100 to 60 per cent. Furthermore, the hemoglobin will be found reduced to 50 or 45 per cent. We therefore recognize that the blood mass is greatly reduced, first as regards the quantity of the red blood cells present, and second as regards the quantity of hemoglobin present. We also note the loss of hemoglobin is more than the loss of red blood cells. I think we would expect this, from the knowledge of the effect of the parasite in destroying so many millions of these cells. If you study the blood before and after a paroxysm, you may find the amount of loss at each paroxysm. This has been done with the result that about 10 per cent. of the red blood corpuscles of the body were found to be destroyed, and 10 or 11 per cent. of the hemoglobin was lost at the same time. In the interval between the paroxysms a considerable quantity of this loss was made up by the remarkably rapid manufacture of red blood cells and hemoglobin, so that they are kept at about an average of 50 or 60 per cent. of red blood cells and hemoglobin.

This being true, it seems to me the first indication in treatment is the destruction of the parasite, which can be best accomplished by our old friend, quinin. The bisulphate is perhaps the most soluble form of quinin, and should be given in conjunction with acid, preferably when there is a certain amount of food within the stomach. At certain periods of its development the parasite is less vulnerable than at others. It seems to me when it is just forming, at the point corresponding to the chill, or just before the chill, if we can have circulating in the blood a sufficient quantity of quinin, we can destroy the parasite; while if we postpone this until later, the plasmodium is in the red blood cells and the quinin does not come in contact with the plasmodium. Therefore it is important that the patient shall have the quinin prior to the expected chill. The remedy that stands next in importance, and one that I administer at the same time, is Fowler's solution, in 3, 5, or 5 drop doses. And in view of the great loss of hemoglobin, it would seem the best results can be obtained by the administration of a remedy that would tend to restore the hemoglobin readily, and the remedy which we believe exerts this influence best is the freshly prepared carbonate of iron. Therefore, I would suggest that 20 or 30 grains of bisulphate of quinin be given in the twenty-four hours. Of course, the indication regarding building up the general health is very apparent.

DISCUSSION.

DR. KINSMAN—How many of these plasmodia will you find on an ordinary slide?

DR. DALAND—The number of parasites varies with the severity of the case. In a well marked quotidian or tertian intermittent fever, you may find as many as we have found here. Each of these represents a quarter of the field. You may have two or three, or sometimes as many as five or six of the parasites in one field. But in the cases of malaria you see here in the North, the rule is quite contrary. They oftentimes require a search of ten, fifteen or twenty minutes to find a single plasmodium; and in other cases they increase in number. So you may say the number may be as many as one to six, and again you may have to search ten or twenty minutes to find a single body. Another form of malaria, which I did not mention, is the flagellated form, which could not be detected by the photograph.

DR. FULLERTON—Is there any culture fluid in which this plasmodium may be or has been cultivated, and have any experiments in regard to the inhibitory or destructive effects of any of the malarial remedies been tried in the test tube?

DR. DALAND—So far as I know, every effort that has been made to cultivate this particular form of microorganism has met with failure. And furthermore, the studies made in regions where the malaria is so prevalent, have not given sat-

isfactory results, in detecting a microorganism like this in the soil or damp places, where malaria is present. Consequently, not having found it outside the body, the experiments are limited.

DR. TUCKERMAN—What is one of the best monographs on the technique of the subject?

DR. DALAND—I think in v. Jaksch's "Clinical Diagnosis."
(To be continued.)

American Electro-Therapeutic Association.

Fourth Annual Meeting held in New York Academy of Medicine, New York, Sept. 25, 26 and 27, 1894.

WILLIAM J. HERDMAN, M.D., President.

(Continued from page 157.)

REPORT OF THE COMMITTEE ON CONSTANT CURRENT GENERATORS AND CONTROLLERS

was given by DR. W. J. HERDMAN, Chairman.

You will remember that the work of this committee as it was defined at the time of its appointment two years ago, was to investigate the apparatus which was designed for the generation and control of constant currents suitable for physicians' use, whether these currents were derived from primary batteries, secondary batteries, or dynamos; and also those appliances which were constructed for the purpose of modifying and controlling such currents so as to adapt them to the various needs of therapeutic work.

As was reported at the last annual meeting, the committee sought to secure a basis for such investigation by conferring with physicians who had long used electricity in therapeutics, and learn from them what sources they relied upon for their currents and in what manner they modified or controlled them, and get their opinions concerning the value of the apparatus which they were employing. It was hoped that enough information would be secured in this manner to enable the committee to take a very broad view of their field of work and draw their conclusions from statistics covering this entire field. It was the purpose to put to the test by laboratory methods the value of such apparatus and opinions as were derived from this correspondence and to display in the reports of such investigations a comparison which would speak for itself as to the superiority of one method over another. The attempt at getting such information from physicians through correspondence was a practical failure at the time of the last report and, although the attempt has again been made during the year just ended, with what has been thought improved facilities at the disposal of the committee, we must again report that we have not met with the assistance from our fellow-practitioners throughout the country that we had hoped for in this direction. We, have, therefore, been compelled to use our own judgment in selection of apparatus for investigation, and in this we have been largely guided by our personal knowledge of what is in use and by information derived from the makers of apparatus as to what is having most ready sale at their hands.

At the last meeting the committee reported progress with reference to many of the investigations which they had been pursuing. This has been continued with much diligence throughout the year and in addition to this we will be able to present some other material. A part of these investigations have been carried on at the electro-therapeutic laboratory at the University of Michigan under the direction of the chairman of the committee. Dr. Newman and Mr. R. G. Brown both members of the committee have been pursuing separate investigations at their respective homes, the latter having been placed in charge of the physical investigations on secondary batteries. These gentlemen have been requested by the chairman to personally present their reports. Dr. Campbell, the other member of the committee, has had in charge the correspondence with physicians and, although he is absent in Europe he has reported to me that his work has been diligently pursued but with indifferent results, as I have already said.

PRIMARY BATTERIES.

Aside from the investigations upon the durability and manner of action of the primary batteries that were reported one year ago, there have been added to the list the Vole battery of fifty cells and the chlorid of silver battery of fifty cells. As has been stated heretofore the cells of these are coupled in series, each cell being exposed clearly to view, so that the condition of its contents can be seen at all times, and then they are subjected to exactly similar methods of

investigation for the same period of time, the aim being to conform to the circumstances that would attend the work in the physician's office as nearly as possible. The main characteristics to which we look for determining the value of these sets of cells are: 1, the amount of constancy of electro-motive force; 2, the slowness of polarization and rapidity of depolarization; and 3, the durability of the elements subjected to chemic action for the freeing of electric energy. Time alone can determine the durability of these various forms of batteries and it is the purpose to continue these tests without renewing the elements until the energy in the cells is completely exhausted. I herewith submit a table of tests¹ of these various forms of stationary battery plants that have been made during the present year. It will be seen by investigating the last of these tests that many of the batteries are yet far from being exhausted, so that in all probability it will be some months before the question of durability will be settled. When the entire number of cells that have been submitted to us have ceased to act, it will then be the proper time for summing up the comparative excellences in action of these forms of cells. Yet it will be apparent to any one who chooses to glance over the tests, as they are here recorded, what is the capacity of any one set of cells upon the basis of the requirements for superiority that we have above mentioned. A copy of the results of these tests has been sent to each manufacturer who has furnished the Association through its committee with batteries for examination, so that they have the opportunity through the comparison which is here presented for making improvements needed upon the cells which they have been placing upon the market. In the judgment of your committee this is the true and just way of aiming to advance the appliances for electro-therapeutic use, since it avoids making us in any offensive way to discriminate in favor of one or the other manufactured article, yet gives all manufacturers an opportunity to compare their work with that of others who are aiming to supply the same trade, and has the effect of stimulating them to their best endeavors.

There are now some thirteen forms of primary batteries being subjected to these investigations in the laboratory at the University of Michigan. These forms of cells represent the majority of those that are most in use among physicians. Almost all of the batteries included in the thirteen sets mentioned are composed of cells too large to be employed in portable work and are suitable only for stationary plants in hospitals and in physicians' offices. The varieties of primary portable batteries are few. Among those most generally in use are the dry chlorid of silver cell battery manufactured by the Baltimore Company and the liquid cell of bichromate of potash solution with zinc and carbon elements, manufactured by various other companies, most notably by the McIntosh Battery & Optical Company of Chicago. A sufficient number of these cells can be inclosed compactly in a small space so as to furnish a comparatively high electro-motive force for bedside work and are therefore suitable for portable batteries.

CHLORID OF SILVER DRY CELL BATTERY.

A fifty cell portable battery was received from this company in June, 1893, with the request that it be subjected to the customary use to determine its capacity and efficiency. It was supplied with a Willms rheostat, a circuit breaker, a pole changer and a switch for throwing in the number of cells needed in groups of ten. The battery was put to work in my office July 10, 1893. At this time certain of the individual cells were tested with a standard voltmeter and found to register from .95 to .98 of a volt each. The character of work that was done with this battery was such as it is advertised to do; electrolysis, epilation and treatments upon the body where for the most part high body resistances are introduced into the circuit. At the beginning of this work the entire fifty cells registered a voltage of 48; at the end of the year, Aug. 26, 1894 the following record was taken:

The first 10 cells registered	10 volts.
" " 20 " "	19 "
" " 30 " "	15 "
" " 40 " "	19 "
" " 50 " "	22 "

It will here be observed that the voltage of the entire fifty cells did not much exceed the first twenty. It was found that the cells between twenty and thirty registered but 5 volts; between thirty and forty, 9 volts; between forty and

fifty, 9 volts. There was, then, evidently some internal resistance which, when the entire number of cells were thrown into action, succeeded in greatly lessening the voltage. It was also found at this time the Willms rheostat acted very unequally, the entire resistance of the instrument being in the first eighth part of the circuit, the remaining part of the circuit giving no additional resistance. These changes in the character of the direction of the battery had so far diminished its efficiency during the year that it was thought best to send it back to the makers for investigation and report. The following letter was received from them, when this examination was made:

"We find that the elements are not one-quarter exhausted. This is not your error, however, and we will endeavor to explain why it occurred. At the time we sent you this battery we were using domestic glass for our cell cases and, although we used every possible precaution, such glass will crack at times when least expected to do so, which it did in the case of several contained in your battery. The cracking of the glass does not affect the elements contained in them but permits the small amount of moisture to gradually evaporate and increases the diameter of the cells which serves to develop the slightest cracking. We are extremely sorry this should have occurred in your battery (for my part I am glad it did) for although it is liable to occur to any instrument containing the same character of glass as this, still we have sent out dozens of them without any trouble. However, being conscious that it is likely to happen at any time, we made provision to avoid it in the future, quite a time ago, and now all our cases are of Bohemian glass and are very fine. We propose to take no chances in your case and therefore place new cells in the machine. We have also made very important improvements in the current controller of Willms rheostat and shall also give you another one of these also."

I may say, when this battery was returned to me there came with it one of the imperfect cells that had been referred to and I found the condition to be as was stated in this letter. It is to be hoped that this company has succeeded in overcoming this serious fault by the means which they have indicated. The new rheostat also I find to be uniform in its resistance and a much better instrument than the one which it replaced. The voltage of this battery since it has been returned is 47, a little less than 1 volt per cell and this voltage is divided up equally in the various groups of cells which compose the battery. The cells which are used with the chlorid of silver battery are the smallest in size employed in any portable battery and the manner of arrangement is such that it makes this a very convenient instrument. If the cells can be so perfected that they will be entirely reliable and the controller can be made equally reliable, this will be made a very perfect apparatus for a portable battery. I have found it a suitable form to employ in cases of diagnosis where I am in need of a constant current, as it can be carried to the bedside without inconvenience or impairment of its action in the transit.

Another line of investigation which the committee has carried on is that of testing the action of the various forms of rheostat and controller.

RHEOSTATS AND CONTROLLERS OF THE CONTINUOUS CURRENTS.

Water Rheostats.—We have found a variety of this form of rheostat in many batteries used by physicians. The character of resistance which it offers to the current is much the same in all, but the amount of resistance is determined by the purity of the water employed and the amount of it which intervenes in the course of the circuit. The methods which are employed by the different instrument makers for varying the amount of intervening liquid differ considerably and upon this mechanism and the ease with which it is managed depends the efficiency of the instrument. The simpler this mechanism is as to freedom and equability of movement, the better the instrument. It should be so arranged that the current is modified gradually. Certain of these water rheostats are constructed so that the interval of liquid is maintained by a moving rod held in position by a set-screw. At times the slightest movement of this set-screw is sufficient to drop the rod instantaneously and so suddenly throw out all resistance. This necessarily gives a shock to the patient in the circuit and is both disagreeable and hurtful. Others of them are so constructed as to permit of a very slow and gradual change in the amount of intervening fluid and require too much time for making even very slight changes in variation of resistance. The main objections, however, to this form of rheostat are that the current passing through the fluid causes decomposition of it by electrolytic action and so

¹ This table is entirely too voluminous to be printed in the JOURNAL, but a copy can be obtained by applying to the Electro-Therapeutic Laboratory of the University of Michigan.

produces corrosion of all metals with which it is brought in contact, if these are corrodible; if they are non-corrodible they are necessarily so expensive that the instrument can not be sold for a price that will enable many to purchase it.

Another, and to my mind, a main objection, is that it is a very indefinite character of resistance, there being no means of measuring the amount of resistance which is thrown into circuit and so leaves it open to the fault of inexactness in measurement, a feature in our work that we are endeavoring to overcome.

Graphite Rheostat.—Of this form of resistance we have had a number to investigate, differing very much in construction, and while they are free from some of the objections that we have just mentioned as attaching to the water rheostats, they have certain deficiencies of their own, depending partly on the nature of the material and the manner of their construction. Yet on the whole we have found this class of rheostats to be superior to the liquid form. But they are likewise indefinite as to the amount of resistance which they furnish in the circuit and by reason of the wear which friction produces they are inconstant, even when the same extent of graphite surface is thrown in.

Among the graphite rheostats that have been subjected to test by the committee I mention the Willms, the Vetter, the Massey and the Gebhart, Reiniger and Schall. The absence of liquid and consequently of electrolytic action renders this class of rheostat more universally serviceable than any form of liquid rheostat we have had under examination.

Wire Rheostats.—These are, for the most part, when manufactured to be used in electro-therapeutic practice, made of German silver wire which alone furnishes sufficiently high resistance for the purpose. The character of the workmanship required to make reliable rheostats of this material and the amount of wire necessary, render them very expensive and few of our American instrument makers have attempted to furnish wire rheostats as a part of the outfit of primary batteries, except occasionally they have been introduced into very expensive cabinets. A well constructed wire rheostat is an instrument of much greater exactness and constancy than any of the forms we have hitherto considered. By care in their construction the amount of resistance can be determined within the minutest fraction of an ohm and the limit of resistance is only to be determined by the expense of construction and the space in which it is desired to place it. Wire rheostats therefore are altogether the best method of introducing a controller into the circuit of a constant current. Certain of the foreign manufacturers, as Gaiffe and Gebhart, Reiniger and Schall, have made such rheostats the controlling elements in many of their better forms of constant current batteries and thereby making them, so far as this feature is concerned, very accurate and reliable instruments.

CONTROLLERS FOR DYNAMO CURRENTS.

Your committee has, since our last meeting, given considerable attention to that class of instruments designed to employ the constant currents generated by dynamos used for electric lighting and other commercial purposes which are oftentimes available for physicians' use. By employing a constant current so furnished all the perplexities and annoyances which attend the maintenance of a primary battery plant are done away with and such currents and controllers of them are coming more and more into demand.

Among the instruments which have been put upon the market for controlling dynamo currents for general therapeutic work, the committee has been furnished for investigation the McIntosh Current Controller, the Gish Ideal Rheostat and the Vetter Current Adapter. All of these instruments act upon the shunt principle, allowing a main current to pass through a continuous wire or other material offering a certain amount of resistance and then possessing an additional mechanism by which more or less of this main current is diverted at the will of the operator into the patient's circuit. These devices have the effect of diminishing the original voltage at the same time that they diminish the current, an effect which to some who are engaged in electro-therapeutic work would appear to be of considerable value. We have made somewhat prolonged investigation of the first two of these appliances mentioned and herewith submit the reports pertaining to them:

THE MCINTOSH CURRENT CONTROLLER.

This controller is designed for portability, though not at the expense of durability. It is contained in a neat hardwood case $6\frac{1}{2}$ inches x 9 inches x 4 inches, having the index and regulating handles on top, the binding posts for the

machine terminals on one end and the reverser and binding posts for patient's circuit on the other end. A handle is fastened to the side for convenience in carrying. A delicate fuse is constantly in the machine circuit, so placed that all the current traverses the fuse before it reaches the point where the patient's circuit joins the machine circuit. This avoids all possibility of a dangerous increase in the current strength in the patient's circuit.

McIntosh Current Controller.

The fuse is so adjusted that a current of one-half an ampere in the machine circuit would instantly melt it and thus disconnect the instrument entirely from the dynamo. Under no circumstances can a harmful current pass through the patient. The reverser is in the patient's circuit to avoid the sparking and burning of contacts that would result from reversing the heavier current carried by the machine circuit. The controller works on the well-known "shunt" principle. The machine circuit consists of a succession of coils, 19 in all, joined in series and having a united resistance of 209 ohms, about the resistance of an ordinary 100 volt lamp. The patient's circuit is so arranged with sliding contacts that the

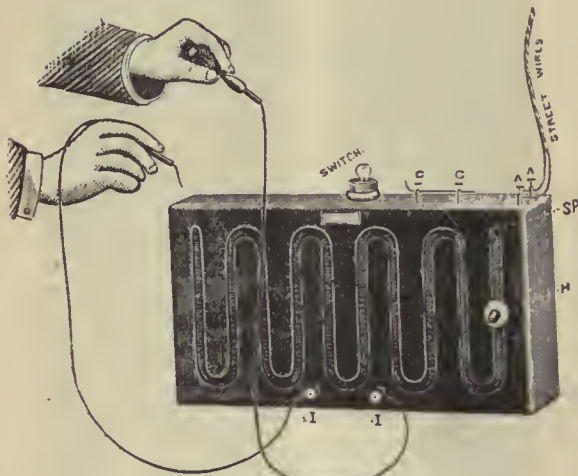

patient may be placed in a shunt to one or more coils. The coils vary in size, but are so proportioned as to modify the current in tenths and hundredths. The sliding contacts are arranged in two rows, each row having its own index. One row is connected with the larger coils, and consequently each coil in this row divides the E. M. F. in the machine circuit by ten. The remaining coils are connected with the other row of contacts, and each coil divides the E. M. F. by one hundred. The two rows may be used singly or together. The contact consists of a heavy brass roller sliding on a flat

brass plate and held tightly in contact with the plate by a flat brass spring. The accompanying diagram illustrates the essential parts of the instrument, and will enable the reader to clearly understand its construction and action. The laboratory test was made with an E. M. F. of 90 volts in the patient's circuit when shunt to the entire number of coils. A resistance of 1,560 ohms was placed in the patient's circuit, in which was included also a Weston milliampère meter. A Weston volt meter was connected shunt to the patient's terminals. The following table will show the E. M. F. and current in patient's circuit, with the sliding contact at various points on the index:

LEFT SLIDE.			RIGHT SLIDE.		
Index.	E. M. F.	Current.	Index.	E. M. F.	Current.
1.	8 Volts.	7 Mil'amps.	1.	1.1 Volts.	.9 Mil'amps.
2.	19 "	15 "	2.	2.3 "	2. "
3.	29.2 "	25 "	3.	3.51 "	3. "
4.	40 "	32 "	4.	4.24 "	3.61 "
5.	50 "	40 "	5.	5.35 "	4.5 "
6.	59.2 "	49 "	6.	6.93 "	5.84 "
7.	69.3 "	58 "	7.	8.21 "	6.9 "
8.	80.1 "	67 "	8.	9.2 "	7.8 "
9.	90 "	75 "	9.	10.63 "	8.98 "
			10.	11.89 "	10. "

It will be seen from these tables that the voltage and current increase and diminish in corresponding ratio, and this holds true, no matter what the source of E. M. F., whether from a constant current dynamo, an alternating dynamo, or a series of primary batteries. The laboratory contains a number of plants of various forms of primary batteries each made up of fifty cells. The voltage furnished by these varies from 60 to 78, according to the make of battery of which they are composed. This current controller seems to work quite as well on the current furnished from any one of these batteries as upon that generated by the Edison or other constant current dynamo, modifying the E. M. F. and the currents by tenths and hundredths proportionate to the initial voltage, whatever that may be. The dynamo generating the current upon which the foregoing tests were made is used for distributing power to motors throughout the city. The current enters the laboratory with an E. M. F. of five hundred, but this potential is reduced by lamp resistance to the desired amount. It appears, therefore, from these observations that we have in this controller a simple and efficient mechanical device for adapting both constant and alternating currents, or currents derived from primary batteries, to the physician's use.

THE GISH IDEAL RHEOSTAT.

The instrument here represented is another apparatus designed to adapt the commercial dynamo currents to the physician's and dentist's needs. It is constructed on the shunt plan and consists of a main circuit and a shunt circuit, the latter of which is the patient's circuit.

The main circuit within the instrument is made up of a continuous German silver wire, No. 22, wound on a succession of rectangular wooden blocks covered with asbestos paper. Ten of these wire-wound blocks are exposed through a sinuous slit in the face of the instrument, and in this slit the slide moves which serves to vary the amount of current

in the shunt circuit of which it forms a part. The remaining blocks, smaller in size, stand in the rear and are not touched by the slide. We here present a diagram of the working plan of the instrument.

AB are binding posts connecting the instrument with the dynamo circuit.
EF are binding posts for connecting the patient with the shunt circuit.

H represents the portion of the German silver wire resistance that can be made a part of the shunt circuit.

H' that part of the resistance wire that can not be included in the shunt circuit.

It will be seen from this illustration that while the instrument is in action the dynamo current constantly flows through the circuit BH, H', C, D, A, and that while the shunt circuit remains open at EF; that is, when no patient is in circuit, or when the slide is at the extremity of the slot nearest to B, no current flows through the shunt circuit. But should the slide be moved toward H with a patient in circuit between E and F, then we will have between the points A and B what is termed a divided circuit, and the electro-motive force with which the current traverses the shunt or patient's circuit will be determined by the difference in potential existing between the points B and A, and the distance to which the slide G is moved away from the post B.

This instrument was designed to be used on the Edison 110 volt dynamo circuit, but it can also be used on the alternating system. The resistance of the circuit from B to A is 185 ohms, and from B to the extremity of the resistance H 141 ohms. The difference of potential therefore that can be admitted into the shunt or patient's circuit would be 141-185 of the potential difference between B and A. In case that difference is 110 volts, as in the Edison incandescent circuit, the proportion that would be admitted to the patient's circuit when given its fullest capacity would be 84 volts. This electro-motive force applied to a body resistance of 3,000 ohms, which is a fair average when the integument forms a part of the circuit in contact with both electrodes, would give a current

$$C = \frac{84}{3000 + 141} = 26 \text{ ma} +$$

which represents the full capacity of this instrument on the Edison circuit, with the amount of resistance named. The majority of treatments with the constant current, when the skin intervenes at both electrodes, does not require a current to exceed 20 milliampères.

When a mucous surface forms a point of contact for one electrode, the body resistance is very greatly lessened, seldom exceeding 250 milliampères. Should this instrument be employed on the same voltage with this resistance, we would have

$$C = \frac{84}{250 + 141} = 215 \text{ milliampères.}$$

as its full capacity, a current sufficiently powerful to meet the exigencies of the present treatment of uterine fibroids, endometritis, etc.

The instrument is provided with a switch for letting on the current when it is needed and shutting it off when not in use. Also, a gate CD, is left between two binding posts on the top of the instrument, opening into the main circuit, which can be used at any time for increasing the resistance of the main circuit. The instrument is not designed for nor will it heat a cautery. Neither is it suitable for lighting exploring lamps. The same company have other forms of apparatus especially adapted for these purposes.

(To be continued.)

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 86 Fifth Avenue, Chicago.

SATURDAY, AUGUST 3, 1895.

THE RIVAL MONUMENTS AT WASHINGTON TO
HAHNEMANN AND RUSH.

The chairman of the Rush Monument Committee, in another column, calls attention to a matter that he justly believes demands the serious attention of the medical men of this country. The erection of a statue to PROFESSOR GROSS by the American Surgical Association, of which he was founder and President, was a very natural and proper demonstration of personal admiration and affection for their late eminent associate and friend, and no one interested in the monument to RUSH ought by word or influence to antagonize the project. Indeed, among the subscribers to the testimonial to GROSS are the names of prominent advocates of a national monument to BENJAMIN RUSH.

It is quite another matter, when a numerically small body of sectarians propose to glorify a foreigner, whose only claim to distinction is that he was the founder of that sect, by erecting at the capital of the Republic as superb a memorial as money can enable its members to procure. The committee on the monument to RUSH very naturally feel mortified that the great body of their professional associates, who at the annually recurring sessions of their representative ASSOCIATION have for ten successive years enthusiastically applauded their efforts and pledged their contributions, forget all about the one and the other when they reach their homes.

BENJAMIN RUSH's claims to the grateful remembrance of medical men in America can not be contested. As DR. GIBON recently stated in the pages of one of our contemporaries, no one pretends that he was impeccable. He was too zealous, ardent and

energetic not to err in word and deed, but his signature, one of the most conspicuous, firm and still legible, on the immortal Declaration of the Independence of these United States of America, written boldly and unhesitatingly by him when other men, who professed fealty to the cause of the rebellious colonies, feared to take this dangerous step, alone entitles him to the most imposing monument his professional brethren can erect.

The project has now gone too far to be abandoned. A monument of some kind will be erected, but whether it will be a commanding structure of artistic excellence, befitting the man and the profession, depends upon the amount of money subscribed. It will be a humiliating contrast if in one portion of the capital city of this country there shall stand the splendid memorial of a little band of homeopaths, and in another an humble pile of bronze and granite, eked to its utmost possibility, by some self-sacrificing sculptor, as the measure of the liberality and appreciation of over one hundred thousand physicians of him, who, in the words of a great living physician, was "the greatest physician this country has ever produced."

The JOURNAL earnestly hopes the profession will realize the necessity for its prompt response to the committee's appeals, and that, as the chairman suggests, every State, Territorial and county medical society will at once take decisive action, and every individual physician contribute of his means toward the completion of this commendable undertaking.

CHOLERA AND YELLOW FEVER.

The news from the Orient in regard to cholera is not reassuring. Cholera is raging in Corea, in the Liao Tung peninsula, in the government of Volhynia Russia, and in Japan. In the latter country 9,000 persons are reported to have been attacked since the outbreak, with a mortality of 5,000. This mortality is about that of the last serious epidemic in Europe, and shows that the world has not yet placed the disease under therapeutic control. We may indeed prevent its spread by careful disinfection, and by supplying pure water instead of contaminated water, but the work of stamping out the disease at its original center seems yet far away. In this, Great Britain has a moral responsibility in the eyes of the world that she can not shake.

The yellow fever has spread from the Island of Cuba to the Island of Puerto Rico, where it is stated that the daily mortality is about 20 per cent. The Spanish troops have suffered greatly in Cuba, and the Cuban patriots have thus had an ally more invincible than armed men. When the island of Cuba is once free and independent, and the military domination suppressed, there will be every incentive to stamp out the yellow fever habitat in Cuba. At present, while

the heel of the despot rests on the "ever-faithful isle," there is no time to seriously consider any sanitary plan, and at no time for the past thirty years have the Spanish masters of Cuba felt strong enough to undertake it. The cutting of a canal from the upper bay to the sea, the cleaning and purification of dwellings, and the reconstruction of house drains, would work wonders in fever-stricken Havana. Whether this generation will see the attempt made is another question. From the personal observation of the editor of this JOURNAL, he is of opinion that no one who has ever seen the stagnant waters of the upper bay, in the vicinity of the Military Hospital, and smelled the vile and nauseous odor emanating from it, could fail to think of the possible change that might be wrought by the construction of a canal or a tunnel to the sea. The bluest, deepest water of the Gulf passes along the coast and bathes the rocks at the foot of Moro Castle, but the Military Hospital remains now, as it has for the last century, on the shores of a stagnant sea of sludge and slime.

VARIOLOUS IMMUNITY OF THE FETUS FROM THE MOTHER.

At a recent meeting of the Paris Academy of Medicine, M. HERVIEUX read the report of the following case by DR. ANNET, a military surgeon: A young woman of 24 was re-vaccinated successfully in the fifth month of her first pregnancy; her child was vaccinated at three and at six months, the latter only being successful. "So far," says DR. ANNET, "nothing is unusual, for we know that immunity transmitted from the mother rarely persists beyond five or six months." But the patient became pregnant again in 1894, four years after, and this second child was inoculated at the second, seventh and eleventh months; all attempts failed, though the vaccine matter had been used in several other children and always with success. M. ANNET expressed the opinion that this immunity could only have been conferred by the blood of the mother. M. HERVIEUX, in discussing the case, said we do not recognize this transmission of immunity as one of the possibilities. A more acceptable supposition is that the second child was refractory, not from maternal immunity, but by reason of its individual constitution. We see persons who are repeatedly vaccinated with the greatest precautions, with irreproachable vaccine matter, and always unsuccessfully. But suppose they were inoculated ten times without success. Nothing enables us to state that the next time would fail also. So, for the child mentioned by DR. ANNET, a fourth vaccination might have succeeded.¹

M. HERVIEUX might have materially fortified his position, had it been necessary, by a reference to that wonderful storehouse of facts and philosophical deductions—"Original Investigations on the Natural

History (Symptoms and Pathology) of Yellow Fever," 1854-1894, by DR. JOSEPH JONES, of New Orleans. In his second chapter, on the "Communication of Yellow Fever Through the Mother to the Fetus in Utero,"² he has brought together a number of important observations covering a period of more than a hundred years, bearing upon the transmission of the poison of smallpox through systems, "themselves entirely protected from its influence and demonstrating the existing of the poison in a potential active state, as shown by the excitation of genuine smallpox in the fetus in the womb of the mother protected by previous inoculation, vaccination and smallpox."

The conclusion is unavoidable that no degree of immunity is conferred upon the fetus through any variolous or vaccinal experience of the mother, and the lesson of DR. ANNET's case, for the sanitarian and health officer, is to repeat vaccination whenever there is exposure to the smallpox contagion, and often enough to demonstrate insusceptibility.

CONTROL OF MEDICAL PRACTICE IN RHODE ISLAND.

After eleven years of persistent effort by the reputable members of the profession—to which the State Board of Health afforded valuable assistance—Rhode Island has finally succeeded in securing legislation which should result in ridding the State of at least a large percentage of the quacks, incompetents and itinerants who have heretofore fleeced the public, uncontrolled and unmolested. The Medical Registration Act, which went into effect July 16 ult., provides in substance the following conditions for the future practice of medicine in the State:

1. The possession of a diploma from a reputable medical college, indorsed by the State Board of Health as such. Only such colleges as require a three years' graded course are to be considered as having the indorsement of the Board; or

2. Satisfactory evidence that the person making the application was reputedly engaged in the practice of medicine or surgery in the State prior to Jan. 1, 1892. This evidence to be subscribed to and verified by oath, in affidavit, and such statements, if wilfully false, shall subject the affiant to conviction and punishment for perjury; or

3. Submission of the applicant—if not included in either of the foregoing—to an examination by the State Board of Health to determine the possession of sufficient knowledge to practice medicine and surgery.

Under the first condition it is necessary for each and every practitioner to present his diploma to some member of the State Board of Health for verification, as well as to swear to the ownership for proof

¹ Bull. de l'Acad. de Med. No. 23, 1895.

² JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, VOL. XXIII, p. 942.

of identity and possession before a notary. Under the second condition the applicant is obliged to make affidavit that he is not and never has been an itinerant doctor, and will not become such in any capacity under a certificate if granted; and that he was reputable and continuously engaged in the practice of medicine and surgery in the State of Rhode Island prior to Jan. 1, 1892. Those not having the privilege of application under the so-called "time limit" or second condition, and provided for under the third condition are allowed an examination before the Board to prove their ability to practice.

DR. SWARTS, the Secretary of the State Board, says that "while this law is not all that could be desired, it has already been of value in suppressing the intentions of many irregular practitioners who are daily excluded from practice in other States, and who, making application, find that they can not meet with the requirements of the act." And adds that "in the execution of the law the Board will make every effort to see that the full meaning of the law is applied, but it will be of the greatest assistance, as it has already been, if each practitioner would consider himself as a member of a sub-committee of the Board and advise in regard to individual cases which may come to his attention, in regard to midwives, "time limit" cases, disreputable or unprofessional conduct in the commercial meaning of the word, and including any questionable methods of regular practitioners."¹

Of the estimated 600 physicians in the State two-thirds of the number had complied with the law before the expiration of the sixty days after its passage and, consequently, before it actually took effect. This is cited as evidence of the favor with which the act is regarded by the profession generally.

THE RELATIONS OF THE NEWER PSYCHOLOGY TO MEDICINE.

It is at once an advantage and also practically a disadvantage to medicine that in its widest sense it embraces a greater compass of sciences than almost any other human occupation or profession. The physician should be a man of broad general culture—that is, the ideal physician should be such—as well as of minute and accurate knowledge, and the difficulty of the combination is found in the necessary limitations of the human intellect. This difficulty increases with the years and the result is an ever-growing tendency to specialism in the cities, and a greater dependence of the general practitioner upon the specialist in every line. The latter, on the other hand, unless he be a neurologist, who ought at least to be, in his way, a sort of "glorified general practitioner," is liable to become narrow in his medical

ideas with the narrowing of his field and to give little attention to matters outside his own limited territory.

It is only occasionally that a physician cultivates or gives very much attention to the lines of investigation that lie on the border lands, so to speak, of medical science; there are proportionally not many indeed who see the practical side of purely scientific investigations into what its cultivators like to style the "newer psychology," the experimental as opposed to the old introspective psychology. Whatever it may have of medical interest, they are inclined to think can be taken second hand from those who are willing to glean in this field for the medical publications. To a certain extent this is true, but it is not altogether so. There is no one who would question the importance of the physiology of the senses, and their psychology is only a step further and one that has most important bearings on their pathology and their utilization and management in disease.

While experience has taught us to use daily many of the facts deduced from ordinary observation, one trusting to this alone is nevertheless at a disadvantage as compared with one instructed and skilled in even the older psychology of introspection, and with only a slight general knowledge of the newer methods. The multitudinous literature of hypnotism, for example, furnishes abundant illustration of this fact. Most of it is of little value and much only cumber the ground and had better never been written.

Taken together with the later discoveries in the finer anatomy of the nervous system, the results of experimental psychology are wonderfully suggestive, and a thorough knowledge of what has been done in this line is almost essential before one can properly theorize on the data acquired by the recent discoveries. We have all known and experienced the symptoms of fatigue, but how much light is thrown on the phenomenon by the physiologic psychology of the day. The disease called neurasthenia, which to many is only a vague term, a sort of limbo to which to consign a large class of cases of indefinite diagnosis without any material lesions, "an ill-defined, motley group of symptoms," which it is often hard to consider as not imaginary, and falling under the same general head as hysteria and hypochondria, is supplied by the experimental investigations of physiologic psychologists on the fatigue of the nerve elements, with a perfectly rational if not absolutely established pathology.

If the pathology of hysteria is to be elucidated, it seems probable that it will also have to be along the same lines, or at least that the psycho-physiologic and pathologic studies will largely aid in bringing it about. Many other questions, such as why is insanity apparently on the increase, why is syphilis followed by tabes and paresis in modern times and among civilized peoples, have answers that are at

¹ Monthly Bulletin, State Board of Health of Rhode Island, Nos. 5-6.

least as probably true as any that have been offered, suggested by the student in physiologic psychology, that it would take too much space to give in detail here.

The whole range of the special senses in their normal and abnormal conditions fall directly under this head, as already indicated, and there is yet another special value of these studies for the physician, in the education as to methods and as to valuation of observed facts that they give. On this account alone it would seem that some instruction in this direction could well be added to the courses of our regular medical schools. But without this, the "newer psychology," the psychology of facts as opposed to that of mere theory, is a perfectly legitimate and highly profitable subject for the occupation of any unoccupied leisure of the scientific physician. And for the nervous or mental specialist some acquaintance with it would seem to be an absolutely essential portion of his professional mental equipment.

PROFESSOR HORATIO C. WOOD.

Our readers will read with pleasure the lecture by America's foremost medical therapist, in this issue of the JOURNAL, in the Society Proceedings Department, under the heading of the Cleveland Medical Society. The important subject, the well-known reputation of the lecturer, and the substance of his lecture, make this article one that will, we are sure, be appreciated by our readers.

NEW INSTRUMENTS.

ELECTRIC MOUTH BATTERY.

The object of this invention is to obtain an electric battery which can be worn in the mouth of a person for its therapeutic effects, and also to give strength to the plate when false teeth are worn.

G, gold plate; Z, zinc plate; N C, non-conducting plate.

This battery consists of a non-conducting plate arranged to fit in the mouth, metal plates of opposite electric polarity imbedded in the non-conducting plate, conductors connecting the metal plates, such conductors imbedded in the non-conducting plate, and such metal plates so disposed as to be exposed to the action of an electric excitation by the saliva or other fluids in the mouth, and the organs of the mouth, to form elements completing the circuit of the battery.

We believe this to be the most rational form of electric treatment for cases which are indicated, inasmuch as we have a mild and uninterrupted current which may be made stronger or weaker to suit the case.

These batteries being in close proximity to the brain, the medulla and spinal cord, the air passages and the alimentary canal render it easy for the current to be carried to all parts of the body, thus charging the entire system; hence it may be seen that it would be beneficial in many diseases common to mankind, especially catarrh, deafness, weak eyes, headache, various nerve disorders, stomach and lung troubles, and diseases of the mouth, reducing inflammation arising from regulating the teeth. In inhalation the air would pass through electrified tissue, rendering it ozonized before entering the lungs. In mastication and deglutition electrified food would pass to the stomach.

Will cite a few practical cases, as far as tests have gone, of positive relief; the method being new, have not had time for extensive experiments.

1. Trial for acute gastric disturbance; wore plate and was relieved in a half hour; had no more trouble for two weeks when it re-occurred. Not being satisfied that the battery had caused the relief in the previous case, different medications were used without relief; then plate was worn again about seven hours, when trouble disappeared. In several weeks, beer-drinking and smoking brought on trouble with renewed vigor, which was allayed in twenty-four hours by wearing plate. A series of experiments were kept up with good results.

2. A case of insomnia treated with electric plate from 11 A.M. until 11 P.M. Patient went into a sound sleep, without waking until 9 A.M. next day. The patient expressed himself as having had the most refreshing sleep he had had for years. Treatment is still continued with satisfactory results.

3. Closure of the Eustachian tubes, dullness of hearing and general catarrh of the nares. Plate worn for about twelve hours; trouble almost entirely disappeared. Treatment continued for two days in daytime only. Head and ears clear as a bell ever since, four weeks having elapsed since treatment was discontinued.

CORRESPONDENCE.

More about Truffles.

PHILADELPHIA, PA., July 26, 1895.

To the Editor:—Referring to your valued JOURNAL of the 13th inst., page 85, I would respectfully call your attention to an error in the article on "Tuckahoe," in the statement that trained dogs are used to hunt the truffle in the Old World; in France, in which nearly four-fifths of the entire production is found, trained pigs are used. They are mostly muzzled by a ring around the jaw to prevent their swallowing the delicacy. The sense of smell in these pigs is very highly developed, the truffles being often exceedingly deep underground.

Asking pardon for thus bothering you, I remain,
Yours sincerely, SYDNEY H. BOHN.

NECROLOGY.

WALTER ALFRED MORTON, M.D., of Brooklyn, died July 22, aged 35 years. He was a native of Westmoreland County, Virginia. He was graduated at the medical school of Dartmouth College, in 1889; also at the Long Island Medical College two years later. Since that time he has been a resident of Brooklyn. He was a member of the Kings County Medical Society. His final illness was due to pulmonary tuberculosis, the attack dating from the latter part of 1894.

ALBERT F. TRACY, M.D., of Westfield, Mass., died of pul-

monary tuberculosis, on July 18, after an illness lasting two years. He was a prominent physician and widely known throughout western Massachusetts. He was born in Aurora, Ont., and graduated from Victoria University in Toronto. Dr. Tracy was the husband of Hattie Schell, the authoress, whom he married in 1893. He was a member of the Massachusetts Young Men's Democratic Club, and of the Board of Medical Pension Examiners; also a member of the Massachusetts Medical Society since 1887.

THE REV. JAMES LIDDELL PHILLIPS, M.D., is reported to have died recently in Calcutta, India. He was a well-known Baptist missionary, and son of a famous missionary, the Rev. Jeremiah Phillips, D.D. He graduated at Bowdoin College, took a medical course at the College of Physicians and Surgeons in this city, and received the degree of M.D. in 1864. He married Miss Mary R. Sayles, of Pascoag, R. I., and went to India in June, 1865. He founded the Bible School in Midnapoor, and was its principal for several years. He returned to the United States in 1885 and became Chaplain of the State Institution of Rhode Island and was subsequently Secretary of the Evangelical Alliance of Philadelphia. He was Moderator of the General Conference in Marion, Ohio, in 1886.

J. WESTLEY ALLEN, M.D., of Altoona, Pa., July 20, aged 57.—Herman B. Wittwer, M.D., of Chicago, July 26.—Walter C. Overstreet, M.D., of Monmouth, Ill., July 26.—W. T. Strachan, M.D., formerly of Lancaster, Pa., July 23, aged 65.—Frances Kyle, M.D., of Sioux Falls, S. D., July 24.—J. B. Lebbond, M.D., of Sioux Falls, S. D., July 24, aged 70.—Augustin J. Dalrymple, M.D., of Baltimore, Md., July 24, aged 65.—Lemuel D. Putnam, M.D., of Grand Rapids, Mich., July 22, aged 72.—Thomas Gunn, M.D., of Chapman, Kan., July 23.—Adam Bryan, M.D., of Detroit, Mich., July 21, aged 66.

PUBLIC HEALTH.

Prophylactic Effect of Sea Air in Tuberculosis.—M. Lalesque has studied the prophylactic and curative action of the change to the sea air of Archachon in 220 subjects sent thither, either threatened with or suffering from tuberculosis in different forms. He gives the following results: prophylactic action, 50 cases, 50 recoveries. Curative action, 170 cases; in the first stage 73 cases—22 recoveries, 39 ameliorations, 12 aggravations or deaths; in the second stage 37 cases—1 recovery, 24 ameliorations, 12 aggravations or deaths; third stage 60 cases—4 recoveries, 21 ameliorations, 35 aggravations or deaths. M. Lalesque observes that the sea air, in common with that of mountains, is notable for its purity.¹

Regulations for Consumption Sanitaria.—The Comité Consultatif Francais d'Hygiene Publique has formally approved the following regulations, drawn up by M. Netter, for the sanitaria for consumptives: 1, sanitaria should be built upon elevated sites surrounded by cultivated grounds and parks, these making a boundary between the public and the patients, who should confine themselves within its limits as much as possible; 2, each establishment should be provided with a steam apparatus for the purpose of disinfection and through which all the body and bed linen and clothing should be passed before being washed; 3, rooms should be disinfected and re-painted before they are occupied by new patients, and all floors should be covered with linoleum; 4, all excreta and dejecta should be thoroughly disinfected before being disposed of; 5, patients must be prohibited from expectorating elsewhere than in spittoons provided, and these must be scrupulously disinfected every day.²

A Plea for Better Registration of Vital Statistics.—Dr. J. F. Kennedy, Secretary of the Iowa State Board of Health, commenting upon a decision of the Iowa Supreme Court, upholding the validity of the statute requiring physicians to report births and deaths occurring in their practice, urges that a faithful registration of births and deaths—"the alpha and omega of life"—would facilitate the identification of individuals and thereby aid in the settlement of estates, assist in the detection of criminals, afford data for the estimation of life expectancies, furnish to medical and sanitary science important and valuable information regarding the state of the public health, throw light upon the causal conditions under which prevailing diseases occur, thus leading to intelligent methods for prevention, and afford reliable information as to climatic influences in the production of sickness and death. He believes, from personal observation as a physician extending over a period of more than thirty-seven years, and from the meager and imperfect reports in his office, that Iowa enjoys an enviable position as to salubrity of climate, physical vigor, high birth rate, proportionately low death rate and longevity, and is sure the figures could be produced to verify this belief if only the physicians of Iowa could be induced to report as required by law. He thinks that patriotism and State pride should overcome any hesitation on account of inconvenience or want of pecuniary compensation. But "if the profession in Iowa, in the face of the statute and its expressed penalties; in view of the decision of the Supreme Court; in view of the incalculable benefits of these statistics to the profession and to science, and in view of their material advantages to Iowa, can not be induced to furnish these reports, I hope every physician in Iowa will unite in petitioning the next General Assembly to remove from our statutes every section and syllable relating to the registration of vital statistics."¹

Bovine Vaccine Plant at Dublin.—A very thorough and intelligently managed vaccine establishment is possessed by the profession in Ireland. The *Press and Circular* reports concerning a special investigation of the institution as follows:

"We have had an opportunity of observing the process of preparing calf lymph in the establishment recently opened by Dr. Denham, at Sandymount, near Dublin. The calves, three or four months old, are obtained from graziers, in such number as may be required, and are stabled at the Vaccine Institute, a house which is kept rigorously clean and is provided with fresh air by an electric fan. Upon admission, each of these calves is examined by the veterinary surgeon to the Institute, to insure that no signs of disease exist. Their temperature is taken, and a pulmonary examination is made. If found perfectly healthy the belly of the calf is shaved. The table upon which the animal is laid is specially constructed for the purpose, the top being capable of being tilted from the vertical to the horizontal position. The animal is ranged up against it when it is vertical, and its head secured in an ordinary head-stall with a pillow underneath to prevent the animal hurting itself. A strap is drawn around the body, and the table is then tilted to the horizontal position with the calf upon it, and the feet are strapped down with padded straps. The belly is then shaved and the surface washed first with boracic solution and afterward with sterilized water. The inoculations are then made, to the number of about thirty, on the denuded surface with lymph, which has been previously tested and found free from any taint. This having been done, the animal is returned to the stall. As the vaccine fever develops, the temperature usually goes up from 102.2 to 102.5, 102 being the normal temperature of the calf; and, as the vesicles develop, recedes again to the normal. One hundred and twenty hours after inoculation the calf is again laid on the table and the lymph is taken off, in which process a clamp like a phimosis clamp and sundry other instruments, all sterilized, are used. The lymph thus collected is then brought to the laboratory, where it passes into the hands of Professor Mac-Weeny, who, by microscopic examination and germ cultivation, tests its purity. This necessarily consumes a good deal

¹ Jour. de Med. de Bordeaux, No. 19, 1895.

² Union Medicale, June 22, 1895.

¹ Iowa Health Bulletin, July, 1895.

of time, during which the lymph stock is kept in a refrigerator. If it is pronounced to be quite pure it is then placed in a 'pulper' or mixer, for the purpose of incorporating it with glycerin and sterilized distilled water. This instrument is driven at a very high rate of speed by an electric motor, and the lymph is delivered from it in a defibrinated condition to be filled into tubes. The lymph is prepared according to three methods: *a*, it is transferred to points direct from the calf and without any admixture whatever; or *b*, it is defibrinated, as above stated, in the electric 'pulper' with a small quantity of glycerin and water, and put into tubes; or *c*, it is made up sufficiently liquid to press into tubes. The only point in this method of procedure which might be open to question, all the rest being strict scientific work, is the care which the animals receive when in the Institute, and this we have specially noted. As far as we could observe, every possible precaution and every care suitable for a human being under similar circumstances was taken with these animals."

Mob Violence Against Sanitation.—Violence, with murder, has been, it is believed, the indirect result of the efforts of Europeans, to apply modern methods of sanitation against cholera in Asia. The riot took place at Jeddah, on the Red Sea, and the rioters are supposed to be Bedouins. In the course of the outbreak, the new cholera hospital was destroyed. It is highly probable that the outbreak was a kind of reaction, or protest, against the new sanitary regulations adopted at Jeddah to prevent the spread of cholera. Jeddah is a port on the Red Sea about half way between Aden and Suez, sixty-five miles from Mecca, the birth-place of Mohammed. The pilgrims to Mecca usually embark there, and at this season of the year there are often 100,000 of them in the city. These pilgrimages have often been the starting point of a rapid spread of the disease. The Paris Sanitary Conference arrived at the unanimous conclusion that a great source of danger was to be found in the filthy condition of the wells and water tanks around Mecca and along the shores of the Red Sea. These reservoirs are open to all pilgrims, and the tanks serve as bathing places as well as for the supply of drinking water. The wells have been deepened and covered over, regular bathing places have been provided, and no one is allowed to bathe in the tanks from which the drinking water is supplied. The pilgrims who had been accustomed to lower their filthy skin bottles into the wells, have this year had pure water measured out to them, and have not been allowed to draw for themselves. As the wells are accounted holy, some dissatisfaction was to be expected, and the late outbreak is doubtless due to it. The pilgrims regarded as an unwarrantable restriction of their liberty, the salutary regulations designed to save their lives and the lives of thousands to whom they might communicate the disease.

Changes in the New York City Board of Health.—On July 23, the Board of Health of New York city retired at his own request, Dr. John T. Nagle, Registrar of Vital Statistics. Dr. Nagle has asked for this action on the score of ill health. By the unanimous vote of the board, Dr. Nagle was retired on an annual pension of \$600, to begin on August 1. Dr. Nagle is the first officer of the Health Department to be retired under the pension law passed last winter. He was himself the father of the law. It allows a maximum pension of \$1,200. The Health Board yesterday promoted Dr. Roger S. Tracy to the office of Registrar of Vital Statistics, with a salary of \$3,500 a year. He has been the Chief Statistician of the department for several years. Dr. Nagle was the chief medical officer of the Third Division of Cavalry in the Civil War, and he lately received a government pension. He was appointed a Sanitary Inspector in the Health Department in 1869, and for many years he was at the head of the Bureau of Vital Statistics. The new Registrar, Dr. Tracy, was born in Vermont in 1841, was graduated from Yale College in 1862, and took his degree from the College of Physicians and

Surgeons in 1868. He was on the medical staff of Bellevue Hospital for some time, and later studied medicine in Europe for a year and a half. Soon after his return he entered the Health Department, and some years later became Registrar of the Bureau of Vital Statistics, which position he occupied until Dr. Nagle was appointed to the position.

Health Reports.—The following health reports have been received by the Supervising Surgeon-General of the Marine-Hospital Service:

SMALLPOX—FOREIGN.

Austria: Trieste, June 30 to July 6, 1 case.
Egypt: Cairo, June 17 to 24, 1 death.
England: Southampton, July 6 to 13, 1 case.
Germany: Prague, June 30 to July 6, 5 cases.
Holland: Rotterdam, July 6 to 13, 2 cases.
Hungary: Buda-Pesth, July 1 to 8, 7 cases, 1 death.
India: Calcutta, June 8 to 15, 19 deaths.

SMALLPOX—UNITED STATES.

Louisiana: New Orleans, July 13 to 20, 7 cases.
Michigan: Battle Creek, July 23 to 30, smallpox reported;
Detroit, July 23 to 30, smallpox reported; Olivet, July 23 to 30, smallpox reported.

Missouri: St. Louis, July 13 to 20, 1 case, 1 death.

CHOLERA—FOREIGN.

India: Bombay, June 11 to 18, 1 death; Calcutta, June 8 to 15, 27 deaths.

YELLOW FEVER—FOREIGN.

Cuba: Cienfuegos, July 13 to 30, 2 deaths; Havana, July 11 to 18, 18 deaths; Sagua la Grande, July 13 to 20, 1 case.
Mexico: Vera Cruz, July 11 to 18, 5 deaths.

HAVANA, CUBA, July 20, 1895.

Sir:—In confirmation of my telegram of the 19th inst., informing you that "yellow fever had, within the last few days, increased considerably among civilians," I have now the honor to say that there were eighteen deaths from that disease during the week ending July 18, and that a large part of them occurred during the last few days of that week. As all of these deaths were among civilians in different parts of the town and none among soldiers, it indicates a tendency in the disease to spread in the city. Up to the present time very few or none of the recently arrived soldiers stay in the city longer than it takes to be formed into battalions, get clothing, etc., and be forwarded to the territory of the insurrection.

Very respectfully,

D. W. BURGESS,

U. S. Sanitary Inspector, M.-H. S.

St. PETERSBURG, July 8, 1895.

CHOLERA IN RUSSIA.

In the government of Volhynia from May 26 to June 22, 1895, there were 136 cases of cholera resulting in 40 deaths.

A conference was held lately in the Ministry of Foreign Affairs between the representatives of Austria-Hungary and Russia, with a view to carrying out the resolutions of the Dresden International Sanitary Conference, concerning measures to be adopted in cholera time for the frontier traffic with Russia, based upon the experience obtained during the last cholera epidemics in Russia and Galicia. A complete understanding was arrived at in reference to all measures for the control of cholera, should it arise in the neighborhood of the Russo-Austrian frontier, and safeguarding the frontier traffic as far as possible.

Further, the Russian Government, fearing that cholera may be carried into Russia *via* Vladivostok from Japan, is taking every precaution. Only a few days ago, six physicians were sent to Vladivostok from the Medical Department at St. Petersburg, with orders to keep strict watch and use all possible means of protection.

JOHN KAREL, Consul-General.

SELECTIONS.

Anchylostoma Anemia in the Vicinity of Naples.—Paolucci (*Riforma Méd.*, 1894) records four cases of anchylostoma in 1894. This malady appears to be limited to the country on the eastern boundary of the city, where the poor tenants cultivate vegetables in fields, watered by dirty streams polluted by manure, and to which they fetch from the city, dung

and a variety of filthy material. All four patients were accustomed to eat freely raw vegetables and to drink the dirty water in their fields. The sickness manifested itself in the usual way with pains in the epigastrium and abdomen, loss of appetite, severe anemia, increase of the white and decrease of the red blood corpuscles, and diminution of the hemoglobin. There was no accompanying enlargement of the liver or spleen, and no hemorrhage. The patients sought the hospital on account of the increasing pallor of skin and mucous membrane, the emaciation and debility. Relative to the therapeutics, the writer praises, after a preliminary emptying of the bowels by sulphate of magnesia or soda, the use of ethereal oil of filix mas in capsules (about 7. gm. in two days), after which incredible quantities of anchylostoma, well developed, were found in the stools. Eggs could be discovered even until the eighth day. He found not the least result after a trial with creosote.—*Centralblatt für innere Medicin.*

Immunity and Susceptibility with Reference to Cholera.—(Met-schnikoff in *Wiener Med. Presse.*) The striking facts of immunity of many to cholera, and of the influence of time and place (the two factors made specially prominent by Pettenkofer) on the course of a cholera epidemic, the writer believes he can for the most part explain, on the strength of numerous experiments and observations, through the varieties of bacteria in the intestinal canal. He noticed, for instance, that different bacteria in plate cultures exerted a distinctly favorable influence on the growth of cholera vibrios, among others especially sarcinae and the white yeast, called torula. On the other hand, he found bacteria among which was the bacillus pyocyaneus, which plainly retarded the growth. By reason of these facts, he examined closely the bacteria in the human intestinal canal in regard to their behavior toward the cholera vibrio and here also he was able to cultivate the previously mentioned torula and a sarcina and a bacillus not liquefying gelatin, all favorable to cholera; and from the intestine of animals he isolated several varieties of bacilli and a thick coccus, having an opposite tendency. He comes to the conclusion that the bacteria of the intestinal canal play an important rôle in the immunity and susceptibility of man and animals toward cholera. Through this, the fundamental truth that the vibrio of Koch is the specific cause of cholera, can be brought into accord with the results of epidemiology and especially with the influence of time and place on the course of a cholera epidemic.—*Centralblatt für innere Medicin.*

Preliminary Report of 1,000 Abdominal Operations by Professor Schauta.—During the ten years (Nov. 23, 1884, to Feb. 10, 1894) the total mortality in these cases was 10.7 per cent. (104 deaths); 46 deaths were traced to the operations. In 54 cases septic processes caused death. Of the 46 deaths directly due to the operations, in 35 there were septic processes, in 8 secondary hemorrhage, in 2 intestinal perforation, in 1 acute anemia. Of the remaining 58 deaths, 12 were due to cardiac weakness, fatty heart and the anesthetics. Of 11 exploratory operations, 7 were fatal. The operations are next arranged in 16 groups: 1, ovariectomies, 198 cases, 182 recoveries, mortality 8.1 per cent.; 2 deaths from operative sepsis, and 2 from secondary hemorrhage; together 2.2 per cent. In 12 deaths indirectly the result of operation, were 2 cases of infection with streptococci from the contents of tumors; 2, adnexa operations 313 for chronic inflammatory affections. Of these 290 were pyosalpinx, ovarian abscess, salpingitis, oöphoritis; 259 times the adnexa were removed on both sides; in 75 times there was discharge of pus; in 27 cases gonococci were found in the pus; in 13 streptococci; in 4 staphylococci; in 5 diplococci whose nature could not be immediately decided; in 1 the bacterium coli commune. In the 25 remaining cases either no bacteriologic examination was made or the pus was found sterile. Of the 290 cases, 273 recovered, mortality, 5.5 per cent. Five laparotomies for hydrosalpinx with 2 deaths (1 pneumonia, 1 peritonitis); 5 for hematosalpinx; 5 for tubercle of the tube with 1 death from intestinal perforation. From these 313 operations, 20 deaths, 14 due to the operation; 3, castration, 56 cases, 2 deaths from secondary hemorrhage; 4, Porro's Cæsarean section, 7 cases (2 for stenosis of soft parts, 1 for osteomalacia, 2 for existing infection of uterus, 2 for rupture of uterus); 5 survived, 2 children lost (dead before removal). Conservative Cæsarean section with suture, 37 cases, 16 times for absolute narrowing of pelvis, 15 for relative, 4 for eclampsia, and 1 for tumor causing stenosis of vagina. All the children survived; 4 mothers died, 1 from sepsis; 5, supravaginal amputation of uterus, 74 cases, 13 deaths; 6, supravaginal ampu-

tation with retroperitoneal provision for pedicle, 2 cases, 1 death; 7, myomectomy (Schröder) with intraperitoneal provision for pedicle, once with unfavorable result (sepsis); 8, supravaginal amputation with interperitoneal suspension of stump (Maydl), 4 successful cases; 9, enucleation of nodular myomata by laparotomy, 18 cases, 14 recoveries; 10, by ventrofixation, 77 cases, all recovered; 11, total extirpation of uterus (by laparotomy) 8 cases, 4 for myoma (1 death), 4 for carcinoma (3 deaths); 12, total extirpation by vagina, 181 cases, 14 deaths; 13, ventro-vaginal total extirpation, 8 cases, with 5 deaths from sepsis; 14, sacral total extirpation for carcinoma of the uterus, 15 cases, with 5 deaths; 15, laparotomy for extra-uterine pregnancy, 49, with 4 deaths; 16, in this group are included laparotomies for various other indications. The most interesting is one for purulent peritonitis following abortion.—*Centralblatt für Gynäkologie, from Wiener med. Wochenschrift.*

MISCELLANY.

Change of Address.—Dr. G. K. Dickinson, to 278 Montgomery Street, Jersey City, N. J.

The Atkinson Medical Society Register.—Dr. W. B. Atkinson, of 1400 Pine Street, Philadelphia, Pa., has now in press his "Register of Medical Societies." It is desirable that no society be omitted, and the publisher requests that secretaries of societies will promptly furnish him with data for publication.

Curran Anecdotes.—Curran's ruling passion was his joke, and it was strong, if not in death, at least in his last illness. One morning his physician observed that he seemed to "cough with more difficulty."

"That is rather surprising," answered Curran, "for I have been practicing all night."—*Ex.*

Ventilating Warships.—Commander Bradford of the inspection and survey board has been chairman of a sub-board which has been examining into the methods for ventilating warships. This has become a very serious problem in the building of the Navy, and several different plans have been suggested. The fresh air is pumped in and the foul air pumped out by fans, this being found the best practicable method. The motive power for these fans is one that has caused considerable discussion. A suggestion which meets with a great deal of favor and which may be recommended by the board is to conduct the power by electric wires, which avoid the heat of the steampipes and the large openings through the bulkheads and save space in the apartment where the fan is operated, as the motor takes up less room than an engine.

Central Wisconsin Medical Society.—At the annual meeting of the Central Wisconsin Medical Society, held at Baraboo, the following officers were elected for the ensuing year: President, J. E. English, Baraboo; Vice-Presidents, Charles Horst, Baraboo; H. P. Johnson, Beloit; D. Pender, Janesville; M. B. Sharp, Madison; Secretary, C. S. Sharp, Madison.—At the annual convention of the Illinois Pharmaceutical Association, held in Decatur, Ill., the following officers were elected for the ensuing year: President, G. Henry Sohrbeck of Moline; first Vice-President, Thomas Knobel of East St. Louis; second Vice-President, J. W. Blood of Chicago; third Vice-President, W. C. Simpson of Vienna; Treasurer, Dr. H. H. Rogers of Kankakee; Secretary, Frank Fleury of Springfield.

Effects of Serum-Therapy on the Urinary Secretion.—As the result of his recent investigations M. Mongour announces that: 1, hyperazoturia is constant after injections of antidiphtheritic serum; the amount of urea is generally double that found before the treatment and in all cases is above the normal—the more rapid the cure the higher the amount, apparently. 2, this hypersecretion of urea is only to be attributed to serotherapy, since it is not due to thermic

influences or to any modification of diet. 3, it only lasts for the twenty-four hours following the injection, after which the amount of urea decreases until the normal is again reached. 4, the inversion of the formula of phosphates and chlorids seems to be a consequence of the diphtheritic infection. 5, the injections of serum destroy this inversion and bring the phosphates and chlorids back to the physiologic figure.¹

The Quick Getting-Up After Childbirth—A Matter of Drainage.—

Dr. A. Rose has written to the *New York Medical Journal*, July 20, in confutation of the doctrine that lying-in women are advantaged by the prolonged recumbency that is almost universally practiced at the present day. Dr. Rose calls attention to the fact that, a number of years ago, the question was experimentally studied at the obstetrical clinic of Halle, Germany. Five hundred women, after normal confinement, were allowed to rise as soon as they pleased and remained up out of bed as long as they felt like it—*i. e.*, as long as they felt comfortable. Some of these women left the bed for a shorter or longer time as early as the second day postpartum. No ill consequences could be observed in any of these 500 cases. Five hundred other women under similar circumstances, were kept in a recumbent posture, or in bed, according to the time-honored custom, for a week or the well-known superstitious nine days. The result was strikingly in favor of the 500 early risers.

Influence of Variola on Menstruation, Pregnancy, Parturition and the Fetus.—

Dr. L. Voigt reaches the following conclusions as to the influence of variola on the uterine functions: 1, variola, both during the period of invasion of the fever and after the appearance of the pustules, causes a congestion of the inner surface of the uterus and this congestion in most cases produces the appearance of the menses or a genital hemorrhage resembling them. 2, the same cause gives rise to abortion or premature birth in half the cases of pregnant women who were vaccinated during childhood. 3, the life of pregnant women is seriously menaced in confluent and above all in hemorrhagic smallpox. 4, hemorrhagic variola is observed much more often in pregnant women than in others. 5, the mortality of pregnant women attacked with variola and who have been vaccinated once during youth is from 30 to 45 per cent., while in that of women delivered during the disease it is 59 per cent. 6, pregnant women who are not vaccinated are in much greater danger than those who are. 7, children of women attacked with variola are in much greater danger than their mothers; nearly all succumb either in utero or shortly after birth from congenital feebleness or they contract variola before or during birth. 8, on account of the great danger to mother and child we should protect pregnant women by a fresh vaccination, and vaccinate newly-born children, if they are robust enough, each time they are exposed to variola.²

Murphy's Button.—Mr. Ernest Lane has recently contributed to the London *Lancet* reports of three cases in which he used the Murphy's button, giving a favorable opinion of the device. Mr. Lane has other cases to add to the list that is kept up by Professor Murphy himself. It is not to be expected that the lists of cases are complete, and probably, as in most similar instances of a new operation or procedure, an undue proportion of successful cases have found their way into print. But this applies equally to all other methods of intestinal anastomosis, and in no way invalidates the comparison of the results of using the Murphy button with other modes of performing the operation. The editor of the *Lancet* proceeds to comment in the following conservative and yet commendatory manner, of the button:

"Professor Murphy's button has now been largely tried by a great number of surgeons, especially in America and Great Britain, and also on the continent of Europe. The consensus of opinion seems to be that it admirably fulfills the two primary requirements; it greatly shortens the operation, and by its use intestinal anastomosis can be made with great precision, and as a result the mortality of these operations has been greatly reduced. Against this most satisfactory result two facts may be mentioned as a set-off. In the first place the button is a rather complicated and very delicate piece of mechanism; it requires to be made very well, and to be used with gentleness and care. Again, the button, when set free by the separation of the rings of bowel compressed between the two portions of it, may linger for a long time in the alimentary canal; but, so far, experience has shown that this retention of the button is not attended with danger. Too much weight must not be given to these objections to the use of the button. Simplicity of construction is to be diligently sought in all our appliances, and we doubt not that Professor Murphy himself, or some other surgeon with a mechanical genius, will be able to devise some simple method of attaining the same mechanical result. Delicacy of mechanism is not a fatal objection—at most it is a remediable defect; and Professor Murphy's tables show that it is compatible with brilliant operative results. He has certainly succeeded in lifting this whole department of operative surgery—not one isolated operation merely—on to a different and better plane, and has given intestinal anastomosis a position in surgical therapeutics it has never held before."

Fakir Journalism.—Fakirism exists in medical journalism to an alarming extent. To the uninitiated the field of medical journalism is an undiscovered country. It is only after one has been on the inside that he can properly discriminate between those medical magazines which are conducted upon an honest basis and those which claim the earth while possessing little of it. Unfortunately for the respectable, deserving and honest journals, fakirism often presents a guise so attractive, a dress so deceptive, that the cloven hoof is not easily seen. However, sooner or later, the true inwardness of things can be made out and our confidence is once more shaken. There are different ways of running and building a medical journal. One way is to resort to exaggeration to deceive the advertiser: "In less than thirty days our books showed a list of 5,800 paid subscribers," is the statement made by one journal which went up like a rocket, and is now coming down. Such statements would cause Don Quixote and Munchausen to hide their faces in shame. Yet this is a mild-mannered statement compared with some. A certain journal is known to claim a circulation varying from 7,800 to 10,000, and yet never prints more than 1,000 copies, including sample copies and exchanges. And so the tricks resorted to by some might be multiplied indefinitely. There is only one correct way to conduct a medical journal. That is to be honest with yourself, honest with your subscribers and honest with your advertisers. In the course of events this plan will outstrip all others, and will result in the permanent prosperity of the journal and the journalist. One subscriber gained and kept is better for all parties concerned than ten sampled or one hundred claimed by a Munchausen sheet. The inserting of the pictures of nude women within the advertising leaves can not be condemned too severely. It is an insult to the doctor and to the reputable advertiser. Based upon the supposition that doctors delight in the nude and lewd, it is a reflection upon the morality and good sense of the profession. The "female form divine" may look well upon canvas, placed in a metropolitan gallery of art, but certainly is out of place in a medical journal which reaches the eyes of the doctor's family, and often is read by the doctor's patients. The frantic efforts of a job printer to herald his lack of good taste are very much in evidence. We hope soon to see the last of this kind of fakir journalism.—*Tri-State Medical Journal*.

Chancre of the Eyelids.—Mr. Simeon Snell, of Sheffield, reported to the Ophthalmological Society of Great Britain a number of *outré* occurrences of primary syphilis, inclusive of nine cases of palpebral chancre. In the discussion of the subject two or more speakers referred to the affection as being one that was not rare in their practice, one specialist going so far as to say that Mr. Snell's paper was chiefly interesting and important from the point of view of diagnosis.

¹ Jour. de Med. de Bordeaux, No. 19, 1895.

² Am. Soc. Med.-Chir. de Liege, No. 5, 1895.

Another speaker averred that cases of this lesion are oftentimes so slight that the patients may recover without resorting to hospital treatment. Mr. Snell is reported, in the *Press and Circular*, to have said he had collected notes of nine cases of chancre of the conjunctiva, and he related one or two of the more typical, observing that very few of such cases had been reported, though they could not be very rare, judging from the number that came under his observation. The first case was that of a woman age 21, with a chancre at the internal canthus, also involving both eyelids, the lower more than the upper. The caruncle was also implicated. The ulcer was the size of a shilling, and there was much induration. The gland in front of the ear and the submaxillary gland were enlarged. She was a nurse, and had probably caught the disease from the infant, the offspring of syphilitic parents. She was engaged to be married at the time, but the marriage was postponed until nine months later. She has been pregnant six times, but has never gone to full time. The sixth child, the only living one, was now $3\frac{1}{2}$ years of age. It was healthy until ten months of age, when it developed signs of congenital syphilis, and had since had fits, followed by paralysis. The patient herself was well and healthy looking, but there was some epiphora marking the site of the chancre. There was no history of her husband having suffered from the disease. The second case was that of a man, age 30, who came on September 20. He was married, and had had five healthy children. He said he had cut his head open, and had washed the wound with some blood-stained fluid, the accident having occurred in a slaughter-house. A month later a small spot formed, and when he presented himself there was an ulcerated surface, with indurated base and raised edges involving the whole of the outer surface of the right upper eyelid. The præ-auricular and cervical glands were enlarged. The patient suffered, among other things, from an eczematous condition of the penis and scrotum. His wife came in June, 1888, having had lumps in the groin, with ulceration of the tongue, etc. The third case was that of a man age 55, with a chancre on the right inner canthus, involving both eyelids at the junction. The præ-auricular gland was indurated. The ulceration healed in six weeks. Nothing was made out with respect to the means of infection, but he lived in a model dwelling-house in which there were only four towels for eighty persons. The other cases more or less resembled those he had related. The ages varied from childhood to adult life, and comprised four males and five females.

Advertisements of Secret Remedies.—The following circular has been issued:

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

To the Editor and Publisher:

Dear Sir:—As a committee appointed for that purpose, we desire respectfully to call your attention to the following extracts from Minutes showing the action taken by the Trustees of the AMERICAN MEDICAL ASSOCIATION and by the Medical Society of the State of Pennsylvania, respectively:

“REPORT OF THE TRUSTEES OF THE AMERICAN MEDICAL ASSOCIATION.

“BALTIMORE, Md., May, 1895.

“During the year no advertisements of secret remedies have been accepted that were not accompanied by a formula, but to still further comply with what appears to be the desire of a large number of those interested in the highest success of the JOURNAL, the editor, with the termination of the present contracts, has been instructed to accept no advertisements of medicinal preparations, the proprietors of which do not give a formula containing the official or chemic name and quantity of each composing ingredient to be inserted as a part of the advertisement.”

“CHAMBERSBURG, PA., May, 1895.

“Resolved, That the Medical Society of the State of Pennsylvania congratulates the AMERICAN MEDICAL ASSOCIATION upon the decision of the Trustees to exclude unethical advertisements from the JOURNAL of the ASSOCIATION.

“Resolved, That a committee of three be appointed to communicate with the editors and publishers of medical journals in the United States, calling their attention to this action of the AMERICAN MEDICAL ASSOCIATION, and requesting them to accede to the wishes of the profession by adopting a similar rule.”

Allow us also fraternally to state that: we believe that the best interests of medical men are coincident with scientific accuracy, so far as this can be obtained; that the practitioner of medicine should therefore know in all cases, the character of the drug, and the formula of the preparation or chemic compound that he prescribes; that the use of a secret preparation or nostrum is undeniably unscientific, and can not be intelligently defended; that, hence the advertisement of such preparations by scientific journals is out of place; its effect being to promote quackery and discourage scientific prescribing; that we believe the exclusion of such advertisements will aid the circulation of medical journals and give them a dignity and character not obtainable without such exclusion; that the hearty manner in which the action of the Trustees of the AMERICAN MEDICAL ASSOCIATION and that of the Medical Society of the State of Pennsylvania was received, shows the very cordial indorsement by the profession of the policy here recommended. We, therefore, most earnestly ask your careful attention to this subject, hoping and in behalf of this society requesting, that you will adopt a similar rule to that of the Trustees of the AMERICAN MEDICAL ASSOCIATION.

Very respectfully yours,

(Signed,) { S. S. TOWLER, M.D., Marienville, Pa.
Special { J. J. BUCHANAN, M.D.,
Committee: { 1924, Penn Avenue, Pittsburg, Pa.
C. H. THOMAS, M.D.,
1807 Chestnut Street, Philadelphia, Pa.

To the Members of the Profession of Medicine in the United States.—The following from the *Evening Star*, of Washington, D. C., of Saturday, July 22, 1895, is commended to the careful, thoughtful consideration of every member of the profession:

“THE HAHNEMANN MEMORIAL—A GRANITE ELLIPTICAL CURTAIN BEHIND THE BRONZE STATUE—TRIBUTE OF THE AMERICAN HOMEOPATHIC INSTITUTE TO THE PHILOSOPHER AND PHILANTHROPIST.

“At the recent meeting of the American Institute of Homeopathy at Newport, R. I., the committee on the memorial to Hahnemann, consisting of one physician from each State and Territory, with the indefatigable worker and father of the project, Dr. J. H. McClelland, of Pittsburg, as chairman, made its report. The committee secured the assistance of several artists, notably J. Q. A. Ward, and an advisory committee, composed of five well-known members of the American Sculptors and Architects' League—three sculptors and two architects. They called for competitive designs from every source and country, offering prizes for the best three. The advisory committee, Messrs. Daniel C. French, George E. Bissell, Thos. Hastings, Olin L. Warner and Russell Sturgis, announced that, in their judgment, the first prize of \$500 should go to the design of Charles H. Niehaus, of New York, the second prize of \$300 to Joseph Loester, of New York, and third, of \$200, to Herbert Adams, of Brooklyn. Marsh, Israels & Houder are the architects associated with Mr. Niehaus in his design, which has been accepted on the expert report by the monument committee. The description of the monument prepared by the committee says:

“The monument is a true ellipse in plan, its fundamental motive being the Greek exhedra form. The main lines of the central portion present a flat curtain wall with decorated tympanum above the impost. This, together with the projecting lines of the ampures, forms architectural vertical divisions of this elevation, which is thus resolved architecturally into component parts, resulting in a well-proportioned and equally balanced composition. Rising from the platform in front of the central portion is a simple pedestal supporting the statue, upon the face of which appears the inscription ‘*similia similibus curantur.*’ Other inscriptions and decorations are of a character significant of and glorifying the work, methods and results achieved by the great reformer. The upper portion of the niche behind the statue it is intended to decorate in glazed mosaic, in colors, of a design composed of the foliage and flower of the cinchona plant. On either side of the arch are decorative emblems in bas relief—a bowl and serpent, the symbols of wisdom, and a lamp and book, typical of knowledge and instruction. The former in association with a palm branch, the latter with a wreath of laurel. The keystone of the arch bears a lion's head, the symbol of strength in leadership. Upon the rear the date of erection appears across the center in Roman numerals and the dates of Hahnemann's birth and death, ‘Meissen, April 10, 1755,’ ‘Paris, July 2, 1843,’ encircled with laurel wreaths, are inscribed to the right and left.

“In the center, filling the tympanum of the arch, appear

two figures in bas-relief, emblematic of the science and art of medicine. Underneath this is a fountain in the form of a fluted basin fed by a stream of running water issuing from a carved dolphin; thus symbolizing the temperance Hahnemann practiced and taught. The style of the design is essentially Greek in spirit and in its form. The statue itself is in bronze. The features will be faithfully copied from the bust by David.

"The commemorative tablets are placed in two panels, on either side of the niche, upon the curved walls, representing in bas-reliefs of standard bronze, periods of Hahnemann's life. The monument is to be built of the finest grained white granite, except the statue and entablatures, which are to be of antique bronze. The ground dimensions are 43 by 30 feet, and the height 22 feet.

"The cost of the memorial will be \$50,000, of which \$29,000 has been subscribed. No particular site in Washington has been selected as yet. Local homeopathic physicians state that there is one which has the preference, but it is not known yet whether it can be had."

After this, shall the Committee on the Rush Monument appeal to you again in vain? We, too, had estimated the cost of this monument at \$50,000. After ten years, we have collected less than one-tenth this sum. This little band of homeopaths with a like estimate of \$50,000, in three years have subscribed *more than half* that amount.

Shall you be willing to place in the same city, and that the capital of this great nation, beside the splendid memorial here described, of a foreign theorist, any less appropriate and artistic testimonial of the great patriot physician of the Revolution? Your committee are not forcing upon you any man of local or sectional reputation. His eulogists are your great men among the living and the dead, in this country and abroad. For the sake of the good name of true Medicine, do not delay this work longer. Let every State, Territorial and county medical society in the United States hold special meetings to act upon it. Let every delegate and member at the recent meeting at Baltimore bear in mind that he was specially constituted at that meeting a member of the Rush Monument Committee, and the duty imposed upon him of collecting funds. Your committee, therefore, earnestly appeal to the professional pride of every reputable doctor of medicine in this country to forward his contribution at once to Dr. George H. Rohé, Secretary, at Catonsville, Md.

ALBERT L. GHON, M.D.,
Chairman Rush Monument Committee.

Washington Notes.

HEALTH OF THE DISTRICT.—The report of the Health Officer for the week ended July 20, is as follows: number of deaths (still-births not included): white, 76; colored, 83; total, 159. Death rate per 1,000 per annum, white, 21.51; colored, 49.61; total, 30.56. Still-births: white, 5; colored, 4; total 9. The increase is general, both as to disease and locality. The principal causes of the mortality were lung diseases and maladies incident to childhood. Seventy-nine of the deaths were those of children under 5 years of age, forty-two of which were from diarrheal ailments. With the exception of two fatal cases of whooping cough, there was an entire exemption from dangerous contagious diseases in fatal form throughout the city. It is to be remarked that neither a case nor a death from diphtheria was reported during the week. In the absence of epidemic diseases, the high death rate may very properly be attributed to the long continued high temperature, the maximum of which was 95 degrees, and the mean for the whole period 73 degrees, with high relative humidity.

REPORT OF THE BOARD OF DENTAL EXAMINERS.—The report of the board of dental examiners for the fiscal year ended June 30, 1895, was yesterday submitted to the Commissioners by Dr. H. M. Schooley, its secretary. It states that during the year twenty-five applications for certificates

of qualification to practice were received and passed upon. Twenty-three applicants were graduates of colleges requiring a three years' course, and were therefore entitled to certificate without examination. One other applicant passed a satisfactory examination, making in all twenty-four certificates issued since last report. These figures, with those dentists already authorized to practice, constitute a total of 247 dentists legally practicing at the present time.

DROPPED FROM MEMBERSHIP IN THE DISTRICT MEDICAL ASSOCIATION.—A circular letter was sent, a short while ago, to the members of the ASSOCIATION, informing them that certain members "having refused or neglected, for a period of two years, to pay their assessments" are therefore dropped from membership in this ASSOCIATION. The list includes the name of Dr. William A. Hammond. The result of the law suit lately in progress between the Columbia Chemical Company and the Hammond Sanitarium Company consequently is of no interest to the regular profession.

Hospital Notes.

THE CHARITIES COMMISSIONERS OF KINGS COUNTY have begun a movement for a new hospital on a site in the neighborhood of the Kings County Penitentiary, on land belonging to the county. Work will begin at once. The building is to cost \$250,000. The hospital is to be used mainly for chronic cases, as a kind of "overflow" to the county hospital located in Flatbush. The Board has also appropriated \$25,000 with which to repair Flatbush Institution. The patients there now number nearly eight hundred, but there are suitable accommodations for not more than five hundred.

Society Notes.

THE FRENCH ACADEMY OF SURGERY.—Professor Guyon has been elected president of this society in place of the late Professor Verneuil, and Professor Lannelongue as vice-president in place of Professor Guyon, named as president.

THE PUBLIC SERVICE.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from July 20, 1895, to July 26, 1895.

First Lieut. ALEXANDER S. PORTER, Asst. Surgeon U. S. A., extension of leave of absence granted on account of sickness, is further extended two months on account of sickness.
Col. DALLAS BACHE, Asst. Surgeon-General, Medical Director Dept. of the Plate, is granted leave of absence for one month, with permission to apply for an extension of ten days, to take effect on or about July 20, 1895.

ADDRESSES.

THE ETHICS OF THE MEDICAL PROFESSION.

Abstract of an Address to the Kentucky State Medical Society at the Harrodsburg Opera House, June 18, 1895.

BY DUDLEY S. REYNOLDS, A.M., M.D.

PROFESSOR OF OPHTHALMOLOGY, OTOTOLOGY, AND MEDICAL JURISPRUDENCE IN THE HOSPITAL COLLEGE OF MEDICINE, LOUISVILLE; SURGEON TO THE EYE AND EAR DEPARTMENT OF THE LOUISVILLE CITY HOSPITAL.

Ethics is the written code of rules of right conduct for societies, professions, and all bodies of people having a common interest in the advancement of themselves in their individual relations to each other, and of the growth and advancement of the class to which they belong. Politics has for its main object the betterment of the forms of government; and political societies, professions and systems grow in importance as nations or states are made up of people willing to mold their personal conduct to a harmonious general standard in respect to each other's rights as defined by law.

Ethics must be construed to mean the right conduct of people toward each other in their associate relations; and so the ethics of a professional class must define the right conduct of individual members of that class, in the growth and advancement of the whole body. The ethics of the medical profession must be preserved or we shall have no advancement; as, without the written code, we could have no standard of correct deportment, and no basis of comparative improvement upon primitive forms. Virtue is the unselfish conduct of a member of society in the interest of the social circle or class to which the individual belongs. Virtue is, therefore a prime ethical feature of all intellectual associations of men.

A high sense of duty flows naturally from the cultivated exercise of the power of reason. Ethics must belong to the educated classes, because it aims to establish harmonious systems for the development and maintenance of the right conduct of those belonging to a particular class, with respect to themselves and all others.

Recognizing the learned professions as the natural result of well-developed educational systems, which have advanced, little by little, as each interested individual added something for the general good, one must see how the ethics of the professions has promoted their development and established their dignity in the sphere of wisdom. Who has not seen the multiplying force of united harmonious action in the common school systems, the natural outgrowth of the ethical principles of free government? Laws are made for the whole people of a nation with respect to the rights of the individuals and of corporations, municipalities, states, and of the whole nation to all other nations.

Knowledge of justice comes from the willingness

to harmonize the personal interests and conduct of neighbors, to combine the influence and power of collective bodies called communities. The ethics of the medical profession could not, therefore, fail to hold each member to the observance of those rules of right conduct defined in the code. If the profession of medicine required no personal efforts to advance it, there could be no means of distinguishing its members as belonging to the true and noble profession, from those hypocrites who adopt empiricism as a means of imposing upon the credulity of the unlearned masses of the people. The people have gradually come to recognize the necessity of respecting the written code of ethics as the only reliable guide in the choice of medical officers for the armies and navies of the world. State laws prescribe the qualifications of those engaging to practice medicine, upon the basis of regularly conducted educational training.

Indefinite organization, common affiliation, without written codes, has always left the members in a state of degeneracy. Definite organization of the medical profession in all nations gives a fixed character to its purposes, unites its working energies, and has led to those great triumphs of experimental research which are the proud boast of the best achievements of the human mind. Who has not heard that human life is prolonged, and the sum of human happiness vastly multiplied by the superior skill and knowledge of the regular medical profession? Who in our day and generation, outside the ranks of the organized body of the regular profession, has made a valuable discovery, or an important addition to the advancement of medical knowledge? I do not know of one, in any country.

Medical societies observing the code of ethics adopted by the representative bodies of the profession in each nation, become constituent elements of the most noble and the most learned profession in the world; and, by local, state, national and international congresses, discuss the best work of all the individual members. Organized upon the basis of a written series of ethical rules harmoniously adapted to the several nations of men, there is perfect community of professional aspiration, and whatever good may come from increasing knowledge is at once the property of the profession throughout the whole world, and mankind everywhere enjoys the full benefits of it.

Karl Koller demonstrated his discovery of the local anesthetic powers of cocaine to the International Medical Congress at Copenhagen in August, 1885, and the people of every country were enjoying its benign influences in every city of the earth within thirty days from the date of the announcement of the demonstration in the session of the Congress.

Koch, of Berlin, published, in March, 1882, his discovery of the bacillus tuberculosis. In September,

1882, the students of the Hospital College of Medicine at Louisville, were taught the details of the methods of demonstrating the presence of the bacillus in the expectorated matter of consumptives.

The great work of Ephraim McDowell, over at Danville, in 1809, did not receive recognition by the profession, generally, for sixty years, because the profession of medicine had no representative national organization; international congresses had not brought the inventor of a great surgical means of prolonging life, face to face with his brethren of all nations.

The great Lister was enabled to inaugurate the universal reform in all surgical procedures, eliminating every element of danger from septic poisoning, and death from surgical wounds, by discussing his methods in society meetings. The medical journal helps the societies to spread quickly over the whole world the newest demonstrations of the members, with such criticisms and discussions as the society indulged at the time. The work done by societies may be well illustrated in the great changes made in Lister's own methods at Edinburgh, and subsequently at London, and those which followed as the natural results of the criticisms and discussions of them by the International Congresses of 1876 and 1879. In the Congress of 1881, antiseptic methods had already been abandoned for the aseptic principle, and the technique of the masters became at once the common property of the members of that congress, and all its constituencies in every country of the civilized world. The ethical codes defining the right conduct for individual members of the regular medical profession, brought about those harmonious relations which led to the organization of representative and delegated assemblies of medical men, and proved at once the common interests of the profession all over the world; established the national and international congresses, and put the newest and best fruits of all original research into the hands of competent practitioners in every town and country place having a member of a regularly organized medical society.

If reading these great works alone were sufficient to convey a knowledge of them so clearly as to enable one to practice them, colleges would not be necessary for the education of students, and societies would not be necessary for the training of practitioners in correct methods of observation.

In 1847, the AMERICAN MEDICAL ASSOCIATION was organized as the representative national body of the medical profession in the United States. It adopted a code defining the right conduct of those fit to become members, and provided rules for the determination of the proper qualifications of individuals by the profession of each city, town, county and district. An obligation to observe the rules of right conduct defined in that code makes any regularly educated physician eligible to membership in a society of representative capacity. Any society adopting as part of its constitution, the code of the national body, can send one delegate for each ten members, and one for any fraction of more than five, to the next ensuing annual meeting of the AMERICAN MEDICAL ASSOCIATION. These delegates are admitted to membership in the national body, on filing their credentials and paying the annual dues of \$5 in advance, and signing a personal pledge to observe the Code of Ethics. Any member of the national body is admitted to all associations and congresses of the pro-

fession everywhere, may enjoy any of the discussions of original matter, and witness the demonstration of newly discovered facts, and convey them to his brethren at home.

The Kentucky State Medical Society was organized in 1851 and adopted the Code of Ethics of the AMERICAN MEDICAL ASSOCIATION as part of its constitution. It has had representatives in each annual meeting of the national body, and in all the international congresses, since the first one organized at Paris, France, in September, 1867, where our lamented brother, Prof. Lunsford P. Yandell Jr., was received with great *éclat*, as from the home of McDowell and Dudley.

The Kentucky State Medical Society admits to its membership all those who hold membership in the local societies at their places of residence, and who obligate themselves to an observance of the national Code of Ethics. We are here in our strictly professional capacity, as the representative body of the regular medical profession described in the code of right conduct, and our deliberations will be received and duly respected by the profession all over the world. Some of the matters discussed at this meeting will be published in all countries.

You see how important it is to have some standard by which to test the qualifications of those claiming membership in the medical profession, and how necessary it is for every community to have its medical society. You see, also, that the medical man who belongs to no society is not in fellowship with his profession, and can not, therefore, be regarded as a member in good standing. He is unworthy of your confidence, because he is, in fact, not a member of the regular medical profession to which he claims to belong.

In the Code of Ethics the delicate and responsible duties of the practitioner of medicine to the patient, are duly set forth. He is counseled to seek consultation in all difficult and protracted cases, for the purpose of inspiring confidence, energy, and more enlarged views in practice, as well as to secure the patient against a possible chance of any neglect to perform even the most trivial service. In the regular profession of medicine, where education is graded and knowledge has a fixed standard for entrance into the profession, there can be no mistake that the patient's welfare will not be duly considered. If, however, consultation were demanded by one of that class who make a pretense to some exclusive system of practice, there could be no possible advantage to the sick, because the limitations of an exclusive system of practice would forbid an extension of the boundaries, or an enlargement of the plan of treatment.

It may be fairly assumed that what is known to one man in any professional class, must receive the sanction of his confrères to give to it the dignified designation of knowledge. For we must limit that which we call knowledge to matters susceptible of demonstration, as it is by demonstration only that knowledge may be conveyed from one person to another. In the pursuit of knowledge, therefore, the regular profession of medicine is bound by no limitations, excepting those imposed by nature; and when we look about us and observe those who claim to practice by some exclusive method, or proclaim their choice of remedial agencies upon the basis of some dogmatical system, we must conclude that, either false pretenses are resorted to, to support this claim

or that it is founded in ignorance so dense as to excite profound commiseration.

The study of the life history of plants, and the laws governing their reproduction, as well as the composition and adaptability of soils and climates, are fields of inquiry open to all. The agriculturist, therefore, who still claims to be governed by the superstitions attaching to the signs of the zodiac, or the phases of the moon, possesses no convincing arguments to support his ignorance; and so it is with the followers of Hahnemann, and other founders of conjectural systems of therapeutics.

There is nothing in the Code of Ethics of the regular medical profession which forbids the broadest liberality of sentiment and opinion, either in consultation or other professional intercourse; and no limitations known to the human mind in the choice of remedial agencies or methods of study.

The members of the medical profession upon whom is enjoined the performance of so many important and arduous duties, and who are required to make so many sacrifices of comfort, ease and pleasure for the welfare of those to whom their professional services are constantly given, certainly have a right to expect and require that their patients should entertain a just sense of the duties and obligations naturally due to their medical attendants. It is manifestly the duty of the patient to select as medical adviser, one who has received a regular medical education. In no trade or occupation in life do men rely upon the skill of an untaught artist or an untrained hand. Does any one suppose knowledge of the profession is intuitive? Are we not all familiar with the constantly increasing requirements medical colleges exact of their students? And this is, after all, but the response to the constantly increasing demands for more learning in the profession of medicine. Patients should, therefore, prefer a physician whose educational training is known to be thorough; whose habits of life are regular; and who is not devoted to social pleasures, to business pursuits, nor bound by any sort of obligations which might divert his attention from the constant discharge of his professional duties. The patient should, if possible, avoid even the friendly visits of a physician who is not attending him; but, when he desires to change his medical attendant he should candidly express that desire.

Every individual, on entering the profession, as he becomes thereby entitled to all its privileges and immunities, incurs an obligation to exert his best abilities to maintain its dignity and honor, to exalt its standing, and to extend the bounds of its usefulness. He should, therefore, observe strictly such laws as are instituted for the government of its members. He should, with unwearied diligence, resort to every honorable means of enriching the science and ennobling the art. He should at all times entertain a due respect for his seniors who have, by their labors, brought the profession to the advanced position in which he finds it.

Our code says it is derogatory to the dignity of the profession to resort to public advertisements, private cards, or handbills, inviting the attention of individuals affected with particular diseases; publicly offering gratuitous services to the poor, or promising radical cures; or to publish cases and operations in the daily papers, or to suffer such publications to be made; to invite laymen to be present at operations, to boast of cures and remedies, to adduce certificates

of skill and success, or to perform any other similar acts. Equally derogatory to professional character is it for a physician to hold a patent for any surgical instrument or medicine; or to dispense a secret nostrum, whether it be the composition or exclusive property of himself or others. For, if such nostrums have real efficacy, any concealment of its nature is inconsistent with beneficence and professional liberality. If mystery alone can give it value and importance, such craft implies either disgraceful ignorance or fraudulent avarice.

The professional life is entirely inconsistent with any sort of avarice. The desire for pecuniary gain never displaces the unquenchable thirst for knowledge and skill. The public ought therefore never to lose sight of the necessity of according to the regular profession suitable compensation for public services.

The assumption of a special title, or the claim of any superiority of methods in practice must expose such person to the suspicion of fraud. For by education alone can any one acquire sufficient knowledge of the profession to be able to practice it intelligently; and the titles bestowed by institutions of learning are always graded in accordance with the amount of systematic study pursued and the degree of excellence in scholarship. Thus, Doctor of Medicine means that person upon whom that title has been conferred is so learned as to be able to teach the profession to others. It does not mean that he can treat diseases of some particular part only, but it implies a sufficient knowledge to be able to engage in any department of practice.

Our code recognizes specialties as legitimate fields of practice, but there are no special fields of practice which may be properly cultivated independently of the state of the general system, or of the most remote organs.

The title of Doctor in Medicine covers the whole range of professional knowledge, and is never bestowed upon any who do not pursue the entire curriculum of the colleges.

Every practitioner owes his best professional services to all the other members of the profession, and all their dependencies. No affluent member, however, would accept the service and tax the time of his impecunious brother without bestowing upon him a suitable honorarium.

SOME MOOTED POINTS IN PELVIC SURGERY.

CHAIRMAN'S ADDRESS.

Read in the Section on Obstetrics and Diseases of Women at the Forty-sixth Annual Meeting of the American Medical Association at Baltimore, Md., May 7-10, 1895.

BY FRANKLIN H. MARTIN, M.D.

CHICAGO.

In selecting for the subject of my address, "Some Mooted Points in Gynecologic Surgery," I am aware that I may lay myself open to criticism for presuming to bring before a body of medical practitioners constituting the highest national representative body of American gynecology, subjects which may be considered hackneyed—subjects upon which but little that is new can be advanced. My excuse can readily be understood by every pelvic or abdominal surgeon. Every such surgeon is a learner and an original investigator from the beginning of his career until its end, or a failure. No one ever learned laparotomy by attending lectures or by watching a master, or by the perusal of books. No one ever learned laparot-

omy in a personal experience of a year in actual abdominal work on animals or on patients, in a series of one hundred cases or two hundred cases. He, who, to his own mind has mastered this intricate and most important branch of surgery at any point in his career, is but an infant to whom greatness and fame will always remain strangers. A laparotomist must become an idealist if he is to progress and approach success. Couple with the idealist enthusiasm, with enthusiasm brains, with brains knowledge, with knowledge industry, with the foregoing honesty, and with all these ambition, and an abdominal or pelvic surgeon will develop who will always be less satisfied with himself than is any one else. As an idealist he will constantly seek to accomplish the ideal in surroundings which can never become so. Thus perfection will be sought, which while it can never be obtained can in this manner, only be closely imitated.

What, then, is my excuse for my subject? It is, that here in the shadow of a renowned institution with its brilliant surgeons, in the hearing of others possessing the attributes which have made them renowned gynecologists, I wish to bring these mooted points, the discussion of which may increase our idealism, which may arouse enthusiasm for our specialty, add to our knowledge, increase our honesty of purpose and industry, and not least of all aid in developing a laudable ambition. Not that all of these desirable things will be accomplished by my feeble effort alone, but the feeble effort, reinforced by the discussion of the subjects presented by this Section, may succeed in accomplishing something in that direction.

In dealing with my subject I shall not quote authorities; I shall not ransack literature in order to establish priorities; I shall not exploit methods.

The methods of every experienced gynecologist are an evolution from the methods of some admired teacher, together with accretions gained by subsequent observations, experiments, readings, reflections, and personal experience—an evolution from these to his own settled routine which has become his technique. Thus I will discuss these subjects from the light evolved from my own experience.

TREATMENT OF FIBROIDS OF THE UTERUS.

The surgical treatment of fibroids of the uterus is always a fruitful subject for discussion in gatherings like this. The fact that the subject is such a fertile one for debate; the fact that it is a debatable question, is the best proof that no one method has yet arisen which meets all indications, and that the question should be discussed until our debates show a lamentable lack of interest as a result of general agreement.

"Do you employ electricity in the treatment of fibroids of the uterus as much as you did formerly?" is a question which I have frequently to answer. To answer this question in the affirmative would be to admit that I ignored the recent great progress in abdominal hysterectomies and other pelvic surgery, and also to admit that electro-therapeutics had not progressed. While I employ electricity successfully in a large number of fibroids, I do not employ it in the same large proportion of cases that I did formerly.

The cases upon which I do the most satisfactory work with electricity now, are those which surgeons who have a wholesome regard for their statistics refer to me to get rid of, or similar cases which come di-

rectly to me. They are usually large hemorrhagic tumors, the subjects anemic, hearts hypertrophied, kidneys diseased, skin waxy, respiration difficult. Filled with pelvic pain, pelvic pressure and pain of peritoneal adhesions. Uterus deep and irregular, menorrhagic when not bleeding, discharging semi-purulent fluid. Digestion ruined, secretions checked, bowels constipated and reflexes run rampant. In other words, among the most deplorable cases that it becomes a surgeon's lot to behold.

These cases I treat with galvanism in strong doses, systematically and rationally applied, combined with the most appropriate general tonics and alteratives. I apply the galvanism with the idea of getting the following well-known effects of the current: 1, most powerful general tonic; 2, powerful local antiseptic; 3, anti-hemorrhagic effect of positive pole; 4, local trophic stimulant.

I have not time to tell how much these apparently desperate cases invariably improve under this treatment; how I have resuscitated case after case so that they have been able to have their burdens removed by skillful surgery and again live; how I have been able with treatment from time to time to keep symptomatically well a score of patients who under no circumstances would have an operation of the safest nature, and who before electricity came to their aid were bedridden.

Another class of cases in which galvanism is a justifiable means of treatment is that of the hemorrhagic variety not of large size, the subjects of which are near the menopause. The hemorrhage can often be controlled and the atrophy of the uterus which is a usual coincident of the establishment of the menopause will do the rest. I have saved many such cases the horrors of an operation, while at the same time keeping them in symptomatic health during this precarious time of their life.

However, in the present state of pelvic and abdominal surgery, I would not voluntarily administer or recommend galvanism for fibroid tumors, the subjects of which were under 40 years of age, whose tumors were suitable for operative procedures, and whose general health would show an average chance for favorable surgery. While I would expect to be able to control the hemorrhages in the majority of such cases, improve their general health, and to reduce the size of the tumor, relieve the endometritis, and stimulate absorption of peritoneal adhesions, I would not expect these results to be permanent in a large enough proportion of cases to justify keeping the patient away from the more permanent and satisfactory results of modern surgery.

I can not admit that galvanism ever does harm in these cases except that it may be the means of keeping patients away from more effective surgery. It almost invariably accomplishes good, even if applied but a short time. Galvanism, except in fatal doses, the opinions of certain surgeons to the contrary notwithstanding, never produces peritoneal adhesions. It is one of the most powerful antiseptics we have, and the only one we can send through deep tissues without traumatism.

Needles, probes and other forms of electrodes improperly employed may carry septic material where they should not; electricity never does. Electricity irrationally and erroneously employed in cases of pelvic accumulation of pus, may, by producing powerful muscular contractions empty a pus sac into

the peritoneal cavity. This would be but the abuse of a powerful remedy instead of legitimate use.

Thus, as gynecologists, the better we understand our armamentarium the more will we value galvanism. The gynecologist who ignores this remedy, given to us by an exact science, will have reason to bark hard at its aggressions, and by his bark can we appreciate his hurt, and at the same time estimate his loss.

REMOVAL OF APPENDAGES FOR FIBROIDS.

This operation, popularized by Tait and his followers, as a remedy for fibroids of the uterus, has in my opinion about run its course. While, since its discovery it has served to relieve and cure many women suffering with fibroids, like all of the minor surgical methods for that difficulty, it has that fatal element of uncertainty, which in the light of the comparatively safe and certain hysterectomy makes it less popular as a remedy than it was before the appearance of this more successful rival.

The curative effect of the operation for the removal of the appendages is based upon: 1, its producing an artificial menopause—thus checking the hemorrhage of hemorrhagic fibroids; 2, the cutting off from the uterus, nourishment supplied by the ovarian arteries, thus reducing the tumor by direct curtailing of the normal blood supply of the uterus; and 3, any indefinite influence which such an operation may exert on the trophic nerves of the uterus, thus giving that organ and its ungainly parasite the benefit of any uncertain results which may occur from such a disturbance.

Theoretically, this is all a little vague. Practically it controls the menorrhagia of fibroids in about 92 per cent. of the cases upon which the operation is performed. Invariably, almost, where the menorrhagia is not checked, the tumor continues to enlarge and in a small percentage of cases it continues to grow, even when an artificial menopause is established. In a small percentage of cases only, does the tumor entirely disappear, even when a symptomatic cure is enjoyed. Therefore the tumor remains indefinitely, a constant source of anxiety, if not of possible future harm.

This operation then, which made an epoch not only in the treatment of fibroids, but in surgery, must be relegated to the rear by the very forces of surgical advance which it did so much to create. Its rival is hysterectomy; and so successfully is hysterectomy standing the test that one can scarcely find justification for the operation of removal of the appendages.

When a laparotomy is decided upon at all for these cases, it is difficult to give one good reason why a clean sweep should not be made and a hysterectomy accomplished. When a tumor is large and the broad ligaments consequently spread, a thorough removal of the appendages is more difficult than a hysterectomy. When the tumor is small the patient is ordinarily in prime condition, and while a hysterectomy is a little more difficult than the appendage operation, no one can be justified in leaving behind a useless diseased uterus, in order to save a few minutes' time in an operation. If the appendages are diseased as a result of infection, they should be carefully enucleated, and no matter how long it may consume (unless the life of the patient is positively to be endangered because of increased time required for a hysterectomy) the latter operation is imperatively

demanding because of the certainty of infection of the uterus. This leaves the operation of removal of the appendages one which should be reserved as a makeshift, when for some good reason after the abdomen has been opened, the operator finds he has underestimated his patient's strength to tolerate a hysterectomy. Dr. Byron Robinson, of Chicago who finds it difficult to shake off entirely the teaching of the Birmingham sage, still opens the abdomen with the deliberate intention of removing the appendages for fibroids, but supplements that operation by tying the broad ligament, including the uterine artery, as it ascends along the side of the uterus. By thus applying my operation from above, he hopes and with reason, I think, to reduce the 8 per cent. of bleeders which follow the old Tait operation. This procedure increases the time of the Tait operation, and still leaves the uterus. It is one step in advance, but still a makeshift, and one more halting place at which the beginner and the timid may in times of discouragement close up and save his self-respect.

VAGINAL LIGATION OF THE BROAD LIGAMENT.

This operation which was devised by me for the treatment of fibroids is one which does not require a laparotomy. It is a minor operation in every sense of the word except in its execution. It consists as many of you know, in ligating from the vagina more or less of the base of the broad ligament of either side of the fibroid uteri. The vagina is first incised at its vault to the right and left of the cervix, at right angles to the base of the broad ligaments. The contents of the broad ligament are separated from the bladder in front and from the peritoneum behind; it is then ligated *en masse* with either a single or a double ligature of silk, kangaroo tendon or chromicized catgut, sufficiently deep and comprehensive to include the main channel of the uterine artery and any anomalous branches of that artery, and also all the nerve supply which finds its way to the uterus by this route. In exceptional cases the ligatures may be carried sufficiently high on one side so as to include the ovarian artery. The ligatures are cut short and buried by closing the vaginal mucous membrane by a running stitch of fine catgut.

The objects of this operation are: to check uterine hemorrhage; to cause atrophy of the uterine tumor by depriving it of blood nourishment; to influence a decrease of the tumor by interfering with its nerve supply.

Here we have a real minor operative procedure for the treatment of uterine fibroids. It has arrived on the scene of action at the wrong time to make itself very welcome. Instead of giving us a certainty, it gives one more possible relief, one more hesitating point. Its claims are so rational, however, and it has the so important advantage of being but a minor operation, that it will undoubtedly become a method of treatment of annoying prominence to the unpromising radical of the future.

This operation may be performed with advantage in all incipient fibroids in which the operation of hysterectomy will not be accepted by the patient and a minor operation will be accepted. It may be performed in all hemorrhagic cases, when the patient has been so reduced by hemorrhage that it is considered unsafe to submit her to a hysterectomy. It may be performed in cases of advanced kidney and heart difficulties in rapidly growing or hemorrhagic fibroids

where a prolonged operation would not be advisable. It may be employed in any case as a direct and permanent curative means, with the understanding that the operation is still on trial and that the remote results may not be of such a gratifying nature as has been the case with the immediate results in the majority of cases already reported. From a rational standpoint as a treatment for fibroids, it should replace the operation of removal of the appendages entirely. It should not, however, from our present light on the subject, ever be substituted for the certain hysterectomy, when in the opinion of an expert laparotomist the latter is reasonably sure of success.

The operation is not applicable to enormous interstitial fibroids (which draw the cervix high into the pelvis), in suppurating fibroids, or in fibroids complicated with diseased appendages.

TREATMENT OF STUMP IN ABDOMINAL HYSTERECTOMIES.

A subject is this, the discussion of which has been long and is not yet ended, a subject, however, which has been discussed with far more amiability than was formerly that of how shall we treat the pedicle in ovariectomy. The question of whether the ovariectomy pedicle shall be intra- or extraperitoneally treated is no longer a mooted point in surgery. Two or three short years ago the question of treatment of hysterectomy pedicles seemed to be as definitely fixed on this one point, as does the ovariectomy pedicle seem to be to-day. At that time surgery demanded that the pedicle of a tumor, the tissue of which was uterine structure, should have an extraperitoneal fixation. To be sure, we were never quite satisfied with that not altogether inelegant and incongruous disposition of the hysterectomy stump. The points of distress were: its immovability, its displacement and its exposure. It seemed, however, inevitable that we should submit to these objections in order to obtain hemostasis. Baer, however, in his simple device of ligating the uterine arteries before they reach the uterus, has rendered the hysterectomy stump bloodless, so that it can now be dropped as safely, and as free from unnatural fixation, displacement and exposure as can the ovariectomy pedicle; or it can with perfect impunity be removed entirely. And with this decided advance, hysterectomy has reached the point where its sequela are as little dreaded as the operation itself, and the operation is as safe as is ovariectomy.

I believe that extraperitoneal fixation of the pedicle in hysterectomies as a routine practice is no longer justifiable. That extraperitoneal fixation may in rare cases be a justifiable procedure I will grant. I have already mentioned what I consider the objections are to extraperitoneal methods, viz., immovability of the pedicle, displacement of the pedicle and exposure of the pedicle to external infection. Byford's vaginal fixation overcomes the first two objections as well as any method of external fixation. But the inventor of that method after making a brilliant record with it, has discontinued it as a routine in favor of the intra-abdominal.

Senn's new cuff method which, while it keeps the substance of the pedicle in the pelvis, fixes it, though distantly, through the intervention of the cuff to the lower angle of the peritoneal wound, and exposes it through this tube of peritoneal tissue to possible surface or external infection. I am sure, notwithstanding its brilliant parentage, that it can never be generally adopted as a routine practice, that it will

appear in history as one of the curious methods, the outcome of the evolution strain for a perfect hysterectomy.

There are yet a few operators whom we have learned to respect profoundly, who still hold to the fixation of the pedicle in the lower end of the abdominal incision, who still employ elastic ligatures, *serre-nœud*, and the accompanying paraphernalia as a routine method of practice. With the results of such men's practice we can not find fault. Some of them are masters and therefore their results would be of the best, no matter what method they adopted. The question of the relative practicability and permanent effectiveness of any operation must be tested by the results obtained in the hands of the average surgeon. It is not enough that some immortal can make a brilliant record with his abdominal fixation. That he can accurately adopt and manufacture a pedicle the length necessary to obviate undue tension, displacement or bladder squeezing; that he can so treat his constricted stump that it will never become infected; that he can therefore prevent in every case, extension of suppuration to broad ligament sutures, and thus obviate interminable fistulous tracts; that he can prevent in every case, an ugly depressed abdominal scar; all of this is not enough. It is necessary that the operation of the future shall be one in which there is the minimum disturbance of normal relations between the organs of the pelvis and the remaining pedicle; in which there is the minimum loss of normal mobility in the remaining organs; in which the risk of secondary hemorrhage from pedicle or broad ligament is reduced to a minimum; in which the pedicle when once disposed of is out of reach of external infection as far as it is possible to get it, an operation which is practically finished when the abdominal incision is closed (instead of one which submits the patient and the physicians to an operative procedure which must last under the most favorable circumstances from ten to twenty days before the patient is finally severed from her tumor and detached from the mechanism of the surgeon); finally, the routine operation of the future must be one of minimum simplicity, easy of execution, and one which can be accomplished in the shortest time consistent with the above requisites.

Such an operation, I believe we have within our reach in employing the Baer method of ligating the blood supply of the cervix and lower portion of the uterus before it enters the tissue of that organ; in other words, ligation of the uterine artery and branches. After this simple procedure has been enacted, it matters little whether the stump is removed entirely, left buried, or projecting into the abdominal cavity.

KIDNEYS.

The failure to recognize obscure kidney diseases in patients before submitting them to a severe operation has been the cause of many avoidable deaths. We should not only recognize kidney difficulties in every case, but we should also know when a case is laboring under some form of kidney trouble, if that stage has been reached beyond which it is safe to proceed.

It is not enough that the urine in any given case is approximately of normal quantity; of approximate normal specific gravity; and that it gives negative results in tests for albumin and sugar. It is necessary to learn the history of the case, to estimate the

specific gravity in a twenty-four hour specimen, to ascertain the amount of urea for twenty-four hours, and to supplement this with a microscopic examination, thorough and complete. In diabetes we should not operate. In interstitial nephritis, when the disease is not far advanced, an operation may be risked with proper preparatory treatment. These latter cases are the very ones which from their great difficulty of diagnosis are often neglected and consequently disaster results.

The importance of this subject must be my excuse for entering into primary details. The following summarizes the signs of chronic interstitial nephritis: lowered specific gravity of urine; patient arising at night to void urine (when there are no bladder or urethral diseases to give rise to such a procedure); an enlarged heart with accentuated second sound, a tense pulse, and diminished urea. Albumin is frequently absent. The diagnosis is doubly sure when hyalin casts are formed.

I scrutinize all of my patients in all these points. If the foregoing state of affairs exists to a marked degree, I refuse to operate; if, however, with the above symptoms, I find a normal quantity of urine, which does not show a reduced specific gravity under 1010 to 1014, and where the amount of urea does not sink lower than six or seven grains to the ounce, and the patient is well preserved generally without advanced heart disease, I am confident that I can operate on them with safety, if I can secure proper preparation.

I prepare these patients by first placing them on an exclusive farinaceous diet, with milk and fruit, an indefinite number of days before the operation. A week or ten days before the operation she is put on a diuretic with instructions to drink large quantities of water. The object is to increase the daily quantity of urine to 60 to 100 ounces, in order to thoroughly flush the kidneys and rid the patient of dangerous accumulations. With 80 to 100 ounces of urine flowing for several days, with the patient living on a non-nitrogenous diet, with the urea in improved proportions, considering the diet, I feel safe to risk an operation.

Dr. Charles W. Purdy, who has had an enormous experience in watching the behavior of kidney diseases under operations, says in reference to chronic parenchymatous nephritis: "I see no reason why these cases, if unaccompanied with dropsy, may not be operated upon if carefully selected."

ABDOMINAL DRAINAGE.

There are now but faint and unimportant protests against the use of drainage in abdominal surgery when certain definite conditions exist. These protests are so few and so unimportant that the question of whether we should ever drain can no longer be considered mooted. The questions, how and when shall we drain, are points upon which there is still some discussion.

Drainage in abdominal surgery has definite indications to meet: 1, the removal of blood, the consequence of venous hemorrhage from points which have been the seat of adhesions; 2, the removal of fluids from ruptured cysts or from sponges, when the toilet of the operation has entirely failed to do so; 3, the removal of septic matter from the abdominal cavity.

The removal of blood from an abdominal cavity where there are numerous oozing surfaces is neces-

sary, because it is the safest and quickest method of stopping the hemorrhage. We all know that many women have bled to death into their own bellies after operations where extensive adhesions have been separated, which might have been saved if some form of drainage had been adopted which would have removed the fluid before it could accumulate. Constant removal of the blood leaves the bleeding surface dry, and coagulations form at the vessels' mouths. If the blood is allowed to remain, the coagulum is dissolved in the accumulated fluid and the hemorrhage continues.

It is necessary to have a drain which will remove all the fluids, blood and otherwise, from the abdominal cavity for two other reasons: 1, because this fluid produces peritoneal irritation even though it does not become septic. The patient will exhibit this by a rapid and weak pulse for several days, while the weak and partially paralyzed peritoneum is accomplishing the removal of the fluids by absorption. 2, this accumulated fluid is the richest culture medium in the world surrounded by one of the most perfect incubators, and is therefore liable to develop any pathogenic material which may have in any manner come in contact with it.

Thus one who does not employ drainage at all in abdominal surgery, must select carefully his cases, so carefully indeed that he would discard about all which most required his assistance, or he must expect an unnecessary mortality. If he enucleates tumors, he must have large extensive oozing surfaces. If he attempts to check every particle of that oozing by ligation, cauterizing or other means, before closing the abdomen, he will be obliged to expose every portion of it not only, but he must carefully and successfully manipulate every portion of these surfaces wherever located in the abdomen. As these surfaces are frequently intestinal, these delicate and resentful organs, too, must come in for their share of manipulation. Much time (time of inestimable value) has been wasted. One can never be certain that all bleeding points have been secured, the delicate intestines have received unnecessary manipulations which weaken their tonicity, and finally the abdomen must be closed with no absolute monitor or guard, and no means of relief, but secondary laparotomy, if intuition should indicate accumulating blood. So, too, the same arguments apply to spilling pus in the abdominal cavity, contents of cysts or *débris* from any source. Excessive exposure of peritoneal surfaces, excessive manipulating, excessive sponging, excessive washing, only, will accomplish its removal and we can not be quite sure that the peritoneum will consent or be able to take care of that which may occasionally be overlooked.

In my opinion, one should drain always where there has been separations of adhesions, the oozing from which is sufficient to accumulate in any perceptible quantity in the dependent portions of the peritoneal cavity by the time one is ready to close the abdominal incision, as indicated by exhausting a glass drainage tube which has been placed in the cavity for that purpose. One should drain also when accidentally or otherwise, contents of cysts have leaked or spilled into the abdominal cavity when there is any doubt of its complete removal. Finally, in my opinion, one should always drain after any operation has been performed which calls for extensive flushing of the abdomen.

On the other hand, I do not consider it necessary to drain, if a perfectly dry condition of the peritoneal cavity is obtained (and there is no source from which fluids can accumulate) even if there has been during the operation a removal of septic material. In other words, I have great faith in the resisting or antiseptic power of the peritoneum, so long as it is in its normal state of dryness. It is only when the peritoneum, in addition to its normal work, is put to the strain of caring for little puddles of culture media which a careless operator has neglected to provide means of removing from its folds, that I am afraid of peritoneal failure, septic development and disaster.

I believe that the glass drainage with the suction pump is the safest and most effectual drain and a form which is almost invariably applicable. It accomplishes promptly and definitely the removal of all fluids from the peritoneum as frequently as it may seem necessary, and in a manner so that their amount may be accurately estimated. While the gauze drain may be used with advantage in other cavities, I must protest against it as a routine drain for the peritoneal cavity. For bleeding surfaces following enucleation, except in extraordinary cases (such as I have seen but few times) it can not compare with glass drainage and the pump. When it is employed I can not but feel that it acts more as a tampon or a dam than as a drain. With it, there is no way of knowing accurately how much work it is accomplishing, or how much it is failing to accomplish, or how necessary its employment may have been.

The glass drain properly cared for never does harm, even if its use in any given case is afterward found to have been unnecessary. *Fistulæ* rarely follows its use, and when they occasionally do it is in desperate cases where an operation without it would have been impossible.

INTRA-ABDOMINAL SUTURES.

Silk is an ideal suture for intra-abdominal work, if it is properly sterilized before using, and if it never becomes infected after it has been placed. The fact that silk, if once infected wherever buried, will never cease giving trouble until it has been removed either by surgery or by the very suppurating processes which it maintains, makes it a questionable ligature under any circumstances in abdominal surgery. One may be quite positive that his aseptic sutures are buried in aseptic tissues. He can never be positive that some septic process may not reach those ligatures during convalescence, or long months or years after convalescence, a septic process which finds exit somewhere in a long fistulous canal and which would heal spontaneously after discharge if it were not for a non-absorbable septic foreign substance at its bottom. The same argument holds good in regard to any form of non-absorbable suture material as a buried suture.

If, on the other hand, an antiseptic absorbable ligature is buried in aseptic tissues (whose life is of sufficient length to effectually accomplish its mission) it disappears promptly and is soon out of the way of septic processes which by accident may reach its vicinity, or if it should become septic before absorption is completed, the completion of the absorption will eradicate what would otherwise become a fixed nidus of infection, and the normal reparative processes of the tissues would be left unhampered.

Catgut and kangaroo tendon are the two forms of absorbable sutures which have been most employed. Kangaroo tendon is scarce, difficult to prepare, and consequently expensive. I have not employed it and therefore can not practically discuss it. Catgut until quite recently has been looked upon with suspicion. Even when with great care it had been successfully sterilized, so that no cultures resulted in its test, it still formed a nidus for suppuration in otherwise practically aseptic tissues, because as was discovered later, of its possessing qualities of a superlative culture medium. Then it was necessary to render it not only aseptic, but to saturate its substance with a harmless antiseptic which would not affect the integrity of the suture or poison the tissues of the patient. In seeking such an antiseptic, it was also desirable that the antiseptic or the process of preparing the gut would increase the life of the suture. Experiments and practice have been able to demonstrate that catgut sterilized by heat and afterward treated by either chromic acid or methyl blue will remain antiseptic and also possess life of sufficient length for most ordinary intra-abdominal work.

If these two forms of suture, on continuous trial carry out the promise that they have already given we will possess an economical, antiseptic, absorbable ligature for buried and intra-abdominal work, which will with great certainty do away with one of our most annoying sequela in that line of work.

Thus, gentlemen, in the half hour allotted to me I have frankly presented my present surgical status. I am aware that this is but one "stock-taking" point in my career. I am aware that in one short year from now, much if not all of this may be old. I would mistake my audience, and certainly the progress of surgical gynecology, if I did not realize that points in my present declaration have already become ancient history to some of you. What was the truth in the light of our progress one year ago is not necessarily so now.

The progress of modern surgery is like the onward march of a mighty army. It waits for no one. The weak, the stragglers and the non-progressive are left behind. The strong, the alert, the industrious, help to swell the crowded ranks and each doing his particular work conscientiously insures a wholesome irresistible advance of the whole.

Therefore let us not straggle, although we may not be in at the ultimate triumph. If we can not fill commanding positions, let us at least do our best in the front of the ranks.

So in the ranks of surgery let us become idealists. But constantly compare our ideals with those of others that they may not deteriorate. Let us be enthusiastic, but temper our enthusiasm with tried facts. Let us have knowledge of the works of others, but prove that knowledge by personal experimental labor. Let us be industrious, but not at the expense of doing unjustifiable work. Finally, let us cultivate ambition, but a laudable ambition, which has for its object the development of our art to a science of transcendent heights of usefulness.

Physiology in the Public Schools.—The following letter was received by the principal of one of our schools the other day, from a parent whose daughter is a member of the class in physiology: "Dear Miss —, I don't want you to learn my daughter any more about her insides. It ain't decent and it turns her against her vitals. Respectfully, —."

A METHOD OF SUPRAPUBIC HYSTERECTOMY
FOR GOOD OPERATORS AND BAD
FIBROIDS.

Read in the Section on Obstetrics and Diseases of Women, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY JOSEPH EASTMAN, M.D., LL.D.

LATE PROFESSOR OF ANATOMY, AND NOW PROFESSOR OF DISEASES OF WOMEN AND ABDOMINAL SURGERY IN THE CENTRAL COLLEGE OF PHYSICIANS AND SURGEONS, ETC. INDIANAPOLIS, IND.

The lines of sound surgical principles converge toward perfection of technique in operating and the ideal operation. The proximity to the ideality of an operation is in direct ratio to the simplicity of its technique and the results obtained. Ideal results in suprapubic hysterectomy are best secured by ideal operators with ideal surroundings, upon ideal patients with symmetrically formed pear-shaped tumors.

I serve notice, in this presence, on those engaged in discussing the technique of hysterectomy that they can not have the last word until their means and methods shall deal with fibroid tumors, regardless of their morphology or pathologic condition, nor until the average operator shall advise the removal of fibroids as unhesitatingly as he does an ovarian cyst.

Despite the efforts of some to name a distinct method of operating because a flap is made here, or a ligature placed there, the problems of suprapubic hysterectomy are rapidly nearing their solution. Those engaged in the work are divided into but two classes: 1, those who have been and are yet satisfied with forming a pedicle and fixing the same in the abdominal wound; and 2, those who are not satisfied that this method was the best that could be devised, and have been earnestly endeavoring to reach some method which shall disregard the morphology of tumor, of broad ligaments, and the location of uterine arteries.

Those workers who have been wedded to the serre-nœud in abdominal fixation method have not emphasized, as they should have done, the important fact that the serre-nœud is quite as much for the adjustment of tissues as to control hemorrhage. When the broad ligaments are properly tied off, the main source of hemorrhage (in an average case) is shut off. On the other hand, the teaching that the uterine artery can always¹ be found in the broad ligaments and tied in a definite way, retards progress, and has in the past and will in the future be the means of sacrificing lives in the hands of beginners and those not familiar with the anomalies of arterial distributions, morphologic changes and pathologic conditions found in and about the fibroid uterus.

Anatomy, from the book of nature and not from the paper books, is the keystone of the arch upon which the principles of surgical progression shall ever rest, and is nowhere more important than in hysterectomy. Some seven text-books which I have examined on anatomy, state that the spiral or curling branches given off from the uterine arteries really penetrate the tissues of the uterus including its cervix. With this idea of penetrating arteries, surgeons have many times ligated and severed a single uterine artery in different places because of its zigzag course at the side of the uterus, the operator thinking he had

secured a distinct vessel each time. I have peeled off the uterine arteries from the sides of the uterus leaving them in the pelvis of the woman, and cut off the cervix with little or no hemorrhage. This was for the purpose of proving how few ligatures could be used. It is well known to every gynecic surgeon that a nodular mass in a fibroid uterus can be peeled out of its capsule without ligating a single artery. What I have stated regarding the nourishment of the nodule by its network of capillaries and not by the penetration (for surgical purposes), holds true with reference to a uterus disorganized by fibroid tumor or tumors, no matter how large or how small—not only the fibroid uterus, but the normal uterus as well—not only the uterus but its entire cervix down to the external os. The uterine tissue may be penetrated by small capillaries, but I am convinced that it is not penetrated by arteries worth considering (as such) surgically.

This anatomic fact being established, the operator

FIGURE 1.—Fifteen pound tumor growing from anterior cervix.

who favors leaving an extraperitoneal but intrapelvic wound, having temporarily clamped the broad ligaments, proceeds without fear of hemorrhage from the uterus or its neck, to peel off the anterior and posterior flaps, and enucleate as much or as little of the cervix as he desires, keeping between uterine artery and uterus. He who expects to use the serre-nœud, having secured the broad ligaments with their ovarian arteries, will also peel down the tissues around the cervix, if the same be large, until he reaches a point where it is smaller, to the end that the same may be raised up to the abdominal wound without undue tension on the pelvic tissues. So what has been done on anatomic lines is really of great advantage, whether we favor uniting our pelvic with our abdominal wound, using the serre-nœud, or whether we will leave an extraperitoneal but intrapelvic wound. On several occasions, when I have presented the subject of hysterectomy, operators have attempted to prove that a pedicle could be made and fixed in the abdomen in every case. Some have even gone so far as to say they would not attempt in any case to follow any other method. I have shown tumors and photographs of cases where it seemed to me that abdominal fixation of the pedicle would have been very difficult if not impossible. Some three times in

¹ Dr. Etheridge, of Chicago, cuts a slab off the sides of the uterus before clamping broad ligaments.

the past year I have been able to remove a fibroid uterus with malignant degeneration of the endometrium, extending well out into the vagina. I will report one of the cases:

Mrs. H., aged 51, was referred by Drs. Murry and Baird, of Albany, Ind., the former believing that for several years the patient had had her pelvis and lower abdomen filled with a fibroid tumor; the latter, by vaginal examination, diagnosing cancer of the cervix and endometrium. Both were correct in their diagnoses. The operation was made in the following manner: an incision made through the vaginal mucosa, was carried around the cervix, extending a half inch from any malignant ulceration. Iodoform gauze was packed into this incision. The abdomen was then opened and the tumor (nearly as large as the human head) was lifted out of the abdomen. The broad ligaments were seized²

FIGURE 2.

and temporarily clamped as shown with these forceps. Having peeled down the broad ligaments and made anterior and posterior flaps, we then secured the broad ligaments with strong kangaroo tendons, cutting away the forceps. Then passing my staff up the vagina behind the cervix, with this gouge we soon found our way posteriorly down on to the staff and continued our enucleation right and left, (leaving anterior surface near bladder to the last) until the entire mass had been lifted out of the pelvis. We then brought the serous lining of the pelvis over the stumps of the broad ligament, and packing some gauze down into the vagina, we made complete sero-serous approximation of the entire pelvic wound. The patient made a very satisfactory recovery.

I report this case in part, naming the attending physicians, to the end that I may at least be credited with one operation where abdominal fixation with the *serre-nœud* could not be considered, and where leaving a piece of the cervix would have rendered the operation positively useless. I have found a number of such cases. If other operators have not, a time will come, if they get cases enough, when they will.

I would submit the following propositions for discussion:

1. There are cases where total extirpation is the only operation possible.
2. Ventral and pelvic extraperitoneal fixation being the only two methods worthy of consideration in average cases, which can be done in the least time.
3. Which operation gives us the greatest immunity from sepsis; (a), in abdominal wound; (b), in pelvic wound.
4. And here let me add, it will require the lapse of time and personal observation in a large number of cases before I shall reach my final conclusions.

² I do not favor beginning in the vagina. It is very difficult to make it aseptic.

Does ventral fixation give us the greatest amount of assurance against vaginal prolapsus, cystocele and rectocele? In pelvic fixation I have been bringing the stumps of the broad ligaments well down, stitching them to the vagina, with a view of holding that tube up as one's suspenders hold up their trousers; but I repeat, sufficient time has not elapsed, nor have I been able to observe a sufficient number of cases, only a little over two hundred, to convince me that the remaining pelvic organs will have sufficient sup-

FIGURE 3.

port with this fixation. So far as my observations have led me to judge, where an atom of cervix is left, vaginal prolapsus is greater than where it is totally removed and vagina stitched to ligaments; the piece of cervix seems to push down, rather than act as a keystone to hold up. I can indorse no method as being better than another, until time, which proves all things and reveals the future with unerring certainty, shall have enabled me to make observation in a large number of cases where hysterectomy has been made both supra- and infrapubic, proving the merits and demerits of different methods.

Hysterectomy will always demand the highest surgical skill. The head to plan and meet the surprises which spring on us during an operation; the eye to see quickly the exact constriction of every ligature and adjustment of every suture; the thinking brain and facile finger, the two coöperating, and backed by an indomitable will to speedily and skillfully perfect the adjustment of the last suture with the same precision as the first, demand a combination of qualifications found only in the natural-born surgeon—the *master* in the *work*.

TECHNIQUE OF NEW METHOD OF ABDOMINAL HYSTERECTOMY.

Read in the Section on Obstetrics and Diseases of Women, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1893.

BY N. SENN, M.D., Ph.D., LL.D.
CHICAGO.

The dangers attending the abdominal removal of the myomatous uterus are shock, hemorrhage, functional injury to important organs near the uterus, and infection. The operation that I am about to describe to you has in view, as far as can be done by an improvement of technique, the removal of these sources of danger.

As you all know, in abdominal operations the exposure of the organs to unnecessary handling and the loss of heat they sustain are most potent agents in the production of shock; hence in the removal of myofibroma of the uterus, the abdominal cavity should be exposed for as short a time as possible. It is therefore the particular aim of this operation to secure access to the myomatous uterus in as short a time as possible and with as little exposure of the abdominal organs; hence, after opening the abdomen in the median line in the usual manner, tying off the broad ligaments on both sides by two sutures, the uterus is brought well forward into the wound and then on a level with the section through the broad ligaments, the peritoneum is divided from one side to the other, and the flap is reflected and sewed to the parietal peritoneum, when the opposite side of the uterus is dealt with in a similar manner. In making such a peritoneal cuff it is absolutely necessary to cut only through the peritoneum, and not through the large subperitoneal vessels in order to prevent hemorrhage. In making the cuff, the dissecting forceps is an exceedingly useful instrument; the process of deperitonization can be carried on readily by the use of the hand or a blunt instrument. As soon as the cuff has been sewed to the lower angle of the wound, the balance of the abdominal incision is closed; we then have the uterus with the tumor or tumors outside of the peritoneum.

I call this an extra-peritoneal operation. Rendering the uterus extra-peritoneal is a matter, in the majority of cases, of only a few minutes, when the balance of the operation can be performed at leisure. The later steps of the operation are not attended by immediate causes which expose the patient to the risks of shock. Having closed the balance of the wound, the uterus is then amputated at the desired point. Usually in cases of single or multiple myofibroma, the cervix is intact. If the cervix is affected the entire uterus can be removed. For the purpose of preventing hemorrhage during the amputation of the uterus, I then proceed to ligate the uterine arteries on each side, which is done by applying an indirect ligature. It is unnecessary to take time in isolating the uterine arteries; we can ligate and tie them very accurately with needle armed with medium-sized silk ligature. The amputation is then made by making an incision obliquely so as to make a cone of the stump of the uterus and a corresponding depression of the parts left behind. Very little hemorrhage attends this part of the operation, provided the arteries have been tied on both sides; at any rate, no additional ligatures are ever required.

After the uterus has been removed, I then excise the mucous membrane of the uterine canal and close

the wound with a row of absorbable sutures, chromicized catgut. For the purpose of arresting parenchymatous oozing the cut surfaces are then closely united by two additional rows of buried sutures; there is no need of elastic constriction, and nothing to induce subsequent necrosis of tissue. We leave the wound in a condition compatible for healing with primary union. If hemorrhage occurs at any time, the amputated cervix remains accessible for twenty-four or forty-eight hours. You perceive that so far the object we have in view is to expose the peritoneal cavity and its contents as short a time as possible, to control hemorrhage systematically and to prevent functional injury to organs near the uterus—the bladder, ureters and intestines. The organ is simply removed sub-peritoneally, leaving behind a peritoneal cuff. If the operator is sufficiently careful to resort to the necessary antiseptic precautions, the only source of infection during the operation will be the hands, the instruments, the sponge. There is no possibility of post-operative infection of the peritoneal cavity. The wound is usually two or three inches in length; its floor is packed with iodoform gauze, and two secondary sutures are at once inserted. Twenty-four or forty-eight hours later the gauze is removed. Usually a little parenchymatous oozing takes place, sufficient to saturate the inner part of the dressings. The wound is then closed. There is at no time any tension upon the stump. If infection should occur after the operation, it is limited to the wound outside of the peritoneal cavity.

Some of you may raise an objection to leaving so much of the abdominal incision unsutured immediately after the operation and may entertain the unfounded idea that ventral hernia will follow; but if you remember what you observe almost daily, that an aseptic granulating wound, when coaptated by suturing, heals as readily and as promptly as a recent wound, you will see that there can be no objection to the temporary packing of the lower angle of the wound until the time has elapsed that we no longer need to fear the two greatest dangers of laparo-hysterectomy—hemorrhage and infection.

Now, in bringing this new operative procedure to the attention of the profession the crucial test must be furnished by its results. Of thirty-three or thirty-five laparo-hysterectomies in unselected cases, not only every one of the patients recovered, but I have failed to observe in a single instance any untoward results. I believe, therefore, the Section will excuse me in pressing the merits of this method in dealing with such a formidable condition as myofibroma of the uterus; and, at any rate, I ask for this operative procedure a fair trial at your hands.

Insecticide for Tree-pests.—The year 1895 has been marked in some parts of the United States with an unusual prevalence of insects destructive to trees. The *Pharmaceutical Era* offers the following combination, which physicians may be glad to use now or put away for use next spring:

Corrosive sublimate	gm.	32.
Soft soap	litres	4,100.
Alcohol or wood spirit.	cc.	500.
Water, q. s.		

Dissolve the corrosive sublimate in the alcohol or spirit and stir it into the soft soap, add water enough to make a stiff paint and apply to the base of tree with a brush. This is the best remedy against the borers of the apple and also for the woolly louse.

THE PRESENT STATUS OF THE ELECTRICAL TREATMENT OF FIBROIDS.

Read in the Section on Obstetrics and Diseases of Women, at the Forty-Sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY A. LAPHORN SMITH, B.A., M.D.

MEMBER OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND; FELLOW OF THE AMERICAN GYNECOLOGICAL SOCIETY; PRESIDENT OF THE AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION.

MONTREAL, CANADA.

At the full flow of the tide of the most successful surgery the world has ever known, one must possess a good deal of courage of his convictions to rise in the presence of such a distinguished audience as this, to ever discuss, far less to advocate the treatment of tumors, even the most benign, by any other method than the surgeon's knife.

Appearing on the program of this meeting, surrounded as this paper and its author are, by papers and surgeons advocating every kind of surgical treatment, from tying the uterine arteries to removing nearly all the pelvic contents, my position is a peculiarly difficult one; the more especially as I have been trained as a surgeon and now occupy a position as surgeon in several hospitals where I am often compelled by circumstances to treat fibroids by surgical procedures.

It is only fair that I should say at the outset that I did not choose this topic for my discourse; it was assigned to me by our esteemed chairman, who, in order to preserve the high reputation for impartiality which has been possessed to an eminent degree by the chairmen of this Section of the ASSOCIATION in the past, no doubt wished that justice should be done to all methods of treatment at present employed. So strong is my own personal taste for surgery, especially of the abdomen, that I might have been tempted to disobey the chairman's command but for one reason, which was that as I reflected upon my work during the past seven years there passed before me the images of some fifty women whom I had treated for fibroids by electricity. First, as they appeared when I saw them with faces anxious with pain and blanched with hemorrhage, and then after their pain had been relieved and their bleeding had been stopped by galvanism and their cheeks had resumed a rosy hue, these fifty women's faces encourage me to do justice, though the heavens may fall, to the treatment which has cured them.

Then there pass before me the dying faces of *ten* women who were treated by total extirpation, at two of which operations I was the executioner; at six of which I was first or second assistant, and at two of which I was only a spectator.

True the majority of the ten operations were performed in the pre-antiseptic days, though by a great master in this department of our art; but four of them were performed within the last few years under the most rigorous aseptic precautions by men who have a low mortality in general for abdominal surgery.

The memory of these fifty women who have been cured by electricity, many of whom I could find, if required, and many of whom to this day stop me in the street to thank me and it for their rosy cheeks; and the memory of those ten women who are now no more, all tell me that I would be a traitor to the cause of truth if I remained silent, not only out of season, but in the very hour when it most needed to be spoken.

True, I can quiet my conscience when circumstances compel me to operate, by the reflection that one woman died while under electrical treatment, not through electricity but through an error of diagnosis for mistaking a tense impacted liquid tumor for a fibroid, which would not have been made if the abdomen had been opened, or, in other words, if the treatment had been surgical instead of electrical. This is the one and only case in which as far as my experience goes, I have ever had to seriously regret the use of electricity.

I can still further soothe my conscience when I am compelled to operate, by remembering that I have operated on ten women, seven by abdominal hysterectomy, treating the stump by leaving it transfixed at the lower angle of the incision; and on three by removal of the appendages, tying the ovarian arteries low down; and several others treated in the latter manner, at which I was first assistant, all of whom recovered and are now in good health.

When I visit the City of Brotherly Love where the surgeons have declared war to the knife upon the electrode, I am often placed in an awkward predicament. When I tell my friend, Dr. Joseph Price, that I am going to spend a few hours at the electrical clinic with Dr. Massey, he is surprised that a man of my intelligence can waste his time in such fiddle-faddling nonsense, and it is useless for me to assure him that I can show him many women in Canada, from Manitoba in the west to New Brunswick in the east, who are pictures of health, and who have been cured by electricity.

On the other hand, when I tell my friend, Dr. Massey, that I am going to spend the morning with Dr. Joseph Price, extirpating fibroids, he looks with pity on my bloodthirsty taste and misguided energy.

In vain I tell him life is too short to treat all my fibroid cases by such means.

In this somewhat peculiar position which I occupy, I have one consolation, and that is or at least I hope that it will be so, that the conclusions which I shall presently lay before you, are those of one who is entirely unbiased and non-partisan, and are consequently to be accepted as far as they go, in good faith.

My own opinion on the present status of electricity in the treatment of fibroids is fully made up, and I shall now endeavor to lay it plainly and honestly before you.

During the last year especially, although it has been growing gradually for several years, the conclusion has become evident that electricity is not suitable for every kind of case nor for every kind of doctor.

But it is as true to-day, as it ever was, that for the cure of pain in, and bleeding from, the uterus, the application of the positive pole of the galvanic current properly applied and of sufficient strength to the uterine mucous membrane, is in the majority of cases effective. The percentage of successes is greatest in those cases in which the fibroid growth is interstitial; not quite so great in the cases of submucous growths, although in several of these cases a few applications have been followed by the expulsion of the tumor from the uterine cavity. The earlier the cases come under treatment the more surely they are cured; many patients with small interstitial tumors in the anterior wall having been completely cured by me, and still more under the care of others. So that

the plea for the early treatment of fibroid tumors by electricity is quite as just a one as is the early plea for operative treatment. Indeed, it is even more so. For while we can truthfully say that the electrical treatment, when undertaken early and with a correct diagnosis is at the present day entirely devoid of danger, no one can truthfully say the same of the treatment by operation. In fact, I am sorry to say that no one knows what is the death rate of the latter treatment. Three of the ten deaths which I have above mentioned have never been reported, and six of them were only reported at my urgent solicitation.

May there not be many other similar cases? When a woman comes to a doctor for menorrhagia and he discovers a small fibroid, is he to urge her to submit to an operation, when he knows with the greatest skill and care she runs the risk of dying from the operation, and if left alone, the death rate is more than 1 per cent., while with electrical treatment the risk is absolutely nothing?

When she tells me that she will not submit to an operation, shall I assure her that I can do nothing for her, when I carry in my pocket the record of fifty similar or worse cases which have been cured by electricity? Surely, that were dishonest. And yet the temptation to operate, in spite of the danger of surgical and the safety of electrical treatment is very great, too great in some cases for us to resist.

Ours is a busy life, and there is not one of us here who has not often felt that life was far too short to accomplish all the good that we would wish to do, and for the want of a few more hours in the day, much work of value to our fellow beings must go undone. With this feeling strong within us, a poor woman applies at the out-patient department of our hospital with a small interstitial fibroid which has, however, doubled or trebled the bleeding surface of the uterine mucous membrane. We believe that we could cure her by a long and tedious course of treatment with electricity, from ten to fifty applications; if there are no facilities at the hospital, then at our office. If at the hospital, the time required for this case would seriously encroach upon the time allotted to our service there; if at an office there is the same, as well as other objections. And when we have made the sacrifice and cured the woman, what is the reward? Perhaps, but not always, the woman's thanks. Our own feeling of having done well, surely. But when we turn to our brethren, whose esteem is and should be the greatest incentive that we can look for, to good work well and conscientiously performed, what do they say? We have no fresh and bleeding tumor to take to the medical society, (as an Indian waves a white man's scalp), before our admiring brethren as a trophy of our prowess and our skill. I have shown the women over and over again; I have shown their clothing which had to be taken in, as much as seven inches, owing to the decrease in size; the women themselves have offered to state on oath that their bleeding had been arrested, their pain removed, and their general health improved. How were these triumphs of therapeutic skill received? With loud applause, you will say. No, indeed. The praise bestowed upon the exhibitor of even an apparently healthy appendix, the removal of which was followed by the death of the patient, is wild in its enthusiasm, when compared with the manner in which is received the report of a case of cure by electricity. Indeed, a sincere friend and admirer in our society warned me

privately that my reputation was injured every time I showed a woman who had been cured by this means, and he urged me to show no more. But I must continue to cure them by that means as far as my time limit and life limit will allow.

How different when we report an operation, whether the patient lives or dies. Everybody seems pleased and praises us in proportion to the danger to which our patient has been exposed. But if she dies there are two at least who must regret that it was performed; the patient and the doctor; and sometimes there are the husband and the little children to be thought about. But how much easier to take the patient into the hospital and in a few days perform hysterectomy which we can do in a quarter of an hour sometimes. It is, as the French say, "*un mauvais quart d'heure*," but it is soon over and the patient's fate is sealed for weal or woe when we have put in the stitch which closes the peritoneal cavity.

After that the house surgeon and nurses take care of her and an average of three minutes a day for the next twenty days is the very most she requires of us. But with the electrical treatment, what with getting the patient ready, carrying out the asepsis of the vagina, and adjusting the apparatus, I have spent as much as one hundred precious hours on a single fibroid case. But the ovaries remained and many of the women are now the happy mothers of children and others are happy wives, capable of having children, though childless.

I have lately asked several well-known men, men of the highest surgical reputation (you would be astonished if I mentioned their names) whether they had employed the electrical treatment with good results, and they have assured me that they had, although they have never reported them; and when I asked them what was the principal objection to it, they replied, in confidence, that it took too much of their time. And this I admit is a serious objection to it, but not an insurmountable one. There are two ways in which it may be surmounted; one is by having an assistant whose time is less precious than our own, who has been trained to carry out the treatment with accuracy and care when we prescribe it for the disease which our more experienced touch has diagnosed. And the other, is by having several rooms and a nurse to prepare the patient, including the antiseptic vaginal douche and by devoting two afternoons a week, and having these patients come only at that time as many as six treatments an hour might be administered.

Never before has it been so well demonstrated, as it is to-day, that by the division and subdivision of labor the workmen become more and more expert. It does not surprise me therefore that the best results of the electrical treatment of fibroids are obtained by such men as Apostoli and Massey, who employ this treatment alone. They both obtain results which neither I nor any other operating gynecologist can hope for. In every large city we should encourage some one man to establish an electro-therapeutic clinic, where our poor patients, at least, might obtain the benefit of his skill in electrical technique, after having obtained the benefit of our experienced diagnosis; in time, his reputation would reach the ears of the rich, and he would then have some substantial reward.

The present status of electricity is suffering as did the status of abdominal surgery a few years ago, because it has been tried by men without sufficient

experience, and has as a consequence been found wanting. The electrical treatment of fibroids requires knowledge of the pelvic contents as well as the electrician's knowledge of the power he is wielding.

I must trespass on your time yet a little more while I refer to two points. One, a claim which has recently been made by Apostoli for the electrical treatment, which I can hardly indorse; and the other an objection which has been made to it, which I can as heartily deny.

Apostoli has discovered that the very failures of electricity can be turned to advantage in the following manner: it has been found that in those cases where the electrical treatment has been badly borne and has been followed by febrile reaction, so that the patients have been turned over to the surgeon for operation, the presence of pus tubes and pelvic peritonitis has been discovered. Apostoli has pointed out that electricity may be employed as a diagnostic agent for the purpose of detecting diseased appendages.

A remarkable instance of this came under my notice a little over a year ago. A young woman who had been employed in a restaurant in a New England town, gradually lost her health, with pain and hemorrhage. She suffered agony with her periods which came too often and lasted long, so that her face was blanched and haggard. There was no difficulty about the diagnosis as the tumor was large, round, symmetrical, in the median line extending up to the umbilicus and could be easily seen and felt, bulging up the abdominal wall. Several physicians in the United States, her family physician in Montreal, as well as myself, all agreed that it was a fibroid. One of them had tried electricity several times, but always with bad results, and so did I. As she was laid up in bed for several days each time, I concluded that the appendages were diseased, and after three applications I decided to stop and to perform celiotomy. On opening the abdomen the tumor was at once seen surrounded by adherent intestines, but it still appeared a symmetrically pear-shaped fibroid. I could not, however, find the ovaries and tubes, and while digging around for them, I made a line of cleavage which being followed up I was able to dissect out of a portion of the tumor which proved to be a sausage-shaped pus tube; this was delivered intact, tied and cut off. Then followed a large cystic ovary; then the other tube which broke and inundated the field with pus, and then the other ovary, by which time the supposed fibroid was gone and only a moderate sized uterus remained. The pelvis was carefully washed out and drained, the patient made a rapid recovery and is now at work and enjoying perfect health. So that in this case Apostoli's dictum, that when the application of his method causes febrile reaction the tubes are badly diseased, was fully borne out.

Now the objection to electricity which has so often been made to it, especially by one of my most esteemed friends in Philadelphia, that it causes adhesions is not true. I maintain that one has no right to bring that charge: 1, if fibroids which have never been treated by electricity do have adhesions; and 2, if fibroids which have been treated by electricity can be proved not to have become adherent.

Now I am in a position to prove both of these facts. When in Baltimore I saw the abdomen opened for fibroid but it was so adherent to everything, intestine and abdominal walls, that the operator, one of the

ablest in the world, did not consider it possible even to get the ovaries out, and the abdomen was sewed up. Now this case, the most covered with adhesions I have ever seen, you will say had received many applications of electricity, and so I thought judging from these statements, must have been the case. But careful inquiry elicited the fact that she had never received a single application of electricity. But that is only negative evidence. Let us see about some positive evidence.

Three or four years ago I treated a lady, head mistress of a large public school a thousand miles away, for hemorrhage and pain, by means of intra-uterine positive galvanism. She had received one year's leave of absence from her important duties and the commissioners had advanced her one year's salary in order to regain her health, she being utterly incapacitated for work. You may imagine that she was peculiarly anxious to get well and therefore submitted to a very rigorous application of the treatment three times a week with great fortitude, as high as 200 milliampères being frequently given at a time. And this was not for one or a dozen applications but for fifty times. By this time the bleeding and pain were nearly, if not entirely arrested, and I advised her to complete the cure by a few months rest at her old home down by the sea in New Brunswick. This she did and came back to me in July with rosy cheeks and sparkling eyes. She and I would have been perfectly satisfied with the result, and I should have reported her among my cures, had it not been for one thing, and that was that she asked me the question: "Can you promise me that the awful hemorrhages will not return after I have gone to my far away home in the West?" This I could not answer her affirmatively.

Her next question was: "Is there any other treatment by which you can guarantee that result?" My reply was "yes, one only, and that is hysterectomy." Although the operation was not required by her then present condition, yet owing to her financial situation which would preclude her ever coming to Montreal again, at her urgent request I removed her uterus.

Now if the charges against electricity have a vestige of truth in them I must have found the tumor covered with adhesions; in fact, the tumor and appendages must have been one agglutinated mass requiring some hours of patient toil to detach them, and for this I was prepared. But what was my astonishment, on opening the abdomen and screwing a cork-screw into the tumor to be able to lift it out smooth and shining as the top of a bald man's head; the transfixing of it with pins and circling it with the serre-neud was the work of a few moments and in a minute more the tumor was off. She ran her 5 or 10 per cent. of risk of death safely and made a splendid recovery and was at the head of her school once more on September 1.

One such case carries more weight than a thousand assertions that electricity causes adhesions.

But I can duplicate it. A young lady who is now a trusted nurse in a New York hospital came to me the first year I used this treatment, for hemorrhage and pressure symptoms caused by a large fibroid. She improved so much that I decided that she ought to go home by the time she had received fifty applications. But after the last application she began to flow before the time, and I asked her to wait until it stopped. It lasted seventeen days, a steady little

stream of dark red blood. I became momentarily discouraged and advised operation which was accepted, but I handed her over to a more experienced operator than I was, at that time. I assisted at the operation and the tumor came out without the slightest difficulty, and was removed in the same way as the case mentioned above. I examined it most carefully and the only trace of an adhesion to be found was a spot about the size of a silver 5 cent piece, where the tumor had rubbed upon the brim of the pelvis on the right side and where she often complained of pain before coming to me. But there was not a sign of adhesion in the track of the electric current nor anywhere else except this one spot. The hemorrhage was due to a tiny opening in a sinus by the end of the electrode.

I dislike electricity, personally, because it takes up my precious time, but I want it to get fair play and not be blamed for sins that are not its own.

There is one charge, however, which was frequently brought against the electrical treatment of fibroids or rather against a method of applying it, in the past, and which was well deserved but no longer applicable, because no longer employed. I refer to the method of galvanic puncture.

The greatest claim for the electrical treatment of fibroids that can be made is that it has no mortality, that it is absolutely safe. If it is not safer than any other treatment, or, in fact, unless it is absolutely free from danger there remains only one advantage in its favor, namely, the saving of the ovaries. But galvanic puncture no matter how performed, whether by the vagina or through the abdominal wall, must ever be a procedure fraught with danger and is to-day practically abandoned. If any one still uses it, in the cause of electrical treatment of fibroids, I beseech him to use it no more. The positive pole of the galvanic current gently introduced into the uterus will accomplish our object by unseen but no less certain means. It dries up the juicy, bleeding mucous membrane and by its tonic action upon the muscular tissue through which must pass the vessels carrying nourishment to the tumor, its blood supply is cut off just as surely as though we tied the ovarian arteries which supply the body of the uterus. The action of the electric current as applied to fibroids is three-fold. The first is not mysterious; it is but the arrest of circulation in dilated capillaries by an electric-chemic cauterizer. The second is no more difficult to understand than the action of ergot or strychnin; it not only tones up the vasomotor system making the caliber of the arteries less, but it calls into play the special and remarkable power which the uterus possesses of controlling its own circulation when it has the strength to contract. The third effect of the current, its electrolytic action is, I admit, as mysterious as it has ever been, but not more so than the invariable absorption of syphilitic gummatous deposits following the administration of iodid of potassium. Whether what we call electrolysis means the actual breaking up of an organic tissue into inorganic atoms, or whether it means, as seems more likely to me, that the growth deprived of its blood supply undergoes fatty degeneration and is partly eaten up by phagocytosis, stimulated to greater activity by the trophic nerves; no one with a large experience with this subtle fluid can deny that a uterus infiltrated with and enlarged by the deposit of fibrous tissue, whether localized in the form of fibroids

or diffused as in areolar hyperplasia, so that the sound will enter four or five inches, will invariably diminish in depth by means of electrical treatment.

Then again, what is the enormously enlarged uterus after delivery but a bleeding myoma? Does it not stop bleeding when the arteries which supply it with blood are squeezed by its contracting walls? Does it not rapidly get smaller when, for the want of blood and exercise, that immense mass of tissue silently undergoes fatty degeneration and returns to the blood from whence it came?

Wonderful and almost incredible as the total disappearance of a fibroid or myoma may seem to some, it is no more mysterious than this wonderful process of nature which we call involution. Have those who doubt and even worse, deny the power of electricity to work a change in fibroids, never reduced the size and weight of a uterus which nature had failed to involute? Has Emmett never reduced its size by repairing a lacerated cervix? Have Churchill and Athill and ten thousand others with honored names never reduced the quantity of tissue in the uterus by the application of iodine? Have not a hundred thousand others ever reduced the weight of blood and muscle and areolar tissue in the heavy uterus by means of glycerin and hot water and other therapeutic measures?

Then why in the name of reason and justice, will you deny that an agent which we can see blanching tissues before our eyes, and making muscles of every kind of contact, why will you deny, I say, that it can diminish the blood supply to, and favor the fatty degeneration and absorption of, the fibrous or myomatous uterus?

The electrical treatment of fibroids, reduced to the above simple equation and stripped of all the extravagant claims which were at first made for it, stands to-day upon a foundation so strong and true, that it will find an honorable place in the treatment of fibroids as long as women shall dread to die by the surgeon's knife, which I believe will be as long as the world shall last.

LIGATION OF THE BROAD LIGAMENTS FOR UTERINE FIBRO-MYOMATA—REPORT OF TWO CASES.

Read in the Section on Obstetrics and Diseases of Women, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY C. C. FREDERICK, B.S., M.D.

SURGEON-IN-CHIEF BUFFALO WOMAN'S HOSPITAL; GYNECOLOGIST ERIE COUNTY HOSPITAL, BUFFALO, N. Y.

The various forms of treatment and the varied surgical operations for the removal of fibroid tumors of the uterus has, in the past decade, been one of the most prolific subjects of discussion in medical circles and the end is not yet.

Abdominal hysterectomy—supravaginal amputation, with or without the clamp, or extirpation through the vagina by morcellation, each have their advocates; while other operators of note advise women with uterine fibroids which are giving no special distress to leave them alone.

A certain proportion of uterine myo-fibromas produce symptoms which necessitate some operative procedure for their relief. Often the distress is occasioned by the association of a pus tube or an ovarian abscess, the diseased appendages, not the tumor, being the cause of pain and ill health. Should an

operator in such a case do a total extirpation? The operation done must fit the case and its varying conditions. If there be double tubo-ovarian disease, it would seem wise to remove the uterus and both appendages, whatever the age of the woman, for a uterus without either tube or ovary is a useless organ. Its removal will not lengthen the operation or add to its dangers in the least.

If, however, the woman be young and only the appendages on one side be diseased, the question is pertinent, Shall we do a total extirpation if anything can be done to cause the fibroid to absorb? If this can be accomplished the woman is left essentially in as perfect a state as though she had never lost the appendages of one side. It can not be denied that woman was created with these organs for a purpose, and if not diseased they are essential to the most perfect state of health during her menstrual life, even if she bears no children.

If the woman be under 38 to 40 years of age, if the uterine fibroid can be absorbed and her uterus returned to its normal size and functions, and if one set of healthy appendages can be saved, it must be apparent to the most radical, as well as to the conservative, that it is the desideratum to be desired. It is truly conservative, it is just to the patient.

Shall we subject every woman who has a fibroid to total extirpation, even if she has no other symptoms than discomfort from the presence of the tumor? I believe that every fibroid tumor of any appreciable size should be dealt with surgically, either to cause its absorption or to remove it *in toto*. Fibroid tumors have been said to be benign. I have seen malignant degeneration in three fibroids, and in conversation with other operators of experience have learned that they too have frequently seen malignant disease develop in uterine fibro-myomata.

Several years ago Gottschalk proposed to cause the absorption of uterine fibroids by ligating the broad ligaments, thus cutting off a part of the blood supply and so modifying the nutrition of the tumor as to produce this result.

Dr. Franklin H. Martin, of Chicago, was the first in this country to carry out the suggestion, and it was by the reports of his successful results that I was led, a few months ago, to try it upon a young woman who would not consent to an hysterectomy, but who would let me do any operation which did not involve entering the abdominal cavity.

The original limits of the proposed operation were that the broad ligament should be tied through the vagina. I have three times tied them through the vagina, and twice while I had the abdomen open for the removal of other diseased structures than the fibroid. In one of the cases in which I tied the ligaments in the abdomen, I should have removed the tumor, because the woman was at the age of the climacteric, had I not been desirous of observing its effect in that particular case.

The results have been so satisfactory that it may be of interest to listen to a brief history of these five cases:

Case 1.—Miss McC., American, age 25, single, virgin, entered the Buffalo Woman's Hospital Sept. 23, 1894. The patient was anemic, having had almost constant uterine hemorrhage for fifteen months. She had hemic murmurs. The fundus of the fibroid uterus extended two inches above the umbilicus. Examination of its cavity revealed no submucous growths. On Sept. 27 the base of the broad ligament, including the uterine artery, was tied through the vagina.

The cervix was first incised as in vaginal hysterectomy, except that the incision was carried backward far enough only to sever the lateral utero-vaginal junction, and at the same time not open into Douglas' pouch. Then pushing back the bladder and the ureters from the front of the cervix, the base of the broad ligament was easily reached and the whole mass ligated. The line of incision was then closed by a continuous catgut suture. The uterus was noticed in two days to have decreased in size and especially in hardness, having a boggy feeling on palpation. She was discharged on the eighteenth day after operation, the fundus of the uterus being easily felt just above the pubic symphysis. An interesting, and at the time a very annoying incident of her history after operation was the high temperature which developed without any apparent assignable cause. On the second day the temperature went to 101 degrees and the pulse rose correspondingly. There was no evidence of peritonitis, no fetid discharge, no pus from the incision; everything was negative. Careful exploration of the chest revealed no bronchitis or pneumonia. The temperature continued to rise and on the fifth day was at 104 degrees and the pulse 120. From this time it continued to fall and reached normal on the tenth day.

I have since seen the patient. She is hearty, full blooded and robust. The uterus is natural in size and her menstruation is normal in every respect.

Case 2.—Mrs. A., American, age 33, married fourteen years, sterile, entered the Buffalo Woman's Hospital Sept. 26, 1894. She has a fibroid of the uterus extending to a point midway between the symphysis and the umbilicus. She gives a history of pelvic inflammation three years ago, followed by almost constant pain in the left inguinal region. She has noticed the existence of the fibroid for about five years, during which period her menstrual flow has been too profuse and often too frequent. Examination under an anesthesia disclose a large mass to the left of the uterus which is probably a tubo-ovarian abscess. September 30 made an abdominal section; removed the left tubo-ovarian abscess out of dense adhesions and tied the base of the broad ligament. Before she left the hospital the uterus was curetted for a persistent muco-purulent discharge. The patient went to her home on October 18, eighteen days after operation. At that time the uterus had decreased rapidly in size. It is now entirely normal but she menstruates more profusely than before her illness three years ago.

Case 3.—Mrs. G., American, age 48, married, had one child twenty-six years ago, was brought from a distance on a cot to the Buffalo Woman's Hospital Jan. 21, 1895. She is very anemic having flowed profusely for the past six months, and has a fibroid of the uterus extending above the level of the umbilicus, and an ovarian cyst on the left side which has pushed the fibroid over to the right. The patient's abdomen is about the size of a seven months pregnancy. February 5 the ovarian cyst was removed and the blood supply to the fibroid cut off by ligating the base of the broad ligament. The patient was discharged on March 9, the fundus of the uterus being easily felt above the pubic bone.

The further history is interesting and raises an important question. She has not menstruated since the operation and has continued to increase in flesh and strength. On April 20, she began to notice a fetid vaginal discharge which rapidly became more profuse. In a few days her appetite left her and she began to have chills and fever. Her physician communicated with me and I asked him to send her back to me at once. On April 26 she returned to the hospital with a pulse of 120, and a temperature of 103.8 degrees. On April 27, the following day, I dilated the cervix and removed from the inside of the uterus a sloughing sub-mucous fibroid the size of a hen's egg. In forty-eight hours the temperature and pulse were again normal and the patient ready to return to her home. The uterus had contracted to its normal size.

Case 4.—Mrs. S., American, age 38, married, one child 13 years old, entered the Buffalo Woman's Hospital Feb. 22, 1895. This patient had been having menorrhagia continuing about two weeks each month for the past six months. During the past six weeks the flow had been constant, at times very painful, necessitating tamponment. Examina-

tion under anesthesia shows an interstitial fibroid of the anterior uterine wall near the fundus, approximately the size of a hen's egg. The uterus was at once curetted and the broad ligament ligated through the vagina. The hemorrhage immediately ceased. On March 15 she was discharged, and menstruated again March 25 rather more profusely than she ought, duration eight days. In April her menstruation was still somewhat more profuse than normal for her. All traces, however, of the fibroid are gone and I doubt not that the next menstrual flow will be normal in amount and duration.

Case 5.—Mrs. B., aged 45, American, married 28 years, sterile, entered the Buffalo Woman's Hospital April 8, 1895, with an interstitial fibroid of the uterus reaching nearly to the ribs on the left side, and on the right side extending to the margins of the costal cartilages. One year ago she refused to allow an hysterectomy for its removal, as she suffered no pain, her menses were normal, and her general health was perfect. The discomfort occasioned by the size and weight of the tumor is her only cause of complaint. On April 10 I tied the broad ligaments through the vagina. The patient returned to her home twelve days after operation. The fundus of the uterus was then one inch above the level of the umbilicus. She also noticed its falling from side to side when turning in bed, owing to the decrease in its lateral diameters. I have not seen her since her return home, but on May 1, a mutual friend brought word from her to me that the tumor was still decreasing rapidly and that she was watching its departure with much satisfaction.

The results obtained in these five cases, even though they be only five, seem to prove that this operation is effective in causing absorption of the tumor. The course of Case No. 3, from whom I later removed the sloughing submucous growth, seems to raise the question whether this operation will cause their absorption or necrosis. There is need of further experimentation to determine whether this slough was caused by the deficient blood supply, or whether it was merely a coincidence. The uterus evidently had begun its efforts to extrude the mass, because the patient gave a history of pain antedating the fetid discharge, hence the uterus may have caused its necrosis by pressure as it often does.

Many operators will object to substitute this conservative operation for the more brilliant hysterectomy. A surgical operation should be done solely with a view to the best interests of the patient. Unfortunately too often the brilliancy of the operation, not the best interests of the patient, actuate the operator in his work. Fortunately, however, the real brilliancy of our work resides, not in that which brings forth the plaudits of those who frequent our operating rooms, but in the ultimate results of that work, upon which our patients and the public will surely pass judgment.

There is no more danger in this than in an Emmett's operation. If the tumor be large there is some difficulty in reaching the broad ligament, as the tumor is apt to lift out of the pelvis by its growth. Furthermore, fibroids occur more frequently in unmarried women, or sterile women, in whom the vagina is small, thus adding to the difficulties of the operation.

If as a result of this operation a uterine fibromyoma absorbs and the uterus returns to its normal size and functions, is it not better for the patient in its ultimate results than an hysterectomy? Especially is this to be desired if the woman be young, as was my first case. She may bear children if she marries.

This operation is not applicable to all fibroids. Very large hard tumors will not be benefited by it. Tumors which spread out broadly in the broad ligaments, displacing the uterine arteries upward, are not appropriate for it. Very large tumors are apt to rise

high in the pelvis making it difficult to get at the broad ligament, especially as fibroids so frequently occur in sterile women whose vaginas are narrow, thus adding to the difficulties of the operation.

The class of fibroids in which this operation will be found most effective is those of medium size, soft, bleeding tumors. The softer the tumor and the more hemorrhagic it is, the more liable is it to absorb after this operation.

There is merit in the operation in properly selected cases. It is conservative. It does not prevent more radical procedures later, if they be necessary.

DISCUSSION OF PAPERS OF DRS. EASTMAN, SENN, SMITH AND
FREDERICK.

DR. GORDON, of Maine—I am very glad to see this Section of the ASSOCIATION alive to the subject of hysterectomy. Two years ago, in this Section, I read a paper entitled, "Hysterectomy without a Pedicle," and one or two years since I read before the American Gynecological Society another paper, in which I took the ground that in every case of fibroid of the uterus, where the woman consulted me for any trouble arising from it, I should perform hysterectomy. It was a bomb-shell in that Society, and my friend, Dr. Mundé, stayed over, it is said, to "wipe up the floor with Gordon." I am very happy to see that the majority of the men present do not join my friend in this attempt to wipe up the floor with me. I have steadily pursued the same course, and I stand to-day on precisely the same ground. If I have any patients coming to me with trouble arising from fibroids of the uterus, I unhesitatingly recommend hysterectomy and resort to it every time. I do it by a process which, I believe, is entirely my own. Every one has his own method. I do it by a continuous suture of catgut, and nothing else. I simply put a clamp under the tube and ovary, then an inch below the clamp, with a long curved needle threaded with catgut I tie as strongly as I can and cut between that and the clamp. I then cut and sew until I get down to the uterine artery on each side. I change sides and cut down to the uterine artery or near it; I then divide anteriorly and posteriorly the peritoneum and dissect it down, the best I can with my fingers and scalpel. I dip my needle down and loop the uterine artery, passing the needle through the loop, and then after it is drawn up I cut the uterine artery, and at that point beside the loop I make a knot with the free end of my catgut. I then dissect the entire cervix; I make a complete hysterectomy. When the uterus is out, I have then simply to pass forceps over and carry the suture along continuously. It is extraperitoneal, yet an intrapelvic operation. It covers the entire thing. I am not particular about closing the vaginal opening except to stop the hemorrhage and leave a small opening for drainage. With rare exceptions I close the opening with silkworm gut and put in no drainage. I believe drainage simply indicates that we have no confidence in our asepsis, consequently I do not use it. I do not say I never use it, but as a rule I do not.

DR. A. H. TUTTLE, Boston—I am glad to hear of the universal success of hysterectomy, as brought out by the different speakers; and although there are slight points of difference in the technique of various operators, still they all have the one object in view. Personally, I believe total extirpation—that is, removal of the cervix—is the proper thing. By removing the cervix we afford better drainage by the vagina. We can close the abdomen, and if there is any secondary hemorrhage or oozing it will leak out through the vagina without causing further trouble. I believe where we leave the cervix there is possible danger of subsequent changes of a carcinomatous nature; in other words, I am satisfied in many cases of fibroids that the ultimate result comes from degeneration of the fibroids in some malignant form. I have good reason to make that statement from cases I have seen.

In regard to the question of hemorrhage, I think where we do a total hysterectomy, the danger of secondary hemorrhage is less than where we resort to a partial hysterectomy, for the simple reason that as soon as the hemorrhage or oozing is detected from the vagina, we can prevent it from terminating fatally. One thing should be emphasized in the treatment of these fibroid cases, and that is with reference to making the first incision into the abdomen. In one case where I had a multilocular fibroid to deal with, as I cut down upon the peritoneum at a point above the umbilicus, I encountered difficulty in entering the peritoneum and opening the peri-

toneal cavity. I discovered the bladder was carried away up on this tumor; the uterus was back out of sight. Had I gone in at the usual point of incision I would have opened into the bladder itself. It was a warning to me and should be borne in mind when we are dealing with large masses. In removing the cervix we should insist upon closing off the uterus in some way, and although it has been shown that infection from the cervical canal is comparatively slight, still we should take no chances whatever from any source of infection. Rapidity of operation depends as much upon the operator himself as upon the technique.

DR. HOWARD A. KELLY, of Baltimore,—could not agree with the statement made by Dr. Gordon, and he sees no necessity for removing fibroid tumors which are doing no harm. He does not urge the operation unless the patient is in some way suffering from the presence of the tumor; that is, unless she has pain, or hemorrhage, or pressure symptoms. He regarded Dr. Senn's method of operating as a retrograde movement in our technique. Dr. Kelly then described the technique of the operation he usually performs in the removal of fibroid growths of the uterus, which has given very good results in his hands.

DR. HENRY O. MARCY, of Boston,—said he was in favor of treating the pedicle by the intraperitoneal method. When he first suggested this some years ago, it was looked upon as an ideal but not a practical suggestion. The evolution through which the operation of hysterectomy has recently passed is one of the marvels of modern surgery.

DR. I. S. STONE, of Washington,—said that in all of the cases coming under his observation where some benefit followed the use of strong galvanic applications there was ultimately a recurrence of the symptoms and growth. The technique described by Dr. Senn he thought worthy of serious consideration. After the removal of a fibroid of large size, there is always considerable shock, and by following the plan outlined by Dr. Senn, he thought the amount of this shock would be minimized.

DR. G. B. MASSEY, of Philadelphia,—said that in the hands of careful men electricity remains the most valuable agent at our command for the treatment of the hemorrhagic forms of tumor. The treatment must be persistent and long-continued. In growths of large size, the improvement following its use may be slow, and a radical surgical operation may be preferable. In one case coming under his observation, in which Dr. Martin had tied the broad ligaments through the vagina, the tumor decreased in size during the first six months and the hemorrhage was less severe, but after that there was a recurrence both of the size of the tumor and the hemorrhage. Under systematic electrical treatment the patient has since improved greatly.

DR. CHARLES P. NOBLE, of Philadelphia—agreed in the main with Dr. Gordon that when a fibroid gives rise to symptoms sufficiently severe to make a patient ill, it requires attention. It may not be necessary in every instance to perform hysterectomy. When they give rise to symptoms, however, it is best to remove them. During the past eighteen months he has seen five cases of fibroids which had undergone malignant degeneration, three of which were sarcomatous, and two were carcinomatous. He had not had good results with Martin's operation. Hysterectomy in his hands has proved less dangerous than ovariectomy. He did not think Dr. Senn accomplished anything by his operation. The method described by Dr. Kelly, and which was familiar to the members of the Section, would save at least twenty minutes in the performance of the operation. Dr. Noble believes that in a short time the general mortality of hysterectomy will be less than 3 per cent.

DR. J. M. BALDY, of Philadelphia—said that he would remove all fibroids that came under his care, because he never saw such a tumor that did not give rise to more or less trouble. An ovarian cyst would be removed as soon as discovered, symptoms or no symptoms, and so should a fibroid tumor, which can be removed as safely as ovarian cysts. As to ligation of the uterine arteries, it is a very plausible, very attractive procedure theoretically, and it is only applying to the uterine arteries what Mr. Tait does to the ovarian artery when he removes the appendages. He gets a shrinkage in his tumors by shutting off the arterial supply. The means of effecting a cure in the operations are precisely the same. Collateral circulation will sooner or later be set up, and the tumor again begin to grow. If the abdomen is opened and the uterine arteries ligated, the operator might as well include the removal of the uterus. The shock is no more, it does not add to the length of the operation, and with all due respect to Dr. Senn's fear of shock to the peritoneum he has none whatever. He rarely sees it. Mere exposure of the peritoneum

does not lead to shock. He was glad that no one had advocated complete extirpation, for he believes this operation would be difficult. Dr. Kelly's method in the hands of expert operators is a good one, but it is a dangerous method for beginners. Dr. Baldy did not believe that it is good practice to tear the tissues in performing hysterectomy; he prefers to ligate and then cut. He agreed with Dr. Kelly in considering Dr. Senn's method as a retrograde procedure.

DR. DUDLEY, of New York—said it was utterly impossible in five minutes to do justice in the way of discussion to the series of papers that have been read, covering as they did a large field in the removal of disease from a woman's pelvis. He said that all the various methods of operating, which were referred to by the different speakers, are applicable in proper cases. We must learn to apply the method to the case, and not the case to the method. A complete and radical operation is the most brilliant, and often the one most easily accomplished, but it is not always the best one for the patient.

DR. FREDERICK had done a good many hysterectomies during the last five months. He had tied the uterine arteries in five cases as a test, and the results were so uniformly successful and he was so well pleased with the method, that he thought he would trespass upon the time of the Section by reporting the cases, so that the members might have the benefit of his experience. In the hemorrhagic forms of tumor in virgins or in young women, by tying the uterine arteries the tumor is absorbed, the patient's uterus, tubes and ovaries are left, and if she marries she may bear children or may not. Whether she does or not, she has in her pelvis normal organs that are better there than an empty pelvis. It is the surgeon's duty to do what is best in his judgment and experience for the patient, and every operation, as Dr. Dudley had said, should be shaded according to the case, and not make the case come up to the standard.

DR. SENN said the members of the Section were not all Kellys and Baldys, and while the operation he had described was not intended for experts but for the average surgeon and gynecologist, he believes that even a Kelly or a Baldy could learn a lesson from the description of the operation. He had seen cases of myofibroma of the uterus—and so had Kelly and Baldy—where a complete hysterectomy, one of the most complicated of all surgical operations, was indicated and called for, and from which men old in experience shrank from undertaking such a task. The veteran Keith, after he had performed thirty-five laparo-hysterectomies, was candid enough to inform us that his courage began to fail him; that he was glad to grasp at more conservative measures, notwithstanding the unparalleled success he had attained at that time.

DR. EASTMAN considered the method described by Dr. Senn a step in advance, and said he was wise in presenting an operation which the average surgeon could perform, and that does not require the facilities that must be had in order to make the perfect operation which Kelly and others have described. He desired to place himself on record, as he did at the San Francisco meeting, to the effect that he had seen very many cases of gangrenous nodules, of fibroid tumors undergoing malignant degeneration, and a fibroid tumor of any size is dangerous.

THE SURGICAL TECHNIQUE OF ASEPTIC WOUNDS.

Read in the Section on Surgery and Anatomy at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY HENRY O. MARCY, M.D.
BOSTON, MASS.

Notwithstanding the revolution already wrought in the technique of wound treatment, I must yet think that no subject more important or practical can be brought before the profession at the present.

Wound infection, in a general way, is fairly well understood, and those who have given special attention to the subject will, at least in a large degree, accept the opinion which I published some years since, that suppuration, supervening in a wound, deliberately made by the surgeon, through healthy integuments, indicates that there has been some avoidable error in its technique. If the conscientious surgeon

accepts this view as the standard by which to criticize his work, and earnestly seeks to determine the cause of the error, he will find a gradual elimination of much that is superfluous, as well as defective in detail. For the scientific skillful surgeon a bacteriologic training is almost a *sine qua non*, since only by such repeated investigations is he enabled to familiarize himself with the special characteristics of the infective material with which he has to deal.

The reparative processes, supervening in the well vitalized tissues of the healthy animal, non-infected by bacteria, are comparatively simple. The necrosis line following a clean incision may be limited to the injured cells, and only a microscopic layer of tissue is involved in the changes which ensue in the impeded surrounding circulation, local stasis, and exudation of lymph. Beyond the line of the exuded lymph which glues the two surfaces together, the changes are very limited, an infiltration of leucocytes and plasma cells supervene, connective tissue cells develop, and a permanent union of the structures is effected. Upon the cutaneous surface the epithelial cells interblend, and this process of healing, even in wounds of considerable size, may go on almost without constitutional disturbance, pain, or edema.

In wounds of important structures and of considerable extent, there is generally a prompt reaction, exhibited by a considerable, more or less, rise of temperature, which is explained probably by the reflex disturbance of the nervous centers. Within limit this may be regarded as a favorable reaction, since within twenty-four to thirty-six hours the temperature falls without serious constitutional disturbance. This must not, however, be confounded with the fever due to septic infection, which usually does not make its appearance until after the third day.

If, on the contrary, the divided structures are not brought into apposition, the space is filled with coagulated blood and serum, and the repair processes become far more complicated. The aseptic blood clot is penetrated by leucocytes and proliferation cells, and, little by little, an organized structure extends through the mass, the so-called healing by blood clot supervenes, which is to say that the regenerative processes, observed in the first instance, take place much more slowly, but effectually utilizing the aseptic blood clot by a metamorphosis of its material in part, and in part by absorption. If in addition to the blood clot we have introduced into the wound a bacterial infection, entirely another class of conditions supervene, dependent upon the character of the infective material. If the wounds are large with much effusion, owing to the development of the bacteria, the blood becomes rapidly decomposed and a large amount of chemic poisoning is produced, the so-called toxins which are absorbed causing a kind of septic intoxication, varying in degree, but which may speedily prove fatal.

In a paper of this limit it is possible to refer only with extreme brevity to the character of the microorganisms with which the surgeon has specially to deal. Fortunately there is less necessity for the description of these organisms than at an earlier period. The staphylococcus pyogenes aureus and albus and the streptococcus pyogenes are almost the only organisms which produce suppuration. The staphylococci in their development produce the typical local suppuration, while the streptococci possess the property of invading the tissues and are, as a consequent, often-

times eliminated with much greater difficulty, causing the acute forms of septicemia and pyemia. Other varieties of microorganisms not seldom develop in wounds, especially the putrefactive bacteria and although their organisms can not penetrate into, or reproduce in, the structures, the toxins which they produce may cause very serious constitutional disturbances. The developing cocci induce a rapid liquifaction of the albuminoids and thus break down the blood clot, and organizing lymph. Thus the toxic chemic material evolved in their growth may act as a local poisoning, devitalizing the surrounding structures, producing coagulation-necrosis. In the surrounding structures a complex process supervenes owing to this toxin infiltration, causing the so-called processes of inflammation, dwelt upon at great length by the earlier writers. There is much yet to be learned in reference to the changes which ensue about the infected wound structures, and from this standpoint the whole subject of wound inflammation needs to be rewritten.

The streptococci extend along the lymphatic vessels and lymph spaces and, when introduced into the blood, growing as they do in long chains, they have a tendency to form emboli in the smaller vessels, and thus set up new centers of suppuration at very considerable distances from their original seat of invasion. On the contrary, the staphylococci, developing locally are soon surrounded by a living wall of leucocytes, which impede the further dissemination of the invading enemy, and the contest goes on *in loco*, and the result of the battle will depend upon the vigor of the antagonists. Hence the practical importance, which must always be apparent, that the surgeon devitalize as little as possible the tissues in operative interference. It is indeed well known that it does not of necessity follow that a few microorganisms thus introduced will reproduce to the detriment of the individual; the superior vitality of the tissues may enable them to destroy their enemies *in loco*, and the processes of primary repair may go on uninterruptedly.

How a certain limited number of microorganisms can be destroyed in a wound, is a question of intense interest which can not be discussed here, beyond the fact that a phagocytic action of cells does supervene under certain favorable conditions and the bacteria fail of development. Of course, much depends upon the vitality of the surrounding structures and the non-presence of the proper pabulum or soil for bacterial growth. It is a fact that any considerable blood clot in the wound infected by developing bacteria prevents primary union.

Inferences of practical importance are clearly drawn from the above facts in regard to the manipulation of wounded structures. Let all incisions be cleanly made with a very sharp knife, avoid the still too common practice of seizing and holding considerable portions of tissue with compression-forceps for the arrest of hemorrhage. Protect the structures carefully from tearing in the separation of wounds, as, for example, in the use of retractors in laparotomy, and perhaps more important than all, be careful in the adjustment and captation of like structures when suturing in the closure of wounds.

It is no excuse, however, for careless surgery that bacteriologic demonstrations show that a few bacteria, even of the pathogenic varieties, when planted in healthy tissues, may fail to reproduce, although

this is the probable explanation why some of the so-called "clean surgery" well performed without rigid aseptic precautions is not rarely followed by primary union.

Just at present, the profession is undergoing a transition state by the more or less general acceptance of the influence and power, which certain chemico substances, the so-called toxins produce. Blood serum affected by these is believed, upon that which many accept as good authority, to possess an inhibitory power to prevent in some way the development of the bacteria within the organism. It seems very probable that this fluid in the healthy body is far more potent in the protection of the individual from the invasion of bacterial enemies than was earlier supposed.

The military student may well profit in his studies of defensive warfare from a careful investigation of the wondrous way which nature has in defending her outposts from the invasion of bacterial enemies.

The thoughtful investigator makes the inquiry, wherefrom come these invisible hordes which endanger the individual at every infraction of surface? The aerial ocean in which we live and of which we must ever breathe is, it is true, rarely without deleterious bacterial organisms, but by general consensus of opinion, based upon abundant demonstrative evidence, these organisms are much less potent for ill in surgery than was earlier believed, and it is not less certain that the all-invading bacteria, contaminating clothing not worn upon the person, and water as usually found in hydrant service contain less dangerous elements than was at first supposed.

It is due in large measure to the very valuable experimental researches, carried on in the bacteriologic department of the Johns Hopkins University, that we have the most important demonstration that the all-pervading source of the pyogenic bacteria is found in the dead and dying epithelial cells. Indeed, it appears that nature with a rare temerity has subjugated this all common enemy and drafted it into her service for the purpose of removing the no longer serviceable plates of the armor with which the organism is clothed and protected. Within certain limits these invisible agents are permitted to riot and with insatiable avidity seize upon every dying epithelial cell, the demarcation line existing in the cell whose inherent organic power is greater than that of the overlying enemy. Hence the surgeon finds at the very door the ever-lurking foe, and the problem of their destruction is of comparatively easy solution with the abundant agencies which are at his command. For the destruction or removal of the bacteria invading the skin, antiseptic measures are of the greatest advantage and even necessary. In their use we find the easy explanation of the seeming difficult question of the good results obtained from different methods. One operator cuts short the finger-nails, soaks and scrubs with hot water and soap, until by a process of maceration he has loosened and detached the infected epithelial cells, and stands out as the bold apostle of cleanliness, having demonstrated, as he thinks, that soap and water are sufficient.

Another repeats the experiments of the early great master, Mr. Lister, and declares that the maceration of the skin of the patient, for some hours, with a watery solution of carbolic acid, is ample. Thus the cleansing process has been varied by the use of many substances, to each of which has been ascribed the

protective power. To all this questioning and experience the laboratory investigation gives the one definite answer, By some means remove or destroy the loosened, worn-out, epidermal cells. The demonstration seems conclusive that the great enemy to all surgery, the hand of the operator, is best disinfected as first taught in Baltimore, by the use of solutions of permanganate of potash and oxalic acid.

If it be true, that permanganate of potash in solution does not color the living cell, and that all devitalized epidermal structures are invaded with pyogenic cocci, then the demonstration is ample, that the hands of few surgeons, relying only upon the ordinary processes of washing with soap and water, are likely to be surgically clean. These epidermal cells, however, may remain so adherent even after the processes of washing and scrubbing have been thoroughly practiced, that a prolonged operation may not cause their loosening and transplantation into the operative wound.

From these investigations we also have the knowledge of the more usual forms of contamination found in hospitals and the ordinary bed-chamber. Proliferating epithelium of the skin becomes disseminated and may prove a source of contamination through the infection of both the air and water. In this way instruments, sponges, and clothing are generally infected.

From the above it is easy to determine why the older forms of wound dressing were so invariably productive of suppuration; the bacterial development went on under the watery dressings and especially poultices, these proving hot-beds of infection.

The destruction of pathogenic bacteria during their period of rapid development is comparatively easy. Moderate changes of temperature affect their growth, and various chemico substances, even in weak solutions, produce their death, but those varieties which reproduce by spores are among the most resistant of living organisms. Exposure at the freezing point, immersion in boiling water for a considerable period often have little effect, but fortunately the surgeon very rarely has to deal with the spore-producing forms of bacteria. All the pyogenic cocci do not reproduce by spores; were it not for this fact it would seem almost hopeless to adopt methods of wound treatment which could successfully prevent the most fatal consequences, such as would follow were their common enemies of a type of which anthrax, tetanus, and tuberculosis may be cited as examples. But here also we find the knowledge of the life histories of these comparatively recent known enemies to mankind most valuable, since the spore producing bacteria are of much slower development which renders it easier for the wounded organism to resist their depredations. Comparatively weak solutions of bichlorid of mercury from 1 to 1000 or 2000 or a 2 to 5 per cent solution of carbolic acid are ample to destroy the pyogenic cocci, if the exposure is complete. These pus-forming agents, however, are quite completely protected by the fatty products of the sweat ducts, unless the watery solutions are for a very considerable period retained upon the skin. This is especially true of the mercuric solution, probably the most efficient antiseptic agent in general use, since the power of penetrating the epithelial cells is far less than that of carbolic acid. Hence in skin disinfection we note the importance of soap, alcohol, ether, turpentine, etc., as valuable adjuncts.

The only class of wounds which this occasion affords the opportunity for discussion is that in which the surgeon is enabled to operate through previously unbroken, undeveloped, superficial structures, and where the wounded parts can be brought into complete approximation. Theoretically under such conditions primary union must ensue, and where this fails from the occurrence of suppuration, as I stated in the beginning of this paper, there has been some fault in the technique. The rule prevails in the treatment of the structures after they have been submitted to surgical interference in precisely the same formula as tersely stated for the treatment of a simple fracture, *fixation, retention and rest*, and as in a simple fracture the wounded structures must be without septic infection.

This naturally leads to the discussion of the terms aseptic and antiseptic, used with confusion, without a correct appreciation as to their meaning, and perhaps it would be better if both terms were entirely discarded. The problem is to make and maintain a wound without infecting the structures involved. This surely should leave the parts *aseptic*, that is free from pyogenic organisms.

In order to do this, it is equally clear that the circumference of the wound, the instruments, sponges, suture material, and hands of the operator must be free from septic organisms. To effect this the various means at our disposal, by which we sterilize the materials in use may still be called *antiseptic*, the name first given to these processes by the great master of modern surgery. I have already entered into the discussion of the infective bacteria as much as the time at my disposal permits, sufficient indeed to point out their danger. Important practical deductions from this teaching are comparatively simple, but most definite in character, and, although there will probably remain yet an infinity of variation as to detail, the great fundamental principles of this class of wounds and their treatment may be considered settled. First, and most important is the disinfection of the skin of the patient and of the hands of the operator. It will be remembered that the cocci growing in the skin penetrate as deeply as the devitalizing processes of the epithelial cells; that the sebaceous and hair follicles are yet more deeply invaded, and that they are here protected from destruction to a certain extent by the glandular and fatty products.

It seems almost superfluous to refer to careful experiments, often repeated, which show that soap and water, applied with the minutest care fail to disinfect the glandular structure of the skin, and, if this is true, although these measures are of the greatest importance, the processes of so-called simple cleanliness are not sufficient. Therefore we must call to our aid some of the various antiseptic agents long since proved trustworthy. The first of these is carbolic acid, objectionable because of its irritating character. It is found, however, that this very irritation of the skin is owing to its penetrating power upon the epithelial cells, and the glandular structures. It has an affinity for oily products and easily impregnates fatty substances. In this respect it is much more efficient than even considerably strong solutions of corrosive sublimate, but in the glandular and hairy portions of the body even the 5 per cent. solution of carbolic acid must remain in contact for a considerable period to disinfect these portions. For this pur-

pose a 10 per cent. solution of oxalic acid is far more trustworthy. Cultivations made from the scrapings of the skin after having been treated carefully with oxalic acid solutions show the epithelial *débris* to be invariably sterile, even when the material to be tested is taken from the deep folds of the finger nails.

The use of the razor is important even where there is comparatively little hair to be removed. The repeated soaping of the parts softens and loosens the epithelium, which the scraping of the razor easily removes. To the soap, carbolic acid and bichlorid of mercury may be profitably added. If possible, these details should be carried out before etherization, because of the saving of time and the more thorough manipulation permitted when haste is not demanded.

Instruments are easily disinfected by heat, which is preferable to immersion in disinfectants, since the damage to the instruments is less than by a considerable period of immersion in antiseptics.

The preparations thus far completed, it now remains properly to protect and care for the patient in order that, during the operation, the surroundings of the parts to be operated upon may be also sterile. This is best effected by packing about with towels sterilized by heat, or by immersion in antiseptic fluids. I prefer the latter, towels wrung from a solution of 1 to 1000 of bichlorid of mercury, since they remain in position much better when wet than dry. It is also important to have on a table near the operator dishes containing solutions of bichlorid of mercury in which the instruments and hands may be occasionally dipped.

I use irrigation much less than formerly, but I am very sure I have seen no ill results from the so-called chemic irritation of warm solutions of corrosive sublimate, even in strength of 1 to 1000, and I am confident that much less damage to the injured parts ensues from it than from the irritation caused by frequent sponging. When the proper technique is faultless, it is very likely that sterilized water is of equal efficiency, but my experience teaches me that the damage from the so-called chemicals, if properly applied, has been greatly overestimated. To one who is an imperfect master of technique I can not question but that the use of weak antiseptics and hot irrigating fluids is of great value.

There can be no question but that marine sponges have been a common source of wound infection, and I do not wonder that operators, who can not first supervise details, have learned to rely on the gauze pad as a substitute, since these are easily sterilized by heat during the preparation for the operation. They are, however, far inferior in their absorptive power and a possible source of conveying lint into the wound.

It is very unwise to continue the use of sponges that have been used in septic wounds, but sponges carefully disinfected may be continued in repeated use with safety in aseptic wounds. Sponges should be thoroughly washed in cold water and after repeated washings with soap and water, I prefer soaking them several days in a 5 per cent. solution of carbolic acid, changing the acid two or three times. They are then put into a jar containing this solution and kept until required for use. This process is conveniently varied sometimes by carefully bleaching in an oxalic acid solution. They must, however, be carefully watched, for if kept too long in it the integrity of the sponge is impaired. If preferred, the sponges may be dried

in a muslin bag wrung from a 5 per cent. solution of carbolic acid and kept in a sterilized jar until required for use. They should then be put into a solution of 1 to 1000 bichlorid of mercury at the time of preparation for operation.

I consider it rather disadvantageous than otherwise to delay the operation by seizing every small bleeding vessel with compression forceps. Slight pressure will usually suffice and the tissues are far less devitalized than by the use of the forceps. This careful attention to the arrest of hemorrhage is also much less important, since the closure of the wound with buried sutures acts as a sufficient hemostasis. I seldom use ligatures except for the larger vessels, adjusting the sutures so as to include all special bleeding points.

Since the introduction of antiseptic surgery, little by little the treatment of the wound *per se* has been radically changed. The drainage tube is thought far less important, although unfortunately its use is still far too frequent. It is now judged wiser carefully to coapt the wounded surfaces and by some means hold them in fixed apposition. The still too common practice is, to effect this by the use of interrupted superficial skin sutures, and hold the adjacent parts firmly in place with compression bandages. These are supposed to consist of antiseptic dressings, applied in the form of pads to serve also the purpose of absorbing deleterious wound secretions.

Nearly twenty-five years have elapsed since I began my experimental studies upon the burying of animal sutures for the coaptation of wounded surfaces and fixation of the same at rest during the processes of repair. The results of these investigations are now very generally known, and the adoption of buried animal sutures gives promise of becoming universal. The catgut suture was the first employed and almost the only material used for some years, but a much better substitute is found in the tendon of animals, preferably that from the tail of the kangaroo. In the tendons of animals the ultimate fibers are disposed parallel to each other and in the processes of preparation the cement substance which holds them in apposition should remain unimpaired. In the connective-tissue sheath of the intestine of animals, the function of the parts demands that the fibers should be obliquely interlaced, and this sheath must of necessity be separated from the other coats of the intestine by the macerating processes dependent upon bacterial growths. When subdivided, these flat bands of connective tissue are not unlike oblique strips of the most delicately woven cloth which have been twisted into string and allowed to dry. When dry, it is comparatively firm and strong; when wet, elastic and yielding. The putrefactive processes of maceration have necessarily made it a hot-bed of bacterial growths which, beside being detrimental to its inherent properties, must necessarily be subjected to processes of disinfection. These may be satisfactory, but the resultant product does not furnish reliable material for buried sutures.

On the contrary, the tendon suture softens very slowly in watery solutions and does not swell and become yielding when buried in the structures. As a consequent, the knot, if used as a ligature, is as trustworthy as that of silk, and a tendon of the same weight and size is very much stronger. When properly chromicized, the tendon suture undergoes a very slow metamorphosis when buried in the living

tissues, and weeks after its insertion, the line of suturing is easily traced. It is speedily surrounded by leucocytes and plasma cells which, little by little, invade its structure. This imbedding material is slowly changed into connective tissue cells which replace in large measure the suture material itself, thus coaptating and holding in position the sundered structures by a living bond of a permanent character.

The importance and value of these resultant physiologic processes have, for some reason, never been duly estimated, especially in the restoration of certain portions of the body, as for example, in hernia, laparotomy and in the suturing of tendons; in fact, in any part, where undue strain is likely to supervene in the restored activities of the individual.

The application of the buried suture may be effected in various ways. Where, for instance, it is desirable to coapt and hold at rest all the sundered structures, especially if they are liable to be hemorrhagic, the double continuous suture is of great importance, double, so that the tissue may be equally and evenly included and the coaptation perfect. This is best taken with a stitch similar to that of the shoemaker in his hand-sewing with a double thread. It is my habit thus to suture the peritoneum, the aponeurotic structures in laparotomy, hernia, etc. A continuous suture has a distinct advantage over the interrupted, in that we reduce to the minimum the knots which from their undue size ever act more or less as irritants. A great advantage results from the even adjustment of the parts, since in continuous suturing the compression must be the same along the whole line of stitches.

In the application of buried sutures, it is of the first importance to remember that we do not use undue constricting force, since we are dealing with vitalized structures in which the circulation must not be unduly impaired. The same force applied to a buried suture as is to often, perhaps generally used, in the application of interrupted cutaneous sutures is very likely to be followed by a process of local necrosis, although the included tissues are aseptic.

For the coaptation of the majority of wounds, the single running suture is to be preferred, as in illustration, after the excision of the breast, the amputation of a limb, etc. I find these best applied by the use of the larger-sized, full-curved Hagedorn needles, carrying the suture deeply from side to side. In this way, coaptation is perfect, the suture is buried in undevitalized structures and crosses the wound only at right angles. It is surprising to note the apparent ease with which nature cares for numerous sutures applied in this way. They may be used freely, but should be minimized sufficient for the coaptation of the parts, adjusting, as far as possible, like structures. Such coaptation of the divided structures leaves no open spaces or pockets to fill with blood or serum, and being aseptic, the use of the drainage tube is worse than superfluous. It withdraws from the wounded surfaces the very exudates that nature furnishes for the purposes of repair; it leaves of necessity a wound open to the extent of the drainage material applied, leaving a route for the possible access of infective material. He who drains an aseptic wound where coaptation of the sundered structures is possible, does it invariably to the damage of his patient. Fortunately, this practice is lessened each succeeding year and the time is not far distant, when, under these conditions, drainage will be absolutely abandoned.

Aseptic wounds should be completely closed at the time of operation. Referring to the bacteriologic conditions of the epidermis, it will be readily noted, what are the advantages arising from the closure of the skin itself by a buried animal suture, which I have advocated for these reasons for many years. A sharp Hagedorn needle, armed with a fine tendon should be introduced from side to side of the incision, through the deeper layers of the skin only, parallel to its cut edges. Each stitch must be taken exactly opposite the emergence of the preceding one, the emergence of the last stitch being through the skin at a considerable distance from the extremity of the wound. When the distal ends of a suture thus taken are drawn upon, the coaptation is as perfect as the seam in a well-made garment, and nothing further is required in the way of dressings, except the application of the collodion seal, which is rendered still more effective by its reinforcement with a few fibers of absorbent cotton. An aseptic wound thus carefully treated, even to the major amputations is subsequently very nearly painless, the parts are not edematous, and the collodion dressing is loosened by the exfoliating epithelium in about ten days. The scar is minimized and is oftentimes scarcely perceptible. This fact alone is no slight desideratum, especially in the exposed portions of the body.

My own experience is now ample to emphasize this method of wound treatment which I, some years ago, first introduced to the profession. Step by step it was carried out, as the result of inductive reasoning on my part, reinforced by my experimental studies upon the lower animals. Happily these methods, which were at first critically considered, as belonging to ideal surgery, have been abundantly confirmed by the experience of many surgeons, and are now advocated as practical, yea even obligatory.

It takes rather longer to close a wound as described than by the methods still too commonly in practice. However, the work of the surgeon is finished when the patient leaves the operating table, and the subsequent nursing is minimized. Economy is subserved in the abolition of all clumsy dressings, while the danger of subsequent infection of the wound is absolutely prevented. The period of detention in bed is greatly lessened, perhaps in a large class of wounds altogether avoided, and the subsequent requisite care on the part of the surgeon and his assistants is minimized to a degree in striking contrast with that of ordinary hospital service.

REPORTS ON TYPHOID FEVER.

Read in the Section on Practice of Medicine, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY J. E. WOODBRIDGE, M.D.

YOUNGSTOWN, OHIO.

When I first publicly declared that "death is a wholly unnecessary consequence of typhoid fever, and that every case in which proper treatment is instituted sufficiently early in the course of the disease can be aborted," I stated also that "I fully appreciated the disgrace and ignominy which would await me" should I be found guilty of promulgating a false doctrine. I knew that I was speaking a language which would be utterly unintelligible to the greatest thinkers in the profession, and also that it would have been so to me, but for the *eclaircissement* of many years of experience. As it took so much evi-

dence to convince me, 1, that *any* case of typhoid fever could be aborted; 2, that *any severe* case could be aborted; and, finally, that *every* case could be aborted, and that death from the disease could be always averted; I can not understand how, without the most indisputable and undeniable proof, these claims can be admitted by any physician, who had been taught as I was in my youth, to regard typhoid fever as a "specific infection," possessed of some occult power of resistance to all curative treatment, which it was hopeless, if not flagitious, to attempt to counteract, and bestowing the title of "quack" upon any one making any pretension to having succeeded in so doing.

I shall, therefore, endeavor, in this report, to present the strongest available evidence, not only that the declaration is true, but, that which for want of a better name I have designated, antiseptic medicine, has a reserve power for good that I have not even mentioned; for this purpose, I wish to reproduce the verdict of a few of the many physicians who have treated by my method a large number of cases of typhoid fever; and also to note some of the most characteristic or otherwise interesting cases which I have treated since our last meeting.

Desiring to give every facility for the formation of a just estimate of the value of my statistics, I have invited the closest scrutiny of my cases of typhoid fever; have ever held myself in readiness to demonstrate the correctness of my theories in hospital or in private practice; at home or abroad; and I have requested the publication of any failure on my part to do all that I have been teaching the medical profession that it ought to do. I have also promised to present a "Report of Cases" before some great medical society each year, until a general assent has been given to the accuracy and truth of my theories, and death from typhoid fever is unknown; and when long-continued constitution-destroying sickness from the disease shall be regarded as a disgrace to the individual practitioner, and not, as at present, a reproach to the great body of the medical profession.

During the past year, as during the preceding thirteen years, I have had no death from typhoid, malarial or any continued fever, or following any pathologic condition which could by any possibility be mistaken for either of them, and I have failed in no instance in which the patient has come under my care before the eighth day of sickness, to abort the disease.

Since my return from San Francisco last July, I have treated, alone or in consultation, fifty-eight well-marked cases of typhoid fever. Of these cases some occurred in Youngstown, or the surrounding country or towns; some in Pennsylvania, some in northern Ohio and some in other States, and no doubt existed, in any instance, in the minds of the attending or consulting physicians, as to the correctness of the diagnoses. I have, during the same time, aborted the disease in a large number of cases of which no charts were preserved.

During this period, there have been reported to me, as treated by other physicians, acting under my advice, given orally, in consultation at the bedside, by letter or otherwise, about eight hundred cases of typhoid fever, with nine deaths; a marvelously good result when it is remembered that they were sailing on an unknown sea, with no pilot to steer the course; that they had unshipped the rudders, thrown over-

board the compasses and were endeavoring to weather, unaided, the fiercest storm that could ever strike the ship—having learned that all recognized methods of treating typhoid fever are so valueless that the cleverest men deny the possibility of doing what 117 physicians have done and are doing every day, viz., curing the disease;—they abandoned all of the procedures with which they were familiar, and with only a brief outline of my *modus operandi*, which must necessarily have proved a most insufficient guide; yet there were enough earnest and conscientious physicians, whose keen insight and mother-wit enabled them to follow these rather incomplete directions to a successful issue in so many typical cases of typhoid fever as to afford me conclusive evidence that the disease can invariably be aborted and every life saved; and which should also carry conviction to the mind of any intelligent physician who will carefully and impartially weigh these reports with my fuller treatises on the subject.

While neither these accounts nor my own observations have added anything to my knowledge of the power of this so-called "antiseptic medicine" to abort typhoid fever when the treatment is begun early in the course of the disease, they have served to convince me that in my original declaration, I did not place too high an estimate on its value. They have done more—they have strengthened in my mind the belief that even in *late* stages of uncomplicated typhoid fever it has power to eliminate all ordinary causes of death, save the accidents of hemorrhage and perforation; and to minimize the danger of their occurrence.

An analysis of the failures in a test of any given method is sometimes more instructive than an equal number of successes would be; and as that happens to be quite true in this instance, the following abstract of cases of typhoid fever, coming as they do from disinterested observers, may possess for this reason a higher import than would the report of a much larger number of universally successful cases from my own practice.

In one large hospital in which the observer held an honorable position under the Government of the United States, several exceedingly serious cases were aborted by the "Woodbridge method," but finally a death occurred, for which catastrophe I could find no excuse, until I discovered that the patient had taken at three hour intervals, the extremely minute dose which I had advised to be given every fifteen minutes.

An instance of the lack of that discernment so requisite to success in so difficult and delicate an undertaking, is well pictured in the following quotation taken from the epistle of an apparently conscientious, just and high-minded gentleman: "The patient had been sick several days; had a morbid appetite; complained of being 'so tired,' chilly, headache, etc., before consulting a physician. I gave him a simple laxative pill containing colocynth, podophyllin, aloes, etc., which had a tremendous effect, so much so that I had to interfere with remedies. His temperature rose to 104.5. I 'pushed' large doses of quinin upon him and for two days the fever stayed away, and he got up and walked about the place. This was against my orders and he was soon compelled to go to bed; real typhoid fever tongue; some tympanitis; high temperature. I began giving guaiacal and eucalyptol, as recommended by you, but mixed with bismuth. He was sponged freely and given 4

ozs. Walker's best whisky. He died that night at 11 o'clock."

The writer closes this eight-page account of his experiences with the "Woodbridge method" of treating typhoid fever with: "Now in this case your powder was not used. All your other suggestions were followed." Were they? The patient did not consult the doctor until he had been sick "several days," and he was then given a "simple laxative pill which produced a tremendous effect;" then "large doses of quinin were 'pushed' for two days"—and finally he was given *two of the ingredients* of my formulas, but not those which to his patient were a veritable "*sine qua non*," i.e., "the play of Hamlet with Hamlet omitted."

Thus in these illustrations one can easily see that not only were the minutiae of my instructions unmistakably disregarded and neglected, but the chief essentials were likewise overlooked to such an extent that neither these deaths nor others occurring under like circumstances should be charged to the "Woodbridge treatment."

Dr. W. T. Dodge, of Michigan, has written me several letters which I consider most valuable contributions to current medical literature, and which I am unfortunately prevented from giving in full, by want of space in the JOURNAL. He says: "I have seen three fatal cases this year, but none of them were uncomplicated cases, though I suppose none of them would have died had it not been for the typhoid element. One case was admitted to the hospital in the second week, as near as we could ascertain. He said he had been sick two weeks; and he had a temperature of 104.5 degrees when admitted. We gave him your formula No. 1, until free catharsis was produced; then the guaiacol and eucalyptol combination in gradually increasing dosage, until he took 5 m. of guaiacol and 10 m. of eucalyptol every two hours. His temperature came down in a few days to nearly normal, but he had severe diarrhea, and pain in the abdomen; became wildly delirious; then comatose, and died about ten days after admission. An autopsy revealed a great many ulcerated Peyer's patches, and a general enteritis as well.

"The next fatal case was also admitted in the second or third week. It was impossible to learn just how long he had been sick. He also had pneumonia when admitted and in the course of a week succumbed to the two diseases. Autopsy showed ulcerated Peyer's patches in abundance. He was given the same treatment as the other case, in the same manner, with addition of appropriate medication for the pneumonic complication. The third case I saw in consultation and was in the private practice of Dr. B. The young man had been sick two weeks, when Dr. B. was called, and had been starved and treated by a 'quack' who 'starves fevers.' He was much reduced and had a hemorrhage the day Dr. B. was called. I have had five other cases that have recovered. Two of them were aborted in the proper sense of the term, and in three, where the treatment was begun about the tenth day, I am satisfied that the course of the disease was modified for the better. I have never before attended cases of equal severity that passed through the disease in so short a time and made so nice a convalescence as did these three cases.

"Two cases (and they were the only two in which I was able to begin the treatment during the first week of illness) were certainly aborted. One of them lived in a neighboring town. I visited him first one

evening, and found that he had been sick four days and had a temperature of 103 degrees. I gave him four grains of quinin, to be taken during twelve hours. The next night he had a temperature of 103.5. I placed him on the powder in half hour doses for twenty-four hours, then 3 minim doses of guaiacol and 6 minim doses of eucalyptol every three hours. I did not see him for forty-eight hours, when he had a temperature of 100 degrees. I did not see him at all after that, but he continued the guaiacol and eucalyptol mixtures steadily and a week later he came to my office, when he had a temperature of 100 or a little less; and had an abundant rose eruption over the abdomen. I ordered him to continue the

this position. I have, however, great faith in the treatment when it can be begun early; even in the second week I think it will generally very favorably modify the course of the disease."

An extract from another letter from Dr. Dodge, dated April 27, 1895, is as follows: "All of the cases of uncomplicated typhoid fever that I have treated in this manner recovered in a much shorter time than such cases have ever done with me before. The two hospital cases that died were complicated, the one with pneumonia and the other with severe enteritis, as the autopsy disclosed.

"The fatal case that I saw in consultation with Dr. B., properly should not be included in your list, as he

Dr. Udell's Case No. 1.—Iva M., age 14 years. Date of admission, July 25, 1894. Treatment: gave alteratives and quinin during first part of sickness; began Formula No. 1 on the tenth day of disease.

mixture as long as he had any fever and I have not seen him since. The other case simply had fever that did not yield to quinin, but was aborted speedily by your treatment. Some might deny this case being one of typhoid fever, as there were no pathognomonic symptoms, but at any rate she had some kind of fever, attended with diarrhea and epistaxis. Quinin had no effect on the temperature, even in large doses, and the fever disappeared two days after the guaiacol mixture was begun. I think the system may be so impoverished by the toxins absorbed in the blood, that no treatment will avail to save the life of the patient, and the three fatal cases I have described may be considered as evidence supporting

had been 'starved' by a homeopath for two weeks and had a profuse hemorrhage from the bowels before Dr. B. was called. He died within forty-eight hours of the time I saw him, and there was no time to get him under the influence of your medicine. Our efforts were principally directed to stimulation and to try to get him out of the state of collapse. Incidentally your formulas were administered but without any idea that it was a fair case to try them in. I merely reported it to you as an instance of the terrible condition in which we sometimes receive these cases. I also rather wished to warn you to dwell upon the necessity of giving your treatment early in the course of the disease, which you have done in

later papers. I found some who thought from reading your articles that you claimed any case might be cured, no matter in what stage the treatment was begun. I was well aware that you had not claimed any such thing, but I desired to call your attention to the fact that some persons had drawn that inference."

Dr. C. N. Udell, of Iowa, wrote me on April 19, 1894, seeking for an outline of my treatment of typhoid fever. This letter was answered in its turn on July 3. On August 25 I received a letter from which I quote the following:

"The first trial was in Case No. 1, Iva M., aged 14 years. The inclosed chart will show you the range of the temperature. This was rather a grave case with bad hygienic surroundings and poor nursing. I did not begin the antiseptic treatment until she had been sick nine days. She made a good recovery, but the case ran some weeks and could not be called aborted.

"Case No. 2, Frank B., was sick when I was called and I then diagnosed typhoid fever. He had the usual prodromic symptoms—with all the phenomena of true typhoid following. I put him on your formula No. 1, and continued that most of the time. In one week he was about well.

"Case No. 3, Mrs. C., was employed as nurse for Case No. 1, in the latter part of her illness. She is now sick with typhoid fever in rather a mild form; yet unmistakably typhoid fever. I think from the present indications, she will run the course in about fourteen days. Treatment: formula No. 1 is given most of the time; No. 3 when the bowels are too loose.

"I have been using the same treatment in cholera infantum with good results. I have procured what is supposed to be pure guaiacol and eucalyptol, but find it difficult to give this to children, the taste is so horribly bad. Some children strangle badly on it even in small doses. I begin to fear impurity. I believe your theory is correct."

Dr. Udell sent me on March 22 another report of cases. He says: "I will give a brief report of a few cases, selected from among those treated with your abortive treatment for typhoid fever. In the management of these, as well as other cases, I relied almost wholly on your prescriptions Nos. 1 and 3, giving a diuretic occasionally when required; also an occasional dose of bromidia when the patient was too restless to sleep at night.

"Case No. 4, A. D., male, aged 42 years, suffered with all the prodromata of typhoid fever for six days without treatment, with the exception of some domestic remedy. I prescribed R. No. 1 for three days; No. 3 for four days; and No. 2 on fourth day. Patient discharged on seventh day, with No. 3 to be continued at intervals of four or five hours for a few days. No relapse. Highest temperature was 103.4. No delirium or eruption.

"Case No. 5, J. C., aged 18 years, taken just as Case No. 4 was, with feeling of weariness, lassitude, constant headache, fever, rigors, foul furred tongue, anorexia, slight nausea, nose-bleed; some diarrhea, tympanitis and tenderness over the abdomen. I was called after the patient had been sick one week, and found that he had taken some cathartic pills. Prescribed R. No. 1 for three days; No. 2 on the third day; No. 3 for one week when the young man began to do light work. No relapse.

"Case No. 6, W. C., aged 20 years (brother of Case

No. 5), with symptoms much the same, so he was treated the same as his brother. No further treatment after six days.

"Case No. 8, D. B., male, aged 21 years, brother to Case No. 7, and taken with the usual premonitory symptoms of typhoid fever. Had taken some cathartic pills on his own motion. I gave him Nos. 1 and 2, and then No. 3 for five days, and he was well, and able to begin light work on the farm. I let him eat anything and all he wanted.

"Case No. 12, Ellen B., female, aged 44 years. Had been sick three weeks with typhoid fever, under the care of another physician. The family and doctor were alarmed and were looking for perforation or fatal hemorrhage. I advised R. No. 1 every half hour for one day; then No. 3 every hour, unless the patient was resting well. Gave bromidia at night if the patient did not sleep. Improvement from the first dose of medicine. Patient sat up in bed on the fourth day of my treatment and was doing some of her own housework in two weeks. I insisted on this patient eating proper food regularly after the first week. Recovery complete. No relapse.

"Case No. 13, Ef. R., aged 23 years, was taken with chills, fever, headache, backache, dyspnea, nose-bleed, anorexia, very dark strong urine; a little blood passed from the bowel. Temperature soon ran to 104.4. Prescribed R. No. 1, with frequent alkaline sponge baths; and flushing the colon every day with an alkaline antiseptic wash. After two days, left R. No. 3, but the patient would not take enough to do any good. Gave very small doses of sugar of milk and was compelled to continue very small doses of No. 3. Patient was up and walked to the dining room on the fourteenth day. Took a relapse and was confined to her room for ten days longer. Continued R. No. 3 in small doses. Patient made a good recovery, but was somewhat fastidious about taking medicine; I could not call this an aborted case. Thus I have given a brief sketch of such cases as would be a fair sample of those treated with the 'Woodbridge method.' The cases I failed to render abortive were those who had endeavored to treat themselves for one or more weeks, or those in which my directions were not carried out according to orders. The one fatal case was doubtless beyond all earthly help when I was called."

On August 13, 1894, I replied to a letter of Dr. H. G. Chritzman of Pennsylvania, giving a detailed account of my method of treating typhoid fever. He wrote me December 20, a letter from which I extract the following: "I have had eighteen cases of typhoid fever this summer and fall. My last case was discharged, cured, last week. In none of these cases was there intestinal hemorrhage, except the first, which I reported to you; and none have died. The most of these cases were not wanting in virulency. I have charts of them and the number of days under treatment was from fifteen to twenty-four. I find also that many of my patients had the disease a week or more before coming under my care. I can not agree with you in reference to the question of giving solid food. Temperature under your method of treatment often becomes normal before the ulcers are healed; care therefore should be used in the administration of solid food. I believe a perfectly clean and normal tongue is the indication for solid food. I found that guaiacol exerts no disturbing influence on any organ except in a few cases; an irritable

stomach rejected it and those cases gave me a little trouble for a while. I believe your antiseptic treatment is the rational treatment for typhoid fever. Under its use the course of the disease is greatly modified; delirium is rare; tympanitis is prevented; the tongue remains moist through the illness; and the intestinal tract is placed in the best possible condition for the healing of the wounds. I am certainly thankful that I discovered your articles in the JOURNAL."

(To be continued.)

IS DIPHTHERIA DOOMED BY THE DISCOVERY OF ANTITOXIN?

Read before the Colorado State Medical Society, June 19, 1895.

BY F. E. WAXHAM, M.D.

EMERITUS PROFESSOR OF LARYNGOLOGY AND RHINOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS OF CHICAGO.
DENVER, COLO.

Probably, with the exception of Koch's tuberculin, nothing has so interested and excited the civilized world as antitoxin, the new remedy for diphtheria. Like all other new advances and discoveries in medicine, it has its advocates who claim it as a specific when properly and timely used, also its enemies who decry its use and proclaim it a huge fraud; others again who admit the value of antitoxin but claim that its dangers more than offset its advantages; still again there are others, and among them Virchow, who acknowledge the dangers of the new remedy and yet claim that the lessened mortality under its use more than compensates for the dangers and risks of its employment. From all this conflicting testimony it is difficult to estimate its true value, but at present date the evidence is decidedly in its favor.

The opponents of antitoxin point to the anatomic lesions found in animals dying during immunization; the changes especially observed in the spleen, liver, kidneys and lymphatics, and also to certain symptoms obviously following the use of antitoxin, the most important being nephritis, skin eruptions, enlargement of lymphatic glands and occasional high and fluctuating temperature. They assert with much reason that antitoxin should prevent rather than produce these lesions and symptoms. They also deny the value of statistics and say that the lessened mortality is due to a lessened virulence of the epidemic at the time of observation rather than to any specific effect of antitoxin. The claim, therefore, that diphtheria is doomed by the discovery of this, one of the most remarkable remedial agents of the present century, can hardly be sustained. If diphtheria were doomed it should no longer exist in those centers of population where antitoxin and other means of controlling the disease are best known and most employed. Diphtheria should no longer exist in Berlin, Vienna and Paris, but on the contrary it is just as prevalent in these cities, although the fatalities may have been somewhat reduced, as before the discovery of antitoxin.

The three great scourges of the human race have been smallpox, tuberculosis and diphtheria; the greatest of all has been smallpox; whole countries time and again have been ravaged and decimated by this disease, and yet while we have an almost certain preventive in vaccination, the disease has never been stamped out. Its ravages have been greatly lessened and an untold amount of suffering and death prevented, and yet the disease still remains and will

continue as long as ignorance and superstition remain in the human breast. This being admittedly true of smallpox, with an almost unfailing and certain preventive, how much more true must it be of diphtheria, for which as yet we have no such panacea.

Antitoxin can in no way be compared to vaccination, for its effect is only temporary, lasting but a few weeks at most. Again, all cases of diphtheria are not applicable for treatment by antitoxin, and I submit that mild cases that would terminate favorably under ordinary treatment should not be subjected to the dangers of antitoxin treatment. Still, again, there are many cases, especially the mixed and septic cases, the most virulent and fatal, that are seemingly unaffected by this line of treatment.

Those who have followed closely the proceedings of the New York Academy of Medicine can not but be strongly prejudiced against antitoxin. Personally, I am convinced of the great value of this new remedy. I believe it is the best remedy that we possess in the treatment of a most dreaded disease, and yet I also believe that it has its limitations. Fancied security is often dangerous; to feel that diphtheria is doomed and that we have an unfailing remedy in antitoxin may lead us to overlook its dangers, to neglect sanitary measures, and to belittle other lines of treatment.

As cases at home are more interesting to us than cases reported at a distance, I beg to allude to the cases treated by antitoxin in Denver. These cases number twenty-one. Fourteen cases were treated by members of the antitoxin committee, appointed by the Arapahoe Medical Society, in conjunction with the attending physicians. Seven are reported to me by the Commissioner of Health, Dr. Munn, to whom I am under grateful obligation. Two cases were scarlatinal and should be excluded from the report, leaving nineteen cases, eighteen of which were proved to be true diphtheria by the bacteriologic examination, with three deaths.

The first death was in the case of an infant of nine months, suffering from surgical diphtheria following circumcision. Antitoxin was employed on the eighth day, and the patient died some five days later. The second case was an infant of seven months; antitoxin was used on the fifth day and the patient died one hour later. The third fatal case apparently recovered from the attack of diphtheria but died of pneumonia seven days after the introduction of the antitoxin. Whether the intercurrent pneumonia was due in any measure to the antitoxin treatment, I am unable to ascertain.

Admitting the value of antitoxin, believing in its efficacy as a most useful remedy, I would still assert that diphtheria is not yet doomed, but will still remain a most dreaded disease. Notwithstanding the new remedy, antitoxin, and its great value as a therapeutic agent, we will still have need of the most rigid sanitary precautions and preventive measures as isolation, disinfection and cleanliness. We shall still have need of all our resources, sanitary, medical and surgical.

One of the latest and most valuable contributions to the literature of antitoxin treatment of diphtheria has been written by Baginsky and Katz, of Berlin. After reporting a large number of cases treated, they conclude "that, while exerting a most favorable influence in the majority of the worst cases of diphtheria, yet antitoxin is by no means a cure all."

While expressing my conviction as to the great

value of antitoxin, while acknowledging the indebtedness of humanity, for the long and patient and scientific investigations which have resulted in the production of one of the most wonderful remedial agents of the nineteenth century, yet I submit that the affirmative side of this question remains to be proved, and that diphtheria, while it may be mitigated and its perils and fatalities lessened, will yet still exist and will still continue to claim its victims.

SOCIETY PROCEEDINGS.

American Electro-Therapeutic Association.

Fourth Annual Meeting held in New York Academy of Medicine, New York, Sept. 25, 26 and 27, 1894.

WILLIAM J. HERDMAN, M.D., President.

(Continued from page 204.)

A special report was presented by DR. ROBERT NEWMAN, ON CONSTANT CURRENT GENERATORS AND CONTROLLERS.

The attention of manufacturers has been called to the circular of the Standing Committee concerning primary stationary batteries. Some have even received two or three communications, but out of all notified, the Leclanche Battery Co., and Vetter were the only ones who have submitted their cells. But I have tested all which have come under my observation in other ways.

Some of the other battery companies have answered with the following results: Kidder Mfg. Co. says, "that we would be pleased to send you complete description of same—stationary battery—we fear their size would somewhat prevent their easy transportation." The primary batteries generating the current can be selected as to the wishes of the operator. The secondary batteries in preparation for test referred to Mr. Brown, of our committee.

Queen & Co., Philadelphia, March 20, 1894, that they "have nothing to submit for investigation." However, they advertise the Acme Portable Voltmeter, a new type for portable voltmeter for both alternating and direct current circuits. Why do they hold back the instrument if it is good?

The John L. Gish Ideal Rheostat Co., Jackson, Mich., March 25, 1894, that they have submitted their instruments to Dr. Herdman.

A portable alternating current-meter has been made by the General Electric Co.; it comes in 25 to 50 and 200 ampere sizes.

The result of batteries and cells investigated is as follows—Constant Current Batteries: Portable; Stationary.

The Vetter Dry Cell Portable Battery is a very complete one in itself, being nicely arranged and very convenient, having a milliampere meter attached and a rheostat. At first the battery worked very well and was thought to be a success—giving a soft even current—but after standing for a short time, on being tried, found scarcely any current at all. On a later trial found it to be in a much better condition. For a dry cell battery it is fair, but like them, can not be relied upon. If more electric power is needed, any number of wet cells may be added by attaching the extra cells to a wire on the case.

My assistant reports on the battery as follows: "The Vetter Dry Cell Battery I tested and found I could get just $\frac{1}{2}$ milliampere with the 30 measure and 50 milliampères with the 300 measure using a closed circuit of cord. I took the instrument to pieces and found six or seven cells badly corroded and so, of course, it would work but little. The machine has been care fully handled and I see no reason for finding the instrument in the condition I did, if it only corrodes on being short circuited, which it has not to my knowledge, I being the only one using it. However, that is the condition I find, and it needs some new cells."

The Vetter is a nice piece of workmanship and is complete as a portable battery, but my experience is that dry cells are not reliable and the worst of all are the dry chlorid of silver cells with which I have had my worst experience.

Dry Chlorid of Silver Cell. I had a 50 dry cell Chlorid of Silver Battery on which the pole P, marked as positive was, on investigation, found to be the negative; notwithstanding my protest, the manufacturers insisted they were right. At last the error was acknowledged in a communication, Nov.

16, 1891, and the battery came back from the factory in Baltimore—the P. altered into an N.

After a 50 dry cell galvanic battery had been put in thorough order in Baltimore, I left it standing as received and later on, in a trial, found it would give no current at all. The battery was sent back to the factory and the manager acknowledging the inactivity only said: "It must have been used on short circuit"—and no redress given. I never received the battery back and lost it. I consider there is no reliance in a dry cell chlorid of silver battery; the E. M. F. is small and insufficient for electrolysis.

Stationary Batteries: the Waite & Bartlett, cabinet, galvanic and faradic; 40 cells—Leclanche cells.

Run from November, 1888, for three years until the end of 1891, in perfect order. Was used every day, often for hours, but mostly with light current. After three years constant use the cells were only filled and somewhat overhauled. In November, 1893, after five years, the cells were thoroughly repaired and new zincs put in. The cabinet is very convenient, easily handled while sitting, has reverser, interrupter, resistance and faradic battery. Milliampere meter is attached on top of case. I consider this cabinet most convenient for my use.

The measurement of cells has been made and reported on last year by Dr. Herdman as chairman of this committee with such care and accuracy, that scarcely anything more or better can be added. My own experiments as far as I could pursue the same without the necessary facilities and laboratory confirm Dr. Herdman's measures, and the following is only reported here by order of the chairman of this committee, serving as a supplementary report.

Generating cells—axo cells. (Leclanche Battery Co.) I have now in use the axo cells made by the Leclanche Battery Co., 111 to 117 E. 131st Street, New York, in both my Providence and New York office, which has given entire satisfaction for medical work. The axo has all the advantages of a sealed cell. The flange of the cup closes the jar and prevents evaporation, so that, when once put up, with care the cells may run almost a year without any attention. At the same time there is sufficient room for the escape of gases through grooves in the sides of the carbon. The electromotor force is 1.60. The internal resistance is 1 ohm.

Closed circuit measurements of one cell through the Whitney volt meter and Whitney ampere meter.

Vole Cell. (Leclanche Battery Co.) Warner gage 36; voltage 1.52; ampère 2.2.

Gonda Cell. (Leclanche Battery Co.) Warner gage 26.5; voltage 1.5; ampère 1.95.

Sampson Cell. Warner gage 26.5; voltage 1.4; ampère 4.

Law Cell. (Regular.) Warner gage 7.5; voltage 0.9; ampère 2.9.

Mesco Dry Cell. Warner gage 17.5; voltage 1.4; ampère 2.

Edison-Laland Cells. Providence, R. I., Feb. 1, 1894. Present, Newman and C. E. Bourn. Six large Edison cells for galvano-cautery. Room 68 degrees F., 9 o'clock, A.M., Weston A. M. meter.

Rheostat in, gave 4 ampères. Rheostat all out, full current and strength of battery $8\frac{3}{4}$ ampères. Rheostat in to one-half, 5 ampères. Rheostat in $3\frac{1}{2}$ ampères. Hence polarization. Jan. 18, 1894, 11 A.M. The same Edison cells—six—for galvano-cautery in series. Present, Mr. Hughes, C. E. Bourn and Newman. Weston's voltmeter, 3 cells in front; 2.75 volts; 3 cells in back row 2.75 volts; 6 cells together 5.14 volts. Temperature of room 63 degrees F.

Edison Small Cells. 50 cells galvanic battery. 25 cells, 22 volts; 25 cells (other), 22 volts; 50 cells (all), 44 volts.

Feb. 1, 1894, 10 A.M., room 70 degrees F. Weston's A. M. meter; 50 cells, Edison galvanic battery, 1 ampère. 40 cells, low tension gravity cells. Weston's A.M. meter $\frac{1}{2}$ ampère. Jan. 18, 1894, Weston's voltmeter 33 volts.

The Wottin Transformer has to be investigated. Has been sent to Dr. Herdman. On an alternating current of 52 volts. It can be made for the Edison street current of 110 volts. They have no meter to measure. June 15, 1894. It heated all my platinum burners, some very heavy ones, made for testing more than for therapeutic use. It also heated well my galvano-cautery sound. It can be used nicely for illuminating. It will light two incandescent lamps, and at the same time run two fans or drills where the motors are suitable, and still supply the transformer.

Rheostat and Controllers, etc. The Vetter Rheostat is a very good instrument when weak currents are used. I have not found a better one. However, the disadvantages are, that at strong currents it may burn out; that on looking at it you never know if the rheostat is off or on. It must be

turned and an expert may get used to handling it, but it has no visible starting point and in a hurry you may deceive yourself, and give your patient a heavy shock, thinking the rheostat is all off when in reality it is turned on.

Willms' Current Controller. Has three patents, May 24, 1892, No. 475,529. The principle looks well, but it works irregularly; when it arrives at the last fourth and fifth pegs the current is suddenly interrupted and the needle of milliamperè meter goes back immediately to zero, patient feels a shock, third peg needle runs up again. On April 13 Mr. Brown witnessed the same experiment. Several other irregularities are in the instrument. The fault is, the rubber walks easy and thereby drives the brass pegs below the graphite, causing an immediate interruption of the current. Again, the apparent nicety of the graphite being covered is an objection, because if any corrosion takes place the injury to the instrument is covered up and can not be seen and the irregularity can not be adjusted.

The commendable point in the Willms' rheostat is, that the instrument has a starting point fixed, and increases the current gradually in its circular movement, so that looking at the dial the operator knows how much of the rheostat is in or out, or at least is expected to be.

The same observations about the Willms' rheostat have been made by Dr. W. S. Watson, Riverview House, Fishkill-on-the-Hudson, New York, in a letter to Kidder. It has also been demonstrated to Mr. R. G. Brown, Drs. Gish and Herdman.

I annex here suggestions for more uniform investigations by a manufacturer, which I think are worthy of a perusal. They have been sent me by Mr. T. F. Livingston.

SUGGESTIONS FOR INVESTIGATIONS SENT BY A MANUFACTURER.

As to the electrical test for the cell necessary for therapeutic work, allow me to offer the following suggestions, which would prove, I believe, quite valuable in the matter of test:

The Society should note the extreme distance apart the electrodes are placed, and approximate the resistance, and note this as maximum resistance.

Assuming how close the poles are brought together, noting same as minimum resistance.

Averaging a point between the extremes as mean resistance.

Placing this mean amount of resistance in the series when the cells are tested.

Assuming the greatest number of hours per day, some part of which may be consumed by electric applications; noting this as maximum hours.

Assuming the least number of hours per day, some part of which may be consumed by applications, noting this as minimum hours.

Averaging the number of hours between the extremes as mean number of hours.

Thus you would have the average number of hours of the twenty-four, to close the cells through the resistance as noted above.

Again, taking the greatest length of time for one application, noting this as minimum time of application.

Averaging a point between the extremes as mean time of application. This is the unit of time of application expressed in minutes. You would then have the average number of minutes, of each hour of the twenty-four hours, to close and open the circuit, together with average resistance, thus placing cells in a condition similar to actual applications; calling upon cells to perform work, then allowing cells to recuperate.

REPORT ON SECONDARY BATTERIES

was presented by Mr. R. G. BROWN, E.E.

On February 1, a personal letter inclosing a copy of the circular issued by this Association was sent to manufacturers and dealers in storage batteries, calling their special attention to this subject as outlined on page 5 of the circular. The letter was virtually an invitation to send in a sample battery for examination and test and included such information and data as was thought would be of assistance to the party addressed in the arranging of a suitable outfit.

The names and addresses are as follows:

Otto Flemming, 1009 Arch Street, Philadelphia.

Metcalf Storage Battery Co., 417 Myrtle Avenue, Brooklyn.

Franklin Electric Co., Passaic, N. J.

Wadell-Entz Co., 303 Broadway, New York.

American Battery Co., 188 Madison Street, Chicago.

C. B. Eliason, Mount Vernon, N. Y.

Electric Storage Battery Co., Drexel Building, Philadelphia.

Meyrowitz Bros, Twenty-third Street, New York.

Bradbury-Stone Electric Storage Co., 5 Grand Street, Lowell, Mass.

W. A. Vail, 136 Liberty Street, New York.

Pumpelley-Sorery Storage Battery Co., 70 South Clinton Street, Chicago.

Galvano-Faradic Co., 400 Fourth Avenue, New York.

Gibson Storage Battery Co. (W. F. Ford), 315 Fifth Avenue, New York.

Storage Battery Supply Co., Twenty-third Street and First Avenue, New York.

Syracuse Storage Battery Co., Syracuse.

Sorley Battery Storage Co. (Eastern Electric Light and Storage Battery Co.), 37 Market Street, Lowell, Mass.

Hirschmann Storage Battery, 17 Park Place, New York.

Union Electric-Bradley Storage Co., 45 Broadway, New York.

Stephen Miles Electric Co., 182 Elm Street, Cincinnati.

S. S. White Manufacturing Co., Philadelphia.

Jerome Kidder Manufact'g Co., 820 Broadway, New York.

The replies to this letter indicated an earnest desire to accept the proposition, and it was confidently thought at one moment that nearly a dozen outfits would be sent in, but in spite of a brisk correspondence and an extension of the date set for the commencement of the test, only four batteries arrived, namely, Franklin Electric Co., Passaic, N. J.; E. B. Meyrowitz, New York; Electric Storage Battery Co., Philadelphia, Pa.; Otto Flemming, Philadelphia, Pa.

Description of the outfits:

The *Franklin Electric Co.'s* battery is of the Planté type (illustrated on exhibit No. 1). The plate consists of a frame filled with alternated straight and corrugated strips of lead. No pastes or applied oxids are used, the active material being formed entirely of and on the plate itself. The formation of the peroxid on the corrugated strips cause them to expand and thus folding on themselves lock the peroxid firmly into place. The plates are separated by sticks of hard rubber and the whole held together by hard rubber bolts passing through the corners of the frames. The outfit submitted consists of two cells, each having a working E. M. F. of two volts and a capacity of 50 ampère hours. There is a sliding rheostat arrangement for controlling the current. The case and accessories of this particular outfit are decidedly crude, but the cells are of the company's standard type—it was sent in simply as a favor to your committee.

The *Meyrowitz outfit* is shown in the illustrations (exhibit No. 2). Like most of the dealers in physicians' supplies, Mr. Meyrowitz is not the actual manufacturer of the cells furnished in his outfits but supplies those made by the American Battery Company of Chicago. The type employed contains five plates—two positive and three negative, samples of which we have here (exhibits 3 and 4). The plate is made up of a series of horizontal strips of rolled lead, grooved on both sides and securely arranged in a frame of special composition not affected by the acids.

The plate is then submitted to the forming process which oxidizes the surface of the lead strips until the spaces between them are completely filled with the oxid. Thus the plate is made up of alternate layers of lead and active material—the grooved surface of the lead effectually keying the active material into place. The plates are separated by hard rubber combs and the whole bound together with rubber bands. (Exhibit No. 4.)

The outfit consists of two cells—each with a capacity of 40 ampère hours and an E. M. F. of 2 volts. It includes a current controlling device and a switch for throwing one or both cells into circuit.

Three styles are made:

No. 1, containing one cell and sold at \$20.

No. 2, containing two cells and sold at \$35.

No. 3, containing three cells and sold at \$45.

The outfit of the *Electric Storage Battery Co.*—manufacturers of the chlorid accumulator—is shown in these illustrations (exhibit 5). Chlorids of lead and zinc are fused together in certain proportions and poured into molds—the plates so cast form the active material and of which we have here a sample (exhibit 6). It is a quarter of an inch thick, has grooves running horizontally and vertically on each side, and at each point where the grooves intersect there is a perforation. (Exhibit 7.) The plate is then placed in a larger mold—into which is poured a molten alloy of lead and antimony; in this manner a strong frame is cast around the squares of active material on both sides of the plate and the frames are joined together by the union of the alloy through each perforation. To "form" these plates they are placed alternately with plates of pure zinc in a trough containing a solution of dilute chlorid of zinc, thus making a

simple primary battery and the cells short circuited in groups. By this operation, the chlorid of lead is reduced to a pure metallic lead, and the zinc is dissolved from the surface of the plate, leaving it soft, porous and spongy, so producing a plate having a remarkably large surface of active material as compared with its weight. (Exhibit 8 is a sample plate as it came from the forming bath.)

This company's outfit consists of two 5 plate cells—each with a capacity of 50 ampère hours and an E. M. F. of 2 volts. The normal rate of charge and discharge is 5 ampères, but the battery is fully capable of being discharged as high as 20 ampères without injury. There is a switch for throwing the two cells in series or in multiple and a current controller. The three small binding posts on top are for the purpose of attaching a 2 volt lamp to be used to test the condition of each cell. The open circuit voltage of a cell is a poor indication of its exact condition, but with a 2 volt lamp one can tell very closely by the brilliancy of the light the real condition of the cell. The cost of this outfit is \$35; new positive plates cost \$1.25 each, and negative 85 cents.

The Otto Flemming outfit is shown in this illustration (exhibit 9). Mr. Flemming does not make his own plates but employs those of the chlorid accumulator just described. He makes a specialty of providing an assortment of outfits to suit the various requirements of medical surgery. They range from one to twenty cells—details of which are to be found in this table furnished by the maker (exhibit 10):

* To be charged in series.

The outfit submitted consists of three 5 plate cells which are permanently connected in series and have a total E. M. F. of 6 volts with a capacity of 22 ampère hours. There is an ingenious rheostat arrangement for controlling both cautery and lamp. It is subdivided to a very fine degree, takes up little room and with excessive discharge there is no heating of the parts. This particular model is intended for those who desire a conveniently portable outfit for occasional work. Its capacity is sufficient to keep an endoscope lamp lighted for twenty-seven consecutive hours or a cautery knife heated two hours. It is sold for \$30.

During the test which was carried on though April, May, June, July and August, the readings were made with Weston standard meters kindly loaned by the Weston Electric Instrument Company, of Newark, N. J., for this test. The batteries were short-circuited for a few moments from time to time, and when occasions offered were used in actual operations.

In conclusion, it may be added that the several types of cell described are well and favorably known in the electric field for their efficiency and strong mechanical structure and are employed very extensively in electric lighting, launch and traction work. The outfits submitted have per-

formed all that was claimed for them; they are well made and with proper attention will serve a physician faithfully for at least five years without renewal of the plates.

DR. ELIHU THOMSON read a paper on

NOTES ON THE EFFECTS OF HIGH FREQUENCY ELECTRICAL DISCHARGES PASSED THROUGH THE BODY.

It is now some four or five years since the writer began experimenting with alternating currents of much higher rate of alternation or frequency than had up to that time been employed in lighting, and he published some notes concerning the physical effects and also the comparative physiologic effects of such currents, as determined by the late Dr. Tatum. This was almost simultaneous with accounts of work done by others in the same field, notably by Tesla and D'Arsonval, and a discussion arose as to the probable cause of the harmlessness of high frequency currents as compared with ordinary alternating or with continuous currents. The writer has never been satisfied with vague explanations, attributing the immunity to the skin effects or the flow of high frequency discharges almost wholly on the surface of a conductor instead of through its interior, nor with the suggested condenser effects, about which no consistent or complete exposition has at any time been forthcoming.

On the contrary, the very nature of the tissues of the body forbade the skin effect. The outside surface of the arm, for example, is fairly dry epidermis, which on account of its high resistance would prevent the passage of current, and the true dermal layer though conducting is of extreme sensibility, so that a concentration of current in the skin should rather enhance pain than annul it. That no condenser effect as such is the cause of the immunity is proved by the simple consideration that two persons may have each an arm connected respectively to the electrodes of a high frequency apparatus, while an incandescent lamp is held between them by the other hands, so as to complete a circuit of which the lamp is the middle. The lamp is lighted, though the actual potential of the source may be so low as not give a spark over more than a twelfth of an inch. The position of the lamp in the circuit forbids condenser action if the potential itself was not too low for such action.

Much absurd talk has been made in the newspapers over the ability of persons to withstand currents of hundreds of thousands or of millions of volts. It is a very old experiment to insulate a person's body and charge and discharge the same by sparks of even ten inches in length without special inconvenience. In this case the person becomes a condenser or charged conductor of very limited capacity, and the current of the charge or discharge is insignificant. Now, it so happens that if an insulated person be subjected to charge and discharge at a high frequency, say over 10,000 per second, and with a voltage of 100,000 or 200,000 there is a comparative absence of sensation during the reception and reversal of charges. Here again the current is limited, though its heating effect may be such as to bring to full brilliancy an incandescent lamp of 110 volts and 10 candle power, if such lamp be interposed between the person and the course of electric charges.

The writer has from time to time conducted experiments that prove beyond question the conduction through the body of currents or discharges, the heating effect of which in a carbon filament, whether the same be inclosed in a vacuum or not, is equal to that which is given by continuous currents of from .3 to 1.5 ampere.

There is little or no sensation experienced in such passage provided the surface of contact of the electrode with the skin be not too restricted. It is needless to mention that with ordinary alternating or continuous currents the passage through the arm of so small an amount as 20 to 50 milliamperes may be quite painful.

The apparatus used in the conduct of my experiments may be described as follows: ordinary alternating currents of 125 periodicity are passed through the primary coil of a special transformer or induction apparatus, the secondary of which is wound to give currents of about 20,000 volts. The secondary terminals have attachments to the two sides of a large condenser whose capacity may be changed at will. Its construction is such that it resists perforation of its insulating dielectric layers. Each dielectric layer is composed of two sheets of built up mica about one-eighth of an inch thick each. Between these double layers the foils are placed and the whole is covered with oil contained in a wooden box or receptacle. This condenser discharges across two air spaces or gaps through which a strong air blast from proper jets is

kept blowing. The gaps are formed between two sets of brass balls, and arrangements are made to connect to the outer ball of each pair any part of a circuit or path which it is desired that the condenser discharge shall take. A plain coil circle or loop of wire, bare or insulated, may form this discharge path. According to the self-induction of this loop and the capacity used in the condensers will depend the rate or frequency of oscillation of the discharges of the condenser crossing the air gaps. A large condenser gives a slower rate, as does also a loop or discharge circuit of larger area or self-induction. Hence, it is easy to make the discharges rapid enough to represent rates of 30,000, 50,000, 100,000 oscillations per second, as desired. It must not be supposed that in such an apparatus we can obtain a continuous unbroken set of waves of current like that of an ordinary alternating current, but of high rate. On the contrary, what we do get is a broken set of discharges in which the time occupied by the discharge itself, oscillating while dying out, is small compared to the periods of rest or no discharge. This is owing to our original source of current used in charging the condenser, which only brings the latter up to the discharging potential, say a few hundred times a second. Had we at hand, instead, a source of continuously sustained potential to charge our condensers, we could obtain continuous waves of high period without the dead spaces or times of no discharge. It is, however, a difficult matter to obtain such a source as is required on a sufficiently large scale for use. If, however, the source of current is of sufficient energy, and the capacity of the condenser not too large, the frequency is high and the dead spaces occupy a smaller fraction of the total time. Some time ago the writer devised an apparatus from which he obtained high frequency discharges from continuous current sources, (such as from a 500 volt railway circuit) but he has not had time enough to apply this method on a large enough scale as a prime source. The continuous current source gave, however, a perfectly continuous unbroken set of waves and not a succession of discharges. It therefore resembled a high frequency dynamo in its effects. The apparatus, however, as used by the writer, with alternating currents, is shown in the diagrams accompanying this paper. It is an induction coil whose primary is fed by ordinary alternating currents of 75 volts, giving about 20,000 volts in the secondary. K is the condenser attached to the secondary; G, G, are the spark gaps or discharge spaces; J, air jets or blast; L, is the discharge loop or coil. No measuring instruments, such as ampère meter or volt meters, exist which are applicable to the rapidly reversing currents, and none are therefore present.

In applying currents to traverse the body, it is convenient to bridge the discharge loop at various points as from *a* to *b* and the nearer these points are to the discharge gaps G, G, the more intense are the effects obtained. Thus, if from *a* to *b* a shunt be made by the body, taking hold at *a* by one hand and at *b* by the other, a certain part of the high frequency discharge is shunted through the body across the loop, and if an incandescent lamp, requiring, say, 100 volts and .3 to .4 ampere is made part of this shunt with the body, it is not difficult to bring the lamp to full incandescence without experiencing any discomfort, and, in fact, without sensation of any kind except perhaps a slight warmth at the wrists. It is only necessary that the surface of metal or damp sponge grasped in the hand be not too restricted. Five or six square inches of contact surface may suffice. If the contact area be unduly restricted there will be a tingling or burning sensation experienced, but only at or near the surface involved. There is no muscular contraction and no sensation whatever above the wrists. The writer has indeed lighted an 8 candle incandescent lamp of 100 volts, .3 ampère, through the little finger by capping it with a metal tube covering the outer half of its length, as one terminal, with the surface of the hand as the other. Also through the two hands laid together an amount of current equal in heating effect to more than 1 ampère of ordinary current has been passed with only moderate sensation, mostly of warmth, at the contact surface of the skin. Results similar to these have been made known through the recent work of D'Arsonval, using similar means for exciting the high frequency currents, and he has more fully examined the different effects or absence of effect upon the animal body. The writer has lately given some time to studying some of the more obvious points involved in the action of these currents, but has not concluded the line of experiments which have suggested themselves. A brief outline of some of the work may be of interest at this time.

The first point to determine was the virtual resistance of the body from hand to hand and to secure, if possible, a pas-

sive substitute resistance which could be used instead of the experimenter himself in further tests where needed. Such resistance substitutes were made by taking boxes about two feet long, one foot wide, and six inches deep, and filling them with sawdust dampened with a weak salt solution. Copper plate electrodes with short heavy cables attached could be inserted into the sawdust at any point in the length of the boxes. Now, placing the body in circuit with an incandescent lamp burning at a given brilliancy it was easy to reproduce the same brilliancy in the lamp by using, instead of the body, the sawdust box and adjusting its electrodes; all other conditions remaining the same in each experiment. A measurement of resistance of the box was made at once after the substitution by passing through it a current due to 106 volts, and measuring the current which passed, gave a resistance of 750 ohms. A similar substitution of a water resistance gave 650 ohms, so that approximately the virtual resistance of the body of the experimenter could be taken at 700 ohms. The contact with the palms of the hand was made by metal surfaces tightly grasped and having about six square inches contact with the palm and fingers.

By substituting a water rheostat for the body, and adjusting it to have the same resistance as indicated by the lamp brilliancy, the increase in temperature of the water during a given time could be made the means for determining approximately the rate of actual heat energy delivery to the body, assuming it to act simply as a resistance, an assumption which, so far at least as the conversion of current energy into heat is concerned, is doubtless well founded.

It was found that the rate of heat delivery to the water was equivalent to 59 watts, or about 2,600 foot pounds per minute. This figure is confirmed by a calculation based upon the continuous current strength required to bring the lamp used to the same brilliancy, and the resistance of the body as found by the substitution method above described. Energy = C^2R , or (.3 amp.) 2×650 ohms = 58.5 watts, lamp current water resistance.

These results, 59 and 58.5, are near enough to indicate that the high frequency current in lighting the lamp does not, as some have claimed, owe a part of its effect to any bombardment or vacuum action. It appears to act as a simple resistance. It can, therefore, be used as an indicator of the heating effect of the current passing in any of these experiments. The significance of this delivery of heat energy is plain. Heat energy may be delivered to the body or a portion of it without exciting the muscles or sensation. Whether this method would, for the purpose of the physician have any advantage over the application of warmth externally is not yet understood.

The writer in conducting these experiments often found a sensation of heat or warmth at the wrist when the discharges were such as would give the effect of .5 to 1 ampère in the lamp. This local effect would naturally follow from the comparatively high resistance of the bony mass at the wrist and the small amount of other tissue, together with the relatively smaller section of conducting material.

To get rid of this effect and at the same time to be enabled to increase the current passing through the body, the metallic electrodes were replaced by glass jars partly filled with weak brine in which the hands and part of the forearm could be immersed. The liquid in the jars was connected by metal plates to the terminals of the source. With an immersion to about four inches above the wrist it was found that a lamp current equal in heating effect in the lamp to 1.5 ampères continuous current could be passed through the body without producing any muscular contraction or sensation other than a warming or feeling of warmth in the forearm near to the surface of the liquid electrode or bath. After the experiment, which was continued for ten or fifteen seconds, and repeated several times in immediate succession, there was noticeable a slight feeling of rigidity or sense of friction or weight, difficult to describe, in the tissues of that part of the forearm which had been immersed. This feeling passed off in five or ten minutes and was only just noticeable at any time. This same feeling was confirmed by another observer. The rate of delivery of energy to the body in this case may have been over 800 watts or more than 1 horse power, assuming that the virtual resistance of the body fell nearly a half, owing to the immersion of the arms in the liquid electrodes.

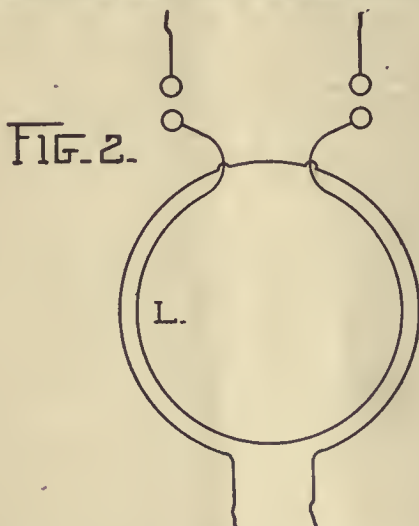

On account of the dead spaces and the nature of the discharges in these experiments, the maximum of current must be high. It is possible that the greater wave amplitude may give 10 ampères or more as a maximum. Examination of spark discharges in the circuit by a revolving mirror would probably render possible a more definite determination as

to how far this estimate approaches the truth. If time permits, the writer proposes to examine the discharges in this way so as to determine the relation of the dead spaces to the time occupied by the discharges, etc.

In some of the experiments, instead of shunting the discharge loop or coil as described, the arrangement was modified by using a secondary or parallel loop or coil, the inductive relation of which to the first or primary could be varied. This was found to be a most convenient arrangement, Fig. 1.

With a single circle of heavy wire, the diameter of which circle was about three feet, constituting the primary or condenser discharge loop, a secondary of three turns of heavy okonite-covered wire coiled to equal diameter with the primary, was sometimes used, Fig. 3, as the source of high frequency

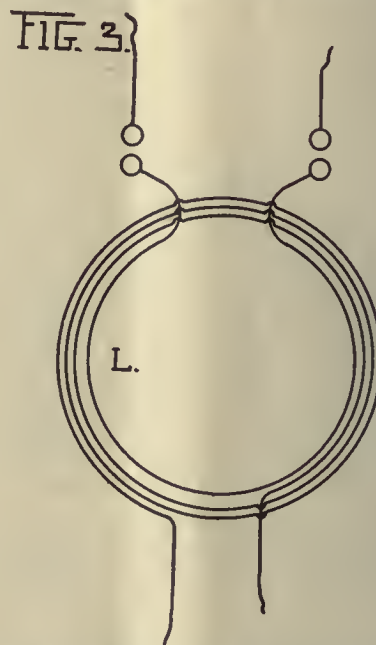

quency discharges to be applied in the tests. By moving the secondary into more or less exact parallelism with the primary the force of induced secondary currents could be regulated at will.

From the terminals of such a secondary, connections are made to the electrodes used in conveying the currents into the body.

By bringing the terminals of such secondary to a distance

of about three-fourths of an inch apart, a torrent of heavy brilliant sparks, accompanied by a very loud roar would be obtained, yet, without altering the conditions such secondary terminals could be bridged by the body, or short-circuited, so to speak, by the hands, with impunity, provided only that the contact surface was not too restricted. It was this coil which when circuiting through the arms immersed in salt solution gave a current of heating effect equivalent to 1.5 ampères as above described. The lamp used in this case was rated at 25 volts, 3.5 ampères, and was brought to redness by the current passing through it and the body in series. The brilliancy being carefully noted could be reproduced by an ordinary current of 1.5 ampères. So far, then, the experiments show that it is not to any peculiar action or distribution of the currents physically that the comparative harmlessness of high frequency currents is due, but rather that the true cause is physiologically, depending on some peculiar relation of nerve excitation to certain stimuli. In other words, nerve matter and muscle seems to be insensitive to such high rates of reversed discharge, and if there be any effects they are certainly different from those experienced at low frequencies, and more different still from the effects of continuous currents.

The normal mental operations and voluntary muscular action were not interfered with to any discoverable extent while the current passed, nor were the involuntary actions affected so far as determined.

In the above notes the writer has endeavored to condense the results of those of his experiments which have had especial reference to the passage of high frequency currents through the body, which experiments have tended to show the true nature of the phenomena in their physical aspect, and has not attempted to discover or confirm the existence of varieties of physiologic effect, or their absence, except incidentally to the other work.

The subject is certainly one of great interest, and one which, from the standpoint of the electro-therapeutic physician deserves the fullest investigation. What will be the limit to the increase of current which may be sustained without injury is not yet known.

(To be continued.)

Emulsion of Castor Oil.—M. Klein, a physician of Kharfa, Syria, reports the following method in use by the Arabs for disguising the disagreeable taste of the oil; fifteen or twenty grams of castor oil are poured into a glass of milk; the mixture is heated, being stirred with a spoon, and in a few minutes there is a perfect emulsion of the oil which can be sweetened with syrup of orange. The oil administered in this manner requires less quantity to produce its effects; thus 15 to 20 grams are sufficient to purge an adult.¹

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 86 Fifth Avenue, Chicago.

SATURDAY, AUGUST 10, 1895.

UNIVERSAL ANATOMIC NOMENCLATURE.

Scientific men are gradually coming to a general understanding in regard to the universal scientific language. For years, science has demanded a language common to all nations, and the two languages most favored have been French and English. The spasmodic study of Volapuk amounted to little and the movement in favor of modern Greek seems already dead. In the meantime, scientific bodies go on making a uniform nomenclature in their respective lines. It is neither French nor English, but Latin. Year by year, then, Latin is becoming stronger, and the world's scholars are working to keep it free from corruption. Our last Pharmacopœia is a striking example of the modern effort toward correctness in nomenclature. This effort shows grammatical and etymological changes from former nomenclature, all of which, being more exact, will not require change in future.

The latest advance in this direction has been made by the German Anatomical Society, an account of which we translate in full in another column from the *Deutsche Medicinische Wochenschrift* of July 4, 1895.

The Society appointed a commission composed of some of the most learned anatomists in Europe, and they have now presented their report, after eight years' labor, and although a similar attempt was unsuccessfully made by GASPARD BAUHIN in 1621, we feel reasonably sure that the work of this committee will be generally adopted. All anatomic names have been considered, and they have given Latin designations only, duplicates being dropped.

We believe that this plan is infinitely superior to the one pursued now, whereby every language

has its own designation for most of the separately named parts of the body.

Notwithstanding our individual preference for the French language, as that tongue on many accounts best adapted to become the universal language, with a minimum expenditure of time on the part of those acquiring it, yet it must be admitted that the Latin language, no longer being alive, is changeless; beside that, until the eighteenth century there were few scientific books in any tongue but Latin. A return to Latin in its purity would place the twentieth century international medical literature in line with almost all that has preceded it.

So far as the study of anatomy is concerned, it is manifest that the adoption of the nomenclature, as proposed, will greatly simplify it, and at the same time afford a common nomenclature for medical students the world over.

In the history of medicine there are no more important chapters than those relating to anatomy, and in its nomenclature we have the voice of antiquity perpetuated from the days of Alexandrian supremacy down to those of the Ecole de Medicine.

THE INDEX MEDICUS AND THE BRITISH.

The London *Medical Press* recites with regret that English editors and others are to be the losers in the discontinuance of the *Index Medicus*. Our English friends appear to feel the loss so badly that it is a wonder some one has not thought it worth while to "pass around the hat" and collect the comparatively small sum that is needed, from "the other side," to keep the machinery in motion. The following paragraph contains the gist of an article appearing in the literary department of the *Press*:

"The *Index Medicus* will cease to be the finger-post of medical writers and reference-hunters, unless subscriptions to the amount of £400 per annum are guaranteed by this country to the American publisher. This gentleman, it may be mentioned, announced two years ago that 'he did not see his way any longer to continue losing \$2,000 a year for the sake of the profession,' and we are quite in accord with him that—although an invaluable guide to the few—as the great bulk have shown such a lack of interest in it, they do not expect him to bear the loss for 'their sake.' In 1893 we made an appeal to the profession, hoping to keep the venture alive. MR. MACALISTER, Librarian of the Medico-Chirurgical Society, is now doing the same, but we fear the *Index Medicus* will go the way of all non-paying commercial enterprises."

Another English medical journal urgent for the continuance of the *Index Medicus*, says: "The yearly cost of production is about £1,000, and it is proposed to raise this sum by 200 subscriptions of £5 each. The United States, it is estimated, will supply 120, Great Britain 60, and the continent 20." In other words, this country is accounted to be good for as much as Great Britain and Europe combined. Whether this is to be considered as a tribute to the greater finan-

cial resources, or to the higher standard of intelligence of the American medical profession, it is equally gratifying and very flattering.

We are still of opinion that the AMERICAN MEDICAL ASSOCIATION should take up this matter, effect a satisfactory arrangement with the accomplished editors, and be responsible for the publication of the work.

ON THE INFLUENCE OF SHELL-FISH IN THE SPREAD OF CHOLERA.

DR. R. THORNE-THORNE, of the Local Government Board of Great Britain, has investigated the occurrence of cholera in England in 1893. His report touches upon the cases occurring at Grimsby and vicinity, and holds that the consumption—or reception, at least, at their homes—by persons taking the disease, of oysters or other shell-fish is involved in the history of those cases.

The trade in shell-fish in and near Grimsby is very large, and the arrangements of the traffic are such that the oysters and mussels are exposed to sewage, both on the “beds” and in the storage-docks. Cockles, mostly consumed locally, come from several “beds,” one of which is stated to be “exceptionally exposed to the influence of Grimsby and Cleethorpes sewage.” Some of these shell-fish are not often eaten raw; others again notably oysters, are largely consumed without cooking, and when so eaten the removal from the shell of the liquid in which the oysters lie is a thing that is generally somewhat carefully avoided. The state and sources of the “waters” in which the oysters are grown or kept come, therefore, to acquire importance in so far as the public are concerned; and having regard to the significant indications afforded by some of the cholera histories of last year, DR. THORNE can not avoid the conviction that shell-fish from Cleethorpes and Grimsby must, in some cases, remain under suspicion as having contributed to the diffusion of the disease.

More positively than that, DR. THORNE declines to speak. He closes by saying: “But one thing is certain. Oysters and shell-fish, both at the mouth of the Humber and at other points along the English coast line, are at times so grown and stored that they must of necessity be periodically bathed in sewage more or less dilute; oysters have more than once appeared to serve as the medium for communicating disease, such as enteric fever, to man; and so long as conditions exist, such as those with which the oyster trade of Cleethorpes and Grimsby is shown to be associated, conditions which may at any time involve risk of the fouling of such shell-fish with the excreta of persons suffering from diseases of the type of cholera and enteric fever, so long will it be impossible to assert that their use as an article of diet is not concerned in the production of diseases of the class in question.”

NATURAL HISTORY OF THE KUMBH FAIR CHOLERA OUTBREAKS.

SURGEON-CAPTAIN HERBERT furnishes¹ from Bombay a contribution to the natural history of the cholera outbreaks at the Hardwar fairs on which he bases what he modestly styles the following “suggestions:” 1, the fouling of the water of the Sacred Pool or of the Bhun Ghora tank, or of both, by an unusually large proportion of bathers to the quantity of water available may render these waters a very favorable medium for cholera development, and so determine the origin of far-reaching epidemics; 2, the growth of the organism may be assisted by unusually hot weather; 3, virulent cholera elsewhere in India may be effective from the character or quality, rather than from the quantity, of the virus¹ carried to Hardwar.

These “suggestions” are at variance with the conclusions arrived at prior to 1892, from observations which definitely associated the outbreaks of cholera at Hardwar with but one condition—the overcrowding at the Kumbh fairs. HERBERT shows that the attendance in the “big cholera year, 1892,” was only about one-half the average accumulation of an ordinary annual fair; the season, however, was not only one of the driest—rendering it impossible to keep the sacred waters as fresh as in the previous year, when there were nearly four times the number of pilgrims present and no outbreak—but it was also one of the hottest, on record. Concerning this previous year—the Kumbh Mela, 1891—HERBERT says that while the exemption from cholera attack was then ascribed to the very elaborate sanitary arrangements, for the first time in force, the evidence is strong that it was due rather to a severe and prolonged winter season with a resulting high stage of water. The complete inefficiency of the sanitary arrangements was conclusively demonstrated the following year—the “big cholera year.” He adds: “There were no extraordinary sanitary precautions in 1885, when the number of pilgrims was the same as in 1891; yet cholera did not break out. The winter was severe, as in 1891, and the river consequently high. And there have been other Kumbh and Adh Kumbh years—*e.g.*, 1855, 1861, 1873, with neither sanitary precautions nor cholera outbreaks. It is now fairly well recognized that the essential sanitary requirement for the prevention of cholera spread here [Bombay] is a free supply of fresh water, especially at the most crowded Melas, in very dry years, and when the disease is unusually prevalent elsewhere in India.”

It is quite apparent that SURGEON-MAJOR HERBERT believes in an increased potentization of the cholera organism when sown in an exceptionally favorable culture material; that to this increased morbid potency is due the fact that the cholera which spreads

¹ London Lancet, July 27, 1895.

from the fairs is not that which is carried to them; that the new growth may acquire powers beyond those of ordinary Indian cholera, capable of spreading rapidly and certainly over country where cholera is comparatively seldom seen and of being the origin of European pandemics. The corollary of this hypothesis would be the gradual attenuation of new growths in less favorable culture media, under less favorable climatic and meteorologic conditions, until there resulted the entire loss of morbid potency and the dying out of the pandemic.

CORRESPONDENCE.

Letters to my Hospital Internes, Past and Present.

BY CASEY A. WOOD, M.D., OF CHICAGO.

LONDON, July 1, 1895.

Gentlemen:—Undoubtedly there are some forms of service which must ever leave the recipient in the debt of the donor. In looking back at the work done for me by you, during my attendance at Cook County Hospital, the Alexian Bros., the Emergency Hospital and the Hospital of the Post Graduate Medical School it occurred to me that I might at least acknowledge certain obligations of this kind by recounting some of my experiences during a short trip abroad. I shall endeavor to avoid the style of the medical guide book and beg to assure you that I will speak only of those men and those things that came under my own personal observation. I might also explain that, although this visit to the English and continental clinics has been a hurried one, its value to you is possibly somewhat enhanced by the fact that I had gone over more leisurely on two previous occasions, and at an interval of several years, practically the same ground.

The London hospitals have not altered much since my last experience of them.* The student has not much to gain from a short stay in the British capital, partly on account of the great distances that must be covered in going from hospital to hospital, and partly because the average Englishman does not take kindly to the stranger until he has become acquainted with him after a proper introduction. But for the man who will settle down for six months or a year and work hard, excellent teaching and numerous opportunities are at the disposal of the visitor. There are admirable post graduate courses, conducted by the best men in London, on all medical and surgical subjects, but it is rather fatiguing to hurry about from one hospital to another, miles apart. Some day these isolated teachers may come together, as with us or as in Vienna, at a common center, and then London will compete on more than even terms with her continental rivals.

These objections do not apply with the same force to ophthalmology or otology. The student, advanced or otherwise, can hardly wish for more or better opportunities than are to be had at the Royal London Ophthalmic Hospital (Moorfields, E. C., three daily clinics, 9 A.M. to 3 P.M., operations eleven to seventeen and Westminster Ophthalmic, Charing Cross, 3 daily clinics, 1:30 to 4, operations two to three). I do not say that other excellent institutions do not also furnish numerous opportunities for work, because large daily clinics are held at the Central London Ophthalmic Hospital (Gray's Inn Road, W. C.) South London Ophthalmic Hospital (near the Elephant and Castle) and in connection with many of the general hospitals, but at the two special institutions first mentioned from forty thousand to

fifty thousand new patients are yearly admitted. In that overwhelming tide of ophthalmic disease, fed by the whole country round about, every possible type and variation of ocular trouble can be studied. It is a comparatively easy matter to attach one's self at Moorfields to the service of Nettleship, Lang, Silcock, Morton, Gunn, Lawford or Couper, or at the Westminster Hospital to the clinics of Jaler, Hart-ridge, Cowell, Dodd, Donald, Gunn, Griffith and several others. After a month or two of probation it is possible to obtain almost complete charge of patients, to do minor operations and to discuss with the chief of the clinic, matters that arise in connection with the conduct of their cases. At Moorfields, instruction on the use of the ophthalmoscope (unusually good, each course six weeks, plenty of cases, fee 2 guineas) is given three times weekly by Gunn, Silcock and Lawford. Classes in refraction are conducted by Mr. Lang (excellent, one month each, 2 guineas) while Mr. Morton gives an instructive course (six weeks, 1 guinea, material from all the clinics) on external diseases of the eye every Friday at 1 P.M. These courses are held during the winter season and tickets are to be had from the secretary at the hospital.

For beginners, Mr. Phillips, the refraction assistant, conducts, when requested, private classes which are, in my opinion, superior to anything to be had on the continent. Indeed, all the continental clinics—especially those in Vienna—are conspicuously weak in courses devoted to the study of refractive errors and muscular anomalies. Mr. Morton also gives an excellent operative course (private, six lessons, 2½ guineas) which is very popular with students. Pigs' eyes and the mask are employed for operations on the globe; pigs' heads for operating on the extrinsic ocular muscles and the lids.

These excellencies in the way of instruction are completed by work in the laboratory under the supervision and help of a very genial man, Mr. Marshall. His predecessor, Treacher Collins, has done and is still doing a great deal of valuable original work and, mainly in consequence of his efforts, the museum possesses by far the best anatomic collection in the country.

I was interested in a plan for using the electric light in the examination of eye patients. As you are aware, my objection (which I had vainly endeavored to remove by various devices) to this light was the difficulty of quickly regulating its intensity so that it could be lowered or raised like gas. Mr. Lang has perfected a plan whereby this can be accomplished and we can now dispense with gas—a decided advance, especially on a hot summer's day in a stuffy dark room.

The study of otology and laryngology is not so satisfactory to the student in London as that of ophthalmology. The London Throat Hospital (Golden Square, clinics every afternoon and evening) with Wolvenden, Hovell and Bond, is perhaps the best known and where, all things considered, one gets nearest the patients—whose name is simply legion. To obtain privileges of any value in this direction it is, however, necessary to take out a ticket of attendance (3 guineas for six months, 5 guineas perpetual, from the secretary) and to wait for a vacancy on the staff of clinical assistants, if there be none at the time of registration.

Dr. Dundas Grant, Mr. Lennox Browne and others hold daily clinics, (beginning at 2 P.M. and lasting until evening, fees 1 guinea a month) where the student may see a large number of ear, throat and nose cases. At irregular intervals lectures are given on otologic and laryngologic subjects. I fear it will be a long time before London is able to hold out inducements to students of otology, and the kindred specialties, equal to those so freely offered by Vienna or, though in a less degree, even by Berlin.

I regret that I was unable to attend the clinic of Mr. Jonathan Hutchinson—a name claimed equally by all departments of medicine and surgery. I am told that every London hospital, whether devoted to general surgery, ophthalmology, diseases of the lungs or what not, furnishes its quota of obscure cases for review by this truly remarkable man. Such fathers of our art should live forever, and one may well wish for a continuance of a life already so replete with useful years.

One of my missions in England was to investigate the subject of the color sense. In my opinion we have as yet, no theory that satisfactorily accounts for all the color phenomena, physiologic and pathologic, commonly met with, and I hoped to find light upon this obscure matter in the work of Mr. Lovibond of Salisbury, who has been engaged in investigating color values and "chromometry" for twenty years past. I have long felt the absurdity of scientific men using such terms as "canary yellow," "magenta," "grass green," "Prussian blue," etc., as their most definite expression of a color sensation. In his search for universal color standards, Mr. Lovibond was confronted with the difficulty of finding a pure white, but at last settled upon a compressed surface of finely powdered lime sulphate as giving the nearest approach to white. When colors are viewed through a tube or box, from which all light is excluded, the slightest difference between them can be readily observed if the colored objects be uniformly illuminated. This, the principle of Chribret's chromophotometer, enables the observer to add, in Mr. Lovibond's instrument uniformly graduated yellow, red and blue tinted test glasses to the white side of the apparatus until it exactly resembles the colored object under examination. When both objects appear exactly alike, the glasses added to the white side are the color measure of the color or shade under examination. The result is always given in, and every color can be resolved into, terms of red, blue and yellow—according to the Lovibond scale. Thus a colored powder is found to be composed of 1.4 standard units of red, 0.9 standard units of blue and of yellow 3.7 units, or a certain fluid (beer, drinking water, oil) is found to be 0.8 red and 0.50 yellow.

Not only have we in this scheme a universal standard of color, but other uses to which the "tintometer" is put ought to interest every medical man. It has been found that the amount and kind of adulteration in most foods and commercial products, as well as the impurities commonly found in drinking water and other fluids can be determined by the deviation, measured by the tintometer, from the normal tint of the pure article. Instead of making a laborious and complicated *chemic* examination of the suspected compound, its color value is determined in a few minutes. Such a chromometric examination is usually found to answer all the purposes of a quantitative analysis. In this way the tintometer is now employed in England and to some extent abroad, by all sorts of commercial houses and it is also used with great success by the health departments of cities for the ready detection of impurities and adulterations in milk, water, beer and other foods. *The slightest departure from purity whether in food or in any other product, is at once shown by a measurable and corresponding variation in color.*

As scientific men the subject of color-music ought to interest you. The July number of the *Nineteenth Century* contains an article dealing with this matter—an attempt to convert musical tones into corresponding color harmonies. I remained one day longer in London than I might attend a concert in St. James' Hall where upon a large canvas beautiful displays of color combinations were given as an interpretation of the music rendered by a good orchestra. Just *how* this was accomplished I could not discover but, *a priori*, it does not seem opposed to our idea of the conservation of energy that sound waves and the cerebral sensations they produce should be convertible into those of color.

PARIS, July 14.

Owing to my acquaintance with the American medical colony in Paris, I was able with their courteous help, to gather many items of interest which would otherwise have taken a much longer time to collect. Drs. Evans of Chicago, Bergeson of Merrill, Wis., and Jehm-Prume of Montreal, are at work here and express themselves as greatly pleased with the opportunities for study in all departments of medicine and surgery. The fees, unlike Vienna, are quite nominal (often excellent courses are free) and every stranger (in contrast to London and Berlin) is welcomed without the least introductory formality.

A students' number of the *Presse médicale* is issued every December and is the best medical guide to Paris I could find and, although intended for undergraduates, is a help to the visitor.

The *Institut Pasteur* (Rue Dutot, 25, open to visitors at 11 A.M., apply to the concierge) was, as you know, built and endowed by subscriptions from all parts of the world and its most useful work, it seems to me, is done in the fine laboratories and research rooms of the main building. There are half a dozen of the former under the care of salaried chiefs of departments who also instruct students, and over twenty-four of the latter given up to advanced workers who are conducting original investigations. The general laboratory courses (50 francs for two months, most of the material free) are said to be the best in Europe. The research rooms are let for the insignificant sum of 50 francs a month and the Institute furnishes all the ordinary apparatus and materials.

The animal rooms contain over one thousand birds, guinea pigs, rats, rabbits, etc. In this appropriate way does France make a generous return to those foreign countries that subscribed money for building the Institute. Pasteur has his private apartments in the buildings, but since the illness of the chief the management of the Institution has fallen entirely into the worthy and competent hands of Dr. Roux. The city of Paris presented them both with medals and a sum of money a few days ago.

Among the most important work done at the Institute and the Children's Hospital is that in connection with diphtheria—by Marmarek. He finds that the disease is not always the result of the diphtheria bacillus, so-called, alone, but that that microorganism is, in many cases, associated with others, notably the streptococcus, and the symptoms may be mixed phenomena due to a composite infection. In certain instances the systemic poisoning may be chiefly a streptococcus intoxication. If this be true, we have an explanation of the irregular action of Behring's heilserum; antitoxin is powerless in a case of diphtheria largely due to poisoning by the streptococcus. Marmarek consequently proposes not only to regulate the dose of antitoxin by the proportion of diphtheria bacilli present in the exudation, but to give doses of streptococcus toxins when that coccus is found. He expects to have the antidote ready for general use in a month or two.

Marmarek is of opinion that the chief danger to which the tubercular patient is exposed is a secondary infection of his lesions by streptococci.

I was also interested in the investigations of Cenarelli in typhoid fever. Most animals can not, under ordinary conditions be inoculated with the disease, but he found that this immunity practically disappears and that they exhibit all the characteristic lesions of enteric fever when they are ill-fed, kept in filthy, badly ventilated quarters or exposed for some time to sewer gas before receiving the typhoid poison. The inference is that human beings are much more likely to resist this form of intoxication if they live hygienically and in a healthy neighborhood—a doctrine taught by our fathers before the days of bacteriologic laboratories. There is a public hydrophobia clinic connected, as an outdoor department, with the Institute, where from eighty to ninety patients are daily treated; the average treatment lasts fifteen days and the method is just the same as that carried out in Chicago by our own Dr. Lagorio. By the way, Chicago is the only Pasteur station except, I think, Havana and New Orleans, marked on the large map of North America at the Institute. I could not discover why New York, with Gibier's station, had been omitted.

I saw the original Pasteur filter, invented by Chamberland, one of the department chiefs at the Institute, and am inclined to think more highly of it than I did of those put on the Chicago market. It is used here for the separation (under pressure) of their toxins from the various microbes. As you are aware, the filter is practically a porcelain cup, dense enough to separate—to a bacteriologic demonstration—even the smallest organism from contaminated drinking

water. I suspect, however, that regular boiling and cleansing of the porcelain cylinder and its attachments would be a useful proceeding in the case of a filter daily employed in the purification of Chicago water.

Some Remarks on Alleged Degeneracy.

ORAN, SCOTT Co., Mo., July 27, 1895.

To the Editor:—This word does not apply to the profession at large (or as a whole). Doubtless there are many physicians who have lost their standing and good name and have ceased to study and improve, but the profession, as a whole, is on gaining ground. Doctors are wiser than ever before. There are more great men in our ranks to-day than ever before, and there are men who know more of medicine than was ever known to physicians of the past. Some of our wisest men undertake to write after their mental powers have begun to weaken, and in this sense may be called "decaydents." Others through sickness or disease may have lost their balance—but to say the profession is losing ground, and that our predecessors were a long way ahead of us is a mistake.

Many of us follow strange gods, but as a whole we are all right. There are many cranks among us on many different subjects, but this is not new; it was always so. Our ability to see ourselves as we are, shows strength instead of degeneracy. Our ability to correct past errors shows mental growth. Our greater control over disease and our ability to cure many maladies that were considered incurable by our fathers also shows progress. Oh, yes; we are all right. No need of the calamity howler in our midst. We are in line with our brethren in other avocations. We are keeping up with the times. Some of us may belittle ourselves by playing hog or dog, but the grand old army marches steadily along, conquering enemy after enemy.

Let not the editor of our JOURNAL join with those who would try to discourage us. Lend your aid in another direction. Never allow yourself to think we are degenerating. The apparent degeneracy is among those who have lost sight of duty and have made medicine a trade. These fellows are not so much degenerates as knaves—they never looked upon medicine as other than a species of merchandise. They, to some extent, have lowered our standing with the laity but have not taken, nor can they take, our lofty and well-earned position from us, and as Dr. Pusey says: "Medicine is not the poor relation of any scientific family."

I am glad the editor joins me in my theory of inebriety, and has a proper appreciation of the so-called *gold cures*. When I was spreading myself out, condemning this fad, only a few men said to me, "you are right," but if the editor joins me, I shall not feel that I am so much in the minority.

Another source of joy to me is the fact that the AMERICAN MEDICAL ASSOCIATION is beginning to set down on the proprietary medicine man. I have had my say on this subject, but somehow editors are a little tenderfooted along this line. These parasites have a firm hold and are hard to unloose, but they will finally have to go. Truth, right and honest dealing must prevail. Secret methods of preparing medicines have no place with us, and the man who refuses to tell anything he knows that would benefit humanity can not last. His time is short. The patent nostrum vender can "hoodoo" the laity and swindle them out of their money, but no man nor set of men can continue swindling us without being exposed. We are "on to" the ready remedy maker's racket, and ere another decade shall pass, his name shall be "Dennis" or "Mud" in "box-car" letters. Very respectfully submitted,

W. D. HOWLE, M.D.

The Nu Sigma Nu Fraternity.

CHICAGO, Aug. 7, 1895.

To the Editor:—Any one who has read the scholarly and very entertaining address published in last week's issue of the JOURNAL, pages 177-180, delivered at Minneapolis, Minn.,

June 3, by Dr. John L. Irwin, President of the Grand Council of this honorable order, can not but sincerely applaud and at heart, at least, extol every sentiment uttered by that worthy gentleman.

For one, I have personally been much interested and delighted at reading his able address; and while I have not the pleasure of knowing Dr. Irwin, nor the honor of being a member of the Nu Sigma Nu, yet knowing something of this fraternity and the character of its members, I am free to state that I am a staunch advocate of its cardinal principles and teachings. It is my misfortune, perhaps, that my name has not, long ere this, been enrolled in this noble brotherhood of our profession. But after all, is it not our duty as honorable men and conscientious physicians, while we live, to follow the precepts of the order of Nu Sigma Nu, whether we are members of this honorable order or not? To sum up the ritual of this order—or rather to summarize Dr. Irwin's address—we should observe and live up to the Golden Rule; to practice charity without ostentation, educate ourselves in our profession, and observe toward each worthy professional colleague and toward all mankind the virtues of brotherly love, purity, honesty, justice, a laudable ambition, temperance and fidelity. As I understand it, these are substantially the teachings in the ritual of Nu Sigma Nu.

If we courteously observe these principles in our professional career, to my mind it does not seem that we have left much undone to "worry" about in the discharge of our duty toward our fellow man.

In Chicago, there are at least three Chapters of the Nu Sigma Nu Fraternity, and I am personally acquainted with nearly every "frater" of the order in this city, for all of whom I entertain high personal esteem. To these gentlemen, and to the members of the Nu Sigma Nu everywhere, I extend my sincere congratulations in having so able and efficient an executive of the Grand Council of their fraternity.

In conclusion, I thank the Great Physician of us all, as well as Dr. Irwin and the JOURNAL for publishing the address, and for being privileged to read it.

I remain sincerely,

LISTON H. MONTGOMERY.

PUBLIC HEALTH.

Subsidence of Smallpox in Chicago.—There were only 2 deaths from smallpox in Chicago during the month of July last, as against 51 for the corresponding month of 1894. There were three cases remaining in hospital at midnight of the 6th inst., as against 117 on August 6 last year.

The Odors of Paris.—The prefect of police has given orders to have a certain number of his inspectors detailed to investigate the sources and causes of the disagreeable smells which incommode the Parisians, especially during the evening. As the number of establishments to be inspected is estimated at 8,000 the work is not yet done. However, from the evidence accumulated it seems probable that most of the noxious odors are caused by the manufacture of bone black.¹

Anti-Vaccinists Not Popular with Politicians.—Before the recent elections in England, the Bristol Anti-Compulsory Vaccination Society approached the various parliamentary candidates for Bristol and the adjoining divisions to ascertain their views on the vaccination question. It is reported that the "cold shoulder" which they received was so unanimous that they could fix on no candidate whom they could support and so abstained from any participation in the campaign and in the election.

¹ Le Progres Medical, No. 25, 1895.

Statistics of the Paris Pasteur Institute.—In the first three months of this year, 345 persons were treated at the Institut Pasteur. Of this number, 23 were bitten by animals proved to have rabies experimentally; 224 were bitten by animals found to be mad after examinations by veterinary surgeons; 98 were bitten by suspected animals. Of the animals, 324 were dogs, 15 cats and one ass. One patient died before the end of the treatment. St. —, a man of 48, from Glasgow, was bitten March 8; treatment began on the 11th. There was but one bite but it was deep, situated in the inferior third of the fore-arm, on the anterior surface. On March 23 the patient, after taking a hot bath, rode on the outside of an omnibus; caught cold, rabiform symptoms appeared in a few days and he died April 1.¹

Scavengers Without Health Officer's Permit.—A regulation of the Health Department of the city of St. Paul prohibited "licensed persons" from doing certain scavenger works "without a permit first obtained from the Health Officer." It nowhere appeared what license was required, or that any persons were prohibited from doing such work without such license. So says the Supreme Court of Minnesota in the case of city of St. Paul v. Lawton, decided July 2, 1895. The defendant in the case was charged with having violated such regulation by doing such work without such permit. It was not alleged or proved that he was a licensed person. Under these circumstances, the court holds that a conviction can not be sustained.

Diphtheria Antitoxin Treatment in Germany.—The results of treatment in 10,240 cases of diphtheria in the German hospitals and in private practice were recently reported to the Society for Internal Medicine by Professor Eulenberg. Of this number 5,790 were treated with the antitoxin serum, with 552 deaths—a mortality of 9.5 per cent. for all ages; 4,450 were treated by other methods with 652 deaths—a mortality of 14.7 per cent. By ages, the mortality was, for those under 2 years, 21.7 per cent. by the antitoxin treatment, 39.7 per cent. without; between 2 and 10 years of age the mortality was 8.8 and 15.2 per cent. respectively; for all cases over 10 years of age the mortality was 4.1 per cent. under antitoxin and 8.8 per cent. under other methods. Professor Eulenberg again called attention to the importance of early recourse to the antitoxin; used within the first forty-eight hours the mortality was only 4.2 per cent.; delayed beyond this period the mortality was increased to 16.8 per cent. These figures must certainly be regarded as a vigorous addition to what Virchow has called the "brute force" of the numerical argument.

Milk Supply of Rome.—The very thorough sanitary regulations as to milch cows which have been in force for some time as to Rome proper have been recently extended to cover the whole commune, which includes most of the surrounding Campagna. All cows and other animals which supply milk in the suburbs and Agro Romano are subjected to rigorous examination by competent veterinarians; healthy animals, capable of furnishing good milk are marked on the horns and licenses issued to the owners. Only milk from such inspected and licensed animals may be sold. The inspections are repeated every year in April, May and June and at such other times as the authorities deem necessary; diseased animals are condemned and slaughtered; those selling milk below the fixed standard are refused license, and cows suspected of tuberculosis are subjected to the tuberculin test at the owner's expense and destroyed if found diseased. The Rome correspondent of the *British Medical Journal* says the extension of these regulations to the whole commune is a great boon to the inhabitants, since all cows which supply milk to the city will now be under

inspection, and this will prevent the sending of tuberculous cows from Rome proper into the Campagna whence they might continue to supply the city.

Disinfection of Tubercle.—The *Public Health* quotes from the *Revue d'Hygiène* an approximate valuation of pyroligneous acid as follows: "Goriansky, of St. Petersburg, has been experimenting to determine the relative value of wood-tar and some of its products. The most active appears to be wood-vinegar (pyroligneous acid), which kills tubercle bacilli in cultures in an hour, in sputa in two hours, and the streptococci and staphylococci in the latter in three hours."

Diphtheritic Specimens by Mail.—According to *Public Health*, the French postal authorities have removed restrictions formerly placed upon the sending by post of the membranes of diphtheria. The precautions that must still be observed are quite elaborate. They may only be sent in a thick glass bottle, tightly corked and sealed, surrounded with wadding and put into a solid metal box, which in its turn is to be inclosed in a well-fitting wooden box. This must be legibly addressed and labelled "Diphtheritic false membranes," and may only be sent to the Institut Pasteur or to one of the recognized provincial laboratories.

New York State Board of Health.—At a recent meeting of this Board, Dr. Daniel Lewis, of New York city, was unanimously elected President to succeed Dr. Florence O'Donohue. Dr. Lewis is an ex-President of the State Medical Society. Dr. Frederick W. Smith, of Syracuse, appointed by Governor Morton as successor to Dr. O'Donohue, sat with the Board. The Board received an opinion from the Attorney General, holding that Dr. O'Donohue could continue as a member of the Tuberculosis Committee for the year, although his term of office as a member of the Board had expired. Dr. Lewis is also an ex-President of the county medical society, editor of the Medical Directory of New York, and member of other medical organizations. He was a strong candidate of the "anti-code people" for appointment as Health Officer of the Port before Governor Morton appointed Dr. Alvah H. Doty to that office. He has now, however, landed on his feet in this very important position, which is destined to have more power for good than has been the case in the past.

City is Not Liable for Acts of Board of Health Employees.—Where the duty of keeping the streets clear of putrid and other substance offensive to the sense of smell, and which tends to imperil the public health devolves, under a city's charter, upon the Board of Health of that city, the Supreme Court of Georgia holds, in the case of Love v. city of Atlanta, decided Dec. 4, 1894, though but recently reported in 22 Southeastern Reporter 29, that the functions of this department of the city government being governmental, and not purely administrative in their character, it follows that if, in the discharge of such functions, and in the discharge of the duties devolving upon this department thereunder, a private citizen is injured by the negligence of one of its servants in and about such work, no right of action arises against the city. But it is to be observed, says the court, that, in order to exempt a city from liability, it is not sufficient to show that the particular work from the negligent performance of which by the servants of the city, a citizen was injured, was being done under the direction of the Health authorities, but it must be shown that the particular work so being done was connected with or had reference to, the preservation of the public health. If the Health Department were engaged in clearing away or removing obstructions from the street which in no way endangered the public health, the responsibility of the city then would rest upon the rule of liability for the work connected with repairing and keeping in order the public highways. It can make no difference in principle as to the character of the agents employed in the discharge of this duty with respect to the public health. The principle of non-liability rests

¹ Bulletin Medical, July 7, 1895.

upon the broad ground that in the discharge of its purely governmental functions, a corporate body to which has been delegated a portion of the sovereign power is not liable for torts committed in the discharge of such duties and in the execution of such powers. It can be no more liable because of the fault to select competent drivers of garbage carts than a city could be held liable for failing to elect a wise, conservative and discreet mayor.

Health Reports.—The following health reports have been received by the Supervising Surgeon-General, Marine-Hospital Service:

SMALLPOX—FOREIGN.

Antwerp: July 1 to 6, 1 case, 1 death.
 Buda-Pesth: July 8 to 15, 3 cases, 1 death.
 Cairo: June 25 to July 1, 4 deaths.
 Calcutta: June 15 to 29, 36 deaths.
 Glasgow: July 6 to 13, 10 cases.
 Guayaquil: June 29 to July 19, 9 deaths.
 Liverpool: July 6 to 13, 1 case.
 Madrid: July 8 to 15, 5 deaths.
 Montevideo: June 22 to 29, 2 cases, 1 death.
 Nogales: July 13 to 27, 3 cases, 2 deaths.
 Odessa: July 6 to 13, 2 cases.
 Prague: July 6 to 13, 1 case.
 St. Petersburg: June 29 to July 6, 4 cases.
 Trieste: July 6 to 13, 3 cases, 1 death.
 Warsaw: July 6 to 13, 1 death.

SMALLPOX—UNITED STATES.

Louisiana: New Orleans, July 20 to 27, 1 death.
 Michigan: Detroit, July 22 to 29, smallpox reported; Battle Creek, July 20 to 27, 2 cases.
 Missouri: St. Louis, July 20 to 27, 1 case.
 New York: Brooklyn, July 27 to August 3, 1 case.
 Texas: Eagle Pass, August 3, 55 cases, 3 deaths.

YELLOW FEVER.

Cuba: Cienfuegos, July 21 to 28, 2 cases at the Municipal Hospital. Other cases in town. Havana, yellow fever increasing. Sagua-la-Grande, July 20 to 27, 1 case.
 Mexico: Vera Cruz, July 18 to 25, 13 deaths.

CHOLERA.

India: Bombay, June 26 to July 2, 1 death; Calcutta, June 15 to 29, 36 deaths; Madras, June 22 to July 5, 3 deaths.
 Russia: Volhynia Government, May 26 to June 8, 79 cases, 20 deaths.
 Turkey: Constantinople, June 20, 2 cases, 1 death; Tarsus and vicinity, June 9 to 29, 41 cases, 34 deaths; Adana, June 10 to 29, 180 cases, 105 deaths; Sis, June 10 to 29, 87 cases, 58 deaths; Hatschni, June 10 to 18, 9 cases, 6 deaths; Pajast, June 16 to 29, 17 cases, 6 deaths; Mesis, June 17 to 29, 27 cases, 8 deaths; Karatasch, June 17 to 29, 89 cases, 44 deaths; Kara-Isdali, June 17 to 24, 17 cases, 4 deaths; Jumurtalik, June 18 to 24, 1 case, 1 death; Bulanik, June 21 to 22, 5 cases, 5 deaths; Messina, June 28 to 29, 3 cases, 2 deaths; Marasch (Vilayet Aleppo), June 10, 2 cases; June 18 to 30, 25 cases, 17 deaths; Djabal, June 26 to July 1, 15 cases, 7 deaths.
 Arabia: Mecca, June 9 to 14, 17 deaths; no new cases from June 15 to July 1; Taif, June 19 to 21, 24 deaths. (Also 17 cases and 16 deaths among 906 Arabian pilgrims who had arrived at Camaran on board the S. S. *Memphi*.)

SOCIETY NEWS.

American Electro-Therapeutic Association.—The American Electro-Therapeutic Association will hold its fifth annual meeting at the College of Physicians and Surgeons, of Ontario, in Toronto, Canada, on Tuesday, Wednesday and Thursday, Sept. 3, 4 and 5, 1895.

DR. EMIL HEUEL, Secretary.

352 Willis Avenue, New York city, U. S. A.

Minnesota State Medical Society.—The twenty-seventh meeting of this Society was held at Duluth, Minn., June 19 to 21. The following officers were elected for the ensuing year: President, Dr. Frank Allport, Minneapolis; First Vice-President, Dr. J. H. Dorsey, Glencoe; Second Vice-President, Dr. E. Y. Chilton, Howard Lake; Third Vice-President, Dr. D. N. Jones, Gaylord; Secretary, Dr. Ignatius Donnelly, St. Paul; Treasurer, Dr. Richard J. Hill, Minneapolis.

American Association of Obstetricians and Gynecologists.—The eighth annual meeting of this Association will be held at Auditorium Hotel, Chicago, Sept. 24, 25 and 26, 1895. The preliminary program is as follows: 1, President's annual address, J. Henry Carstens, Detroit. 2, Relation of pelvic suppuration to structural changes that may occur in the Fallopian tubes, A. P. Clarke, Cambridge. 3, Nephrorrhaphies, George Ben Johnston, Richmond. 4, Detached fibroids, George H. Rohé, Catonsville. 5, A clinical contribution to lateral displacements of the uterus, Edward J. Ill, Newark. 6, Appendicitis, A. Vander Veer, Albany. 7, Intermediate treatment of puerperal sepsis, A. B. Miller, Syracuse. 8, Kraurosis vulvæ, a contribution to its pathology and therapeutics, H. W. Longyear, Detroit. 9, Report of three recent cases in gall bladder surgery, Edwin Ricketts, Cincinnati. 10, Subject to be announced, H. E. Hayd, Buffalo. 11, Intestinal obstruction following peritoneal operations, A. H. Cordier, Kansas City. 12, Subject to be announced, S. Y. Howell, Buffalo. 13, Cure of tubal distension without laparotomy, F. A. Glasgow, St. Louis. 14, Subject to be announced, W. B. Dorsett, St. Louis. 15, Subject to be announced, C. C. Frederick, Buffalo. 16, Hysterectomy in bilateral diseases of the appendages, giving remote results, Florian Krug, New York. 17, Discussion: Vaginal hysterectomy vs. Abdominal section for pus tubes. (a), title unannounced, (affirmative,) X. O. Werder, Pittsburgh. (b), when shall hysterectomy accompany bilateral removal of the appendages? Reuben Peterson, Grand Rapids. (c), pathologic and surgical contra-indications of the vaginal route in dealing with puriform diseases of tubes and ovaries, Joseph Price, Philadelphia. (d), title unannounced, (affirmative,) Geo. H. Rohé, Catonsville. 18, Discussion: Eclampsia gravidarum. (a), etiology, Frederick Blume, Allegheny. (b), pathology, George F. Hulbert, St. Louis. (c), title to be announced, W. H. Taylor, Cincinnati. (d), prophylaxis, H. W. Longyear, Detroit. (e), puerperal convulsions vs. Insanity, W. P. Manton, Detroit. (f), treatment, J. M. Duff, Pittsburgh; A. H. Wright, Toronto; Thomas Lothrop, Buffalo. 19, Exhibition of various types of rectal papillæ, R. T. Morris, New York. 20, Subject to be announced, E. Arnold Praeger, Los Angeles, Cal. 21, Ruptured interstitial pregnancy, L. H. Dunning, Indianapolis. 22, Has gynecology received just recognition as a specialty? M. B. Ward, Topeka. 23, Indications for operation in puerperal sepsis, L. S. McMurtry, Louisville. 24, Pneumo-peritoneum, James F. W. Ross, Toronto. 25, Subject to be announced, J. B. Murphy, Chicago. 26, Subject to be announced, Charles A. L. Reed, Cincinnati. 27, Subject to be announced, M. Rosenwasser, Cleveland.

The regular program will be issued September 1.

J. HENRY CARSTENS, President.

WILLIAM WARREN POTTER, Secretary.

NECROLOGY.

LEVI D. MILLER, M.D., of Newton, N. J., died July 21. He was one of the oldest and best-known physicians in Sussex County, and was a graduate of the College of Physicians and Surgeons, New York, in the year 1855. He practiced medicine for twenty-seven years, was surgeon of the Fourth New Jersey Regiment in the late war, a member of the Grand Army and Legion of Honor, and secretary of the Sussex County Medical Society.

EZRA GRAVES, M.D., of Amsterdam, N. Y., died July 1, 1895, aged 56 years. He had served as coroner of Montgomery County, and also as city physician of Amsterdam. He was a graduate of the Buffalo Medical College, of the class of 1865. A widow survives him.

WILLIAM C. JARVIS, M.D., professor of diseases of the throat at the University of the City of New York, July 30.—Henry Shimer, M.D., of Mt. Carroll, Ill., July 30, aged 65.—Walter C. Overstreet Jr., M.D., of Monmouth, Ill.—Solomon C. Salter, M.D., of Lena, Ill., August 1, aged 64.—J. W. DeHoog, M.D., of Chicago, August 1.—C. Plummer, M.D., of Wooster, Ohio, July 27, aged 74.—Harlow Williams, M.D., of Centerburg, Ohio, July 27.—Sheppard Lowrey Van Valzah, M.D., of Milton, Pa., July 28, aged 59.—L. S. Zeiner, M.D., of Easton, Pa., July 27.

MISCELLANY.

Dr. S. Weir Mitchell of Philadelphia, has been honored with the degree of LL.D., conferred upon him by the University of Edinburgh. As he has this title from another university, he is now, indeed, a double LL.D.

Large Charitable Bequests at Hartford.—The will of Mrs. Sarah Tuttle of Hartford, Conn., gives \$10,000 to the Old People's Home, \$5,000 to the Hartford Hospital, \$5,000 to the Hartford Orphan Asylum, \$6,000 to the Larrabee Fund, \$2,000 to the Union for Home Work, and \$1,000 to the Church Home.

Condensed Milk Swindlers.—A recent report by Dr. Bernard Dyer, Public Analyst, and Mr. Cassal, made to the *British Medical Journal* shows that of seventeen samples examined, fourteen are prepared entirely from skimmed milk. It is a source of pleasure to note that of the brands of milk examined none were from American manufacturers.

A New Professor of Bacteriology in the University of Minnesota.—F. F. Westbrook, an instructor in bacteriology at Cambridge University, England, has been elected to a similar position in the College of Medicine and Surgery University of Minnesota. His duties will be assumed with the completion of the new laboratory building in October.

College of Physicians and Surgeons.—Dr. Bayard Holmes, Librarian of the College of Physicians and Surgeons of Chicago, requests all authors who have reprints made of their articles to send a copy of each to the Library, 813 W. Harrison Street, Chicago. Each reprint will be put in a stiff cover and treated in the catalogue as a book.

The Neanderthaloid Man of Java.—The discovery in Java, by Dr. Dubois, a surgeon in the Dutch-Indian Army, of the remains of prehistoric man has now been fairly well discussed by the anatomists of two continents. Prof. A. S. Packard, of Dartmouth College, has given in the *Independent* a digest of the opinions, concerning this discovery, by some of the chief of the authorities in anthropology.

Can Correct Registration of License.—Where, instead of registering his license as a physician with the county clerk, as required by law, a physician filed it with the Board of Health, the general term of the New York Court of Common Pleas holds (Mayor v. Bigelow, June 3, 1895) that due registration made after suit had been begun to recover the penalty imposed for a failure to make proper registration, but before trial, was a defense to such action for the penalty.

University of Pennsylvania.—This institution has invited Dr. John S. Billings, U. S. A., to take its professorship in hygiene. It is stated that he has accepted the offer to take the position before many months, after he shall have completed his mammoth undertaking, the Index Catalogue of the Army Library. It is reported that a subscription paper is in circulation, for the benefit of Colonel Billings, as a substantial recognition of his labors in the interest of medical science.

An Enterprising Midwife.—A French contemporary¹ clips the following "ad" from *L'Independance Bretonne*, which shows the thrifty spirit of the French peasantry: "Mdlle. Guezennec, oyster culturist at Lezardrieux, has the honor to make known to the public that her oysters will be sold in the Halls of St. Brievé every Friday. There will also be a depot in the Hall of Guingamp the first of next April. Moreover, Mdlle. G. always practices her profession of midwife of the first class and places herself at the public's disposal."

Postponed to 1896.—It has been decided by Dean Smith of the Yale Medical School that the lengthening of the course shall not take place this year as was originally the plan, but will go into effect September, 1896. This fall's entering

class will be the last to take a three-years' course; beginning with the class entering in 1896 a four-years' course will be required. Several important changes are announced in the faculty of the Medical Department of Yale: Dr. Charles Bartlett, Dr. Louis De Forrest, and Dr. H. L. Swain have been added to the list of professors, and Assistant Professors T. Osborn, H. B. Ferris, and Graham Lusk have been promoted to the positions of professorships in full.

Reports of Committees.—The *British Medical Journal* of July 27 is largely devoted to the reports of the regular and special committees of the British Medical Association, intended to be presented at the annual meeting. It appears that the regulations for the conduct of annual meetings require that all reports of the committees of the Association shall be printed in the *Journal* before the annual meeting. Our own ASSOCIATION might wisely adopt this plan, the benefits of which are so obvious as scarcely to need enumeration. One point in its favor is that by this plan every member has ample opportunity to become familiar with the reports, and to prepare intelligently for their discussion should he so desire. Notices of motions are also similarly printed in advance in the *Journal*.

Hansen's Bacillus in the Blood of Leprous Patients.—Fischella has instituted a series of experiments to determine under what conditions we may find Hansen's bacillus in leprosy blood. He has arrived at the following conclusions: (a), positive result in blood from an incision or puncture near a leprosy tubercle; (b), a uniformly negative result in blood taken at some distance from the leprosy manifestations; (c), negative result in leprosy blood submitted to treatment by Koch's lymph; in the blood of tuberculous patients treated by Koch's lymph we may, on the contrary, find the tubercle bacillus, which ordinarily is not found in the blood; (d), by injecting leprosy bacilli into the blood of rabbits the author found that they disappeared about ten hours after inoculation.¹

"Struck the Keynote."—Commenting editorially on what it styles the "most excellent article of Dr. Julius Kohl, of Belleville, Ill.," the Physician of the Past, the Present and the Future—A Definition of His Social Position, published in this JOURNAL, June 22, 1895, the *Medical Review* of the 3d inst., says: "Dr. Kohl advocates a thorough classical education and examination by the State before a student is admitted to any medical college. A student equipped with the knowledge required by such an examination, is too intelligent to allow himself to be 'taken in' by the bogus medical colleges so that the latter would be compelled to close their doors. The idea is a most practical one, and Dr. Kohl does by no means stand isolated in his views upon this subject. He has struck the keynote and suggested the only remedy against bogus colleges, the cancer of the medical profession. He has applied his ax to the roots of this malignant growth."

Tuberculosis of the Cecum.—MM. Pilliet and Thiery state that tuberculosis localized in the cecum may be disseminated in several directions and it is useful to know these in order to judge the contra-indications for operating. 1, by the peritoneum; this may be slow, localized and of but little gravity; the peritoneum enveloping the tumor is generally adherent to it, and we know from this that the tumor and the intestinal wall form one mass. 2, by the intestines; the majority of the lesions are descending; the maximum is found at the end of the cecum, thence tapering off into the colon; the small intestine, contrary to the usual opinion, is but rarely affected. 3, by the ileo-cecal glands, when we observe sometimes an infection of the mesenteric and mesocolic glands, sometimes an infection of the vertebral glands

¹ Le Progres Medical, July 6, 1895.

¹ Rev. Int. de Med. et Chir. Prat., 1895, No. 11.

reaching to the diaphragm; exploratory laparotomy will enable us to ascertain which condition is present. 4, by the iliac glands; this form is usually accessible to the touch and constitutes a contra-indication.¹

Veterinary Surgeons must Prove Qualification.—A physician, surgeon or dentist, it has been said, undertakes in law to supplement his reasonable care and honest endeavors with ordinary professional skill. The same is true, according to a decision of the Supreme Court of Michigan rendered July 2, 1895, in the case of Conkey v. Carpenter, of a veterinary surgeon, because it requires education to be able to treat diseases of dumb animals as well as diseases of men. There is no presumption of qualification. A "quack," without education or experience, employed upon the representation that he is a qualified veterinary surgeon, can not recover for services. Professional employment stands upon a different basis from other businesses. It is, therefore, the common practice, when a professional man sues for services as such, to prove his qualification. This is done by showing his admission to practice under the statute, his graduation from some reputable college or school, or his study and experience, if his right to practice is not regulated by statute.

Pneumonia a Disease.—By the terms of a certain insurance policy, if the death of the insured was from "pulmonary disease," the beneficiary could recover only \$32.50; otherwise, she would be entitled to \$65. The insured died of acute lobar pneumonia, conceded to be a pulmonary affection, but denied by the beneficiary to be a disease. Strangely enough she found an "expert" to testify and a judge to decide that a mortal pneumonia was not a disease. In reviewing the case on appeal, the general term of the Court of Common Pleas of New York city and county says (Kiernan v. Metropolitan Life Insurance Company, June 3, 1895) it hardly consists with judicial gravity to argue against a proposition of which the absurdity is self-evident, which involves at once an affront to common sense, a misconception of the plain sense of a plain word, and a contempt for the uniform and universal signification of scientific nomenclature. That pneumonia is a disease is a notorious fact, and so a fact of judicial cognizance. As the court takes notice of the fact, no proof of it was requisite, and no issue could be joined upon it. In support of these points the court cites a number of authorities, and modifies the judgment to \$32.50.

Clinical Results of Double Castration.—In summing up the results of 111 cases of the operation for the relief of senile enlargement of the prostate, as proposed by Dr. J. William White about two years ago, the author says² that the theoretic objections which have been urged against the operation of double castration have been fully negated by clinical experience, which shows that in a very large proportion of the cases (87.2 per cent.) rapid atrophy follows the operation and disappearance or great lessening in degree of long-standing cystitis (52 per cent.); and that more or less return of the vesical contractility (66 per cent.), and a return of the local conditions not very far removed from the normal (46.4 per cent.) may be expected in a considerable number of cases. The deaths have been 20 in 111 cases (18 per cent.); excluding those cases which died from uremia alone the mortality is 7.1 per cent. It may be interesting to note that the desperate cases which make up the series of deaths showed improvement of symptoms or shrinkage of the prostate before they died. Comparison with other operative procedures seems to justify the statement that, apart from the sentimental objections of aged persons on the one hand, and the real, entirely natural and very strong repugnance to the operation felt by the younger patients, castration offers a

better prospect of permanent return to nearly normal conditions than does any other method of treatment.

Fake Patent Medicine Men.—From the *Minneapolis Journal* we learn that fake patent medicine men are working the country districts in the vicinity of that city quite successfully. They sell their medicine and take the farmers' notes in payment, the notes returning for payment in a much different form from that in which they were signed. Deputy Sheriff Megaarden received a letter from C. W. W. Dow, of the Interstate Sheriffs' Association, recently, giving the following description of a man who gives his name as H. Miller and who purports to represent a Buffalo Medicine Company: "He is working among the farmers, taking their notes and discounting them. He is described as follows: Height about 5 feet 6 inches; age about 45, perhaps 50; dark hair, but bald in front and on top of head; a trifle gray; dark eyebrows; had no mustache, may have now; dark complexion; Jewish cast of features; nose slightly Roman; weight about 160; talks broken English, and claims that he can not write English—has his victim do the writing. Had on a black or brownish derby hat, dark coat and vest; laced shoes. He hires a team with a driver, and has driver witness signatures. Had three grips with him. He has operated in southern Nobles County, Minnesota, about June 6, 7 and 8. Last seen at the depot at Little Rock, Iowa." The police are warned to be on the lookout for Miller.

Failure of Emmerich's Antitoxin of Carcinoma.—The Berlin letter of the *London Lancet*, for July 13, refers to the acrimonious debate that has been had in the Berlin medical journals over Emmerich's treatment for cancer. The letter gives a brief description of the present status of the discussion, as follows:

"The article communicated by Professor Emmerich and Dr. Scholl to the *Deutsche Medicinische Wochenschrift*, which was mentioned in my letter inserted in *The Lancet* of May 4, was received here with general skepticism. That this feeling was justified is now proved by the published observations of Professor Bruns (Tübingen), and Professor Augerer (Munich). Professor Bruns was quoted by the authors as vouching for the efficacy of the treatment, but he now states that in no instance was a curative effect remarked, while in some cases the general state of the patients was very unfavorably influenced. Cardiac trouble and raising of the temperature were very frequent, and must have been due to a septic condition of the fluid. To this suggestion, Professor Emmerich answered that the antitoxin was originally aseptic and must have been spoiled by Professor Bruns or his assistants. Professor Bruns replied that the fluid was examined immediately after its arrival in the bacteriologic laboratory of the University, and numerous streptococci were found in it. Professor Augerer stated that two of his cases were attacked with real erysipelas during the antitoxin treatment. The controversy between Professor Emmerich and his opponents sometimes assumed a very personal character and continues to fill the columns of the medical papers. The general impression is that the real carcinoma antitoxin has not yet been discovered."

Not Liable for Mutilations by Post-mortem Examinations.—A widow brought suit to recover damages from the coroner who ordered, the physician who conducted and the college which furnished a room for, the post-mortem examination of her deceased husband, on account of the alleged wrongful mutilation of the body and its unlawful detention from burial when demanded for that purpose. The damage alleged to have been caused by those acts was great mental excitement and distress and bodily suffering on the part of the widow. Death occurred in the Baltimore City Hospital one day, after the man, a brakeman, had had his right leg mashed below the knee. The college in question supplied the medical and surgical service to the hospital, and the coroner who ordered the post-mortem examination and the physician who made it were connected with the college.

¹ *Gaz. Med. de Paris*, No. 27, 1895.
² *Annals of Surgery*, July, 1895.

Judgment was given in behalf of the defendants in the trial court, and the Court of Appeals of Maryland affirms it (Young v. College of Physicians and Surgeons of Baltimore, June 18, 1895) on the ground that the post-mortem was a lawful proceeding, the coroner being required to hold inquests whenever a person is found dead and the manner and cause of death shall not already be known as accidental, or in the course of nature, and the accident preceding this man's death, and disabling him not being, in the coroner's opinion, sufficient to cause the death of a healthy person, while in the coroner's judgment and that of other professional witnesses, proper and sufficient inquiry could not be made without an autopsy. If anything irregular or improper occurred in the prosecution of the post-mortem, the court says that the college took no part in it. Neither did the coroner. The question regarding the charges which alleged the wanton mutilation of the body, the court holds, was fairly left to the jury in an instruction that if they believed that the medical examiner who performed the post-mortem did it at the order of the coroner, as the city examining physician, and in performing the same treated the body with ordinary decency, and did not wantonly disfigure it, he acted within the scope of his official duty and was not liable for damages.

Protection for Purchaser of Good Will.—A dentist who had carried on his business at a certain place in New York city for a period of ten or twelve years, sold out the business and good will thereof for \$1,500, agreeing not to re-enter the practice of dentistry for a period of four years from date of sale within certain territory within the city. He thereafter violated the covenant by opening and maintaining a rival establishment within the restricted territory. The claim that he did not understand the nature and effect of the covenant, or that it was without consideration, the special term of the superior court of New York city said (Niles v. Fenn, decided May 25, 1895), was not borne out by the testimony. A card issued by him in December following the sale, containing his name, address, and the word "dentist," showed that he was, to an extent at least, still in the same business close by the "old stand." This presented a case calling for equitable interference, and to preserve and enforce the covenant an injunction, it was held, should be granted. Although the business sold was a professional one, the court said that the law recognized the fact that it had a good will, which might be sold as an incident of the business. If the customers declined to go to the "old stand," this would be the purchaser's misfortune, but the seller must not interfere to his prejudice.

Treatment of Foreign Bodies in the Uterus.—Albertin of Lyons, having had two cases of foreign bodies in the uterus—one a laminaria tent, the other an electrode,—has collected some data bearing thereon. All authorities except Poulet, he says, are silent on the subject. Foreign bodies may come from within—polypus, fibroma or mole calcified; fetal *débris*; or from without—the introduction of instruments for producing premature birth or abortion or for therapeutic purposes as dilatation, cauterization, replacement, etc., or for purposes of masturbation. Among the objects found are needles, catheters, wooden knitting needles and above all hairpins. From the standpoint of symptomatology there are two classes: 1, when the uterus is enlarged, as in abortion or premature delivery, by perforation or separation of the membranes—if the body is aseptic, no infectious phenomena; metropéritonitis, if it is septic. 2, when the uterus is not gravid there is often long tolerance of aseptic foreign bodies e.g., large sponges mentioned by Pichevin; infectious metritis follows from septic objects; lesions of neighboring structures by propagation—salpingitis, pelvi-peritonitis, sal-

pingo-ovaritis, and disorders of menstruation, amenorrhœa and menorrhœgia. The process evidently will differ when the foreign body produces a wound of the uterus—initial hemorrhage, perforation, fistula, abscess opening in the groin or perineum. The principal diagnostic elements are inquiry into the history, vaginal touch, examination per speculum and with sound, and, if need be, the use of Sims' small curette. The prognosis is variable; if the object is tolerated it is good; if septic phenomena are present it is of course, grave. As regards treatment: the diagnosis being positive and the body loose, Albertin advises immediate extraction; if it is fast, and local antiseptics is possible, expectant measures should be resorted to, awaiting spontaneous expulsion; if these are contra-indicated dilate by tents and intra-uterine irrigation; as a last resort, use either uterine dressing forceps or Sims' curette or, in exceptional cases, incision of the cervix. The strictest vaginal and uterine antiseptics must be observed before, during and after any manipulations. The patient must be kept under surveillance for some time after extraction of the body, since late septic complications may ensue.¹

The New Anatomic Nomenclature.²—(Karl v. Bardeleben in *Deutsche Med. Wochenschr.*, July 4, 1895.) At its ninth meeting in Basle April 17 to 20, 1895, the Anatomical Society accepted the "Nomina Anatomica," arranged by the Commission intrusted with this work, and recommends to all professional associates the use of the names included in the list.

In obedience to the request of the editor of this JOURNAL to explain the new nomenclature briefly, I note first, historically, that at the business session of the first meeting of the Anatomical Society, in April, 1887, in Leipsic, the board of directors (at that time v. Kölliker, Gegenbaur, His, Waldeyer, K. Bardeleben) proposed the following plan: "The Anatomical Society desires to begin the regulation of a general anatomic nomenclature. . . ." After the acceptance of this proposition the directors were commissioned to undertake the necessary preliminaries before the next meeting. After it had been proved that the directors could not carry on this business in addition to other work, a special nomenclature commission was elected at the third meeting, in Berlin, October, 1889 (chairman, v. Kölliker; members, O. Hertwig, His, Kollmann, Merkel, Schwalbe, Toldt, Waldeyer, Bardeleben). This commission chose next an editor, W. Krause, and sought then to obtain the necessary funds. Beside 3,800 marks which the Society gave, over 8,000 were contributed by the Academies in Berlin, Vienna, Munich, Buda-Pesth and the Society of the Sciences in Leipsic. The commissioner, at least temporarily, associated others with them: Braun, Henle, v. Kupffer, v. Mihalkovicz, Buda-Pesth; Rüdinger, Zuckerkandl, Lebouck, Ghent; Thane, London; Turner, Edinburgh; Cunningham, Dublin; Romiti, Pisa, and others. For some parts of the work, special committees were chosen: for veins and lymph vessels, Merkel, Thane, Toldt; for regions, Merkel, Rüdinger, Toldt; for syndesmiology, Toldt. Finally, a special publication committee took care that the whole work should maintain a uniform character.

Fixed limits were established for the extent of the undertaking; only the descriptive, that is, the systematic³ and the typographical, human anatomy, and this only so far as it is the subject of macroscopic examination, should constitute the object. Secondly, it was resolved that the terms

¹ Rev. Int. Med. et Chir. Prat., No. 11, 1895.

² Die anatomische Nomenclatur. Nomina anatomica. Verzeichniss der von der Commission der Anatomischen Gesellschaft festgestellten Namen, eingeleitet und im Einverständnis mit dem Redaktionsausschuss erläutert von Wilhelm His. Mit 90 Abbildungen im Text und zwei Tafeln. Sep.-Abzug a. Arch. f. Anat. u. Physiol. Anat. Abthlg. Suppl. Band. 1895. 183 S. Die obige Darstellung schliesst sich an die "Eiuleitung" von His an.

³ The two expressions, "descriptive" and "systematic," are frequently applied erroneously, as having the same significance, whereas the former is the more comprehensive.

should be in one language, that is, Latin designations only, and to permit the individual nations to translate these eventually into their languages. The following principles were recognized in applying the names: each part shall have but one name. The names shall be Latin and etymologically correct. They shall be as short and simple as possible. They shall be mere tokens for the memory, and not contain descriptions or interpretations. Connected names shall be as far as possible analogously framed (for instance, femur, A. femoralis; V. femoralis; N. femoralis). Too firmly fixed names have made exceptions necessary, so M. sternocleidomastoideus has remained, Valv. ceceespidalis is to be used together with Valv. mitralis, pyramis and pars petrosa, vola and palma, nates and clunis. As regards proper names, a compromise has been decided upon; that is, many remain, others not. For some parts the proper names have been temporarily retained in addition to the other names, and the final decision for the time relinquished.

One very weighty question was, to what extent attention should be paid to the anatomic nomenclature of the specialties in medicine, psychiatry and neurology, the aurists, ophthalmologists, laryngologists and others. Here the decision was restrictive, that the specialists had been forced to the creation of their nomenclature through necessity and that anatomy, as a collective science, has to follow this. The student, who goes out from his anatomy into the clinics, can demand that he receive those ideas and the language which he needs in his more advanced studies, and that it should not be necessary for him to learn a new anatomy in place of an antiquated one.

The original plan, to proceed in a purely conservative way and to select from the already existing designations the most suitable, could not be adhered to. Not only antiquated expressions, but also such as are vague and used with various meanings must be excluded; or, on the other hand, they must be clearly fixed in their significance. The latter was only possible many times by specially devised means, where literature was inadequate. The writer chooses only certain examples from single headings in systematic anatomy in illustration of what has been said:

Osteologia. Scapula:

Facies costalis, Lineæ musculares, Fossa subscapularis, Facies dorsalis, Spina scapulae, Fossa supraspinata, Fossa infraspinata, Acromion, Facies articularis acromii, Margo vertebralis, Angulus inferior, Angulus lateralis, Angulus medialis, Cavitas glenoidalis, Collum scapulae, Incisura colli scapulae, Tuberositas infraglenoidalis, Tuberositas supraglenoidalis, Incisura scapulae, Processus coracoideus, Margo axillaris, Margo superior.

Splanchnologia. Pulmo:

Basis pulmonis, Apex pulmonis, Sulcus subclavius, Facies costalis, Facies mediastinalis, Facies diaphragmatica, Margo anterior, Margo inferior, Hilus pulmonis, Radix pulmonis, Incisura cardiaca, Lobus superior, medius, inferior, Incisura interlobaris, Lobuli pulmonum, Rami bronchiales, Bronchioli, Bronchioli respiratorii, Ductuli alveolares, Alveoli pulmonum, Lymphoglandulae bronchiales, Noduli lymphatici bronchiales, Lymphoglandulae pulmonales.

Angiologia. A. radialis:

A. recurrens radialis, Rami musculares, Ramus carpeus volaris, Ramus volaris superficialis, Ramus carpeus dorsalis, Rete carpi dorsale, A. metacarpeæ dorsales, Aa. digitales dorsales, A. princeps pollicis, Aa. volaris indicis radialis, Arcus volaris profundus, Aa. metacarpeæ volares, Rami perforantes.

Neurologia. N. medianus:

Rami musculares, N. interosseus (antibrachii) volaris, Ramus palmaris n. mediani, Ramus anastomoticus cum n. ulnari, Nn. digitales volares communes, Nn. digitales volares proprii.

Organa sensuum. Apparatus lacrimalis:

Glandula lacrimalis superior, Glandula lacrimalis inferior (Glandulae lacrimales accessorie), Ductuli excretorii (Glandula lacrimalis), Rivus lacrimalis, Lacus lacrimalis, Puncta lacrimalia, Ductus lacrimales, Papillae lacrimales, Ampulla ductus lacrimalis, Saccus lacrimalis, Fornix sacci lacrimalis, Ductus nasolacrimalis, Plica lacrimalis (Hasneri), Lacrimæ.

Aus der topographischen Anatomie:

Regiones colli:

R. colli anterior; R. submentalis, hyoidea, subhyoidea, laryngea, thyroidea, suprasternalis, Fossa jugularis, R. submaxillaris, Fossa carotica, R. sternocleidomastoidea, Fossa supraclavicularis minor; R. colli lateralis: Fossa supraclavicularis major, Trigonum omoclaviculare; R. colli posterior: R. nuchæ, Fovea nuchæ.

We will now hope that the new anatomic nomenclature, called to life with the expenditure of so much toil, time and money may be a common source of agreement not only for anatomists, for investigators and teachers of different nations and languages with one another, but also between teachers and pupils, between anatomists and physiologists, pathologists and practitioners, also between theory and practice! Then will the long and toilsome work of the commission not have been in vain.

Hospital Notes.

THE LONG ISLAND STATE HOSPITAL FOR THE INSANE is the name under which the two asylums of Kings County, in which Brooklyn is located, will hereafter be known. These asylums, located in Flatbush, and King's Park, Suffolk County, have passed into control of the State by virtue of an Act of the Legislature of New York; but the new board of managers to be appointed by Governor Morton, will not take formal possession until October 1. For the purpose of carrying out the provisions of the Act, the county authorities will, under direction of the board, execute a quit-claim deed to the State, in consideration of the sum of \$1. The asylum property in Flatbush will only be leased to the State for a period of five years, with the privilege of extending the time from year to year, not exceeding five years additional. At the end of the leasehold, the old asylum buildings will be converted into general hospital purposes.

The transfer of the insane asylum to the State will save the county an annual expense of about \$300,000.

THE new hospital pouches have been issued to the Regimental Hospital Corps of the Connecticut National Guard. Each pouch contains the following: 2 roller bandages, 2 ounces boracic wool, 2 ounces patent lint, 1 Esmarch tourniquet, 1 first aid packet, 1 medicine glass measure, 1 pus basin, 2 small sponges, 4 ounce bottle chloroform, 1 ounce bottle aromatic spirits of ammonia, book of diagnosis tags, 1 ounce carbolated vaselin, 1 No. 8 catheter, pair scissors, paper sorted pins, one-half dozen assorted safety pins. One pouch to each corps, to be carried by the acting hospital steward, contains the following articles in addition: medicine case containing tablets and a hypodermic syringe with morphin, and cocain tablets. The medicine case contains the following in tablet form: bichlorid, acetanilid, brown mixture, quinin pills, opium and camphor pills, cathartic pills. The pouches are made of brown canvas and weigh about five pounds.—St. Joseph's Hospital at Providence, R. I., is to be improved by the addition of a laundry to cost \$2,000.—The Rev. William L. Bull and his mother, Sara R. Bull, of Whitford, R. I., have given \$8,000 to the management of the Chester, Pa., County Hospital, to be used in erecting a memorial building to Mrs. Bull's daughter, Annie.—The report of the German Hospital for the period from June 20 to July 23 shows the number of patients on June 20, 136; admitted since that time, 226; discharged, 205; deceased, 18; remaining in hospital, 139. The number of cases treated in the dispensary was 2,827.—The house physician of St. Luke's Hospital at Jacksonville, Fla., announced on August 1 that no more patients would be received at the hospital. The closing of this charitable institution is caused by lack of adequate financial support by the citizens of that city, and it is to be hoped that this condition of affairs is but temporary.

Washington Notes.

WEEKLY REPORT OF THE HEALTH DEPARTMENT.—The report of the Health Officer for the week ended July 27 is as follows: number of deaths (still-births not included): white, 60; colored, 47; total, 107. There was improvement in the health of the city last week. The number of deaths as reported at the Health Department was 107, as against 159 in the preceding week. The death rate fell 33 per cent., reach-

ing 20.5 as compared with the previous report of 30.5. The deaths of children under 5 years of age declined from 70 to 53. It is thus seemingly indicated that the intensity of the annual rise in the mortality from summer maladies reached its climax last week, and the outlook for a gradual improvement during the balance of the summer may be considered favorable. There was but one death from diphtheria and none from scarlet fever nor from any of the dangerous contagious diseases reported, while there were four deaths from typhoid fever last week, and four from the same disease in the former week.

THE CENTRAL DISPENSARY AND EMERGENCY HOSPITAL.—The annual report of the Central Dispensary and Emergency Hospital for 1894 is being distributed. It contains, beside the record of its extensive work for the past year, an interesting history of the institution from its organization.

FIRE ESCAPES OR NO LICENSE.—As the only way of reaching hotel keepers who do not comply with the regulations of the fire-escape law, the Commissioners have decided to refuse a license to all proprietors who decline to provide fire escapes for their establishments after sixty days' notice. The enforcement of this law will prevent a repetition of the preventable loss of life and limb which has so frequently shocked the community recently. The law is very perfectly drawn and is a good and necessary one.

DIED FROM SWALLOWING GLASS.—A 13-year-old colored boy died last week under circumstances which caused the parents to suspect poisoning. The boy said he had been given beer to drink which contained arsenic or strychnin. Upon investigation by the coroner no trace of poison could be found. A perforation of the intestines by a piece of glass and resulting peritonitis was discovered. The glass is supposed to have been in the beer he drank.

Louisville Notes.

PERSONALS.—Drs. Henry E. Tuley and S. G. Dabney were returned from a summer vacation. Drs. J. M. Mathews, J. B. Marvin and J. A. Oetelony are still absent.

UNIVERSITY OF LOUISVILLE.—The Medical Department recently elected Prof. H. A. Cottell to succeed Dr. E. R. Palmer in the chair of physiology. Dr. H. M. Goodman was elected professor of chemistry to succeed Dr. Cottell.

MILK.—Much commendable work is being done by Health Officer White, in his endeavor to obtain pure milk for Louisville. The question of milk supply of cities was first brought to the notice of the local profession in a paper read by Dr. Tuley, before the Louisville Academy of Medicine; a paper was later read by Dr. J. A. Larrabee and a general discussion had upon the question of legislation. A committee was appointed from the Academy to draft suitable resolutions recommending to the local council the passage of a new ordinance, creating a milk inspector, and new laws under which he could work. The committee has met with no encouragement from the Mayor who states he will oppose any ordinance in which a new office is to be created. Dr. White has been doing excellent work under the present inadequate laws, and has secured samples of milk from dairymen, the offending ones being arrested, a fine of \$50 being imposed upon one, and \$25 each upon two others, for watering and otherwise tampering with the milk. One dairyman in his defense very ingeniously said that he added two gallons of water to every twenty gallons of milk; in the first place to cool it, and in the second to prevent its becoming "stringy." He was fined.

TEXAS (SPLENIC) FEVER.—The cattle at a number of points near Louisville recently became afflicted with this disease, and indications pointing to a severe and disastrous epidemic, the State Board of Health appointed as State Veterinarian, Dr. F. T. Eisenman who has been making vigorous efforts to

stamp out the disease. In this he has been nearly successful, as only isolated cases are heard of from time to time.

MEDICAL LEGISLATION.—The board of aldermen have passed the contagious disease act and it will shortly become a law. It provides for the placarding of houses in which there is diphtheria or scarlet fever; quarantining of other children from school; proper isolation of children after convalescence; in case of death, early and private funerals, the body to be buried in a sealed casket. It has been decided to erect urinals over the sewer catch basins at the street corners for the G. A. R. Encampment.

DEATH REPORT.—For the week past there was a total of 55 deaths; of these 24 were male, 31 female; 37 white, 18 colored; 34 single, 16 married, 5 not stated. For the month of July there were only 294 deaths, while there were 333 deaths in July 1894. Annual death rate per 1,000, 15. White death rate per 1,000, 164,261 population, 14. Colored death rate per 1,000, 35,739 population, 23. For month, white, .013; for month, colored, .022.

Samples of milk examined, 82; diseased cattle killed, 48; diseased cattle condemned and sent to the country, 85.

THE PUBLIC SERVICES.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from July 27, 1895, to August 2, 1895.

Capt. W. FITZHUGH CARTER, Asst. Surgeon U. S. A., is granted leave of absence for one month.
Major C. K. WINNE, leave of absence granted for seven days, is hereby extended twenty-three days.
Capt. JUNIUS L. POWELL, Asst. Surgeon U. S. A., is hereby granted leave of absence for one month, with permission to apply for an extension of one month.

Marine-Hospital Changes. Official list of changes of stations and duties of medical officers of the U. S. Marine-Hospital Service, for the fifteen days ended July 31, 1895.

Surgeon W. H. H. HUTTON, to proceed from Washington, D. C., to Pensacola, Fla., on special duty, July 18, 1895.
Surgeon J. B. HAMILTON, granted leave of absence for three days, July 30, 1895.
Surgeon W. A. WHEELER, detailed as chairman of board for physical examination of candidate, revenue cutter service, July 23, 1895.
P. A. Surgeon D. A. CARMICHAEL, detailed to make physical examination of candidate, revenue cutter service, July 26, 1895.
P. A. Surgeon L. L. WILLIAMS, granted leave of absence for ten days, July 20, 1895.
P. A. Surgeon G. M. MAGRUDER, to proceed from Galveston, Texas, to New Orleans, La., for temporary duty, July 27, 1895. Order to proceed to New Orleans suspended, and directed to proceed to Eagle Pass, Texas, for special duty, July 31, 1895.
P. A. Surgeon J. C. PERRY, granted leave of absence for twenty days, July 16, 1895.
Asst. Surgeon E. H. SPRAGUE, to proceed from Mobile, Ala., to Key West, Fla., for temporary duty, upon completion of which to rejoin station at Mobile, July 18, 1895.
Asst. Surgeon A. R. THOMAS, to proceed from Buffalo, N. Y., to New Orleans, La., for temporary duty, July 20, 1895.
Asst. Surgeon H. S. CUMMINGS, detailed as recorder of board for physical examination of candidate, revenue cutter service, July 23, 1895.
Asst. Surgeon J. B. GREENE, to report at Bureau for temporary duty, July 16, 1895.

ORIGINAL ARTICLES.

HYSTERECTOMY FOR SUPPURATIVE DISEASE OF THE PELVIC ORGANS.

Read in the Section on Obstetrics and Diseases of Women, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY J. M. BALDY, M.D.

PHILADELPHIA, PA.

When on the evening of Oct. 5, 1893, I read before the Obstetrical Society of Philadelphia, a paper entitled "Removal of the Uterus and its Appendages for Pelvic Inflammatory Disease," and for the first time proposed this procedure as a matter of election, my remarks met with a strong protest and almost universal disapproval. At almost the same time, Polk made a similar proposition in a paper read before the New York Obstetrical Society, which was received by an almost equal amount of condemnation.

During May, 1894, I read a paper on the same subject before the American Gynecological Society at its Washington meeting, and it proved to be a matter of considerable surprise that in the short interim so large a number of the members had already practiced and approved the new procedure, as was developed by the discussion. Since that time, I have had many opportunities of demonstrating the feasibility and advisability of this operation to many physicians visiting Philadelphia from all sections of the United States, and find that many of them on returning home have adopted the method.

To-day the operation is established on a sure and firm basis, and many women who were before doomed to a partial recovery are now blessed with a complete return to health. My object in again encroaching upon the time of the profession with this subject, is not that I believe anything is needed to establish its feasibility, but rather to again freshen the minds of those who may feel that hysterectomy is either a more difficult or more dangerous operation in these cases than salpingo-oöphorectomy. For this purpose it may not be out of place to once more review certain general considerations arising in this connection which were formulated in my paper before the American Gynecological Society one year ago. I there propounded the question, "Is the uterus essential or useful after the ovaries have been removed?" At that time I assumed, and still assume, that this query can only be answered in the negative. If it is granted that the uterus, deprived of its appendages, is a useless organ in the human economy, as far as its relation to this matter is concerned four questions are pertinent:

1. Are all patients cured after an operation requiring double salpingo-oöphorectomy?
2. Are patients cured after hysterectomy when double salpingo-oöphorectomy has failed?
3. Does the operation of hysterectomy increase the

mortality over that of double salpingo-oöphorectomy?
4. Is the retention of the uterus of any disadvantage or danger to the patient?

As to the first and fourth questions nothing can be added in answer, other than was advanced in the paper to which reference has already been made. There is no one who has practiced gynecologic surgery to even a limited extent, but who knows that patients suffering from chronic pelvic inflammatory disease are not always cured of their symptoms by the removal of the tubes and the ovaries alone. The matter is so notorious that it is hardly necessary to more than call attention to the fact to quiet any criticism from this direction. As to whether or not patients are cured after hysterectomy, when double ovariectomy has failed, as stated in my former paper experience must decide. I there said: "In my paper read before the Philadelphia Obstetrical Society, Oct. 5, 1893, two cases are reported in which the uterus had been removed subsequent to a simple extirpation of the appendages. After the primary operation these patients had continued to suffer from leucorrhæal discharges, bleeding and pain. The secondary operation for removal of the uterus proved that the appendages had been thoroughly and completely extirpated at the first operation and that no such cause as incomplete removal existed to account for the continued suffering. The removal of the uterus in both cases cured the patients, and at the present writing they both remain in good health.

"Two other similar operations have been performed since that time with like results."

It may be stated that these four patients now, a year and a half later, remain in good health without any return of their old symptoms. I am at this time able to add two cases to this list, with like results, making a total of six patients who have been rescued from chronic invalidism by a hysterectomy subsequent to a double salpingo-oöphorectomy. During this period, from fifteen to twenty patients have passed through my hands on whom the salpingo-oöphorectomy had failed to relieve the symptoms, but whom I was unable to persuade to try the hysterectomy, on account of their suffering at their former operation and a sentiment against losing the womb, which many women by reason of false professional teaching appear to consider a vital organ. These facts seem to answer my second question most emphatically and in the affirmative.

The whole subject must after all hinge upon the answer to the third question, "Does the operation of hysterectomy increase the mortality above that of double salpingo-oöphorectomy?"

If the mortality be increased and the relief be not commensurate, the proposed procedure must fall and we must return to the old one of double salpingo-oöphorectomy, or seek for a substitute in some other direction. That much greater and surer relief of

symptoms are obtained has already been demonstrated. In my paper of last May there are reported twenty-two patients who were suffering from chronic pelvic inflammatory disease, upon whom I had performed hysterectomy. In that report I said: "Of this number all recovered from the operation, and the great majority have been cured. My highest mortality in the past has always followed removal of the appendages in this same class of patients. At no time have I been able to pick out anything like twenty-two successive successful double ovariectomies in cases of the same character as those upon whom I have found it advisable to perform hysterectomy. Not only has hysterectomy, in my hands, lessened the mortality very markedly, but it has rendered the convalescence infinitely smoother, easier and more satisfactory."

At the present time, I have twelve more to add to the list, making in all thirty-four cases without a death.

In addition to my own cases, I may submit in evidence the work in this same direction by other operators to date: Baldy, 34 cases, no deaths; Kelly, 70 cases, no deaths; Polk, 20 cases, 1 death; Pryor, 9 cases, no deaths; King, 65 cases, 4 deaths; Penrose, 25 cases, 1 death—making a grand total of 223 cases with 6 deaths, a mortality in the hands of six operators of 2.7 per cent.

What better argument can one possibly offer in favor of any new procedure? A greatly lessened mortality, a surer and more thorough relief of symptoms, an easier and shorter convalescence, a freedom from any possible future disease of the womb! Can there be any who are yet skeptical?

Hysterectomy being determined to be the proper procedure in certain chronic pelvic inflammations, it remains to determine in what cases to choose this operation. In this connection, I can not do better than quote *verbatim* from my last paper on the subject:

"It is well-known in pelvic inflammation the disease first affects the mucous membrane lining the womb and, secondarily, invades the Fallopian tubes and the pelvic peritoneum. In many cases not only is the endometrium affected, but the inflammatory products invade the deeper structures which go to make up the uterine walls. These infiltrates undergo the same changes as do the same elements in the walls of the Fallopian tubes whether it be suppuration or partial organization; in either case the process is apt to become a permanent one.

"With Fallopian tubes and uterus, both of which are diseased by the same factor and to the same extent, is it reasonable to suppose that a cure is to be always obtained by the removal of the tubes alone? Theory and practice both combine in this matter to force the conclusion.

"It must not be understood that the removal of the uterus together with the Fallopian tubes and ovaries is recommended in all cases of pelvic inflammatory disease. I am forced to dissent at this point from the views of some other surgeons with whose opinions in other respects I am thoroughly in accord. In many cases the uterus, possibly on account of its anatomic relations which are so favorable to good drainage, has succeeded in throwing off the original infection and is comparatively healthy, if not entirely so. Under such circumstances, hysterectomy is not indicated. But where an abdominal section has been

performed for the removal of the uterine appendages and the womb is found enlarged and diseased, especially if it has been surrounded by extensive adhesions, the destruction of which leaves large areas of denuded peritoneum, hysterectomy should be the operation of choice. Even when the uterus is not greatly diseased, if during the course of the operation it be largely denuded of its peritoneal covering, it is best to complete the operation by its removal.

"The sole objection which could be urged against this procedure is an increased mortality; but, since this has been proved fallacious, opposition from any standpoint must necessarily be withdrawn. It is freely granted that in accepting this practice, uteri will often be removed which might safely have been left behind. Even in the face of this possibility the procedure is fully justified, in view of the possibility of future harm on the one hand and the certainty of no extra risks on the other.

"The decisive *pro* or *con* is at times a difficult one at the time of the operation, in which case the patient should be given the benefit of the doubt and the uterus should be removed. In all cases it is assumed that both ovaries must of necessity be sacrificed. Except in the presence of malignant or tubercular disease, the womb should never be disturbed if even a portion of one ovary and a Fallopian tube can be preserved. Nor is an operation to be extended to the performance of hysterectomy, where the double salpingo-oophorectomy will even temporarily answer the purpose, should the patient be in such condition that the prolonged manipulation might render the result of a given case doubtful. Common sense must be used in the application of this principle, as in all other surgical procedures."

VAGINAL HYSTERECTOMY FOR SUPPURATIVE DISEASE AND ITS RESULTS.

Read in the Section on Obstetrics and Diseases of Women, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY I. S. STONE, M.D.

WASHINGTON, D. C.

Since we have found that the uterus may be removed by the vagina with less shock to the patient than by the abdominal method, we may consider the operation of abdominal hysterectomy as well applied to other diseased conditions than cancer, for which the operation was first designed.

Dr. Engleman has well set forth the historical facts in papers recently published (Trans. Southern Surgeons and Gynecologists' Association, 1893-94). The uterus has been successfully removed so often for cancer by various surgeons as to no longer admit of doubt in any respect as to its low rate of mortality, or the vast number of complete and permanent cures.¹ This satisfactory result has induced the writer in common with many others, to remove the uterus and the adnexa by the vaginal route for the following reasons:

1. In cases where partial hysterectomy had been done by the supravaginal method, leaving a sinus or fecal fistula.

2. Where operations have been performed for salpingitis or purulent collections within the pelvis,

¹ The writer has only one return of the growth in his experience, a case in which the bladder was involved at time of operation. The patient, however, is still living in comparative comfort, although slight return nearly three years after operation.

leaving extensive adhesions and often an irritative endometritis and vaginitis.

3. In sepsis of the uterus (septic metritis) as after abortion, etc.

4. In purulent collections outside the uterus, pelvic abscess especially when the disease is extensive.

This classification indicates the evolution of the operation in the writer's hands. Every operator of experience must have encountered difficulties when he attempted to deal with fecal fistula or old sinuses after operations for pus, when there may or may not be tubercular disease of the region involved. I have myself encountered peculiar and insurmountable difficulties on a second opening of the abdomen in such cases. For these conditions the writer finds in vaginal hysterectomy a solution of the problem, and to which he resorts with the utmost confidence.

The second class of cases also affords a degree of comfort to the operator, and relief to the patient in no other way so safely and satisfactorily obtained. In a large number of these cases the uterus was intensely septic when the tubes and ovaries with their purulent contents were removed. Adhesions must frequently follow in the wake of such conditions, giving pain to the patient and at times anxiety to the surgeon.

In addition to these results of operations for disease outside of the uterus, we occasionally find patients who after an ideal operation do not have a satisfactory recovery. They may continue to menstruate. They may have a decided endometritis and vaginitis. I have had my share of these cases, and without hesitation advise hysterectomy to complete the cure, for I know of nothing more annoying than these post-operative symptoms which have their origin chiefly within the uterus, and which no amount of local treatment will cure.

In the third class we must likewise give the preference to the vaginal method for many reasons: 1, because of less traumatism and consequently less shock to the patient; 2, because the time required is less, and because we can secure thorough drainage, and if necessary we can complete the operation without prolonged or profound anesthesia. The abdomen must always be closed with the patient under profound anesthesia if we would avoid all danger of catching the omentum or loops of bowel in the sutures, as may happen at the close of the operation, especially if the patient vomit. In many cases we may be in doubt as to the extent of sepsis outside the uterus and here we can remove diseased adnexa, or separate intestinal adhesions, with the positive certainty that only good can follow such surgery, if indeed any surgery can save the patient. In a recent case I lost a patient after supravaginal extirpation of the uterus when the vaginal method might have succeeded, in a case of sepsis following abortion. The vessels of the broad ligaments were loaded with thrombi, plainly seen at the time of the operation. The case was exactly parallel to one reported by Dr. Baldy in the *New York Journal of Gynecology and Obstetrics* for March. My patient, like his, developed croupous pneumonia, and died two weeks after the operation. In my case I made a very unfavorable prognosis, and the patient died, as I predicted, of pneumonia. Dr. Baldy says his patient would have recovered but for the pneumonia; I was not so sanguine about my own case. It is worthy of note that these two cases, reported so nearly at the same time,

should have died of croupous pneumonia and not septic or pyemic embolic pneumonia. In view of this, and other reasons, I shall hereafter regard the vaginal route as offering many advantages over the abdominal in such cases.

Lastly, we shall consider the removal of the uterus for the purpose of entirely eradicating septic foci from the pelvis of women who have had gonorrheal or other sepsis which has extended into tubes and ovaries or even beyond this limit. When Dr. Baldy read his paper in Washington before the American Gynecological Society in 1893, I was not prepared to take this step, for the reason that I could not believe so many uteri were the seat of septic disease in the body of the uterus itself. I was confident that the endometrium was almost entirely and alone the seat of the disease. A curetting ought to cure this, and I argued that if we sealed up the cornua of the uterus, no further infection of the peritoneum could or would probably occur. But increasing experience has shown that the position assumed by Dr. Baldy and others is right, at least in a majority of cases. If we examine uteri removed in operations for purulent collections in the pelvis, we will often find abscesses in the uterine wall. These pus collections may give the appearance of small fibroids under the peritoneum, and even with the uterus in my hand in one case, I was about to demonstrate to visitors a small fibroid, and found an abscess containing one-half drachm of pus.

In conclusion, then, the writer would in many pus cases, and especially where we have very ill patients and extensive suppurative disease, suggest a trial of this operation. In the technique of the operation I can not yet follow our German and French brethren, who so confidently resort to the morcellement operation, and use the forcep clamp to the exclusion of the ligature. But I do find the operation wonderfully facilitated by amputation of the lower third of the uterus, as soon as the broad ligaments are separated thus far. The fundus uteri can then be readily turned forward, and the operation at once becomes simplified and facilitated, because it is completed in full view, permitting the separation of remaining bowel adhesions with the help of the sight added to that of touch.

Of one feature of the new operation I can not speak with experience. The pus sacs, according to Jacobs, may be left and merely washed out and packed with gauze; this gauze to remain four to six days. This feature is repugnant to my taste, and not in accord with surgical experience. To remove the uterus and leave these pathologic and wholly useless organs appears unsurgical. We are told that actual results show the innocuousness of these pus sacs if properly drained. Again, in nearly all the cases where gauze packing is used, and comes in contact with peritoneum, we will find it firmly adherent in twenty-four to forty-eight hours, and requiring decided force for its removal. Hence many surgeons are avoiding the use of gauze for drainage. It surely drains for a short time only, and then it becomes an obstruction to drainage, and when removed denudes the peritoneum over the intestine or elsewhere of its epithelium and invites the formation of adhesions.

After reciting these reasons for extirpation of the uterus, we may well ask, Why not remove the uterus in all cases where it is now only useless, as without the appendages, but is also dangerous when it is the seat of numerous abscesses. We may therefore con-

clude that when the uterus is to be extirpated for any purpose, the vaginal route is to be preferred to the abdominal. There is less danger of peritoneal infection, less traumatism and shock, and the resulting cicatrix is not a permanent source of annoyance to the patient. The writer confidently asserts that in the future there will be relatively more vaginal and fewer abdominal extirpations of the uterus for pelvic disease.

INDICATIONS FOR TOTAL HYSTERECTOMY.

Read in the Section on Obstetrics and Diseases of Women, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY AUGUSTUS P. CLARKE, A.M., M.D.

CAMBRIDGE, MASS.

DEAN AND PROFESSOR OF GYNECOLOGY AND ABDOMINAL SURGERY OF THE COLLEGE OF PHYSICIANS AND SURGEONS, BOSTON, MASS.

I can vividly recall to mind the able discussion which took place at Washington in 1887, during the meeting of the Ninth International Medical Congress, on the subject of extirpation of the uterus for relief of carcinoma. Since that time my attention has been more particularly directed to the subject.

At the time that the treatment of cancer by extirpation of the uterus was brought before the congress, I felt that the advocates of the measure had taken an advanced step. We all now recognize that the various procedures necessary in abdominal surgery have been more carefully considered and that the individual experiences have tended to do much toward placing that kind of work on a firmer basis. So far as statistics are concerned, as to the results of the different cases treated, they can not afford any very definite help, for in dealing with any case in which hysterectomy is indicated we shall find that the result will depend on many and often upon diverse factors, often upon the individual skill of the operator, upon a wise selection of the case, careful discrimination and accuracy of diagnosis, upon a full appreciation of the fact that the morbid process to be relieved is the chief offending cause of the illness, and that there is not some more obscure and dangerous lesion that may give rise to the suffering. Assuming that these conditions have been met, the success of the case may often depend upon the facility with which the method of technique can be carried out.

The results achieved by the method of operating by the employment of the hysterectomy staff have led to the consideration of the use of other means for overcoming the difficulties encountered in a total hysterectomy. We are still more fortunate in having brought to our attention the perfection of other devices, the proper employment of which can greatly facilitate the most difficult part of the operation and give assurance that the entire cervix in a vagino-abdominal hysterectomy may be removed without incurring danger to the paracervical structures.

By means of the intra-uterine stem attached to a disk or cap, as a center for hermetically sealing the parts from the foci of infection, and also of a staff to assist in elevating the uterus and the morbid mass to be extirpated, as devised by my friend, Dr. A. H. Tuttle, we are enabled to remove by total hysterectomy many tumors, neoplastic developments, and to relieve other conditions that have been deemed most difficult to overcome by the older operative measures. From the help that may be thus gained, and from

experiences in other directions, it is not unsafe to say that total hysterectomy is indicated, *cæteris paribus*, in cases in which the uterus may be in a position opposite to that of prolapse and in such a state of immobility, superinduced by previous inflammatory processes affecting the adnexa and producing such adhesions of those parts, as to necessitate for relief operative interference. In an operation for overcoming the adhesions, it will be found that the appendages, by the previous morbid condition that had been set up, have undergone destructive degenerative changes. In deciding in such cases that total hysterectomy should be attempted, the question of moral consideration will not be involved, for the reason that the uterus itself will in all probability be found to have lost its functional activity. By the facility with which the whole organ can be removed by the operator's adopting the improved methods of technique, the dangers usually attendant on the carrying out of such radical measures will be greatly lessened.

Total hysterectomy should be had recourse to in cases of rapidly growing interstitial fibroids, or in cases of large subperitoneal growths developing from a broad sessile base. The operation is indicated, not only from the hemorrhage which they occasion, but also from the pressure which may take place upon the surrounding parts, and from the obstruction they may produce in the vascular tissues in the abdominal and pelvic organs. Palliative measures of treatment, including employment of electricity, may be helpful in overcoming hemorrhage, but the adoption alone of such a course of procedure must necessarily prove disappointing. The importance of resorting to total hysterectomy will be appreciated when the real history of the degenerative processes of such tumors has been more carefully considered.

If a large and rapidly growing fibroid should take on a retrograde process, either spontaneously or through the influence of regular and systematic treatment by electrolysis, or otherwise, the positive ultimate dangers arising from the presence of such a growth will be far from being wholly removed, for in such a stage, when the patient is seemingly improving, the morbid growth may afford a culture chamber into which other disease cells may migrate and then undergo a malignant degeneration. In such a condition, total hysterectomy is the only expedient that will afford a complete and permanent cure. A fibroid tumor developing in the interstitial and parietal portions of the uterus may so extend as to involve the entire body of the organ, overlapping and inclosing in large measure the adnexa, and taking a downward course, include and bury the cervical structures also. In this condition the morbid growth involving the uterine structures may elevate itself from the lower pelvic cavity and thus afford a greater facility for removal through an abdominal section. This was the special feature in one of Dr. Tuttle's cases, to which I was also called, when total hysterectomy was accomplished by a vagino-abdominal incision.

The removal of a fibroid should not be deferred because it appears, or is first observed, at or near the menopause, for it is not infrequent for such a tumor to continue to develop long after the occurrence of that period, and it may assume all the phases and present all the untoward results that are attendant on one that has had an earlier beginning. Treatment of fibroids by a resort to salpingo-oöphorectomy, to

say the least, is of doubtful utility; this method for awhile may give seemingly beneficial results. When it does so, it is evidently because the growth is principally sustained by the ovarian artery; in other cases the results following this method are so unimportant that an operation would seem to offer but little advantage. There are undoubtedly many cases of fibroids in which the nourishment is at certain periods of their growth derived chiefly from the uterine artery. There are also cases of uterine myomata, in which the physical condition of the patient will not warrant a resort to hysterectomy. In this class of cases the method adopted by our President, Dr. Franklin H. Martin, of ligating these vessels has proved to be of considerable service. With our advanced knowledge, however, of the pathology of these neoplasms, and with our increasing experience and achievements in abdominal surgery, we should not advise a woman who is comparatively free from disease, except from the effects which a fibroid may have occasioned, to rest content with merely submitting to such an uncertain surgical measure.

A nodular fibroid of the slower growth should not be regarded with unconcern, for the pressure that may be made by the mass upon the surrounding parts, and especially upon the ureters, may cause chronic edema and finally contracting kidney, as did once occur in one of my own cases, in which the autopsy showed that had the growth been removed the renal lesion would undoubtedly have been avoided and the patient's life been saved. In this connection it might be remarked that the effects of pressure are to be considered, aside from malignancy, as among the most baneful influences that are attendant on the presence of uterine and ovarian tumors. Uterine myomata in all their various stages call for removal; this should be effected as early as possible. In certain cases the curette can be advantageously employed; if this method is unsuccessful, hysterectomy should be the next surgical expedient. In one case in which a multilocular fibroid appeared, there was but little enlargement of the uterus. Hegar's method for removal of the uterine appendages was performed by a distinguished surgeon resident in another State; the patient, however, did not recover until after the lapse of six years, when she submitted to total hysterectomy.

The ordinary methods of treatment of the more extended forms of adenoma frequently prove unavailing. The study of the pathology of adenomatous formations shows that the hypertrophy of the glands of the lining membrane often extends throughout the entire cavity of the mucous lining. When a uterus has once been affected with this kind of morbid process and the condition does not speedily yield to curettement and to other milder measures of treatment, a more radical course should be instituted. Total hysterectomy offers the best advantage for permanent relief. After sarcoma in any part of the uterine system has been suspected to exist it should be an indication for action; its malignant nature and its unfavorable tendencies when viewed according to the present light afforded by the pathologic history is unquestioned. As in the early stages of cancerous disease, before the para-uterine tissue has become involved in the morbid process, so in sarcomatous developments partial removal by the supravaginal method will prove inadequate; nothing less than total ablation of the uterine tissue, including

the entire cervix as well as the fundal portion, should for the most part be deemed sufficient for a cure.

The question has been asked, Should hysterectomy be resorted to for ovarian tumors? In answer to this it may be stated that carcinoma appearing in the ovary is almost always dependent upon the disease previously occurring to some extent in the uterine tissue. Not long since I was called to a case in which the adnexa had a year before been removed for what then appeared to be a malignant condition of those parts. Since that time the uterus and the parametrian tissue had become extensively involved. Had total hysterectomy been carried out at the time of the first operation, before the cancerous elements had advanced, the patient could undoubtedly have been saved. According to later observation and experience, sarcomatous developments occurring in the ovary should be promptly removed; this can best be effected by total hysterectomy. When papilloma and fibroma occurring as ovarian tumors are recognized at an early stage of their existence, and before they have extended downward to the neighboring tissues, they should be thoroughly and promptly removed, even if it has to be done at the sacrifice of the uterus and its appendages.

It should be here stated that carcinomata and sarcomata in all their various forms call for immediate and thorough removal as soon as a diagnosis of the condition can be made. Experience, however, shows that the results following the removal by hysterectomy of a sarcomatous growth, when the operation is undertaken in a late stage of its existence, will prove to be more satisfactory than will those that may be attendant on the removal, by this method, of a cancerous mass at a similar stage of its existence.

Total hysterectomy is absolutely necessary for uncontrollable prolapse, after anterior and posterior colporrhaphy and other plastic operations have been repeatedly tried, but have failed to produce permanent relief. In such cases the vaginal method is the operation to be preferred. Total hysterectomy is the only safe surgical expedient to be adopted in cases of hemorrhagic polypi which present suspicious microscopic appearances after removal, and which leave as a result an enlarged uterus, as may be determined by palpation or by the sound.

Hysterectomy is called for in ectopic pregnancy; in such cases the hemorrhage can be more safely controlled, and the patient is enabled to make a more rapid recovery than by the other methods of procedure. This method of treatment should be undertaken in ovarian abscess, in pyosalpinx, in old inflammation of the appendages, in a post-clinical severed uterus which has been productive of pain and has been a source of disablement. The operation should be resorted to in all suspicious diseases of the adnexa and in cases of large cysts, as well as in papillomatous developments and in otherwise irremovable cysts and intraligamentous fibroids and tumors of the broad ligaments.

Later experiences show that total hysterectomy can be accomplished with as little danger as may be attendant on many other important surgical measures. When properly performed, there is often but little tenderness left about the vicinity of the broad ligaments. When done in ectopic pregnancy, in ovarian abscess, in pyosalpinx and in purulent liquifaction of a uterine fibroid better drainage can be established. On the other hand, when the uterus or

a portion of it is left, the condition resulting is liable to be followed with many complications, with uterine catarrh, malignant degeneration, certain neuroses and with other sequelæ of a painful or of a clinically depressing nature.

Another advantage total hysterectomy insures is that the posterior and anterior folds of the pelvic tissue can be brought together and united by suturing so as to secure better results than when other surgical methods are employed. In bringing these folds together after the uterus has been totally removed, their margins can be turned outward and downward; this arrangement of the parts will thus practically invest the operation with all the advantages that can be secured by the choice of the extraperitoneal method.

I have already stated that the vagina is the natural avenue through which an uncontrollable prolapsed uterus may be removed. This avenue for removal should be especially chosen when the uterus is not enlarged, or when the condition of prolapse is not complicated with the presence of a fibroid or other tumor. In such cases the technique of the operation may not be as difficult to carry out and the patient may not be exposed so long to the influence of the anesthetic as by other methods. The consequent shock will, therefore, not be as great. The same method may occasionally be recommended when hysterectomy is indicated for a cancerous affection which has not extended beyond the cervical portion of the uterus. In those cases, however, of cancer in which the fundus is involved, total ablation of the uterus can best be effected by the vagino-abdominal method. I am not unaware that statistics have been brought forward to show that the adoption alone of vaginal hysterectomy when undertaken by certain operators has yielded exceptionally good results. In all reports in which such records have been established by work accomplished on a large number of cases I have often felt that the many favorable terminations were, after all, but mere coincidences, or that only those cases for operation were selected that would be advantageous to the showing.

TOTAL HYSTERECTOMY BY A NEW VAGINO-ABDOMINAL METHOD.

Read in the Section on Obstetrics and Diseases of Women, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY ALBERT H. TUTTLE, S.B., M.D.
CAMBRIDGE, MASS.

Those of you who have seen much of the work in total extirpation of the uterus, have watched the progress of the cases through convalescence, and have studied the after results will, I believe, no longer express a doubt of the greater value of the total over the partial methods of hysterectomy, but will agree that the now important question for consideration is in regard to the method to be pursued and to the detail of operative finish.

Owing to the variety of conditions for which the operation is indicated, and the great diversity of circumstances under which the operation is performed, no one method will entirely do away with all others, but improvements in the technique of any one will give it a wider range of usefulness, which must necessarily be at the loss of some other.

In determining the value of an operation for total extirpation of the uterus, statistics of mortality, the

principal items formerly considered are important, but now they can not be entirely relied upon, because owing to the improvement in methods, and the increased skill of the operator, death should be unusual, and depend much more on the disease and condition of the patient than on the operation *per se*. The fatal cases should first be considered individually, noting their differences in strength and natural vitality, the variety and extent of the pathologic conditions and complications, and the ability of their several operators to deal equally well with a given technique. They should then be compared with those nearest alike that have recovered in the same series, and again with like cases in the series of other operators who have selected another technique. Finally, one should reason *a priori*, like a skilled mechanic who studies a problem set before him for the first time, noting the dangers and difficulties in each movement necessary to attain a given result, comparing the various means which the method offers for reducing the amount of technical skill necessary for the operator and for obviating the danger of injury to contiguous parts during the dissection, as well as for furnishing the requirements of the patient's life, health, and rapid convalescence, expressed in a short operation, little ether, diminished shock, etc.

It was after a careful consideration of these various circumstances, and a review of the advantages and disadvantages peculiar to the several techniques of vaginal and abdominal hysterectomy that I have conceived the following operative method, selecting the best parts in each other operation, avoiding, so far as possible those attended by greater difficulties, and meeting the new requirements by special means.¹ I have developed it by careful study of every case, slightly modifying the order of detail procedures and now and then improving the instruments in such manner as to require the least possible time for their manipulation.

I have repeatedly put the method to a practical test, under most trying circumstances, inviting the inspection and criticism of many members of our profession, and now in a more mature condition it affords me pleasure to offer it for the consideration of this honorable body.

The vagino-abdominal method of hysterectomy is characterized by a division of the labor into two parts vaginal and abdominal.

The vaginal part consists of:

1. Sterilization of the cervix and vagina and their maintenance in this condition by closure of the uterine canal with a metal stem which also serves as a guide for the limits of the cervix and for the attachment of an elevating staff.

2. Abscision of the vagino-uterine attachment; dissection of the cervix from the bladder in front and the peritoneum behind, and the packing of the cavity thus formed with gauze.

3. The closure of the vaginal vault from below.

In all, except cases of cervical cancer, the order of items 1 and 2 are partly reversed.

The abdominal part consists of:

1. Opening of the abdomen by a median incision.
2. Ligaturing and section of the ovarian vessels and lateral folds of the broad ligament.

¹ First communicated to the Gynecological Society of Boston in the early spring of 1894, and later presented in a paper at the June meeting of the Cambridge Medical Improvement Society. ("Total Extirpation of the Uterus by a New Method," *Boston Medical and Surgical Journal* Oct. 18, 1894.)

3. Incision of the peritoneal covering of the uterus in front and behind and its separation, with the bladder, to the lines of vaginal dissection.

4. Clamping of the uterine vessels, abscision and removal of the uterus.

5. Eversion of the flaps of peritoneum, with the ovarian stumps, and closure of the lower abdominal opening with concealed sutures, the serous surfaces in contact.

6. Closure and hermetically sealing of the external abdominal wound.

The special instruments employed in the operation are the uterine stems and the elevating staff. The uterine stem is a device used to cork up the contents of the uterus; to give support and attachment to a staff used for elevating the uterus; and to serve as a guide for determining the position and limits of the cervix. It consists of a cap to cover the cervix, and a central stem that fits into the canal, the whole being cast and turned from one piece of metal. The cap is concave on one side and convex on the other, has a groove in the edge to serve as director, and a number of T-shaped slots about the periphery for holding sutures. The central stem, two inches long, is either smooth or has a thread cut upon it, and is held in place either by the thread or by a line of sutures. Perforating the stem for the depth of an inch is a conical shaped cavity which receives the staff and holds it by a simple slip joint. The staff is a steel rod bent on the curve of a prostatic catheter, except that the point is directed a little more outward, and is made to fit the cavity of the stem. Both instruments are inserted through the vagina, but the stem is removed with the uterus from the abdominal opening.

Preparation of the Patient.—When the result of an examination determines for the first time the requirement of hysterectomy, the physical and constitutional condition of the patient is carefully noted, and unless this is favorable for an operation she is placed on tonic treatment and the heart beat regulated. Especial attention is paid to the examination of the urine and kidneys, which almost always show some defect, and unless there is about the normal secretion of solid constituents, operation is deferred. If the uterus is enlarged and filled with soft cancerous or sarcomatous material, and for some time previously has been emitting a serous or bloody discharge, a preliminary thorough curettement, followed by rest in bed, will result in a very short time in the temporary improvement of the physical condition of the patient.

For a few days before the operation the patient is given a liquid diet and kept quiet in bed. By packing the vagina daily for a week before the operation it will be stretched and softened considerably and give greater facility for the after manipulation. The day before the operation the bowels are thoroughly cleared of all fecal matter and made less septic by the administration of 10 grains of calomel in one dose, about noon, followed by teaspoonful doses of magnesium sulphate every hour until several movements have occurred. The hair over the pubes is then shaved away; the patient given a warm bath, and scrubbed with soap, rinsed with bichlorid solution (1 to 5,000), which is allowed to dry on, dressed in sterilized clothing, and put to bed, with a bichlorid pad over the abdomen, between sterilized bed clothing. For supper is given a hot drink of malted milk or similar food. On the morning of, and at least four hours before, the operation, rectal enemata of warm water are re-

peatedly given until the return is clear, then a vaginal douche of bichlorid (1 to 1,000). The lower limbs are clothed with woolen wraps; 2 ounces of whisky and 20 minims of freshly prepared tincture of digitalis are administered by the rectum before the patient is taken to the operating room, and at the beginning of the operation 1-4 gr. morphin, 1-150 gr. atropia, and 1-10 gr. strychnia are given subcutaneously in one dose. In order to avoid all unnecessary length to the period of anesthesia, the ether is not given until the preliminaries are nearly completed, and in the beginning is often substituted by the use of chloroform, either pure or in the form of the A. C. E. mixture.

Operation.—A short speculum is introduced into the vagina and the perineum depressed. With the help of vaginal retractors the cervix is exposed to view, and drawn as far as it will come into the introitus by means of tenacula forceps. A probe is now passed, and the direction, shape and size of the uterine canal determined. Unless the canal is freely patent it is dilated, and treated with equal parts tincture of iodine and carbolic acid, applied on a cotton stick. If the character of the disease is other than cervical cancer, a circular incision is made, simply cutting through vaginal structures about the uterine neck, keeping as close to the os as possible, yet at the same time sufficiently remote to include all diseased tissues, as in the usual manner of performing vaginal hysterectomy.² The uterus is now separated from its anterior and posterior attachments and coverings as freely as possible, by means of the finger or handle of a scalpel, and then the cut margin of the vagina is caught with forceps and loosened sufficiently to allow it to be drawn together and sutured. A line of continuous suture is taken about a quarter of an inch from the cut margin, and is like the ordinary purse-string suture except that the first stitch which is placed at the back, is carried around the vaginal artery, the suture drawn so as to leave both ends of even length in the vagina, the threads crossed, and then one side of stitches taken with one end, and the other with the remaining end. In this manner the principal vessel is caught in a loop and when the ends of the suture are drawn tight, not only is the vault of the vagina closed in, but also any tendency to hemorrhage from the vaginal artery is obviated.

The patient is now placed in position for abdominal section, with means ready for obtaining the Trendelenburg posture. The usual incision is made and of variable length to meet the requirements of the case. The peritoneal cavity is opened at the upper angle of the wound, in order that the position of the bladder can be determined before the opening is completed and injury to it avoided. The incision is carried close to the pubes to gain as much room as possible for working in the pelvis. The contents of the abdomen are carefully inspected and the method of dissection determined. If the case is a simple enlarged uterus with appendages approximately normal, the tumor is drawn out of the wound and to one side; the fold of broad ligament, including the tube and

² In most cases this maneuver is comparatively simple, but with a large tumor in a single woman, somewhat advanced in age, with a rigid vagina narrowed and elongated by long continued upward traction exerted by the uterus as it is forced out of the pelvis to seek room for the growing tumor, and with a cervix perhaps almost entirely "taken up" by the distension exercised by the new growth; or, with a senile uterus firmly fixed by old adhesions in the upper region of the pelvis and nearly hidden from external inspection by the contraction of the vagina that often occurs after a certain age, it is a matter of great difficulty, and contrary to what might be expected, little help will be gained by incision of the sphincter vaginae.

ovary of the other side is put on the stretch, and a row of sutures passed below the ovary from close to the side of the uterus to the free margin of the ligament, so as to include the ovarian artery. This line of sutures is inserted by means of a perineal needle; is taken like a shoemaker's stitch, but each stitch—which includes but a small amount of tissue—is drawn tight and secured by taking a turn of the loose end of the suture about the other, so as to form a series of single knots. The uterus is then pulled over to the other side, and the remaining tube, ovary, vessel and ligament secured in the same manner. The ligaments are cut away above the ligatures; and between the points of their excision, across the uterus in front and back, about an inch above the attachment of the bladder anteriorly, and an inch above the cervix posteriorly, the peritoneal covering of the womb is incised. With the help of a scalpel handle, the bladder and peritoneum are now rapidly dissected up from the uterus in front until the line of former vaginal dissection is reached; the posterior layer of peritoneum is treated in the same manner; the sides of the uterus are freed from peritoneum as much as possible; when the lateral attachments, including the uterine artery, can be easily clamped, and the organ cut away, and removed. In cutting away the uterus keep as close to that organ as possible.

During the dissection an assistant holds up firmly the uterus by means of the staff which shortens and defines the neck, and enables the operator to quickly and easily perform what is usually the most difficult part of the operation, the enucleation of the cervix. An uterine stem is then selected, according to the length of the cervix and size of the canal; with a soft uterus and large easily dilatable cervix, one with a wide thread is used, but with a cirrhotic organ, one with a fine thread or even smooth stem is preferable.

The uterine stem is inserted and forced into place, after filling the cap with iodoform either by simple pressure, or in case one with a thread is used, by turning it up with a screw-driver, at the same time holding the cervix firmly by means of tenacula forceps fixed into the anterior and posterior lips. If the case is one of cervical cancer the stem must be inserted before any incision is made, and the contents of the uterus and infective parts tightly sealed by sewing the vagina to the edge of the metal cap with sutures taken through normal vaginal structure, and sufficiently remote from the uterus to include all diseased tissue. One should then proceed as above described for non-infective cases.

It is often advisable to tie a smooth stem into the cervix with one or more sutures to prevent slipping. The staff is now inserted into the central cavity of the uterine stem and held in place by an assistant; the parts sponged clean and dry; tampon of iodoform gauze packed into Douglas' pouch, under the peritoneum, and between the cervix and bladder; and the ends of the purse-string-like suture drawn tight and tied, closing in the vault of the vagina below the cervix, gauze and uterine stem, except for a small opening through which the staff passes.

In exceptional cases, already mentioned, not only is this careful toilet of the vagina very difficult or impossible, but unnecessary and time consuming, and should be omitted. In these cases it is better to simply make a circular incision through the vagina, free the cervix, and then pack hard about the cervix and the whole vaginal cavity with sterile gauze.

This elevates the uterus, pushes the ureters further away to the sides of the pelvis, and serves as a guide during the dissection in the abdominal cavity.

The gauze packing acts also as a guide, and is of material assistance during this dissection. The uterine vessels are firmly ligatured with kangaroo tendon, the clamps removed and all oozing of the blood from the pedicles stopped by suturing. The anterior and posterior peritoneal flaps are brought together; the cut edges are turned in so as to bring the serous surfaces into contact, and the stumps containing the ovarian arteries are folded in at the angles so as to become extraperitoneal, the whole being closely united by a line of blind sutures, which when drawn tight are situated outside of the peritoneal cavity. All clots are removed by dry sponging, the abdominal wound closed layer by layer with animal ligature, and finally sealed with cotton and collodion.

Although ordinarily it is preferable to remove the ovaries, should one or both be found firmly bound down by old adhesions and in a cirrhotic condition, it is better to leave them *in situ* than to delay the operation by such time necessary for their removal. They will, as a rule, give rise to no further symptoms, as has been repeatedly demonstrated by vaginal hysterectomy, where often they must necessarily be left behind.

When a large multiple fibroid mass is encountered, the topography of the parts must be carefully studied and the position of the bladder and, if possible, the ureters, determined. If the growth forms with the uterus a single tumor, the same directions for operating as above described hold good, but where there are several distinct tumors, which are sessile in attachment and appear to have a large pedicle, a sufficiently long cross incision is made through the peritoneal covering, and each tumor is enucleated as far as possible. By this means the pedicle will usually be found much smaller than expected, forming a part of the uterine attachment, and easily included in the clamp employed for securing the uterine vessels of the same side. Care must be taken in cutting and dissecting back the peritoneal covering not to tear or injure the ureter, the position of which can not always be recognized. If it is determined passing over the tumor it should be dissected up and carried to one side with the overlying flap of peritoneum, but if it can not be distinguished, any and all tissue which resembles it should be treated in the same manner, and as the clamps are applied prior to the final abscision, bear in mind the watchword of this operation, *stick close to the uterus*.

If, upon opening the abdomen, bladder, omentum, bowels, uterus, tubes and ovaries present as a confused and conglomerate mass, firmly bound together by adhesions, the uterus can still be removed subperitoneally, as follows: a point is selected on the fundus of the uterus that is not obscured by adherent viscera, and a small cross incision made through the peritoneal covering. The edges can then be picked up with forceps; the opening intelligently enlarged without injury to the adherent organs; and the peritoneum dissected from the uterus in every direction, well down on the sides and sufficiently to admit of the easy adjustment of the clamps. The organ is cut away, the vessels secured, and the peritoneal openings closed as before, leaving the tubes and pelvis under the peritoneum to drain *per vaginam*. In other words, the uterus is removed by the

combined method with the same consideration for its surroundings which the French operators have when they extirpate by the vaginal method.

The advantages of the vagino-abdominal method over the vaginal method are:

1. The peritoneal cavity is completely closed, and left with no raw surface for subsequent adhesion with viscera.

2. Primary union is the rule and convalescence rapid.

3. The subsequent complication of rectocele or vesicocele is avoided.

4. The uterine vessels in all cases can be perfectly secured and there is no danger of secondary hemorrhage.

5. Abscesses of the tubes and ovaries are more completely removed.

Over the abdominal methods:

1. Complete subperitoneal drainage can be established.

2. The length of time which the peritoneal cavity is exposed is greatly reduced by the previous vaginal dissection, and shock is consequently diminished. (A large uterus can be removed in from twenty to thirty minutes.)

3. The limits of the cervix are closely defined and the necessary extent of the dissection readily determined.

4. The sepsis is more complete and there is less danger of subsequent infection.

Over both:

1. The dangers of hernia are reduced; vaginal over the vaginal method; ventral, over the extraperitoneal treatment of a constricted stump.

2. Danger of injury to the ureters is avoided.

3. The manipulation is easier in the most difficult parts of other operations.

4. There is less danger of injury to the bladder and other viscera.

5. Hemorrhage from the vaginal artery is avoided.

6. The operation is practically bloodless.

7. It offers a means for removing large uterine tumors with extensive adhesions, which could only be done with great difficulty or not at all by the other methods.

8. Its greater perfection of the principles of modern aseptic surgery.

Appended are the reports of six consecutive cases, all of which made a good recovery, that illustrate the principles of the method:

Case 1—Sarcoma of uterus. Vagino-abdominal hysterectomy. Recovery. Family physician, Dr. E. de la Granja. Mrs. L. W., nullipara, several miscarriages, married. First seen, February, 1894. Age 60 years, housewife. Family history not ascertained. Previous history; good health until a few months ago; tumor detected a year ago; later, watery and bloody discharges, progressive weakness, emaciation, attack of la grippe, circumscribed peritonitis, and distress with pressure symptoms. Previous treatment with ergot and tonics. Present condition extremely weak and nervous, tumor reaching to umbilicus; bloody and watery discharges; emaciated; frequent attacks of pain; insomnia; requires much opium. Physical examination; enlarged uterus, short cervix, long, narrow and rigid vagina, clean os; sound passes four and one-half inches; lungs, heart and kidneys normal. Urine low sp. gr., 1015; no albumin. Preliminary treatment: removal of nearly a quart of soft, friable, sarcomatous tissue by curetting in two sittings, the second necessitated as the great loss of blood and feeble condition of the patient during the first attempt would not admit of it being finished. Tonics and stimulants. Curettings February 12 and March 17.

Operation of hysterectomy April 10, 1894. The patient

made a good recovery, enjoyed fair health during the summer and moved out of town, thus passing out of my hands. I learned that she died with symptoms of renal disease during the early winter.

Case 2.—Multinodular fibroid uterus. Vagino-abdominal hysterectomy. Family physician Dr. F. C. Osman, of Dorchester, Mass. Mrs. S., married, 1-para, no miscarriages, first seen, April, 1894. Age 42, housewife. Family history negative. Previous history: a slowly developing tumor of the right broad ligament, cystic, causing such disturbance that its removal was advised and performed by Dr. Wm. T. Lusk, six years previous, and at the same time both ovaries were also removed. Small multiple fibroids had been recognized before, and the diagnosis was verified at the time of operation. The health improved, but there was constant pain, discomfort and disability up to the present time, with swelling of left leg of recent origin. She had received various anodyne, stimulating, tonic, and local treatment, without much benefit. Perineorrhaphy seven years ago. At the time of operation she was pale, emaciated, feeble, but of a cheerful and hopeful mind. Good steady pulse, and no evidence of renal disease. Menstruation (metrorrhagia) regular to time of hysterectomy. Physical examination showed an enlarged uterus, nodular, and lying back against the promontory, and somewhat low in the pelvis. The os was clean, the canal four inches deep, and there was nothing peculiar about the vagina.

Operation for hysterectomy was performed May 1, 1894. The details of the operation were carried out carefully in every particular, according to my previous description. There was no appreciable shock and the patient made a complete recovery and has since been perfectly free from pelvic pain and discomfort, although she still suffers from some cystitis. Urine 1031; no albumin or sugar.

Case 3.—Fibro-cystic disease of both ovaries. Enlarged uterus. Vagino-abdominal hysterectomy, recovery. Family physician, Dr. Rich. Hogner, Boston, Mass. Mrs. N. O., married, nullipara; no miscarriages; first seen August, 1894. Age 29 years, housewife. Family history shows a sister, 2-para, about 40 years old who died in June, 1893, from sarcoma-cystica-ovariorum. Previous history: for several years she has suffered from excessive and long continued menses, occurring about every two weeks. Last May after heavy lifting she had an attack of pelvic peritonitis, with metrorrhagia, so extensive as to threaten the patient's life, complicated with slight nephritis and acute endocarditis as well as embolic pneumonia. For a year and a half, menstruation has been regular, except for two periods. Previous treatment consisted of gynecologic kinesitherapy, according to the method of Thure Brandt, and Swedish medical gymnastics. Her condition at the time of operation was excellent as far as the general health was concerned. Examination showed a tumor reaching nearly to the umbilicus and closely connected with the uterus. The fundus could not be determined. The urine was normal. The cervix was normal, uterine canal four and one-half inches, and vagina roomy.

Operation Sept. 11, 1894, was unusually long, owing to numerous adhesions. Very little shock followed; the urine of the first ten hours was smoky and albuminous. Recovery was perfect, and the patient has remained well since.

Case 4.—General interstitial fibroid uterus, submucous fibroid, ovarian fibro-cystic tumor on the right side. Vagino-abdominal hysterectomy, recovery. Family physician Dr. Mary E. Bates, Boston, Mass. Miss E. A.; single; nullipara; no miscarriages; first seen April, 1894. Age, 43 years. School teacher. Family history; mother has suffered for years with an abdominal growth. One sister and brother well. Previous history: dysmenorrhea from childhood, steadily growing more severe, and especially during the past ten years. Ten years ago it was claimed she had a misplacement of the uterus and a ring pessary was worn for several months with relief of symptoms. For several years she has had flatulent dyspepsia with headache occasionally. Five years ago she was curetted by Dr. Marcy. For several years menstruation has occurred nearly every two weeks and very profuse. A watery discharge has been noticed most of the time and required the constant wearing of a napkin for two years. She is extremely feeble and exhausted on slight exertion, although well nourished. There is pallor and discoloration of the skin. Heart, lungs and kidneys normal. Uterus considerably enlarged; cavity four and one-half inches deep, tender; os clean. Vagina somewhat close; right ovary painful to pressure; urine normal.

Preliminary treatment by curetting in May, 1894; rest in bed, tonics and sent to seashore for the summer. Came

back with increased tone and weight, but incapable of work. Operation Oct. 25, 1894. Primary union of parts but some bladder catarrh followed with occipito-cervical neuralgia. Steady improvement from the beginning and she resumed her occupation as teacher April 1, 1895.

Case 5.—Large uterine myomata. Vagina-abdominal hysterectomy. Recovery. Family physician, Dr. John E. Somers, Cambridge, Mass. Miss M. R., nullipara; no miscarriages; single. First seen December, 1894. Age 32 years; domestic. Family history: both parents living; of thirteen children one sister died from uterine tumor, and two others in confinement. Previous history of excellent health until the summer of 1893, when a large bunch, at first pulsating, but not later, was discovered in the lower abdomen. It was not tender to touch, and did not increase in size for a year. Menorrhagia was severe after the tumor appeared, requiring two dozen napkins at a period. It was painless. There was some leucorrhœa but not enough to require the wearing of a napkin. Previous treatment with tonics. At the time of operation she was pale and cachectic looking with a doughy condition of the face. The heart was irregular and there was an indistinct systolic murmur. The urine has a sp. gr. 1020; no albumin, but many squamous and pavement epithelial cells with some mucus. She was well nourished and without evidence of emaciation. The uterus reaches above the umbilicus, is symmetrically enlarged with a cavity six inches deep, and a clean os. The vagina is roomy.

Operation Jan. 17, 1895. While on the table patient was at times considerably cyanosed and the pulse could not be determined. She reacted well, however, and made a rapid convalescence with primary union. After the operation the urine showed traces of albumin, and some hyalin casts. The mind gave indications of impairment but there is improvement in this particular.

Case 6.—Large uterine myomata. Vagino-abdominal hysterectomy. Recovery. Family physician, Dr. John E. Somers, Cambridge, Mass. Miss Lily B. A., nullipara; no miscarriages; single. First seen December, 1894. Age 37 years, school teacher. Habit of taking long walks. Family history negative. Previous history: well until the summer of 1891, when after a long and fatiguing walk on a very hot day menstruation occurred, a week before it was due. After this event, frequent and profuse metrorrhagia followed and continued at irregular intervals to the date of operation. In the fall of 1893 and spring of 1894, the attacks of hemorrhage were especially severe. In January, 1894, phlebitis occurred in both legs and confined her to bed and room several weeks. The tumor was first discovered in June, 1894, and in the fall of the same year a watery discharge from the uterus appeared, so profuse as to necessitate the use of a napkin constantly. Previous treatment of tonics and electricity since July, 1894 relieved, to a certain extent the exhausting hemorrhage. Her present condition in general is fairly good, pallor being the worst symptom. There is some edema of the limbs; the urine is increased in quantity, with a sp. gr. 1020; the solids are in normal amount. Heart, lungs and kidney are free from disease. The uterus is symmetrically enlarged and reaches above the umbilicus; the cervix is short and "taken up" high in the pelvis. The os is clean and the vagina long and narrow. Sound passes nearly five inches.

Operation March 7, 1895. A stem could not be inserted and after freeing the uterus from the vagina, the parts were packed with gauze and the operation finished from above in the usual way. Twenty-five minutes only was consumed in making the incision and removing the uterus, and the toilette of the peritoneum and closure of incision was finished in the same time. The patient rallied quickly from the operation and made a good recovery. This was the first case in which I had been obliged to leave the vagina open from above, and although the recovery was as complete as the others, a daily variation of 1 to 2 degrees of temperature and slight vaginal discharge showed the cavity at the vault of the vagina healed by second intention with granulation.

The Red Cross Society of Japan.—The Japanese branch of the Red Cross Society was founded in 1877. At the beginning it had only 38 members. At present it has 141,000 members and an income of \$380,000, besides possessing a hospital. On Sept. 2, 1889, it was officially recognized by the International Committee.

HYSTERECTOMY FOR PUERPERAL INFECTION.

Read in the Section on Obstetrics and Diseases of Women at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY REUBEN PETERSON, M.D.

MEMBER OF THE CHICAGO GYNECOLOGICAL SOCIETY; FELLOW OF THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS. GRAND RAPIDS, MICH.

The advances which have been made in the science of bacteriology and the discovery that the same germs are responsible for wound infection and puerperal sepsis, has given a new impetus to the consideration of certain surgical procedures looking to the cure of various forms of sepsis met with during the puerperium. During the past few months the question of removal of the uterus, as a method of treatment for certain conditions arising during the course of puerperal infection, has been discussed by some of the prominent gynecologic societies of the country and much difference of opinion in regard to the advisability of this mode of procedure has been shown to exist.

In spite of the diminished mortality from puerperal sepsis, brought about by the introduction of antiseptic and aseptic measures, probably many thousands of women die annually from puerperal septicemia. The favorable results have been obtained in the large maternities, where perfect technique can be secured. Outside of these hospitals, on the other hand, there exists still a large amount of septic infection, following abortion or labor at full term. It is next to impossible to gather accurate statistics relative to the mortality from this disease, because of the inaccuracy of the death certificates. The public have learned to blame the attending physician for any death resulting from septic infection subsequent to labor, from which naturally arises the discrepancy between the actual and reported diagnosis. If to this be added the sepsis arising from accidental and induced abortions, it will be seen that no effort should be spared to perfect all methods of treatment for the relief of this condition. The present paper is offered as a slight contribution to the study of the subject.

A clear conception of the bacteriologic and pathologic changes in the birth canal is highly essential to the evolution of correct principles of treatment. Bumm describes two forms of endometritis, putrid and septic. The germs which are active in producing septic endometritis are the streptococcus pyogenes aureus, the staphylococcus pyogenes aureus and the streptococcus erysipelatus. The septic process may be localized and the germs shut off from the underlying tissues by a granulating zone, or this zone may be absent and the pyogenic cocci be found distributed in the lymphatics leading to the peritoneum. In septic endometritis although putrefactive germs may be present, they do not predominate, hence fetid lochial discharges are apt to be absent in the more septic processes, a fact of much significance as a point of diagnosis.

In putrid endometritis there is always to be found decomposed material within the uterine cavity and a necrosis of the epithelial layer. The granulation zone is also present in this variety, and acts as a barrier to the penetration of the germs and their products into the lymph spaces of the uterus. The putrefactive focus within the uterine cavity favors the development of certain toxins, the absorption of

which into the blood gives rise to a form of systemic poisoning termed sapremia, the symptoms of which differ in many respects from those accompanying septicemia.

Generally speaking, cases of puerperal sepsis may be divided into two large classes; 1, those where by means of the lymphatics, a large number of germs have found their way into the general circulation without giving rise to localized inflammation in the broad ligaments, adnexa or peritoneum; and 2, where the septic process has resulted in areas of localized inflammation in and about the birth canal, the general circulation containing, as the case may be, many or few of the pyogenic cocci.

Considering the second class first, we meet with a variety of local manifestations. The septic inflammation may spread from the interior of the uterus to the peritoneum and a localized peritonitis result. The germs may travel by way of the uterine lymphatics or Fallopian tubes. These are the cases which offer the best results from operative interference, because the products of inflammation are walled in and shut off from the general peritoneal cavity by adhesions. This variety of inflammation results in localized collections of pus, which often assume such large proportions as to be mistaken for, and reported as, cases of general septic peritonitis cured by celiotomy and drainage.

The broad ligaments may be involved by an absorption of the septic germs by way of the pelvic lymphatics. Here we meet with true pelvic cellulitis and abscess, the evacuation of which often results in a subsidence of the puerperal symptoms and a cure. Again we may have a general purulent peritonitis resulting from absorption by way of the lymphatics. This usually proves rapidly fatal and where fully developed is probably not amenable to treatment, the system being overwhelmed by the poison absorbed from the large amount of surface involved in the septic process.

In speaking of the pathologic conditions found in septic endometritis, it was stated that in a certain class of cases the granulating zone, shutting off the necrotic endometrium and offering a barrier to the invasion of the germs into the underlying tissues might be absent. Then the pathogenic cocci are absorbed directly by the lymphatics and veins and find their way directly into the general circulation setting up a virulent septicemia. These are the cases belonging to the first division mentioned above. Localized inflammatory processes in the cellular tissue, adnexa and peritoneum are absent or only appear secondarily just before the fatal issue brought about by the general systemic poisoning. Even in those cases of septic endometritis where a granulating zone is primarily present, active absorption may take place if, through the injudicious use of the sharp curette, this protective zone is removed. To recapitulate, we may divide puerperal sepsis into two large divisions:

1. Where general infection predominates, and localized inflammatory processes appear only secondarily and are of minor importance compared with the general septic condition.

2. When the septic absorption results in the formation of localized inflammation either in the adnexa, pelvic cellular tissue or peritoneum. General infection, however, may accompany or result from these inflammatory collections.

There should be no difference of opinion in regard to the proper treatment to be instituted for the relief of the cases coming under the second division, except where absorption has resulted in general purulent peritonitis. All collections of pus in the adnexa or cellular tissue should be evacuated with the least possible delay, and the tubes and ovaries removed if necessary. It will usually be found best to reach the pelvic abscess by way of the vagina, but so much more can be learned in regard to the condition of the peritoneum and uterus by the abdominal incision, that it would seem preferable to remove the appendages by this route, when the general condition of the patient presents no contra-indications.

Surgery has scored some brilliant successes in the treatment of localized puerperal septic inflammatory deposits, as a review of the reported cases will reveal. What confronts the surgeon to-day is the treatment of the other class of cases, where absorption is taking place from the interior of the uterus by way of the lymphatics, and the resulting infection is becoming general and not local. Medical treatment for these cases is practically valueless. Can surgery prove of any avail?

The cases of general infection now under consideration are of two descriptions, as might be supposed from a study of the two varieties of septic endometritis, which have been pathologically considered:

1. We have those cases where the veins and lymphatics at the placental site are loaded with germs; and 2, where the zone is present and impedes to some extent the further penetration of the cocci. Clinically, it is extremely difficult, if not impossible, to differentiate between these two conditions, which a histologic study of the endometrium has revealed to us. The symptoms of both are pronounced and denote a general septic absorption. The lesson to be learned is that a dull and not sharp curette should be used in intra-uterine treatment, if we would preserve nature's barrier which has been thrown out in the form of a granulating zone. The treatment of these septic cases must be rigorous and thorough, if it is to prove of any avail. The source of infection must be got rid of at once or else the blood will become so loaded with the poisonous germs that any treatment will be valueless. Could we differentiate between the two conditions clinically, it would be advisable to curette and pack the uterus with gauze in the second class of cases and exchange this method for more radical procedures for those of the first class. But inasmuch as a differentiation is almost impossible, the plan of treatment just suggested should be employed in all cases.

A careful examination has already revealed the fact that the beginning septic infection is not complicated or has not given rise to localized inflammatory deposits. The main diagnostic symptoms to be relied upon are the high fever, rapid pulse, possibly chills and the history of the case. A careful curettage will remove everything from the uterine cavity which can give rise to septic absorption. If the curettage and packing with gauze causes no amelioration of the symptoms within twelve or eighteen hours, the only logical procedure that remains to us is to remove the source of infection, namely, the uterus. If this be done early enough the patient may live. In other words, provided the organ, whose lymphatics have been shown to be loaded with germs, can be removed before too many have found an entrance into

the general circulation there would seem to be no reason why a cure should not be effected. It may be urged that such a procedure is too radical and that it is useless, because the disease is general not local, hence the removal of the uterus can have no effect. It is a radical procedure but not more radical than the disease is fatal, if allowed to proceed unchecked. The outcome must be fatal, unless the source of infection be removed. If the absorption has progressed to a certain point, hysterectomy is a useless operation, because we are then dealing with a general and not a local disease. The plea that is made here is for the radical operation while the disease is still local. The writer is convinced that by early operation a certain number of cases may be saved. It is not right to condemn hysterectomy in these cases because it has failed when undertaken too late. Successful cases have been reported and will become more common as we become more skilled in diagnosis and more expeditious in treatment. The writer has arrived at these conclusions from a careful study of the following case, which is reported in full because of its bearing on the subject under discussion:

Sunday afternoon, Feb. 3, 1895, the writer was asked by Dr. A. J. Pressey to see in consultation Mrs. W. The attending physician gave the following history of the case: the patient was 28 years old and married. She had had two children. The doctor had attended her for a number of miscarriages. January 28 he was called to see her and found her with a temperature of 105. She had been flowing according to her statement, for four days. The next morning the temperature was 102 and the next 106. She then confessed that she had brought on a miscarriage, the method employed not being stated. She was immediately placed under an anesthetic and the uterus thoroughly curetted with a sharp curette. A putrid placenta, half the size of the hand was brought away, the uterus carefully douched with bichlorid solution and packed with gauze. The next day the latter was removed and showed itself free from any odor. The temperature ranged from 101.6 to 102.2 and the pulse was over 100. During the next three days there was but little change in the patient's condition except a gradual rise in the temperature, in spite of liberal doses of antipyretics. A number of intra-uterine bichlorid douches were administered, although there was absolutely no odor to the vaginal discharge.

At the consultation, February 3, the temperature was found to be between 104 and 105, pulse 110. There was no abdominal tenderness and no signs of peritonitis. Vaginal examination revealed a slight thickening in the right broad ligament, otherwise the examination was negative. There was no odor to the vaginal discharge. The patient's general condition was excellent and she expressed herself as feeling perfectly well and as not seeing the necessity of a consultation of physicians. It was decided to curette again the following morning if the patient's condition was not improved. This was thoroughly done at the appointed time, as the temperature was still high, and the uterus again packed with gauze. The following noon, Tuesday February 5, as the temperature was over 104 degrees and the pulse high, it was decided, as the last chance, to open the abdomen, prepared to remove the seat of the infection, even if a hysterectomy should be necessary. The entire peritoneum was found to be deeply congested. Espe-

cially so was the surface of the intestines and broad ligaments and the peritoneum over the fundus of the uterus. The appendages were found to be normal in size and position and the bunch felt in the right side of the pelvis was seen to be a true puerperal cellulitis. The question that arose in the operator's mind was, Shall the uterus which is or has been the seat of infection be removed, or shall the incision be closed and no further attempt made to save the patient? A hysterectomy was decided upon, for reasons which will be stated later on, and the uterus and appendages removed entire in a comparatively short time, if it be taken into consideration that the surroundings were unfavorable, the operating room being little better than an attic.

There was little or no shock after the operation, but it proved of no avail, for the septicemic symptoms became more and more pronounced and the death of the patient occurred two days later. An autopsy showed that general purulent peritonitis had developed subsequent to the operation.

This detailed description of the case has been necessary, in order that certain deductions might be drawn which may help us in future cases. It would seem, in all probability, that the high temperature and other symptoms which were present just prior to the first curetting were indicative of the presence of a powerful poison within the blood. In other words, we had to deal here with a sapremia and not a septicemia, the toxins being produced because of the presence of the putrid retained placenta. It is also probable that the sharp curette, while it removed the foul placenta, may have opened the uterine sinuses and veins and allowed the entrance of the pathogenic cocci themselves. At any rate, the curetting and packing with gauze did no good, if no positive harm were done. In the opinion of the writer, the second curetting was a mistake. The history of the case should have been taken into consideration and the celiotomy performed then and there. If it had been done at that time or better, just after the first curetting had failed to accomplish any good, there is every reason to believe that the removal of the uterus would have saved the patient's life. The moment should have been seized when the germs were within the uterus and but few had penetrated into the general circulation. Could such a time be chosen and the uterus, which is the source of the infection, be removed, there seems no good reason why the septicemic process might not be aborted. The mistake that is made is delaying until the system is so overcharged with the poison that the removal of the source of the infection can not avert the fatal termination.

SUMMARY.

1. Puerperal sepsis is still a common disease, although in the hospitals the mortality from this source is practically *nil*.
2. There are two forms of puerperal endometritis: (a), putrid; (b), septic.
3. In the septic form there may or may not be present a granulating zone, acting as a barrier to the further penetration of the germs.
4. Putrefactive germs may be absent, hence fetid lochia may not be present.
5. Putrid endometritis signifies necrosis of the lining membrane of the uterus and the presence of decomposed material.

6. This variety is prone to develop toxins, the absorption of which gives rise to sapremia.

7. Clinically, cases of puerperal sepsis may be separated into two large divisions: 1. where general infection predominates; 2. where localized inflammatory deposits are present, the general infection being secondary and less important.

8. The areas of septic inflammation may be in the adnexa, pelvic cellular tissue or peritoneum.

9. This class of cases present the most favorable field for operative procedures.

10. It is almost impossible to make a differential diagnosis between those cases of septic infection having a granulating zone in the uterine tissue and where this is absent.

11. These cases should be curetted with a dull instrument and packed with gauze.

12. If there is no improvement in the symptoms within twelve or eighteen hours the source of the infection, namely the uterus, should be removed.

13. Hysterectomy should not be condemned because of its failure when performed too late.

14. If this operation be done early enough it will be the means of saving a number of lives.

DISCUSSION.

Dr. A. LAPHORN SMITH, of Montreal—said that when we have to deal with a case of puerperal fever which, in spite of careful curetting and irrigation continues to grow worse, an operation should be resorted to. He was among the first to open the abdomen for this condition. In such a case the infective process has invaded the walls of the uterus itself and the lymphatics that run along its side, and the only rational thing to do is to open the abdomen and remove the uterus. He is strongly in favor of the abdominal method in preference to the vaginal, as it gives us a better opportunity to completely eliminate the source of infection.

Dr. HENRY P. NEWMAN, of Chicago—commended the two papers as they were in the line of better work in this very distressing ailment, puerperal septicemia, following birth at full term, and following abortion. He expressed the opinion that by merely curetting the uterine cavity we accomplish very little. Curettage, as it frequently done, was in his opinion extremely faulty in puerperal cases. We can do comparatively little in covering the entire endometrium with an ordinary curette. It is his practice to supplement the curetting by swabbing out the uterus with a 95 per cent. solution of carbolic acid, subsequently packing the uterus with iodoform gauze.

Dr. L. H. DUNNING, of Indianapolis—desired to place on record his cases of pus in the pelvis, antedating delivery and leading to the development of peritonitis. The first case was one of pyosalpinx, resulting in death three days after delivery, immediately subsequent to operation. Preceding and following the operation there was a discharge of pus from the uterus, due without doubt to suppuration in the uterine walls. The second case was one of tubo-ovarian abscess, following a miscarriage at four and a half months. After the miscarriage, evidences of septic peritonitis occurred. An operation was advised, but declined, and post-mortem examination showed that the abscess had ruptured.

Dr. J. HENRY CARSTENS, of Detroit—said that in certain cases, where the puerperal symptoms are due to the presence of small pieces of placenta or membranes in the uterus, curetting and swabbing with strong carbolic acid are all that is necessary. He is not in favor of packing the cavity with gauze after curetting, believing that freer drainage will take place without it. There are other cases of puerperal septicemia, coming on late, that is, about the ninth or tenth day after delivery, which are the result of some peculiar kind of infection and often end fatally.

Dr. W. H. HUMISTON, of Cleveland, Ohio—referred to two cases of puerperal septicemia that had come under his observation during the past year, in both of which he advised hysterectomy, and in both cases the operation was refused. One of the patients died after a prolonged illness, while the other recovered.

Dr. JOHN MILTON DUFF, of Pittsburg—believes that if the pulse still keeps rapid, and only a slight decrease in temperature follows curettage and irrigation of the uterine cavity,

the patient, if let alone, will die. Under such circumstances hysterectomy is necessary.

Dr. L. S. McMURRAY, of Louisville—said he thought it would be a great misfortune to have the statement go out from this meeting that in every case of puerperal fever which does not yield to ordinary treatment a hysterectomy is demanded. Puerperal fever is very common, and the majority of the cases recover under an expectant plan of treatment. In his opinion, hysterectomy should only be resorted to on the same principles that it is done in other conditions. When there are some demonstrable lesions in the pelvis, then it is proper to resort to an operation.

Dr. M. PRICE, of Philadelphia—said he never employs the curette, the use of which he regards as very injurious in any form of puerperal fever. Tamponing the uterus with gauze should also be avoided. As regards the performance of hysterectomy in puerperal septicemia, it should be considered nothing less than a criminal procedure. The woman is already septic, and to create an additional raw surface can only add to the danger. If this operation is done in such a case and recovery follows, it is the result of a happy accident and not the surgeon's skill.

Dr. J. M. BALDY, of Philadelphia—said there was not an authentic case on record in the literature of medicine, of general suppurative puerperal peritonitis that had been cured by operation; no surgeon had ever gone on record as strongly as the Prices, of Philadelphia, that surgery should be done where there is pus, and when one of these gentlemen makes the statement that he has had two patients in bed for two months with pus and tells us not to operate in such cases, there is something wrong. They say, operate when you put your fingers on disease; in other words, remove the tubes and ovaries, but if there is disease or pus in the uterus ignore it. He would ask, Of what service is it to remove the tubes and ovaries only, when the pus is in the uterus? If the patient be left alone, she will probably come again into the hands of the operator for a secondary operation. It would be much wiser to perform the primary operation, and save the patient months of a dangerous condition.

Dr. W. E. B. DAVIS, of Birmingham, Ala.—believes that surgeons sometimes make a mistake in peritonitis, in that they do not consider the germs which produce the disease. While the germ of gonorrhoea was the most prolific cause, there were other germs than the gonococcus which sometimes entered into the production of the disease. He agrees with the essayist that cases of general suppurative peritonitis are not cured by surgery. He fails to see how cases of peritonitis, which have gone through the different stages with pus formation, can get well by surgical interference. By this time the system is thoroughly infected, and it is impossible for surgery to relieve the condition; in other words, the patient is septic, and even if the peritonitis was cured by operation the patient would die. He was aware that some surgeons had made the statement that they had removed pints and even quarts of pus from the peritoneal cavity and cured the patients, but he did not believe it.

Dr. J. C. DACOSTA, of Philadelphia—had never done hysterectomy for puerperal septicemia, and almost every case he had known to be operated upon had died. If we take a woman with puerperal sepsis, with a temperature of 104.5 degrees, thoroughly curette the uterine cavity, remove the *débris*, etc., and wash it out; we will find the temperature will come down to 102 degrees; and a second curettage, followed by thorough packing with iodoform gauze so as to distend the uterus and drain it, will cure some of the cases if they are not too far advanced.

Dr. CHARLES P. NORLE, of Philadelphia—said Dr. Carstens had made the statement that if the uterus is curetted early and swabbed over with carbolic acid the patient would recover. The position he took in his paper was that hysterectomy should only be performed when these measures failed. He went one step further and recommended that hysterectomy be done in cases in which the general condition of the patient was such that she was in imminent danger.

Dr. REUBEN PETERSON, of Grand Rapids, said the class of cases he had mentioned and dealt with in the paper were among the most embarrassing and perplexing cases with which the gynecologist had to deal, largely because our studies had not led us to definite conclusions. Yet, it seemed to him, that the indications for surgical interference were clear. It is unreasonable for us to wait until we get palpable disease in the pelvis before operating. In the cases touched upon, nothing could be found of a definite character on either side of the uterus; the appendages were normal; and bacteriologic examination is apt to show that the lochia are not even involved. There is no tenderness; apparently no

symptoms of peritonitis—indeed, nothing except we know that the woman is lying at the point of death. He could not agree with Dr. Carstens that by using the curette early in cases where there was pus collection and swabbing out the uterus with carbolic acid they would get well. He believed that ninety-nine of every hundred would die.

DIAGNOSIS OF URETERAL AND RENAL DISEASES IN WOMEN.

Read in the Section on Surgery and Anatomy, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY HOWARD A. KELLY, M.D.

PROFESSOR OF GYNECOLOGY AND OBSTETRICS IN THE JOHNS HOPKINS UNIVERSITY, BALTIMORE, MD.

It is my purpose in this paper to consider in outline the new methods of ureteral examination in women which I have developed recently. I shall therefore pass over those important diagnostic points which are already well recognized, such as clinical history, urinalysis, and ureteral and renal palpation.

My method lays stress upon three steps in the investigation, namely:

1. Inspection.
2. Catheterization of the ureter.
3. Catheterization of the pelvis of the kidney.

It will be observed that each of these procedures gives direct and positive information in marked contrast to the inferential methods of diagnosis of ureteral affections hitherto deemed sufficient.

I.—INSPECTION.

Inspection is limited to the orifices of the ureters and notes: 1, the appearance of the orifice and its immediate surroundings; 2, the character of the fluid discharged from the orifice; and 3, the character of the flow, whether absent, intermittent, or continuous.

Inspection is accomplished by placing the patient in the knee-breast position, or elevating the pelvis, and introducing a cylindrical speculum, 10 millimeters in diameter. The bladder at once fills with air, and all parts of its lining mucosa are accessible upon directing into it the rays of a good light held over the sacrum, by means of a head mirror. The ureteral openings are found at the base of the bladder, about 2 cm. from the internal ureteral orifice, and at an angle of twenty-five to thirty degrees to the right or left.

1. The appearance of the orifice in inflammatory disease of the ureter and kidney is often characteristic; being deeply injected, or pouting, mammillated, or swollen and edematous. A small area of ulceration may sometimes be seen in the bladder at the orifice. In tubercular cases, when the disease descends from the kidney down to the bladder, the first infection is apt to be distributed about the ureteral orifice over a triangular area with its apex at the ureter. The explanation is obvious; this is the area which comes first into contact with the urine from the infected side in its concentrated form, before dilution with the opposite urine and before distribution over the wide area of the bladder.

2. The character of the fluid as it is seen issuing from the ureteral orifice may be sufficient in itself to settle the diagnosis and determine the treatment, but before reaching a decision it is necessary to examine both ureteral orifices, watching them for a few minutes, until there is an escape of fluid. If no discharge takes place from one side, it may sometimes be started, when there is a renal tumor, by bimanual compression of the tumor in the flanks.

I recall in this connection, cases of hematuria in which bloody urine was seen flowing out from one side while the other discharged clear urine. In one case there was a layer of blood over the floor of the bladder, and the first and natural suggestion was that the vesical mucosa was the source of the hemorrhage. But upon cleansing it with a little pledget of cotton, the mucosa was discovered to be normal. Both ureteral orifices were surrounded with blood, but on one side the flow of normal urine kept clear a little path of uncovered mucosa, immediately in front of the opening, showing that that side was sound.

In a case brought to me by Dr. H. B. Marriott of Battleboro, North Carolina, we saw thick pure pus

Fig. 1.—Cystoscope.

issuing from the right ureter, and limpid urine from the left. I operated and removed a large number of stones from the right kidney. I have repeated this experience many times.

3. Normally, with the patient in the knee-breast position, the urine flows in clear jets, spurting out and often down the speculum. If there is a prolonged delay in the discharge from one side, there must be some stoppage there. When the discharge is purulent, it simply oozes from the opening and may continue to run out for a considerable time without intermission.

I would call attention to the important fact that,

with the patient in the knee-breast position, the fluid escaping from the ureters can be collected for microscopic and chemic examination, as it trickles down the speculum, without catheterizing either ureter.

11.—CATHETERIZATION OF THE URETERS.

Catheterization of the ureter is but a step beyond inspection, and by my method the ureter can be catheterized almost as easily as it can be seen. I must insist upon careful attention to aseptic details throughout this procedure. These are in brief:

1. A clean external urethral orifice.
2. The introduction of an aseptic speculum.
3. A ureteral orifice cleansed with a pledget of cotton saturated with a boric acid solution.
4. A sterile ureteral catheter not contaminated by handling.
5. Avoidance of contamination of the catheter during introduction.
6. Placing the sterile end of the catheter in a sterile test tube to collect urine as it flows from the ureter without contamination.

In order to catheterize the ureters the patient kneels upon a table or a bed with a board under the blanket to keep the surface flat. Then with the speculum introduced into the bladder the right or left ureteral orifice is found and kept within the lumen of the speculum, while the metal catheter is taken up by its outer end and slowly passed in. The end of the catheter is pushed on up to the ureteral orifice under constant observation, until it touches it; it is then engaged and gently pushed in toward the pelvic wall. Any resistance felt must not be overcome by force, but by withdrawing the catheter slightly and pushing it in a little different direction. It will generally be found, after the catheter has advanced 2 or 3 centimeters, that it is necessary to draw the speculum out a little, and then carry the point of the catheter more directly outward toward the pelvic wall.

The speculum is then wholly withdrawn and the catheter left in as long as desired. If the patient is turned over on her back, this must be done with extreme care, to avoid striking the end of the catheter and wounding the ureter.

To secure uncontaminated urine for bacteriologic investigation, the outer end of the sterilized catheter should be protected by a sterilized piece of rubber tubing before introduction. This can be taken off after the catheter is in place, and the urine which flows over the end can be collected without admixture with extraneous elements. I sometimes sterilize the end which has been touched during the introduction, by holding an alcohol flame under it until the escaping drop of urine boils on it.

Although the simple metal catheter is easier to handle in the introduction, I prefer, as less dangerous and therefore more to be recommended for general use, flexible silk ureteral catheters which I have had made, 30 cm. long and 1½ to 2 mm. in diameter (see Fig. 5). These have a large eye below a conical point which is easily pushed up 15 or 20 cm. beyond the ureteral orifice. If kept in a cool place the catheter is stiff enough to push up the speculum and into the ureter without the aid of a stylet, with which a soft catheter may also be easily introduced.

Short metal catheters 6 cm. (2½ in.) long, with fine rubber tubing on the end, introduced on a stylet, is also often convenient when both ureters are to be drained.

To put a catheter into both ureters, one may be catheterized first and the speculum taken out entirely and reintroduced alongside the catheter, when the opposite ureter may be exposed and catheterized in the same way. The patient may then be turned on her back without fear of the catheter coming out, and the urine drained from right and left ureters into separate receptacles. It is important to note the time of the flow, so as to establish a relation between the kidneys which is quantitative as well as qualitative. To collect uncontaminated urine from these and the renal catheters, to be described, a piece of sterile fine rubber tubing is slipped over the end to

Fig. 2.

Fig. 3.

Fig. 4.—Searcher, above, for investigating a doubtful ureteral orifice. Short ureteral catheter, below, with rubber tubing attached.

protect it from the handling during the introduction into the ureter. Then when the patient is in the position in which she will remain during the flow, the rubber sleeve is drawn off and the end of the catheter placed in a sterile tube plugged with cotton. I have found a simple wooden block with a hole bored in it, as shown in diagram, Fig. 3, the easiest way to keep the tube in place. A good way of making the connection between the tube and the catheter is by a piece of fine glass tubing, twisted to reduce the chances of atmospheric infection. The rubber sleeve is then simply drawn over this instead of being pulled off.

I would ask those who follow me in this work to adopt my enumeration of catheters and specula, by

their diameters in millimeters, because this gives at once a better idea of the size used.

Short metal catheters are also useful in draining both ureters. They are only 5 cm. long, and are pushed in with a stylet up to the very end, so that the catheter lies wholly in the ureter and bladder. The urine is carried out by a piece of fine rubber tubing on the end of the catheter.

CATHETERIZATION OF THE PELVIS OF THE KIDNEY.

My renal catheters are 50 cm. (20 inches) long, and $1\frac{1}{2}$ and 2 mm. in diameter. In special cases, I use still larger sizes. They are introduced in the same way as the ureteral catheters, but are pushed up until the end impinges on the upper part of the pelvis of the kidney. Their special field of usefulness is in demonstrating the condition of the pelvis of the kidney, whether infected or not, and whether there is or is not an obstruction at the upper end of the ureter.

Fig. 5.—Diagram showing flexible ureteral and renal catheters introduced. On the left side the ureteral catheter is introduced just beyond the pelvic brim; on the right side the renal catheter is in the pelvis, touching the kidney. The curves shown can be seen in the catheter on taking it out and laying it on a flat surface.

By means of the renal catheters, I have completely evacuated a hydronephrosis. I have also emptied a renal pelvis full of pus, and by forcing fluid back into the kidney have washed out the pelvis repeatedly, and cured a pyelitis.

After using these soft catheters, they are washed out well with warm water, and then with a 1 to 1000 solution of mercuric bichlorid, and carefully dried and put away in glass tubes about 8 mm. in diameter and enough longer than the catheter to plug the ends with cotton.

During the introduction the glass tube is presented over the left shoulder for the right ureter, and the right shoulder for the left, with the end of the catheter projecting a little out of the tube. This should be dipped in boro-glycerid to facilitate introduction.

In order not to infect it with the fingers during the introduction, I wear sterilized rubber coats on thumb and first finger, put on just as I am ready to grasp the end of the catheter and draw it out of the tube push it in, up into the ureter. The glass tube is held still while the catheter is being withdrawn.

REPORTS ON TYPHOID FEVER.

Read in the Section on Practice of Medicine, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

(Concluded from page 241.)

BY J. E. WOODBRIDGE, M.D.,
YOUNGSTOWN, OHIO.

I quote this letter from Dr. Balmer of Pennsylvania: "I have treated a number of cases of typhoid fever this summer, by your method, with remarkable success and will endeavor to copy the temperature charts and send them to you soon. I presented these cases and the method of treatment before our (the Jefferson County (Pa.) Medical Society, at the last meeting and I had introduced it previously orally in the society and to individual members. Dr. S. M. Free of DuBois, Pa., one of our members, is very enthusiastic, also Dr. J. J. Brewer of Clarrington, Pa., who treated a number of patients by the method, at my suggestion."

I very soon received a letter from Dr. S. M. Free of DuBois, dated December 26: "I have used your plan of treatment in a few cases of typhoid fever. It is the best I have ever employed. I have tracings and fairly complete notes of my cases, and am having my assistant make copies which I shall take pleasure in sending you as soon as complete. I trust that they may be of some service to you. I am under great obligations to you for your kindness to me. I am thinking of preparing a paper for presentation to our West Branch Medical Society on your plan of treatment, and will exhibit my charts and notes. Do you object to such a procedure? I feel sure that the more we can induce to use the treatment, the less will be the mortality in typhoid fever."

A quotation from another letter from Dr. H. K. Meyers of Indiana, dated Jan. 6, 1895, is as follows: "I will say here that I have carefully tried your mode of treatment in three well-marked cases of typhoid fever in the past few months, and was well pleased with it.

"Case No. 1, girl aged 14; very poor; surroundings bad; parents as ignorant as they were poor, yet willing to do as I directed. Temperature was from 104 to 105.5; bowels tympanitic; very tender; rose spots; tongue literally dried up, red edges. During the first three days the nose bled almost constantly. I tried to carry out your treatment to the letter, and I think I succeeded as near as any one can carry out another's ideas. The temperature was normal on the eleventh day and she made an excellent recovery. I should have stated that she had been sick a week before I was called. The other two cases were treated in the same manner and made as good recoveries. While my success in treating typhoid fever has been fair in the past, the fever was always protracted and tedious. I think your treatment is correct in principle and bound to succeed."

Dr. W. N. Sherman, of Merced, Cal., wrote me in August, 1894, asking for more definite rules for the management of typhoid fever than I had given in my papers. These directions were sent on September

13, and on the 29th he wrote me a letter from which I extract the following: "I have given your remedies in a modified form, in two cases, resulting in a normal temperature in both cases on the eighth day. I am highly pleased thus far."

Other letters followed, reporting cases successfully treated; the last one on Feb. 6, 1895, in which he says: "I am greatly pleased to inform you that I succeeded in inducing my patient to take your remedy and this third relapse is yielding to the treatment promptly. As the bowels were somewhat constipated I first gave 5 grains of calomel; followed by mineral waters and sul. magnesia. These failed to establish catharsis and I gave 1 oz. of castor oil with turpentine. I started with your combination No. 1 and kept it up all the time and this morning, the sixth day, the temperature touched 98.8 degrees. Has been able to eat all of the time and is cheerful and comfortable—a very material difference from the other attacks."

In another letter he says: "You are at liberty at any time to use my name as one who has proved and practiced your treatment and believes it to be superior to all others."

Dr. G. Law of Colorado, published a paper in the Denver Medical Times of December, 1894, from which I take the following:

"Dr. John Eliot Woodbridge of Youngstown, Ohio, read a paper on typhoid fever, in the Section on Practice of Medicine at the forty-fifth annual meeting of the AMERICAN MEDICAL ASSOCIATION, in San Francisco, June 5-8, 1894. I was present and heard the paper" . . . "on looking over the action of the drugs named by Dr. Woodbridge, I came to the conclusion that the carb. of guaiacol was the central and efficient agent, if there were any efficiency in the prescriptions. . . . Hence I framed a formula for myself. . . . From July 25 up to to-day, November 23, I have treated thirty-five cases of typhoid fever, without losing a single patient. I have not had a case in which the fever lasted beyond twenty days, and have had a number of cases where complete subsidence of fever had ensued at the end of fifteen days. Cases that started with a temperature of 104 F. in the afternoon, after about four days of this treatment showed usually an afternoon temperature of 102 F. and a morning temperature of 100 to 101 F., with some sweating, which usually occurred about midnight. No one of the thirty-five cases ever had a dry tongue at any time; not one of my cases ever manifested the slightest delirium. It was not necessary to give any of these patients anything for the purpose of securing sleep or rest. Not a single relapse occurred in the entire number treated. The guaiacol compound was continued for one week after the total subsidence of the fever, but given every three, and then four and, finally every six hours. In none of the thirty-five cases was there noticeable meteorism or the slightest hemorrhage from the bowels. During the last twenty-four years I have seen and treated from twenty to fifty cases of typhoid fever each year. I never before treated thirty-five consecutive cases without losing a patient, and never before treated that number of consecutive cases without a relapse. Typhoid fever during the present year (1894) in our town has manifested about the usual characteristics, with about the usual mortality, in the hands of practitioners other than myself. I saw several fatal cases in consultation with other doctors, but I did

not regard them as being suitable cases for the "Woodbridge method" as they were almost if not quite, *in articulo mortis*. I am not sanguine of the value of this treatment if instituted late in the course of the disease after the nerve centers have become profoundly poisoned by the fever toxin. I have made no secret of what I was doing with reference to my

Dr. McGarvey's Case No. 7.—Archle R.; age 6 years. Date of admission, March 10, 1895. This patient never took his bed.

Dr. McGarvey's Case No. 8.—John J.; age 30 years; African; occupation, cook; residence, Lorain, Ohio. Date of admission, March 26, 1895. This was a cook at the hotel, a large corpulent negro; but not one bad symptom. Result: recovery.

work, to my colleagues in the city. However, only Dr. R. F. Graham seemed to attach any importance to it. He has been giving the matter some attention, and I thank him for his courtesy and will leave him free to speak for himself at his own elected time. I am aware that the bright and brilliant lights of the profession have scouted the idea of there being any efficiency in

the plan of intestinal antiseptics, and I will admit that it has not hitherto happened to be markedly successful. But let me ask, is it not in line with the present trend of so-called rational, not to say scientific medicine? In conclusion, I am inclined to infer, that either I have had a remarkable and continuous succession of mild cases, or the treatment on the lines of intestinal antiseptics that I have steadily pursued during the time indicated has been remarkably efficacious."

During the recent epidemic of typhoid fever at Lorain, Ohio, I was called there in consultation with Dr. J. F. McGarvey who I found was treating the disease by my method, so scientifically and so successfully that I knew that time would give the "Woodbridge method" at least one more warm advocate on the shores of Lake Erie. The evidence convinced him more promptly than I expected, and every few days he sends me a clinical chart of a patient in whose case he has aborted the disease. Your attention is called to his charts, marked "Dr. McGarvey, Case Nos. —."

treatment I am farther convinced, not only by your own brilliant success, but by a very remarkable run in four cases, which I treated in September; following your directions as nearly as possible. No one with intelligence, it would seem to me, would question the treatment after having tried it, especially with such testimonials as you have presented from those who can not possibly be interested in your success. . . . I think as you say, that possibly your treatment could and may be improved upon in the future, but not materially changed; and it will have to be carried out on the same lines. . . . I was an interne in the Memphis City Hospital nearly two years and had good opportunities of treating typhoid fever with ammonia salycil., but although it seemingly modified the disease, I have no recollection of one case being cut short. I have been in private practice for five years and can not say that I have seen any better results than in hospital practice, my cases all running from three to five weeks. These four cases I am just through with; in two of them with morning temperature of 102 degrees, even-

Dr. Yost's Case.—William McC.; residence, Hazleton. Date of admission, March 16, 1895. Commenced "Dr. Woodbridge's Abortive Treatment" Sunday evening—the first day the patient thought the services of a physician necessary—he had been complaining for five days before. On the tenth day he was covered with rose-spots, and about the house.

Dr. J. O. Yost, of Hazleton, Ohio, in whose family Dr. Bennet treated with me three cases of typhoid fever last autumn (See charts of Cases Nos. 92 and 96; of the third case no chart was kept) has contributed a chart of a remarkable case, in which he reduced the temperature of 106 degrees, to normal in ten days; when he reports the patient around the house, covered with rose spots. (See Case marked "Dr. Yost No. —, William McC.)

Dr. W. B. Shields of Arkansas, under the date of Oct. 2, 1894, says: "I have been for some time past, keenly interested in articles from your pen, which have appeared in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION in regard to the treatment of typhoid fever. That you have struck the correct

Dr. Cunniffham's Case, No. 6.—Mary R., age 12 years. Date of admission, April 11, 1895.

ing temperature 104 and 105 degrees several times in the first week; were free from fever at the end of the thirteenth day of treatment and fifteenth day of disease. One other case with evening temperature of 103.5 and 104 degrees several times, was free of fever on the fifteenth day of treatment and seventeenth day of disease. The last case had evening temperature of 104 and 105 several times, was free on the seventeenth day of treatment and twentieth day of disease. This last case had such a bad attack as to suffer from incontinence of feces for several days. All of these cases felt strong at the end of the fever, and could walk around. With my limited experience in this treatment, I have to allow patients no solid food. I have used no coal-tar derivatives whatever, but had my patients sponged off once or twice in the evening on days when the fever was high. As you said, after

two or three days of treatment their fever could be and was controlled by the antiseptics administered. I feel that with further experience in this line I can have as good results as you have. . . . These few cases which I present, . . . few in number, but brilliant in results, convince me that you have struck the keynote, and while begging your pardon for monopolizing your valuable time, I must return thanks for the great benefit I have seen result from your teachings."

Dr. C. I. Burt, of Iowa, wrote me on December 10 saying: "We are having an unusual epidemic of typhoid fever in our locality. I have at present some thirty-eight cases. . . . Your antiseptic treatment was favorably called to my attention to-day by Dr. Wright, of Carroll, Iowa, and he requested that I write you for reprints of your late articles on typhoid fever. . . . Our source of contagion is such that

time, understand, some of them were sitting up, others moving about, and in a manner attending to their usual business. Many cases I began upon when the fever reached the 103 and 104 point, but they had no serious intestinal lesion. However, when I discover the matter has passed to an intestinal infection, I yet obtain splendid results. Now this point is one to which I wish to call your attention. Leaving out the abortive effect of your treatment, what are your results after the case has progressed even to hemorrhage? I find, by pushing the treatment then, as persistently as at other times, that I obtain pleasant results, at least, a thorough intestinal disinfection and, in fact, a better general tone. . . . Without doubt, Doctor, any one who uses your treatment as effectually as prescribed by your directions, will have none but the most happy results for the outcome. I have had several nurses from Omaha, and recently

Dr. Cunningham's Case, No. 7.—Zonie G., age 3 years. Date of admission, May 5, 1895.

the physicians of this town will yet have to contend with some hundred more cases." Very soon afterward I received another letter (unfortunately mislaid) in which the Doctor complained of his inability to secure the results I had promised, notwithstanding the fact that I had written him a long letter, giving him the fullest possible details of my method of procedure, but on Jan. 22, 1895, I received another letter from him from which I make the following extracts: "I do not seem to get quite the promised results from the tablets, in the nature of producing effect, as stated in a previous letter; but I am now having better success and push them to their limit. However, I have at all times followed very closely your directions, and must state that the effects have been wonderful. In no instance have I failed in relieving my patient within three weeks and often in two. In that

Dr. J. F. Reed's Case, No. 2.—John W., age 28 years; residence, Massillon, Ohio. Date of admission, Sept. 23, 1895. Temperature remained normal after October 7. Temperature stood at 103.20 after taking 120 grs. sulph. quinin. Treatment: "Woodbridge's." Had most typical symptoms of any patient I have had; nose bleed, tympanitis, etc.

one from the Royal Infirmary, Dundee, Scotland who is in this country for her health, (they are all noted typhoid fever nurses) and let me tell you, they were absolutely paralyzed that a country doctor could produce such effects as they had never seen in Omaha or any western city. They think they will go home now and treat typhoid fever on their own accord. They say the only objection they have to this treatment is that it cuts off their time in nursing. . . . In every instance I prescribe a full bottle, without erasing formula or other attached notices. My nurses fully understand where the credit is due."

A letter from Dr. Burt written on March 21, says: "I am still using your treatment and now obtain all the results that you claim. I have a patient, one

case re-infected four times within eighteen weeks, under my care for the last five weeks and strictly under your treatment. I have avoided any high jumps of fever from 104 to 106, as had previously been the case. My patient is now convalescent, but if I stop the treatment two days I note a rise of temperature often from 103 to 104. I am not experimenting farther on this case but am rigidly keeping to the "Woodbridge treatment" and the happiest results follow. I note that you are to defend yourself, . . .

. . . it does not seem to me that one ought to produce a defense in the line of argument; if any of the gentlemen will permit themselves to follow out your instructions and use your treatment, there would be no need of argument; they would all coincide with your views. It is just as positive that typhoid fever can be aborted by your method as it is that it can not be by any other treatment, to my knowledge. I have had some sixty cases this winter, and there has been no mistake in diagnosis, as our eminent local authorities have assisted me from time to time. I note that some physicians criticize the fact that they can in no instance find the "typhoid fever curve" in your records; were they to do this, after using the treatment a few days the treatment then would be useless; the treatment is to prevent this curve. It does so most satisfactorily. Most of my cases have been among the poorer classes and scarcely any attention was given, other than the medicine. I have lost one case, but that was not under the "Woodbridge method." It may, no doubt, seem an exaggeration, as to the number of cases I have had and the happy results, but every fact can be verified. I have not kept a presentable account of cases in children, but my best and quickest results seem to be with them. In ten or fifteen days they were not only convalescent but quite recovered. I consider it would be an honor to render you any service in my power, and from the above statements if matters can be condensed or rearranged in any manner that would be useful to you, kindly command me, and I will respond to the best of my ability at once."

Dr. Moore, of Iowa, in a letter dated Dec. 17, 1894, says: "I am very much pleased with your manner of going at the dread disease and I am much indebted to you for the treatment. I have treated thirty cases of typhoid fever during the last three months, without a death. . . . Early in the autumn I had five patients in one family and all recovered in from eight to fifteen days. The correctness of the diagnosis was questioned; they were thought not to be sick enough for the disease to be typhoid fever. George V., living opposite, was taken sick, so I thought I would put him on the old "expectant method" of treatment, and as you will notice by looking at the chart of Case No. 3, his temperature was not high and he seemed to be getting along fairly well, but about the thirteenth day he had a hemorrhage of the bowels and then I gave him your medicine, but it was too late. I merely send you the chart and relate this instance to show how skeptical a community is, and how laymen and physicians, too, stick to an old custom. I will never be caught so again."

At the last meeting of the Mississippi Valley Medical Association, I had read my paper on typhoid fever and during its discussion, which occupied three hours, my theories had been assailed in a most vindictive manner. Learned professors, and the editors of med-

ical journals had vied with each other in making ungentle speeches. He who declared most positively in his harangue the time-honored aphorism: "Typhoid fever must run its course of four, five, six, or ten weeks or longer," was most loudly and emphatically cheered. Of all of the more than three hundred members in attendance, not one voice was raised in behalf of the principle I had so earnestly promulgated, or to give the slightest countenance to the treatment which will ultimately save an hundred thousand lives annually in the United States alone. No man in all that assemblage dared or cared to say that "typhoid fever can be aborted," and to the end of the discussion I remained the single and lone defender of this great and fundamental truth that means so much to the human race. After the session adjourned, I was introduced to Dr. Dalton of St. Louis, with whom I had already had some correspondence and who had written me (after having tested my method of applying antiseptic medicine to the treatment of typhoid fever), that he had been six

Dr. Moore's Case, No. 1.—Ethel D., age 6 years. Date of admission, Sept. 11, 1895. This was a case with very severe symptoms of typhoid fever. Child was taken sick away from home. She was treated by Dr. B. by the old method for five or six days. She has since had very much better health than before her illness. Although the temperature was so high, she was never "out of her head." When I first saw her, rose-spots were abundant, and great tympanitis and tenderness in right iliac region. years at the head of the great St. Louis City Hospital, through which 10,000 patients pass annually, and he regretted that he did not then know of the "Woodbridge method." And Dr. Dalton healed all the wounds which that three hours' debate had given me, when he said: "I am very sorry that I was not at hand when your paper was under discussion; I would have waited until those disputants had finished and would then have said: 'Gentlemen, I would like to inquire how many of you have used Dr. Woodbridge's treatment of typhoid fever?' and when they admitted that not one of them had (as they would have to do), I would have said: 'That is about as I expected; you have been endeavoring to discuss a paper that you do not understand, and a treatment that you have never tried. I have investigated the matter and know that

the treatment will abort typhoid fever.'” Dr. Dalton has in various letters to me indicated his entire satisfaction with my therapeutic procedures and has reported so many cases in which he has applied them, as to give assurance that the abortive treatment of typhoid fever in St. Louis is in a master’s hands. Quotations from his last letter, written April 25, are as follows: “When I first tried your treatment for typhoid fever I was a ‘doubting Thomas,’ but luckily the excellent result in the first case caused me to try it in a number of other cases, and I have not the slightest hesitation in saying that the treatment undoubtedly aborts the disease. Two months since I purposely allowed a typical case to run the usual course for eight days, using the old treatment. The temperature followed the general course, being a degree or two higher each evening. On the eighth day, I put the young man (18 years of age) on prescription No. 1, giving the powders every fifteen minutes for the first twenty-four hours, and every half-hour for the next twenty-four hours. On the third day they were administered every hour and the fourth day every two hours; after that every four or five hours for a week. When I began the medicine, the temperature was 103.5. On the evening of the second day it fell to 101, and in two days more it was entirely gone, never to reappear. The bowels moved freely, six or eight times daily for several days. Ptyalism did not appear. I used no other treatment after beginning the powders. Put me down as a firm believer in the treatment; an enthusiast, in fact. Let the doubters try the treatment and be convinced.”

The original letters and reports from which these extracts are taken, and more than a thousand others on the same subject; as well as the original charts (of which you have been inspecting copies, many of them containing the verification and signature of the physician who attended the patient or who watched the results of the treatment) are over at my hotel, and I shall be pleased to have you inspect them. They contain much valuable information and would well repay a careful examination. I should like to have presented more of this unimpeachable testimony, but the line has to be drawn somewhere, and these documents, with those that I have already transcribed for presentation before the Ohio State Medical Society should be amply sufficient to accomplish their purpose, especially since through the courtesy of Dr. Cunningham I have been able to present the anatomic specimens showing the ulcerated Peyer’s glands, the tumefied mesenteric glands, and the intussusception which caused the death; and with them the clinical chart, kept at the bedside, in which the thermic line as it approached normal, indicates that the disease was aborted and the patient practically cured of his typhoid fever on the seventh day of treatment. (See chart marked Dr. Cunningham, No. 3.)¹ And if it be admitted that even one case of typhoid fever has been aborted, the total fabric of those who dissent from my views, reared as it is upon the antiquated and illogical hypothesis—that this “specific infectious;” this “self-limited disease” can not be aborted—is demolished.

The reports heretofore made by me should have

¹ The report of this case after having been read in connection with this paper, was presented, and the anatomic specimens exhibited, before the Ohio State Medical Society, in the Transactions of which it will be published. This double report is fully justified by the rarity of the case—no other instance having ever come to my knowledge in which death has ensued after typhoid fever had been aborted—and because of its great value, since it establishes the truth of my theories beyond question or cavil in the court of final resort.

left no doubt on this point; nor do I believe that they would have done so, could all or even two or three of the dozen papers which I have written on this all-important subject during the last few years, have been listened to, and deliberated upon by one body of scientific men. They have, however, been so much diluted by their great distribution (having been presented before so many widely separated societies, from the Atlantic to the Pacific) that very few physicians have heard more than one discussion of the subject; but when all these papers are gathered together and published under one cover, what Virchow calls “the brutal force of the figures” can not but convince any thinking and unprejudiced physician “that typhoid fever can be aborted.” “*Bis ac ter quod pulcrum.*”

Summarizing, you have my nineteen years of fairly satisfactory clinical experience with the method I have advised (the last thirteen years without a death in my own practice from typhoid, malarial or any continued fever); and as long practice added to my proficiency, a gradual reduction of the duration of the disease as well as a lessening of the intensity and violence of the symptoms.

You have the 800 cases, with 9 deaths, reported by 117 other physicians, some of whom have treated large numbers, as many as 60 cases through severe epidemics, without a death, approximating my best results; and showing a grand total of 1,200 cases of typhoid fever, taken at all stages of the disease, with only 9 deaths; 7 or 8 of which were clearly due to grave complications, to the late stage of the disease at which treatment was begun or to faults of preparation or administration of the remedies.

The foregoing is a brief summary of this, at present, voluminous and cumulative evidence; absolutely apodeictic as to the possibility of aborting typhoid fever; strongly presumptive as to the truth of the declaration that every case can be aborted and that death is a wholly unnecessary consequence of the disease; and more than competent to convict me of grave dereliction of duty, did I not impart my theories to the medical profession in unmistakable language.

RATIONAL TREATMENT OF PERTUSSIS.

BY FRANCIS T. B. FEST, M.D.

PLANK ROAD, MICH.

With every disease its etiology shows us the way for its treatment. Therefore it is necessary to recapitulate the etiology of every disease for which we wish to outline the therapeutics.

Pertussis or whooping cough is a contagious disease, which manifests itself in spasmodic cough. Although some bacteriologists have found in the sputum, bacilli, we are unable so far to determine their rôle, whether causing, accompanying or only accidental. It is a local disease of the larynx, acting upon the nerve supply, and causing spasms of this organ. The course of the disease shows three distinct phases: the catarrhal, paroxysmal and declining.

The first stage shows only symptoms of mild catarrh of the bronchi, nose or conjunctiva. Pathognostic for pertussis is only the excessive watery secretion from the affected regions. This phase lasts from two to seven weeks, with infants often a few days only.

The paroxysmal stage affirms the diagnosis by its

characteristic "whoops." The expectoration is watery, sometimes bloody. In many cases vomiting follows the paroxysms by mechanical irritation. The vomiting in return can cause disorders of the digestive apparatus. The whoops at times occur as often as every half hour, and as thereby the cyanotic condition which accompanies the whoops occurs too frequently, they lead to asphyxial convulsion and even death.

In the respiratory apparatus the irritation causes, in many instances, capillary bronchitis and catarrhal pneumonia. After duration up to ten weeks the paroxysms are less severe, show themselves more rarely and the disease goes over into the declining stage. At this time the sequelæ or secondary lesions mainly demand our attention.

As we have seen, the disease is a local one. It primarily affects only the larynx; all other symptoms are secondary. This circumstance forms the basis of our treatment. The disease is local—ergo, we treat it locally; it is of neurotic character—ergo, we give a drug that acts upon the nerves.

With contagious local diseases, rational local treatment consists in destruction of the contagion by antiseptics—the most powerful is the most rational. Therefore every local application of any antiseptic improves to a certain degree pertussis. If we cast a glance at the literature, nearly everything was tried; phenol, boracic acid, thymol, resorcin, naphthalin, creasote, benzol, bromoform, mercurials, etc., but they all more or less are of irritating action upon the surface they are brought in contact with, or if not irritating, their action is so mild that their therapeutic effect is as mild too. The experience of the last few years proved the superiority of peroxid of hydrogen over all other antiseptics, except when we have to handle metallic instruments. An exception which interferes not in pertussis.

In pertussis, I use the peroxid with great success for local applications in this way: the child's head is leaned backward and held firmly, another person pulls out and depresses the tongue to bring the glottis into good view; then by means of a bulb atomizer consisting of glass and rubber only, I direct a spray of peroxid of hydrogen solution toward the larynx and if possible through the glottis. This is much facilitated if the child is old enough to pronounce the sound *â*.

I always prefer the 30 volume peroxid of hydrogen (hydrozone) and dilute it in the following manner: hydrozone, one part; distilled water ten parts; glycerin one and one-half parts.

If the parents are docile they can be instructed to repeat the application twice or thrice a day. If the physician has a chance to apply it himself, he does well to make the solution fresh every time. At all events it should be made fresh every other day on account of this mixture being unstable.

Of all drugs only one has a really aborting influence upon pertussis, the old reliable, often abolished and always restored belladonna. The only secret of its right administration is the circumstance that we have to give such doses to get the belladonna action; the flushes, (Jacobi); otherwise the administration is without value.

A child of 2 years requires 6 drops of the tincture, three times a day; with the age the dose has to be increased to the proportion of 1.00 as a maximum single dose for an adult (gtt. xxv).

The root, the extractum alcoholicum fluidum can be given to infants of six to eight months in doses of 0.01 t.i.d., children of 3 to 4 years require of the same 0.3. Atropin may take the place of belladonna, beginning in a child of two years with 0.00065 t.i.d. and increase proportionately.

All complications must be abated in time, else our patient will be emaciated. If vomiting occurs at the paroxysms, give menthol. If there be gastritis and catarrh of the bowels, give calomel, bismuth, or still better glycozone. Often we meet gastralgia; then I prescribe for a child over 2 years:

R Belladonnæ, tinct.	2.00.
Mentholis.	2.50.
Spir frumenti.	10.00.
Glycerin	20.00.
M.D.S. Teaspoonful every two hours.	

Glycozone administered in the proportion of two teaspoonfuls, diluted in a wineglass full of water, gave me the most gratifying results in acute cases.

Are the paroxysms severe, we can easily control the spasms by an application of cocain to the larynx.

For the general treatment we shall advise fresh air, good nourishment, tonics and inhalations of ozone. With such treatment the disease can be cut off to a period of only a few weeks.

A GLIMPSE OF IRISH SURGERY.

BY N. SENN, M.D.

CHICAGO.

The wear and tear incident to a large hospital practice, the fatigue following the work during a long college session, and the unrest attending the demands of a progressive and exacting profession made it absolutely necessary for me, this year, to tear myself away from my sphere of activity and transplant myself to some foreign country to seek a much needed mental rest. I selected for this purpose Ireland, Norway and Sweden. It was my object to combine recreation with a study of the clinical advantages to be found in these countries. After an unusually smooth passage of less than seven days, on one of the palatial Cunard ocean greyhounds, I landed at Queenstown Saturday, July 13. At this time of the year, Ireland is at its best, the deep green of the lawns and meadows imparting to the landscape a most pleasing aspect. The stranger here has no difficulty in recognizing the nature of his environment when he sees and hears the ruddy, talkative cab driver, ever ready to give him the first ride on the Irish soil. The open cart is the vehicle peculiar to this country. It is used almost invariably to convey strangers and citizens to their place of destination quickly, if not in the most gentle manner.

The city on my arrival was undergoing one of those convulsive political movements incident to a general election. The political issues were discussed in a most animated manner on the streets, in all public places and in front of churches before and after service. The women appeared to be, if anything, more enthusiastic than the men. The newspapers were brimful of accounts of political meetings and speeches, and the American looked in vain for news from his native country. The Irishman is a born orator and politician. The humblest cabby admires and honors oratory and takes a lively interest in the issues of the day. Eloquence sways the views and actions of the public masses more than argument. The man who can make the best speeches

has the first and last claim upon the favor of the people.

From what I have seen and heard, I am satisfied that the great question which has agitated the Irish people for years—the land ownership, will be amicably settled by the ballot box and not by the sword. What this country needs is not a separate government, but a more just and equitable disposition of the land question. The possession of a home, no matter how humble this may be, makes its inhabitants better citizens. As soon as the Irish soil is owned by Irishmen, the burning question now before the people will be disposed of, to the mutual advantage of both countries.

The first medical center in Ireland from the south is

CORK.

This is a typical Irish city of about 100,000 inhabitants. The dialect, customs and habits of the people have not been much affected by outside influences. The most important hospital is the Northern Infirmary. This institution is under the management of the Sisters of Charity. It has recently been enlarged and many improvements have been made. It is a charitable institution where all the poor sick and injured find the doors wide open during all hours of the day and night, regardless of creed. The Sister Superior will soon celebrate her golden jubilee. She has served the order faithfully for nearly half a century. Although advanced in years, she retains the vigor and ambition of her youth. Her history would furnish ample material for an interesting story, replete with many acts of heroism and stirring events. She served on the battle-fields of the Crimean War and smoothed the pillow of many a poor soldier who died of cholera in Algiers. She is the beloved sister of the distinguished Bishop of Cork, the most Rev. Dr. O'Callaghan. Brother and sister work incessantly in one common cause—the relief of suffering of the deserving sick poor.

It is at the suggestion, and through the influence of the Bishop that a training school for nurses has recently been established in the Northern Infirmary. Seven robust rosy-cheeked young women are now serving as probationers, who furnish the nucleus of a noble institution, the blessings of which will soon reach the rich and poor alike. The surgical clinics in this hospital are conducted by Professors Sullivan and Hobart. The hospital furnishes a rich material for the teaching of accidental and emergency surgery. Fractures can be studied here to great advantage. Antiseptic rather than aseptic surgery is practiced here.

DUBLIN.

This is the great center of Irish surgery. The city with its numerous suburbs contains nearly half a million of inhabitants which furnish an abundance of clinical material for the two medical schools and the many hospitals.

It is unfortunate that this old and otherwise enterprising city does not possess a general hospital where the clinical material could be centralized and made more available for clinical teaching. Not any of the hospitals contain more than 120 beds and these, where the clinical teaching is done, are often distant from the medical school to which they are attached. The teaching of clinical surgery of the Trinity Medical School, by Professor Bennett is done at Sir Patrick Dun's Hospital. This hospital is a very old one and

lacks many of the modern improvements which are so essential in the practice of ideal surgery. Notwithstanding the many defects, excellent results are obtained. Professor Bennett has made the study of fractures his life work. A visit with him to the Pathological Museum of Trinity College is a rare treat. Hundreds of the most interesting specimens of all kinds of fractures are shown and explained. The museum is especially rich in specimens illustrating fractures of the neck of the femur and Colles' fracture. The classical specimens which enabled Colles to describe a special fracture through the lower end of the radius which bears his name can be found here, and constitutes an object of increasing interest to the present occupant of the chair of surgery.

Professor Bennett has made a most instructive collection of specimens, illustrating fractures of the first phalanx of the thumb. It appears from this collection that fracture of this bone occurs as frequently as fracture of all the remaining phalanges of the hand.

This museum contains also the skeleton of the famous Irish giant. The Professor is of opinion that it represents a good illustration of acromegaly. The equally famous "card player of Cork" enriched the collection by furnishing it with a skeleton illustrative of extensive and far advanced myositis ossificans. The new bone is everywhere in connection with preëxisting bone, no floating bone being found at the post-mortem, which demonstrates conclusively that this disease is not primarily an affection of the muscles but of the periosteum, the muscles serving chiefly the purpose of a temporary framework for the bone-producing process. The disease begins in the bone-producing tissues corresponding with the origin or insertion of the muscles. Many of the large muscles, notably those of the thighs and shoulders, in this case have been entirely replaced by bone, the muscles in advance of the osteo-genetic substance having been removed by degeneration and absorption.

Numerous specimens of so-called rheumatoid arthritis, which have been deposited in this museum, show the frequency with which this disease occurs in this country, and to what extent pathologic conditions are produced in its advanced stages. The specimens show well the various stages of the affection, from a slight enlargement of the head of the femur and limited deposits of new bone upon the head, neck or trochanteric regions, to complete immobility of the joint by the formation of enormous, rough, irregular masses of bone connecting the pelvis with the trochanteric regions of the femur.

The anatomic department of the museum contains a wonderful collection of dissections and frozen sections that are of such great value in the teaching of anatomy by demonstrations. The professor of anatomy is an original and enthusiastic worker. His whole time is spent in teaching and advancing both the science and art of anatomy. It is much to be deplored that in our own country this part of teaching suffers greatly, by the teachers of anatomy being active practitioners who have to depend for their living largely upon their income outside of their college work.

By far the most prominent surgeon in Ireland today, is Sir William Stokes, a son of the distinguished Irish physician, Dr. Stokes. He is professor of surgery in the College of Surgeons, and attending surgeon

to the Meath Hospital where he operates, and delivers his clinical lectures. He has inherited the inimitable qualities which characterized his father, and has done much toward the advancement of modern surgery in Ireland. He is a fluent and forcible speaker and an excellent operator, is honored and respected by his patients and is a great favorite with his students. He bears his title with modesty and dignity. He will read a paper on "Fractures of the Neck of the Femur" at the forthcoming meeting of the British Medical Association. He has collected numerous specimens which he has studied with great care and which he will use as a groundwork upon which to base a new classification of fractures of the neck of the femur. The views which he will advance and elaborate will do much to illuminate a dark corner in surgery.

Professor Bennett is making elaborate preparations to open the discussion upon this paper, and we may expect a flood of new light upon this subject from these two Irish surgeons. During my visit to the Meath Hospital, Sir William made an amputation of the thigh through the middle third by Teale's method, for sarcoma of the leg. He is painstaking in his work and it is evident that he has the interests of his patient more at heart than a desire to impress his audience with the brilliancy of his work. A visit through his wards satisfied me that the Irish surgeons are wide awake in the development of surgical pathology, and in the adoption of new surgical resources. The museum of the College of Surgeons contains a vast amount of material available for the study of surgical pathology. It seems to me that this almost inexhaustible mine should be more frequently explored in the preparation of scientific papers which require illustrations of morbid anatomy to explain the text.

The training schools for nurses in connection with all the hospitals in this city are in a flourishing condition. The Rotunda Hospital is an object of great interest to every visiting physician. If the old building could speak, it could tell of many sad events, it could narrate many disappointments in love and could tell of many reverses in life. It is here that many young physicians have laid the foundation for their future success as family physicians, by receiving a thorough practical training in obstetrics. Recently, ten children came into the world in this institution in one day, and the number of births during the last year, I was informed, numbered over 2,000. That prudent conservatism is practiced in this institution is evident from the fact that, on an average, only one Cæsarean section and one symphysectomy are made during a year. Antiseptic and aseptic precautions which are conscientiously carried out have succeeded in almost completely stamping out puerperal infection. The lady Superior is a remarkably bright and intelligent woman, who takes interest in her work and who, at the same time, takes a great delight in the success of the Master of the institution. Professor Smyley, the Master of the Rotunda, met with an accident a few days before I visited the hospital. Like many physicians in this country he rides a wheel, and during one of his excursions he fell and fractured his arm. For a speedy and satisfactory repair of this injury he has sought a quiet country resort from which, let us hope, he will return with new vigor to pursue his good work.

Professor Myles is professor of operative surgery

in the College of Surgeons and does excellent clinical work at the Richmond Hospital. He is one of the rising young surgeons in this city. Among the older Irish surgeons who have made Dublin famous as a medical center, must be mentioned Crampton, R. W. Smith, Abraham Colles, Robert Adams, Butcher and John Cusick, all of whom made valuable contributions to surgical literature, beside being influential and eminent teachers.

BELFAST.

In the north of Ireland is the stirring city of Belfast. It is a Chicago on a small scale. The enterprise of its business men has done much toward absorbing many of the commercial interests which naturally belong to the two other large Irish cities—Dublin and Cork. The city bears an aspect of great activity and prosperity. The medical school is a part of the University, and is built upon the same grounds. It is a spacious and commodious building, but the laboratory facilities are as yet quite limited. As is the case with all medical schools that have existed a hundred years or more, the most interesting and attractive part is the museum, which has been made the depository of many rare and unique specimens. Professor Sinclair, the occupant of the chair of surgery in this school, showed me the collection and pointed out many specimens which are of interest to the writer. The museum contains hundreds of specimens illustrating the different kinds of fractures and the process of repair. He informed me that the Irish surgeons understand, by a Colles' fracture, a fracture through the radius near the wrist joint *without* impaction, as Colles described a fracture in this locality which could be readily reduced, with a tendency to re-displacement. English and American surgeons describe under this term, impacted, as well as non-impacted fractures, which is evidently a mistake according to the teachings of Colles, whose views on this subject have been retained by the Irish surgeons. I examined a number of specimens of intra-capsular fractures of the neck of the femur with bony union, in this collection, none of which have evidently ever been described in print.

About a dozen female medical students aspire here for the degree of Doctor of Medicine, preparatory to placing themselves on a level at the bedside with the male members of the medical profession. The "new woman" can be found here as elsewhere, in competition with the sterner sex in the various walks of life.

Professor Sinclair is a young surgeon of considerable promise, who avails himself of all the recent advances and improvements in surgery. His clinical work is done at the General Hospital, an old building with a capacity of about one hundred and forty beds. The operating amphitheater is small and inadequately supplied with modern facilities.

The Irish surgeon has to contend everywhere with the disadvantages incident to old buildings and poorly equipped operating rooms, and yet the results obtained compare favorably with those obtained in institutions supplied with all modern facilities; the best possible proof that they are doing good honest work.

In the General Hospital accidental surgery predominates, which gives the students an excellent opportunity to become conversant with emergency work. Dr. Byers, the professor of gynecology, has fitted up

a model little operating room for abdominal surgery, which is supplied with all the necessary conveniences to perform aseptic operations. All of the patients recently subjected to abdominal operations for various indications were doing well.

The classes in the Dublin and Belfast Medical Schools number on an average about two hundred and fifty.

Fearing that the length of my communication will tax the patience of the readers of the JOURNAL, I will close with the statement that Irish surgery, as practiced at the present time, under the leadership of such men as I have mentioned, is a credit to the profession and the country it represents.

Belfast, Ireland, July 18, 1895.

SOCIETY PROCEEDINGS.

Amerleann Electro-Therapeutic Association.

Fourth Annual Meeting held in New York Academy of Medicine, New York, Sept. 25, 26 and 27, 1894.

WILLIAM J. HERDMAN, M.D., President.

(Continued from page 246.)

DR. EDWIN J. HOUSTON read a paper prepared by himself and DR. KENNELLY on some experiments on

DEATH BY THE ALTERNATING CURRENT.

Having observed a communication in the *Comptes Rendus* of the Academie de Sciences, from M. D'Arsonval in June, 1894, respecting a case of apparent death produced by accidental contact with an alternating current circuit, and the means successfully adopted for reviving the person shocked, we desire to enter our earnest protest against what we regard to be the unwarranted conclusion that Dr. D'Arsonval has apparently drawn from this case, taken in connection with his previous experiments with animals. While we do not for a moment doubt the correctness of the general observations in this case, nor that similar cases may frequently arise in practice, and while we are desirous of fully accrediting to Dr. D'Arsonval the great value of the suggestions made by him, namely, that a person shocked by electricity should be treated as a person drowned, a treatment which we would indorse as being proper to employ in all cases where even the shadow of a doubt exists as to the actuality of death from electricity; yet we desire most emphatically to call in question the correctness of the general conclusion reached by Dr. D'Arsonval, that because in this particular case resuscitation was possible, that all cases in which no marked lesions or evident destruction of the tissues are effected, death is only apparent and resuscitation possible.

In the communication referred to, Dr. D'Arsonval arranges all cases of the passage of powerful alternating currents through the human body into two classes, viz.:

1. Where lesion or destruction of the tissues is produced. (Disruptive and electrolytic effects of discharge.)
2. Where the excitation of nerve centers takes place, producing arrested respiration and syncope but without material lesion.

In the first case Dr. D'Arsonval claims that death is absolute; in the second, on the contrary, it is only apparent. As far as we can learn this classification, so far as human beings are concerned, is based on the actual observation of but a single case. This case he appears to believe sufficiently convincing to warrant the conclusion that all cases in which alternating currents pass through the human body without producing evident lesions are capable of resuscitation.

Further, Dr. D'Arsonval appears to believe that the evidence in this case is sufficiently convincing to warrant the monstrous statement made in his communication that even in the electrocutions in the State of New York, death is not produced by the current, thus leaving the public to infer that it has been produced by the knife of the surgeon, in the autopsy which always follows.

In view of the importance of the subject, we append a translation of the facts described in Dr. D'Arsonval's communication as being those upon which he apparently bases his opinion:

"The following is a statement of facts communicated by MM. Picou and Maurice Leblanc, two well-known electricians who were eye witnesses of the accident and who res-

cued the man to whom the accident occurred. When the accident happened at Saint Denis, the electrometer at D'Epinay connected between two of our three wires showed 4,500 volts, and an ammeter introduced in one of them showed 0.7 ampere.

"At the spot where the accident occurred the three wires were carried by insulators supported by a bracket on the wall about 6 meters above the floor. The man who was shocked was seated astride the lowest bracket holding one of the conductors in one hand. He had with him a telephone wire which he was about to place in position. This wire rested on the bracket on which the man was seated and came in contact with another of the three wires. The circuit was closed through the man, entering by one hand and leaving by one buttock in direct circuit. He was, therefore, subjected to the full pressure of 4,500 volts at a frequency of about 55 periods. It is difficult to say precisely how long this circuit was maintained but certainly for several minutes. The short circuit established set up sparks at the commutator of the D'Epinay apparatus. The operator who attended it believed that an accident had happened on the line and telephoned to La Chapelle to stop. All this represents a sufficiently long time. We were leaving D'Epinay at the moment and we were already on the train when informed of the accident which had just happened. About a quarter of an hour afterward we arrived at Saint Denis. The man was still sitting on the bracket and gave no sign of life. There was considerable difficulty in bringing him down and this operation took at least half an hour.

"Following your advice, we practiced artificial respiration by manipulation of the arms and, at first, without result. I then forcibly opened his mouth and pulled forward his tongue. His lungs then operated almost immediately. In two hours he could speak. He was burned on the right hand and on the buttock. He is now well.

"Several days ago they wrote to me again; the injured man is progressing favorably. It is to be observed that no particular trouble due to the passage of the current through his body has been manifested. No attention has been necessary, except to his burns."

In the first place we desire to point out that the pressure alone of 4,500 volts mentioned is without significance, unless it is taken in connection with the current actually passing through the subject under such pressure. We would also point out the fact that a marked difference exists between cases of the application of the alternating current, as employed in electrocution in the State of New York, where the current is deliberately conducted through the body for the purpose of killing, and such cases of accidental contact as that referred to by D'Arsonval. Here, assuming the correctness of the ammeter reading quoted, namely, that a current of only 0.75 ampères was passing, the resistance of the body could not have been less than 6,000 ohms. The resistance of the body between the electrodes used in the electrocutions of New York, *i. e.*, one on the head and the other on the right calf, is sometimes as low as 200 ohms, and usually not more than 300 ohms, the current strength employed being from 5 to 8 ampères, say seven to ten times stronger than that which is stated to have passed in the case mentioned.

In view of these facts we submit, that, in our opinion, Dr. D'Arsonval is entirely unwarranted in drawing the general conclusion already alluded to. Unwilling, however, to base our opinions on mere surmises, we arranged for a series of experiments on dogs in our laboratory, under conditions in which actual facts only were admitted. Being unwilling to leave to our own judgments the question of the actuality of death, we were fortunate in securing the coöperation of the following eminent members of the medical profession in Philadelphia, namely:

Dr. Judson Daland, Instructor in Clinical Medicine, University of Pennsylvania; Dr. G. G. Faught, general practitioner; Prof. L. Webster Fox, Professor of Ophthalmology, Medico-Chirurgical College; Dr. E. Laplace, Professor of Surgery, Medico-Chirurgical College; Dr. William L. Zuill, formerly Professor Veterinary Medicine, University of Pennsylvania.

One of the observers kept the time of all observations; a second recorded all the observations with the time of their occurrence; a third observed the reading of the Weston alternating current voltmeter placed across the supply mains; a fourth observed the reading of the alternating current ammeter placed in circuit with the dog. The alternating current employed was from the street mains making about 130 cycles per second, and at a pressure of about 1,250 volts, reduced in some cases through a 1.5 K.W. transformer to about 700 volts. Four good-sized dogs whose

weights were noted were successively subjected to the current and the following observations made:

Observations 8:30 P.M., September 18, 1894. The contacts in these experiments were made by cotton waste, thoroughly soaked in an aqueous solution of common salt of density 1.055, the waste being bound to the part with copper wire to which the electric terminals were attached.

Dog No. 1. Weight 31.5 pounds. Contact points right forefoot, (carpus) and left hind foot. Resistance of dog between electrodes 20,480 ohms. Effective alternating voltage 1,250. Circuit closed through animal 8.35 to 30 to 8.35 to 50, *i.e.*, maintained twenty seconds. On the closure of one of the first of the two switches in the dog's circuit, the dog experienced some sensation evidenced by excitement and yelping. This was subsequently ascertained to be caused by leakage through the substance of the slate base of the remaining switch and was found to amount to approximately 2 milliampères. On closing the second switch about three seconds after the first, there was instant rigidity of the animal, the dog leaping forward about a foot, the body balanced on hind legs as in standing, the fore legs apparently flexed, the plunging movement bringing the snout to the ground first, the animal then falling on its side. Dog remained in a state of tetanus till circuit opened. No cry made. Some smoking at points of contact, but no burning. 8:36 P.M., muscles relaxed except in right fore leg where marked rigidity remained. Flesh hot to the touch in the legs which had carried current; 8:37, no evidence of cardiac movement under stethoscopic examination; 8:44, contact points on body still show marked elevation of temperature. 8:45, surface temperature of hind leg (left) 122 degrees F., 50 degrees C. The rhythmic tractions of the tongue as advocated by Laborde of Paris, were continuously made from 8:45 to 9:43 without effect. It was the opinion of all present that death was instantaneous and painless, and that resuscitation was impossible.

Dog No. 2. Weight 26.5 pounds. Evidencing great fear Rectal temperature 103.1 degrees F., 39.5 degrees C. Contacts right fore and left hind leg near carpus; 9:05 to 30 P.M. Resistance 17,430 ohms. The voltage 690 before closing circuit, 685 during closure; 9:08, circuit closed for twenty seconds through dog. Current through dog 1.0 ampere steady. Immediately on closure the animal fell on his side without forward movement in condition of tetanic rigidity. Opisthotonic curve of back. No smoking of contacts. Death evidently instantaneous and painless; 9:11, body removed to examining table; 9:12, no cardiac movement by stethoscopic examination; surface temperature of body evidently raised to touch. Optic nerve pale pink; blood vessels full (normal condition in dog stated to be veins prominent, arteries thin and narrow). Corneal epithelium wavy; pupils dilated to fullest extent. Iris almost disappeared. 9:16, rectal temperature 104 degrees F., 40 degrees C.; 9:17, veins on retina have shrunk to a hair line. Optic nerve growing brownish; 9:20, surface temperature, right axilla, 104.4 degrees F. (40.2 C.); 9:34½, optic nerve pale. In the opinion of all present death was instantaneous and painless. An attempt to resuscitate it being considered hopeless.

Dog No. 3. Weight 44 pounds, short hair; 9:23, optic nerve bright pink, pupils dilated. Blood vessels full and easily discerned; 9:35, rectal temperature 102 degrees F. (39 degrees C.); contacts made one on each fore leg above carpus; 9:40, stethoscopic examination of heart shows rate 60 per minute; 9:45, resistance 31,820 between electrodes: 9:47, voltage 700, during application of current, steady at 690; 9:48, circuit closed and current maintained for ten seconds. Current steady 1.8 ampère. Immediately on closing the circuit the dog which had been lying quiescent on one side was thrown into a tetanic state, except a slow waving motion of the left hind leg which rapidly ceased; 9:49 P.M., deglutitious movements. Corneæ insensible. No cardiac movement. Apparent respiratory movements; 9:50 P.M., deglutitious movements still present, flexion of head, no cardiac movement. Respiratory motion ceased; 9:53 P.M., resistance between electrodes 1,207. Rectal temperature 102 degrees F. (39 degrees C.). Rigidity absent. No perceptible surface elevation of temperature; 9:55, optic nerve pale, with complete change of color. Arteries disappeared; veins growing thinner; 9:55, 30, veins thin as hairs, completely emptied in spots and presenting a beaded appearance; 9:56, optic nerve grayish pink.

In the opinion of observers, death was painless and took place within a minute after the closing of the circuit; also that movements after opening circuit were reflex and spinal. Immediate observation after opening circuits failed to show any evidence by a stethoscopic examination of cardiac

movement, nor were they present at any subsequent time. It was also believed that it would be impossible to resuscitate.

Dog No. 4. Short hair, 29.5 pounds. Optic nerve pink, blood vessels full. Contacts made by cotton waste pads soaked in saline solution pressed into ears with ear flaps bound over them. Heart rate 140 per minute; 10:11, resistance between electrodes 1,200 ohms; 10:13, voltage 700; 690 during application of current; 10:14 P.M., circuit closed for five seconds. Much smoking and slight charring of hair at electrodes. Current not accurately measured owing to brief interval of application, but estimated at 6 ampères. Progressive rigidity. Rectal evacuations. 10:15, irregular movements of extremities somewhat resembling those made in walking. Most marked on left side. Tail wagging; 10:16, same, more marked; 10:16, 30, eyes rotated upward and inward, moderate muscular rigidity of body; beginning to breathe; 10:17, horizontal symmetrical oscillation of eyeballs. Pupils contracted; 10:17, 30, movement of eyeballs gradually ceasing; 10:18, movements of eyeballs ceased; 10:19, confused heart sounds indistinguishable; 10:19, 30, heart sounds now stronger. Convulsive movements of eyeballs; 10:20, heart rate 108, intermitting every third or fourth beats; 20:21, respiration 28 per minute; leg apparently responds to touch; 10:23, Dr. Zuill states that in his opinion the animal is not suffering, but is conscious. It lies perfectly quiet; the respiratory movements good in volume and fairly regular; 10:28, cornea reflex present. Pulling the tail is followed by movements in that appendage, (possibly reflex); 10:31, no response to sensation, such as pin pricking; 10:32, 30, rectal temperature 103 degrees F. The animal lies in a position of full extension; 10:34, attempts voluntary movements to slight extent of disturbance; 10:35, 30, same more marked but unaffected; 10:39, evident response to disturbing touch. Pupil markedly contracted; 10:40, contraction of pupil as persistent as when observed at 10:17. Hearing evident, responds by muscular movements to sound of a table dragged across the floor; 10:42, placed on his feet with difficulty; finally attempts to stand, but staggers and falls. Coördination wanting and improving every second; 10:43, condition apparently dazed, respond to whistle and call. Stands with difficulty and wags tail momentarily. No evidence of suffering. No sound or whimpering; 10:44, condition apparently stuporous, does not respond readily to call or whistle, but evidently notices both; 10:45, 30, again responds distinctly to call and whistle. Standing with some effort and wags tail. Apparently conscious. Gives no evidence of suffering, except possibly slow to-and-fro movements of head may be due to pain in it; makes no sound or cry; 10:46, administration of chloroform; 10:47, unconscious with deep inspiration; 10:47, 30, stertorous breathing. Hard, rapid, irregular and feeble; 10:48, heart stopped. Relaxation of sphincters. Dog dead.

It was the unanimous opinion of the medical gentlemen present that death was absolute and resuscitation consequently impossible in the first three cases. In the third case, however, reflex movements exhibited themselves and although the heart had ceased to beat when the first examination was made, death was not reached until about one minute from the time of closing the circuit; also that in the fourth case where a much stronger current under 700 volts pressure passed through the head during five seconds, the loss of consciousness was instantaneous and complete, but the animal revived without the aid of artificial respiration.

We desire to acknowledge our indebtedness to the able scientific observers who aided us in this investigation, and consider ourselves fortunate in having obtained for this purpose the coöperation of men of such acknowledged eminence in their respective specialties. We hope shortly to be able to make more complete investigation of the conditions under which absolute death follows the passage of powerful alternating currents.

We believe that the following conclusions may fairly be drawn as the result of these experiments:

1. That the passage of a sufficiently powerful alternating current through the body of an animal is followed by instantaneous, painless and absolute death.
2. That, consequently, where electrocution is properly carried out, there is not even a remote possibility of subsequent resuscitation of the criminal.
3. That in cases of accidental contact, where the current passing is not excessive, it is quite possible that death may be apparent only, and that the method of artificial respiration suggested by Dr. D'Arsonval should invariably be followed.

It is a remarkable fact that in the last experiment where

the strength of current was much greater than in the previous instances and passed directly through the head (very trifling leakage only being possible over the surface of the skin) the effect of this current was much less upon the vitality than in the preceding cases.
