Dr. Houston, in closing the discussion, said that Dr. Morton had stated that the burden of proof rested with those who made a particular assertion. Now, M. D'Arsonval had asserted that those who were supposed to be killed by electrical shock had not been killed; therefore, it was the duty of M. D'Arsonval to prove his assertion. However, passing by this point he would ask in all seriousness, of this body of scientific persons, accustomed to weigh evidence and not sentimental vagary, what their verdict was after weighing the evidence given by instruments that could not lie—the ammeter and the voltmeter? Assuming that the burden of proof rested on the authors of the paper, had they not more fully met this than the opposite side who urged that death was only apparent? Could they tell in every instance when a person was dead? Had they ceased to put confidence in the results of stethoscopic examination of the heart beat? Did they still disbelieve in the signs of death as given by ophthalmoscopic examination of the retina? Did they believe that four capable witnesses chosen by the State would declare deliberately that they believed the person dead when it was not so? Would they, as the leading body of electrotherapists in this country, dare to assume the grave responsibility of throwing doubt on such a death? It seemed to him that the picture painted by Dr. Morton was even more horrible than that painted by M. D'Arsonval. He only wished that the members could have been present and could have seen with their own eyes the instantaneous effect of the passage of the current through the bodies of those dogs, for, if there were any lingering doubts in their minds about the ability of the current to cause death, such doubts would have been quickly dispelled. Electrocutation was a most humane way in which a criminal could be executed. Society for self-protection, through its legally appointed bodies, had determined that certain lives should be stamped out, and it was but natural to attempt to produce as speedy and as painless a death as possible. The same assertion had been made about death by the guillotine—that the severed head could for some time afterward do some great thinking. Again, it had been asserted that some animals were harder to kill than others. According to this reasoning, as the ready capability to death varied in different individuals, the fact that you could prove in the case of twenty people that resuscitation did not fail, did not prove anything in the case of the twenty-first individual who might have been of a different type! In his opinion this argument was a dangerous one. Death had been produced by hanging, and every opportunity had been given for resuscitation, but it had failed. Again, death by the electrical current was now very common, and there was a reasonable probability that in the case of every one who had been killed by such an accident every effort had been made to resuscitate him, and yet with one or two marked exceptions, resuscitation had failed. As scientific men, Mr. Kennelly and himself had tried certain experiments, and had brought before the Association certain facts, the correctness of which could not be questioned. Did the members think that they would be justified as a scientific body in passing any such resolution as that suggested—a resolution which would pledge the Association, practically, to the belief that it had grave doubts as to whether or not death could be produced by the electric current? If that resolution were passed, he would certainly move to amend, by resolving that the authorities also be requested to inquire carefully as to the absoluteness of death produced by hanging.

Dr. A. D. ROCKWELL, of New York city, presented a paper on

GENERAL FARADIZATION.

He said: It has seemed to me that there is a general tendency to undervalue the faradic current at the present time. I would urge that other mechanical measures such as tapping, massage, and rapid vibratory motions are equally serviceable. It seems to me that those who take this view have a very incorrect appreciation of the faradic current. Many years ago when I first began to use electricity in medicine, my efforts were confined almost exclusively to the use of the faradic current. For the time being it enabled me to concentrate my observation on this form of electricity, and one of the most common observations made at this time was the relief of muscular tire after prolonged muscular activity. At this time there was a great pedestrian craze, and I had

one of these pedestrians under my observation. I made a general and thorough application of the current to him, and I recall distinctly how much more relief it gave him than the ordinary methods of massage and rubbing. We do not have to seek far for an explanation of these phenomena. Mechanical effects are prominent. There is undoubtedly in these cases, cell exhaustion with sluggishness of the circulation and a deposit of a toxic product of metabolism, all of which are much benefited by mechanical action. On this same principle it is, I think, that we obtain such excellent results from faradization in uterine congestion and induration—there being a sort of circulatory drainage produced. If the faradic current gave only mechanical effects, we would still find it very useful in therapeutics. But it also produces marked physiologic effects, accelerating the circulation and increasing the activity of the excretory and secretory functions. To what extent these effects are purely mechanical, it is impossible to say, yet I think in addition to these mechanical effects there is a direct and peculiar effect on the nerves themselves. So far as the galvanic current is concerned, we have advanced in the way of introducing new and better instruments of precision. With faradic currents of high tension, passed through low resistance, especially by the bipolar method we get very valuable effects, but as regards the outward application I doubt very much if we have advanced greatly. So far as my experience goes, the so-called continuous coil of twenty years ago, yielded a current the characteristics of which have not been surpassed as an aid to nutrition and as a general tonic. It has always seemed to me that the most important thing in electricity in medicine is its nutritional power. This idea of its influence over nutrition was enunciated by Dr. Beard and myself over twenty years ago, and I have advocated it ever since. After the particular form of electricity which gives these nutritional effects, opinions differ according to the extent and character of each one's experience. Static electricity is a very valuable addition to our armamentarium, and I could not do without it; no one can afford to be deficient in the completeness of his electrical outfit. With a magnificent static apparatus and all its pyrotechnic glory set in motion, the treatment becomes exceedingly simple, and I should be glad to assure myself that it was the most efficient method, and that it gave the best therapeutic results. After many years of trial, I can not, however, come to such a conclusion. I regret it in one way, because it is so easy of application, and requires comparatively little judgment. In another sense, I do not regret it because it is a very expensive apparatus. I should be sorry if it were necessary for every practitioner desiring to use electricity, to get such an apparatus. So far as obtaining the nutritional effect of electricity, I think much good is accomplished by faradization alone. Let me commend to you, general faradization alone. It is a sort of child of mine, and parents generally commend their children. It is a method which is tiresome both to the physician and patient, and requires both time and attention to the details, but my own experience for many years past is such that I look upon it as a most important therapeutic resort. The majority of those who use it, use it in a haphazard and incomplete way, sometimes even relegating its work to a nurse.

DISCUSSION.

Dr. W. J. MORTON, said that none could fail to appreciate the pleasure and honor of having Professor Houston at this meeting, or fail to appreciate the high scientific work represented in this paper by the authors. Accordingly, if any differences of opinion were expressed it would certainly be in the most courteous spirit. He was one of those who differed with everything that had been stated in the paper except as to the scientific data. He could not agree with the attitude and logic of the writers of the paper. They started by saying that the conclusions of M. D'Arsonval were unwarranted, questioning the facts concerning the death of an individual observed by D'Arsonval, and stating that one such case did not prove anything. The State claimed that the criminal subjected to electrocution was killed. He would say that the proof that death was so produced should be offered by the State yet this had not been done. The burden of proof lay on the State authorities. It had been asserted that this claim of M. D'Arsonval was "monstrous," but it seemed equally monstrous to submit a person, who was the victim of electrocution, to the knife without proof that the electric shock had actually produced death. There seemed to be only one way to settle this question, and that was: 1, after the supposed electrocution to endeavor to resuscitate the victim, for he might be in a state of trance and conscious

of everything going on about him. He thought every neurologist must admit to-day that it could not be denied that such a criminal might be entirely conscious of what was going on about him, and even conscious that a post-mortem examination was about to be made on him. 2, if the resuscitation failed, the body should be allowed to remain under observation until decomposition ensued. He did not feel that it had been *proved* that these criminals were dead; he would not say that they were either alive or dead. The authors had told us that they could kill dogs, but dogs could be easily killed. Animals differed in this particular; all knew that cats had nine lives. What was wanted was an experiment on the criminal, and not on the lower animals. He would ask any physician present if he would be willing, in the present state of medical knowledge and electrical science, to put his knife into a criminal, with a millionth part of a possibility of causing that criminal's death. Were we not therefore right in insisting that those who supported electrocution should prove their case? Only a few years ago the electricians had objected most strenuously to the assertion that the ordinary street currents could kill, yet now they had become eloquent exponents of this claim. In conclusion, he thought D'Arsonval was perfectly justified in declaring his doubt as to the criminals being killed by electricity.

DR. GOELET said that he felt like sustaining the position taken by the authors of the paper, for the reason that if there were a sufficient amperage registered as passing through the body of the victim the result was no longer in doubt. However, if the death were made certain by the use of the knife, and the application of the current had been painless and the patient rendered unconscious, then the claim of the State had been satisfied. It was possible that in the majority of instances the actual current received by the body in cases of accidental contact with electrical conductors was only a shunt current, and that therefore the vital organs were not subjected to its full force, and that resuscitation might be sometimes possible after such accidents, as he had suggested in a recent contribution to the *Electrical World*. Accidental shocking, as was well known, produced suspended animation which would result in absolute death if nothing was done to counteract it. Therefore it would seem unwise and useless to raise this opposition to electrocution, certainly in the face of such evidence as had been presented. If the law required the death of the criminal, and that death was rendered painless, he could not see why it should concern us.

DR. WALKER said he regretted to hear that Dr. Goelet advocated killing men by slow degrees. It seemed quite proper for this Association to pass a resolution directed to the proper authorities, requesting that the necessary means be taken to definitely test this matter in the manner suggested by Dr. Morton, and in this way satisfy the world at large.

DR. R. J. NUNN suggested that if the criminal was not killed by the electrical current that it would be unlawful to kill him in any other way, *e. g.*, by the knife. This would not be in accordance with the provisions of the law, for it required that the criminal should be killed by electricity and not by being chopped into mincemeat. He therefore heartily indorsed the suggestion made by the last speaker. The whole subject reminded him of a case in which the coroner's jury refused to render a verdict until a post-mortem examination had been made to make sure that the person was actually dead.

PROF. A. E. KENNELLY said that the question at issue was not whether electricity could or could not kill, but whether under the conditions of electrocutions at Sing Sing, M. D'Arsonval was justified in saying that the criminals there executed probably died under the knife of the surgeon. The speaker said he had witnessed an execution at Sing Sing. At the time, there were four medical men present, all of whom examined the criminal immediately after the application of the current, and they all stated without hesitation that the man was dead, and not only that, but they called attention to the fact that all animal life had ceased, as they could not obtain the slightest evidence of life in his tissues five minutes after the execution. Half an hour later the body was opened. There was not the shadow of a doubt in the minds of these eminent medical gentlemen that this criminal was dead. Further than this, he had read the report of the physician who was intrusted with the work of the executions in the State of New York. In that report there was not the slightest suggestion that, in the eight or nine executions that had been done, there was any evidence of suspended animation. The general impression among the

medical witnesses of the execution referred to was that it was really a waste of time to wait as long as they did before performing the autopsy. Regarding the experiments upon which the present paper had been based, he said that as they could not kill human beings in the laboratory they had presented the analogy exhibited in dogs.

DR. A. D. ROCKWELL said that the doubts that had been expressed about the criminal not being killed had seemed so puerile that he had at first intended not to enter into the discussion. We might as well say that a man dying a natural death from disease should not be buried for three or four days, in order to be sure that he is really dead, as to say that we should wait for putrefaction to set in before disposing of an electrocuted criminal. Individuals were killed by accidental contact with an electric wire, and there was no doubt expressed about death having occurred; yet when the State deliberately executed a person in this way such a doubt was expressed. When he had at first read M. D'Arsonval's remarks on this subject he had felt that M. D'Arsonval must have been sadly in need of a theme for discussion.

DR. ROBINSON, of Albany, said that when this matter had been first brought up, a most excellent committee had been appointed by the State, and its members had given much time and thought to the most expeditious and humane way of executing criminals. He was personally familiar with the conscientious work of the committee. As a result of their labor they unqualifiedly recommended electrocution. It seemed that this attempt to take the sentimental side and throw discredit on this work was very unfortunate, to say the least. These electrical executions had been witnessed by quite a large number of physicians in this State, and they seemed to be thoroughly agreed as to the fact that the criminals had been killed by the electrical current. It seemed to be much more humane than hanging, and he hoped no effort would be made to throw a sentimental doubt on this subject.

DR. BEAVER said that the description given in the paper of the condition of the first three dogs experimented upon, indicated to him that the dogs suffered from surgical shock. If he had understood correctly, the current had been passed from the forearm to the hind limb, and had not directly traversed the vital organs; hence, the effect upon the brain must have been reflex. In the case reported by M. D'Arsonval, with a similar location of the points of contact, was it not possible that surgical shock also existed? Under such circumstances as this which obtained in the experiments on dogs, he would feel very much as Dr. Morton did, like waiting for decomposition to occur. He was free to say, however, that when a person was subjected to a powerful current in the manner employed by the State in electrocutions that it was quite probable that a direct effect would be produced on the brain and other important organs in the body, and that therefore immediate death would occur.

DR. NEWMAN said he wondered how it was that Dr. Morton did not assert that those who had been executed by hanging had not been killed. Post-mortems were made after hanging in the same way as after electrocution. Why had not Dr. Morton gotten up before this and asserted that we should always wait for decomposition to ensue before feeling sure that death had occurred? It seemed to him absurd to throw a doubt on such careful and positive reports as those made by Dr. A. D. Rockwell, Dr. Carlos Macdonald, and others, and the only effect of such an agitation would be to throw a doubt on our very humane attempts to execute criminals.

DR. LUCY HALL-BROWN said that it was a very simple matter for the authorities to allow those who had been electrocuted to remain until Nature had announced them to be actually dead, and in that way to prove that electrocution had really done its work. In her opinion much valuable time was being wasted by such a discussion as this.

DR. AUGUSTIN H. GOELET read a paper on
THERAPEUTIC APPLICATION OF THE INTERRUPTED INDUCED CURRENT IN GYNECOLOGY.

In the application of the interrupted induced (faradic) current in gynecology, much depends upon the method of administration, as well as upon the selection of a suitable current appropriate for the pathologic conditions under consideration. To apply a fine wire current indiscriminately, in the belief that it will always produce sedation and the coarse wire current when stimulation is desired, must result in failure in the majority of instances, and when success follows such empirical application of the current it must be regarded as purely accidental.

It is true that in a general way it may be said that the current derived from the long line wire secondary coil is sedative, and that derived from the short coarse wire is stimulating. But the fine wire current may be employed in such a manner as to produce stimulation which would result in irritation and be actually harmful in some instances. This is true because it is possible to obtain either sedation or stimulation with the high tension current according to the method of application, as will be explained further on.

The stimulating property of this current is in direct proportion to its volume or amperage; that is, the greater its volume and the less its E.M.F. (the resistance of the circuit being appropriately low) the more stimulating it is; and the greater the E.M.F. and the less the volume the more sedative the current becomes.

In the modern induction apparatus this is taken into account, and a simple device is utilized by which these qualities of the current may be varied by varying the length and size of the wire composing the secondary coil. To explain, the greater the length of the wire the greater the number of turns in the coil and consequently the greater the E.M.F. Correspondingly, the greater the length of the wire, the greater the internal resistance and the less the volume of the resulting current. The finer the wire the greater the number of turns possible on a helix of a given size, and the greater the number of lines of magnetic force intersected. The coarser and shorter the wire the fewer the number of turns, therefore, the fewer the number of lines of magnetic force intersected and the less the E.M.F. Also the short coarse wire coil has less internal resistance, hence the greater the volume or amperage of the resulting current. It is only necessary to understand the principle of the transformer to be able to appreciate the principle of the modern induction apparatus.

It must be admitted that these induction currents, whether interrupted or alternating, are always stimulating, yet this does not signify that the ultimate result may not be sedative, nor does it involve any inconsistency. Opium is a cerebral and circulatory stimulant yet its effect is sedative.

Stimulation may be of two kinds: 1, exciting when it is painful and irritating; and 2, sedative when it is non-irritating or soothing. In order to make the stimulation of the faradic current non-irritating, it is necessary to eliminate that quality of the current which produces painful contraction. To accomplish this the amperage of the current must be reduced to an almost inappreciable degree, and in doing this the E.M.F. of the current will be greatly increased. That is, the long fine wire current is ordinarily sedative in its effect because its amperage is inappreciable and its E.M.F. is high; and it produces intense muscular contractions which are painless. Therefore, when we desire a current for sedative effect one must be selected which has a high E.M.F. and an inappreciable volume; then if it is properly administered sedation will be the result of the stimulation that it produces.

The rate of interruptions has, likewise, an important bearing upon the effect produced as, ordinarily, the more rapid the interruptions the more sedative the effect, and the slower the interruptions the more painful and stimulating the current becomes. The possible explanation of this is that with the very rapid interruptions a tetanic contraction is induced which ultimately results in temporary loss of muscular power which is essential for sedation.

As said before, much depends upon the method of application of the fine wire current, since two effects are obtainable with it according to the manner in which it is used.

1. *Stimulation* in the nature of an excitation when the intensity of the current throughout the application is maintained at a point where it is constantly and forcibly appreciated by the patient. In other words, when the force of the current is increased rapidly.

2. *Sedation* when the increase is so gradual as to make it barely perceptible and the application is continued until complete relaxation and insensitiveness are produced.

In other words, if the current even from the longest and finest wire be administered so as to maintain a point throughout the application where the structures are conscious, so to speak, of the excitation, stopping short of that local loss of consciousness which must be reached to secure sedation, the result will be a stimulation, an excitation or irritation which at the same time has been painless.

This form of stimulation is extremely useful and is particularly applicable to conditions in which stimulation with the coarse wire current would be painful and injurious. It is not appropriate, however, in all cases; that is, it is not sufficiently stimulating. Therefore it is necessary to vary

the length of the wire so as to vary the stimulating property of the current, and when the current ceases to be sufficiently stimulating it is rendered more so by shortening the wire in the secondary, thus lessening the E.M.F. and increasing the volume of the current.

A coil of one length of wire, as has been suggested, is not sufficient because it gives an unvariable current. The volume of the current from such a coil may be lessened by interposing a resistance like a rheostat, but it would not be possible to increase the volume of the current beyond what such a coil is capable of giving.

In gynecology the faradic current is particularly useful in painful affections of the female pelvic organs and those attended with congestion, as well as in subacute and chronic inflammatory states. Here the fine wire current is appropriate.

When there is general loss of tone and at the same time the parts are sensitive, stimulation with the fine wire current is more satisfactory. In these conditions the stimulating property of the current may be greatly increased by using, from time to time, a shorter length of wire until finally the coarse wire current may be employed with benefit and without injury. In the beginning, usually in such conditions, this would be impossible.

The coarse wire current is more directly applicable to conditions of subinvolution and where there is venous engorgement. In these cases the fine wire current would be usually inappreciable and, therefore, without effect, though occasionally cases of this character will be encountered where, at first, the coarse wire current will not be tolerated. Then a current from a finer wire must be employed at the start. I have always contended that the current to be effective must be appreciable, in the beginning at least, and clinical experience confirms this opinion.

To enumerate in detail the diseases of the female genitalia to which this current would be applicable, and outline the method of application in each would consume altogether too much time for this discussion; but I will briefly mention some conspicuous examples where, if properly employed, its use is attended by marked and satisfactory results.

In ovarian hyperemia, ovaritis and edema of the ovary, as well as in ovarian neuralgia, the results from the use of this current have been highly satisfactory, and I may say that it has been the exception when these conditions have not yielded promptly to the current employed in a proper manner. These conditions are often secondary to disease of other organs operating to produce them, when faradization alone will not accomplish the desired result. For example, edema of the ovary, due to varicocele of the pampiniform plexus, could not be influenced permanently by faradization, likewise an ovaritis due to an active endometritis would not yield to faradization unless treatment were instituted for the diseased endometrium.

In subacute and chronic salpingitis, as well as in catarrhal endometritis and some other forms of endometritis, depending upon pelvic congestion, the faradic current has yielded excellent results in conjunction with negative galvanic applications to the endometrium.

In salpingitis it acts by subduing the turgescence and tumefaction or edematous infiltration of the tubal mucous membrane and the tube walls by stimulating contraction and peristalsis of the tubes, thus favoring drainage by causing them to empty into the uterus. In this manner, very often accumulations are removed and the condition may be cured, provided, that at the same time, appropriate treatment is instituted for the coexisting endometritis, for I am satisfied defective drainage from the tubes is more often caused by obstruction of this nature than by actual occlusion.

Recent inflammatory exudates usually disappear under faradization frequently repeated. It is my experience that the result is more speedily obtained by this current than by the galvanic.

I have repeatedly demonstrated the possibilities of faradization in this condition at my clinic. In one case which I recall, there was complete fixation of the pelvic contents with extreme sensitiveness which, according to the history, had existed for some time, yet mobility was restored by faradization alone, nothing else having been employed.

In uterine displacements nothing has been found to yield such uniformly satisfactory results as a combination of faradization with galvanism of the uterine body through application to the endometrium. The results which I have been able to obtain lead me to regard this as the only satisfactory treatment of uterine displacements. Since my paper upon this subject, read before the New York Obstetrical Society several years ago, I have been following it up in the same

lines laid down there, and nothing has yet occurred to change my views as therein expressed. On the contrary, a riper experience confirms me in the belief that it is, as I have said, the only satisfactory and rational treatment of these conditions.

Dysmenorrhea dependent upon any of the above named conditions as a cause is promptly relieved by faradization, especially if negative galvanism of the endometrium is employed conjointly. The induced current is also useful in relieving the pain associated with fibroid growths of the uterus.

In relaxed conditions of the uterine supports, allowing descent of the organ, the faradic current is particularly useful; here the coarse wire current is most often indicated, but in some cases fine wire stimulation is better tolerated and is to be employed in the beginning. It is necessary, however, to make the current as stimulating as is possible for it to be borne without producing actual pain and discomfort.

One case which I recall will serve to illustrate what this current can accomplish in these relaxed conditions. The patient who was referred to me by Dr. F. C. Valentine of this city, was 26 years old and suffered with complete proclivencia resulting, no doubt, from repeated miscarriages. The condition had existed for several years when she came under my observation and most of the time the uterus was completely prolapsed outside of the vulva. It had been impossible to find a pessary which would remain in the vagina, and the only relief she had been able to obtain was from hot water douching. When this was employed and she remained on her back afterward the uterus would not come down for an hour, but if she assumed the erect position it would immediately protrude. The uterus was enlarged and heavy, though the cervix was not lacerated and the perineum was intact. I advised bipolar faridization with the coarse wire current. After the first application, which was given in my office, the uterus did not protrude for several hours though immediately afterward she returned to her home a distance of several miles. After the second application it was retained for twenty-four hours, though she was constantly on her feet. At the end of a week, the application having been repeated every day, the uterus occupied the normal position in the pelvis, except that it was retroflexed. The applications were afterward made at longer intervals and a complete cure was obtained.

I will not burden this discussion, or tax your time, by relating in detail in support of the value of this current in the pathologic conditions enumerated, but I can not refrain from a brief mention of some cases where it seems to me the results obtained have been more than ordinary.

For instance, Mrs. A., a young married woman, consulted me in the summer of 1893 for pelvic trouble, having been told by several gynecologists that laparotomy was necessary for the removal of the pelvic organs. She had been married four years but had never been pregnant. Examination revealed an endometritis with the right tube considerably distended and the left thickened, ovaries enlarged and excessively tender. Here was a case with a grave outlook for conservative treatment; she had declined an operation and had been referred to me, believing that I could cure her without removing the diseased organs. It was impossible for me to promise from treatment anything more than temporary relief of the symptoms, and I frankly said I would do all I could for her, but I also thought an operation would ultimately be required. I found, however, that the treatment instituted established drainage of the tubes into the uterus and the distended tube rapidly diminished in size. She was kept under treatment for two months when she left for the West to join her husband, who is an actor, her condition being so greatly improved that further active treatment was deemed unnecessary. She wrote me in the early part of the summer that she had been perfectly well since discontinuing treatment though now she thought she was pregnant. Within the past month I have seen her and find that pregnancy has advanced to the seventh month. This is the best possible evidence that the cure is complete.

I recall another case of a milder character which also illustrates the value of this current. The patient, a young married woman, was referred to me by Dr. R. W. Taylor of this city. A year before coming under my observation, a prominent gynecologist advised laparotomy, but it was declined, and she improved somewhat under the treatment then instituted, though she continued to suffer particularly at her monthly periods. The diagnosis in this case was endometritis with antelexion and catarrhal salpingitis and ovaritis. Faradization and galvanism were both employed. A cure was complete at the end of three months.

By way of conclusion, I will show you some improved patterns of induction coils, in which are embodied the essential features suggested in my communication to this Association at its first meeting in Philadelphia. I have had this particular combination of coils in use now for more than two years, and am fully convinced that the variable qualities of the current as obtained from these different coils make the apparatus suitable for all purposes where the faradic current is to be employed.

After the adjournment of the morning session, Dr. GOELER exhibited various forms of faradic apparatus, and explained the advantages and disadvantages of each.

(To be continued.)

SELECTIONS.

Advances in Brain Surgery.—(von Bergmann before the Congress of the German Society for Surgery in Berlin.) He alludes quite briefly to the operative treatment of cranial tumors. According to Starr's trustworthy researches, out of 100 tumors of the brain only 6 are at the same time recognizable and removable, and of these a successful operation will be performed upon scarcely a half. So surgery can do little enough in the treatment of such affections, in spite of the advances in diagnosis and particularly in the technique of operations. The hope to cure epilepsy, at least Jacksonian, by operation proved deceptive, and one can now really regard as an object for surgical interference only those cases of cortical epilepsy, in which a tumor, for instance a cyst, which may arise not altogether rarely from a traumatic intra-meningeal extravasation, lies in or over one of the circumscribed cortical centers.

Very significant, on the other hand, are the advances in the domain of the surgical treatment of intracranial suppurations, especially the aural abscesses involving the brain, the meninges and the sinuses. These are relatively rare. Out of 1,000 acute and chronic suppurations of the ear, three or four cause death from extension to the meninges, the sinuses, or the brain itself. The chronic processes are particularly dangerous, and especially those arising from masses of cholesteatoma in the inner ear. Those cases are very critical which are marked by acute or subacute outbursts and have an intermittent fetid discharge, and in which at the same time temporary obstructions arise to the discharge of pus, through the growth of polypus-like granulations in the middle ear and the deeper part of the external meatus.

The aural affections of the brain, the meninges and the sinuses begin, as a rule, at the point where the original suppuration in the temporal bone has pushed up to the vault of the skull. But a main point of aural suppuration is the cochlea. Thence the process spreads in two directions, into the mastoid antrum, and through its roof, the tegmen tympani. The spread of suppuration in the latter direction leads directly to a pachymeningitis, from this to an extradural (epitympanic) abscess or to an intradural abscess of the brain. Most cerebral abscesses of aural origin lie in the temporal lobes, and so the chief extension is through the small and circumscribed point of exit in the vault of the tympanic cavity. Bergmann explains his method of reaching the roof of the tympanum from the cranial cavity by lifting up a parallelogram $2\frac{1}{2}$ cm. high by 3-6 cm. wide from the vault of the temporal bone, and shows how one can in this way easily enter the mastoid process, the external meatus and the sigmoid fossa.

The greatest advance which brain surgery has made in recent years, Bergmann sees in the operative treatment of thromboses of the sinuses caused by and associated with suppuration. Most of these are due to the extension of aural affections of the mastoid process to the wall of the sigmoid fossa and the consequent infection of the adjacent sinus wall. In many cases there is extensive suppuration enveloping the sinus, very often at the same time epitympanic abscess. It was Zanol's idea to thwart the disastrous results of septic thrombi of the transverse sinus by tying the jugular vein and then opening and clearing out the sinus. The sinus can be reached also from the mastoid process as well as from the cranial cavity after craniectomy at the vault. The latter method Bergmann describes as the ultimate supplanter of the former. Thrombosis of the transverse sinus with the abscesses around the sinus is also the usual connection between middle ear suppuration and abscess of the cerebellum, the latter generally situated near the sigmoid fossa.—*Wiener klinische Rundschau*, June 23, 1895.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 56 Fifth Avenue, Chicago.

SATURDAY, AUGUST 17, 1895.

PROFESSOR HUXLEY.

The death of this very eminent man who was an educated physician and most learned biologist and teacher, brings out one phase of his work which every physician should copy. All his writings are models of concise exact expressions conveying the precise meaning intended. This was not easy to him, but was acquired by hard labor and persistent study. Many of his works were written three and four times over, and cut down and altered continuously. He explained that his idea of good writing was to make it so clear and concise that no critic could draw any other conclusion but the one intended. In this he succeeded, and the various polemic discussions he had with learned theologians always brought out a clear, crisp, ringing range of thought, in contrast to the heavy learned logic of his opponents.

Physicians and even teachers show great faults in this direction. PROFESSOR HUXLEY'S idea that clear methods of expression were equally essential to the thought itself, is not recognized in much of the medical literature of to-day. The slang phrase in newspaper offices, "boil down," meaning condense, is only valuable when combined with clearness and exact words, that have only one meaning in the form they are used.

PROFESSOR HUXLEY'S writings are models of scientific clearness, and should be studied. While his work was not along the lines of practical medicine, he rendered great service to the higher ranges of comparative anatomy and paleontology. He was not only a great teacher, but he was a great student all his life. Nothing that interested him was examined or studied in a superficial manner, or presented to the public in a vague uncertain way.

He never grew egotistical with all his learning, but rather became more conscious of his limitations, and the great unknown world that widened constantly about him. He was literally a self-made man, coming from a family of school teachers, and was obliged to earn his living and rise by his own exertions exclusively. He died, one of the leading scientific men of this century, whose name and work will be most intimately associated with the scientific advances of the age. Science, to him, had no commercial side. It was the search for truth, for the pleasure it gave.

"MODERN HYGIENE."

In an editorial article under the above title, a valued contemporary¹ makes an assertion which the JOURNAL has been unable to verify, and yet which involves a question of such practical importance, both to health authorities and to the public, that it demands verification if correct, or withdrawal, if the reverse, because of the mischief that might result if accepted as a basis of action by those charged with the protection of the public health.

The text of the editorial is a circular on tuberculosis for the guidance of the laity, issued by the Health Commissioner of Brooklyn and in which, according to our contemporary, "conditions seem to have been taken for granted which are not by any means incontrovertible facts; on the contrary, to some extent, they can be proved to be incorrect; and unless the ground upon which such provisions are based is indisputable and capable of being defended against any attacks of authorities upon such subjects, health authorities should be very cautious in formulating laws with regard to matters of this nature."

After commending, with some reservation, the advice in the circular that "consumptives should not spit upon the sidewalk, or on public conveyances or in places of public congregation"—advice which it very properly urges should "be extended so as to include everybody, whether consumptive or not"—our contemporary says, "it has been found, however, that *tubercle bacilli die in the sputum as soon as the latter becomes thoroughly dry*, which fact will considerably diminish the urgency for such a law." If this really is a "fact" it must be admitted that not only the urgency for a prohibition of indiscriminate expectoration would be considerably diminished, but that the spread of consumption is by no means to be limited so easily as optimistic sanitarians assert in their circulars and other preachments.

But, is it a "fact?" Without having made an exhaustive search of the literature of the subject, the JOURNAL will not undertake to deny the assertion, but would like "a bill of particulars." The only quasi-affirmative statement recalled is that of Pro-

¹ Medical Review, July 20, 1895.

FESSOR KOCH at the Tenth International Medical Congress, Berlin, 1890, to the effect that, when exposed to direct sunlight in sputa, the tubercle bacillus is killed in from a few minutes to several hours, depending upon thickness of the sputum; but in diffuse daylight it survives from five to seven days. This, however, can hardly be the basis of our contemporary's assertion, since it takes no account of bacilli expectorated in cloudy weather or otherwise protected from the direct rays of the sun.

On the other hand, the previous experiments of KOCH, SCHILL and FISHER² show that dried tuberculous sputum retains its infectiveness for several months, though gradually diminishing in degree, CADÉAC and MALET³ dried and pulverized the lung of a tuberculous cow, and were able to produce tuberculosis in guinea pigs by its inhalation at the end of one hundred and two days. LAWIZKY's experiments⁴ to determine the length of time of the infectiveness of sputum in living rooms, show that, while the virulence is gradually lost, it is retained for from two to five months in the diffused light of an ordinary living room. So resistant, in fact, is the bacillus to heat and desiccation that FRAENKEL and EHRLICH were led to study the possibility of spore formation to account for it.

From all of which it would appear that the "sometimes greatly erring health officers," who, "in a circular of this kind . . . portray the present tendency of sanitary efforts of overzealous enthusiasts," are still in good company and, at most, can only be asked to modify their advice to consumptives to the extent of restricting them from spitting on cloudy days, and of urging them to secure exposure of their expectoration to the action of direct sunlight.

MILITARY SURGERY OF THE FUTURE.

An interesting abstract of SIR WILLIAM MCCORMAC's address before the British Medical Association at the annual meeting last week, is cabled by the London correspondent of the *New York Sun*, under date of August 3. The eminent surgeon's theme was the effects of the latest forms of weapons used in recent wars, and a forecast of the surgery of the next great war. The new fire-arms, throwing smaller projectiles at higher velocities, do not seem to possess the disabling power of the larger caliber weapons which they are superseding; but the increased ranges, the greater rapidity of fire and the use of smokeless powder must result in a larger proportion of wounded, even though the injuries should be less serious from a surgical standpoint.

The important matter for consideration is, will the injuries inflicted by the new projectile be more amenable to successful treatment? VOLKMAN had

pointed out that the subcutaneous character of gunshot injuries of bones and joints makes them less dangerous than compound fractures, with the more extensive damage to the soft structures produced by other causes. During the recent war in Chili, flesh wounds, which had not been probed and thus infected, healed rapidly. The favorable character of the lung wounds was especially noticeable, and bones were less comminuted and were united in about half the time formerly required. DE RIVIERO, of Valparaiso, had made similar observations; he had noticed the smallness of the apertures made by the Männlicher bullet, and the injuries generally were less dangerous to life. Similar results were observed by the medical officers of the Chitral expedition. The British troops were armed with the Lee-Metford rifle and SURGEON BURDEN reported that its wounds through soft tissues, at both short and long ranges, were clean and incised with little bruising and healed quickly. Holes through bones were made with little splintering and in no case was there any explosive action. The damage caused by the large bore bullets of the enemy was much more severe.

It might be taken for granted that the number wounded, in proportion to the number engaged, would, in the future, be much greater than before, and the supply of ammunition would be larger as the facility for carriage would be greater. Moreover, smokeless powder would increase the accuracy of aim and SIR WILLIAM thought the next great war would be more destructive to human life, and that the number of injuries, and, in many cases, the severity of the injury, would be largely increased; but very many cases would remain less severe in character, more capable of successful treatment and less likely to entail future disablement, while improved sanitation and antiseptic methods would increase enormously the proportion of the recoveries.

BACTERIOLOGIC EXAMINATIONS IN NORTH CAROLINA.

The July Bulletin of Board of Health of North Carolina, conveys the information that bacterial investigation is an accomplished fact in that State. The Secretary, DR. R. H. LEWIS, gives the following account of the beginnings of this most commendable advance in the "Old North State:"

"At the conjoint-session of the Board with the State Medical Society at Greensboro, in 1894, PASSED ASSISTANT-SURGEON KINYOUN, who was present as the representative of the U. S. Marine-Hospital Service, announced that the Service would be glad to give, in its laboratory at Washington, free of charge, a six weeks' course of instruction in practical sanitary bacteriology, to duly accredited representatives of our Board. DRs. ALBERT ANDERSON, of Wilson, and W. T. PATE, of Gibson's Station, promptly signified their desire to avail themselves of the opportunity.

² Mitth. aus dem K. Gesemdheltsamte, Bd. II, 1884.

³ Etude expérimentale de la transmission de la tuberculose par l'air expire et par l'atmosphère. Rev. de Med., No. 7, 1895.

⁴ Inaugural Dissertation, St. Petersburg, 1891.

They were duly accredited, and in January of the present year went to Washington, at their own expense, and spent the full time in practical study and work under the immediate instruction of Dr. KINYOUN."

Since their return, they have each fitted up a laboratory, and are now prepared to make biologic examinations of drinking waters, and of the cultures in suspected cases of tuberculosis and diphtheria. They have agreed to a special arrangement for official work in drinking waters. Owing to very small appropriations by the State, permits for such examinations, at the expense of the Board are given with much circumspection. Physicians who suspect a water as the cause of disease, must first submit the matter to their county superintendents of health or to the health officers, if there be such in their respective localities, who will report to the Secretary. If, in the judgment of the latter, the expense would be justified, a permit will be issued, with the necessary instructions regarding the taking of the sample for examination. The Board will pay for the work done under this form of permit.

We trust that this modest initiative will result in a substantial appropriation by the Legislature of the State, for the building up of a well-organized State laboratory for sanitary investigation.

NEUROIDIN, AN ANALGESIC.

DR. UGO LIPPI has, in *Il Policlinico*, given an account of his experiments with the new analgesic remedy of VON SCHIERING. His experiments included those made on persons not having pain of any kind, in order to determine the limits of tolerance of the drug, and the possible toxic effects which might be caused by it. Also, experiments were made on persons suffering from pain of various kinds, either in the form of neuralgia, or as symptomatic of organic lesions. These included four cases of sciatica, one case of slight attacks of angina pectoris in a patient with atheroma of the aorta; one case of intestinal pain caused by malignant growth of the retroperitoneal glands; one case of neuralgia in a person suffering from polyneuritis; one case of brachial neuralgia in a neurotic subject; one case of gastric pain caused by epithelioma of the gall bladder; one case of headache in a neurotic person, the subject of a neuralgia simulating polyneuritis; one case of neuralgia of the bladder and stomach in a patient suffering from cancer of the liver; one case of muscular pains, probably rheumatic, in a tuberculous subject; one case of pains in the arms, symptomatic of spinal irritation.

As a result of these experiments, LIPPI draws the following conclusions:

1. Neuroidin may be given in doses from 0.5 to 3 grams; these are effective and well borne, and may be repeated several times a day.

2. These doses are perfectly harmless, and produce no other ill-effect than occasional diarrhea, with or without intestinal pain.

3. Hardly any physiologic effects were noticed; in rare cases there was a very slight diminution in the heart-beats; no marked effect on the kidneys was observed.

4. As regards the analgesic action of the drug, it was found to have the property of soothing and even abolishing pain, whether neuralgic in character or symptomatic of an organic affection; its action, however, is uncertain, and notably inferior to that of other similar remedies, such as phenacetin and antipyrin. The remedy is not readily soluble in the vehicles in common use.

ALCOHOL BY SYNTHESIS.

Chemists have known that ethylic alcohol can be made artificially, and with such exactness that it can not be detected from alcohol made by natural processes. The alcohols of commerce are governed by a breaking down process, from a complex to a simple, by transforming starch or sugar through the aid of yeast and fermentation. Building up alcohol synthetically from carbon hydrogen and oxygen is a new phase that promises great revolutions in many directions of science and art.

The recent discovery of Mr. WILSON, of acetylene gas from lime and coal-dust treated with electricity from carbon electrodes, has made it possible to produce ethyl alcohol so cheap that all other processes will be abandoned. Organic chemistry has been leading in many fields of commerce, and the question of building up products in demand, cheaper than they can be made by natural processes, is answered affirmatively by the constantly increasing substances on the market. Fruit flavors, colors, and sugars and many other products are made far cheaper and of equal value to the same substances as produced by nature.

Foods of various kinds are now made in the laboratory, and chemists have asserted that not far away beefsteak will be built up and furnished to the masses. The possibility of doing artificially or chemically what is now done by nature, seems to be limited only by a want of sufficient knowledge and control of natural forces. Should WILSON's discovery of cheap acetylene prove to be what is expected, ethyl alcohol will be made for 2 or 3 cents a gallon or less. Its uses in the arts will be largely increased, and as a beverage it can be cheapened to an enormous extent to the consumer. The occupation of distilling will be superseded, and the manufacture of whisky and other alcoholic beverages will change, and the great problems which center about them commercially, scientifically and socially, will have new features.

Who can predict what discoveries will follow in

the combinations of carbon, hydrogen, oxygen and nitrogen, and the possibility of tearing them down and putting them up again?

WAIVER OF PRIVILEGE MAY BE MADE AT ANY TIME.

The New York code provides that "a person duly authorized to practice physic or surgery shall not be allowed to disclose any information which he acquired in attending a patient in a professional capacity, and which was necessary to enable him to act in that capacity." This, another section declares, applies to any examination of a person as a witness, unless expressly waived upon the trial or examination by the patient.

Commenting upon the foregoing, the general term of the Supreme Court of New York says, in the case of *Dougherty v. Metropolitan Life Insurance Company*, decided May 13, 1895, the Legislature locked up the secret and gave the key to the patient. He can forego the privilege, and unlock the lips of the doctor. The statute requires that to be done expressly upon the trial, but there is no method prescribed for the accomplishment of the object. If the patient be alive, an entry upon the record at the trial by his counsel would be sufficient. In case of his inability to attend the trial, a written stipulation signed by him, and entered upon the record, would remove the prohibition. That being so, it must certainly be immaterial when the stipulation is signed. It may be signed long before the trial in anticipation of that event, and with the design of having it used thereat, as by signing an application for life insurance containing a stipulation that such statutes as the above "are hereby waived, and it is expressly consented and stipulated that in any suit on the policy herein applied for, any physician who has attended or may hereafter attend the assured may disclose any information acquired by him in any wise affecting the declarations and warrants herein made." The reasonable construction of the statute, says the court, is that the provisions are expressly waived upon the trial if a proper stipulation to that effect be produced thereat, and entered upon the record, regardless of the time when the waiver was executed. Nor is the provision for such waiver contrary to public policy. The general public can have no interest in the execution of the statute in question. Its operation can neither be injurious nor disadvantageous to the public, and it is not opposed to good morals. It simply prescribes a rule of evidence between party and party upon the trial of a cause.

THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

It is hard to separate the enthusiastic members of our profession, and it is certain that they will come together without regard to geographic boundaries, at

the Detroit meeting. The program, elsewhere printed, shows no lack of good papers; an average of nearly twenty for each day being promised; and the well-known hospitality of the citizens and the Detroit profession insures that all available time will be spent profitably and agreeably.

The Mississippi Valley Society has now become a National medical society, and is rapidly extending its membership east of the Alleghenys—and it is pleasant to record that nine-tenths of its members are loyal members of the AMERICAN MEDICAL ASSOCIATION and enthusiastic workers in the great cause of professional organization.

We doubt not, however, that gradually the medical men of the whole interior valley of North America, as described by DRAKE, will become one medical organization, potent for good to all worthy members of the medical profession.

WISCONSIN SESSION LAWS.—The statutes enacted at the last session of the Wisconsin Legislature are now published and made accessible to the public. Elsewhere we print such extracts from them as are of interest to the medical profession.

CORRESPONDENCE.

Letters to my Hospital Internes, Past and Present.

By CASEY A. WOOD, M.D., OF CHICAGO.

II.

PARIS, July 14, 1895.

Gentlemen:—Perhaps the most noticeable fact connected with the more prominent oculists of Paris is their foreign names and origin. We find several Germans, a Pole, a Greek, a Netherlander and even a Canadian graduate on such a list. Whatever else this may mean, it is at least evidence of the tolerant and cosmopolitan character of French surgery. Evidently, also, they have been asked by the French public, not where they were from, but what they knew about ophthalmology.

Probably the best known ophthalmologist in Paris is De Wecker (public clinic 55 Rue Chercher Midi, 4 P.M. daily; operations at 5 P.M.), one of the fathers of ophthalmology and justly celebrated as author, teacher and operator. He has always a large following of students and patients and is very courteous to strangers. He showed me his new glass-and-nickel steel operating chair, made on the model of one in which he said he had done 30,000 operations. He gave his own anesthetic on several occasions, not for want of an assistant but because he had "views" upon the subject of general anesthesia. De Wecker prefers the illumination from a small electric hand-lamp, while operating, to sunlight, as he thinks that the operator, his assistants and the onlookers can all see better. It seems to me that this is merely an example (and we find many of them among surgical appliances) of the adaptation of an instrument to the requirements of a particular surgeon. He finds that some form of instrument suits *him* better than any other and forthwith discovers reasons why it should be adopted by the rest of the world. De Wecker is markedly short-sighted and is obliged to approach his own eyes to the patient's face while operating; consequently an electric lamp *is* better for all concerned when *he* is operating.

I saw Panas, another well-known oculist (professor in the University, Hotel Dieu, fifty-nine beds for eye patients, entrance off the Place Notre Dame, noon daily, operations 2 P.M.), and the man who advocates the substitution of biniodid of mercury for sublimate as an antiseptic in surgery, on the ground that it is less irritating than, is quite as good a germicide as, and can be more effectually employed in one-half the dose of mercuric chlorid. Lately he has been in the habit of using the iodid dissolved in sterilized olive (or almond) oil as an antiseptic application to the lids and lashes (and for hypodermic injection in general medication) before operating for cataract. The ocular region generally is thoroughly cleansed the evening before the operation and the oil applied. The eye is then bandaged until the moment of operation. Laboratory experiments have proved that the conjunctival sac and the lid edges contain fewer pathogenic bacteria after this treatment than when any other plan is followed; also the evidences of ocular hyperemia are few or wanting. During the operation he uses a large Graefe knife and cuts through one-half the corneal circumference. His extractions are without iridectomy and he does not hesitate to employ what appeared to me to be a good deal of force and much manipulation in replacing the iris, using a large scoop-like repositor. But this rough treatment, he says, is never followed by iritis. He has given up the use of the syringe for washing out the anterior chamber after removal of the cataract, since employing the iodid oil solution. The presence of pathogenic microbes is what he fears in producing ocular inflammation rather than traumatism (*e. g.*, the use of the iris repositor) or foreign bodies in the anterior chamber—such as lens matter and capsular remains after cataract extraction. He uses eserin ointment 1 per cent. after the operation for cataract, then iodoform dressing, both eyes being bandaged for three days.

Some of the English operators, Lang, for example, always examine the eye twelve hours after such operations, as in their experience prolapse of the iris occurs, if at all, within that time. They also say that the prolapse is more easily dealt with then than later.

After enucleation, Panas sutures the conjunctiva and puts in rubber drainage, thereby securing a better socket for the artificial eye.

I saw a good many cases dressed with iodoform in all the clinics, and I can not help thinking that the French nose is after all less susceptible to that odorous application than are our American olfactories; you will remember that even the poorest public patient objects, with us, to iodoform dressings when applied to the nasal region.

In the clinic of Abadie (172 Boulevard St. Germain, 1 to 4 daily, operations at 3) I saw the chief give a subconjunctival injection of one drop of a weak eserin solution immediately after removal of cataract. He did his extraction without iridectomy, like almost all the French operators—as opposed to the English surgeons, of whom it may be said that the converse is true. Abadie, for cataract extraction, uses an eye speculum with the spring turned toward the nose, having previously cleansed the conjunctival sac with cotton-covered retractors. This latter proceeding recommended itself to me since reading Gasparini's report, in which he showed that the useful action of certain fluids (borated solutions, sterilized water, weak bichlorid mixtures, etc.), employed in irrigating the eye, depends not so much upon their germicidal powers as upon the stream of water acting as a mechanical agent in detaching and washing away the colonies of cocci.

Abadie's first assistant kindly showed us a number of syphilitic patients whom he was treating after the method of Marcelli, of Milan, by the intravenous injection of mercuric cyanid. When employed in the usual hypodermic

manner the following is the formula commonly prescribed:

Cyanid of mercury	1	grm.
Muriate of cocain	0.50	ctgr.
Distilled water	100	grms.

Of this, 1 cubic centimeter every two days. The cocain is omitted when the injection is made *intravenous, i. e.*, into any of the superficial veins of the arm, and a centigram is given at one dose every two days. A special syringe is used, there is very little pain and I saw no disagreeable after-effects. Abadie claims from this treatment much better and earlier results than when mercury is given by inunction or by any other method.

The Quinze-Vingts, probably so-called because it had 300 beds when first founded, is one of the oldest hospitals in Paris and has connected with it the largest indoor eye hospital in the world—the *Clinique Nationale d' Ophthalmologie* (Rue de Charenton, 28, daily clinics, 11 to 12, operations at 1 P.M.) with 190 beds and a very large dispensary practice. Prominent on its staff of surgeons is A. Trousseau, a member of that family illustrious in the annals of French medicine. He is a very genial man and received us with great kindness. I have never seen a more rapid operator in any department of surgery. The way in which cataracts were removed, squints straightened and lid operations performed was simply amazing.

The Gilet de Grandmont operation for congenital ptosis was done in two minutes, while cataracts were extracted in about twenty seconds! For the latter, which were without iridectomy, he used only a Graefe knife like the English operator Critchett. Separating the lids with his left thumb and forefinger, he quickly punctured the cornea, used the point of the advancing knife as a cystotome, made his counter-puncture, completed the incision, pressed upon the lower third of the cornea with the back of the knife, and before one could say "Jack Robinson," the opaque lens lay upon the cheek. I saw him do half a dozen such operations, with good immediate results, inside of fifteen minutes. A starch bandage was applied in all the cases. To this hospital are also attached Valude (operates every Thursday at 2 P.M.), Kalt, who sutures the corneal wound after cataract extraction to prevent hernia of the iris, and others. Regular instruction in ophthalmology, illustrated by cases from the vast supply of clinical material at hand, is given by members of the staff and is practically free to all comers. The assistants in this hospital have unusual opportunities for doing major operations upon the eye. They are chosen by competitive examination and the appointments are eagerly sought after.

Landolt (12 to 2, at his clinic, Rue St. Andre' des Arts, 17) is the ophthalmologist who has translated into simpler language those complicated formulæ connected with physiologic optics to be found in the exhaustive treatises of Helmholtz and Donders. Indeed, most of the smaller works and text-book chapters on the refraction of the eye, that have appeared during the past ten years, have been copied from his masterpiece, "On the Refraction and Accommodation of the Eye." He is still a young man and speaks and writes admirable English. Every American visitor or student may count upon receiving a cordial welcome from him. I regard his early and smaller work on the "Examination of the Eye" as the best thing of the kind yet published. Unfortunately, it has been out of print for several years and so far, the author has not seen fit to re-write it.

The *Hospice de la Salpêtrière*, combination of hospital, poor-house and lunatic asylum with its 3,800 beds for women has attached to it, as surgeon oculist, Dr. Parinaud (his own clinic in the *Avenue de Clichy*, No. 50, is held daily) who is probably best known as an authority on hysterical amblyopia and on the relations of the eye to nervous diseases generally. I saw

several of his cataract cases where the corneal incision was made, without subsequent iridectomy, within the clear cornea in such a manner (he claimed) as to insure early healing of the wound and to form a sort of corneal dam against extrusion of the iris. His clinic is a very interesting and instructive one and might, with benefit, be attended by every medical visitor to Paris. He speaks little or no English. Parinaud's first assistant, Morac, has also written extensively on subjects of special interest to the neurologist.

The personality of Galezowski, one of the oldest and best known oculists in the French [capital (Rue Dauphine, 41, daily 1 to 3, operates 3 to 4) rises superior to one's judgment of him as an ophthalmologist. He has by far the largest private clinic in Paris and probably as large a student following as any other teacher. In his overcrowded and far from (surgically) clean operating room, aseptic conditions can not possibly be obtained nor was there, so far as I could learn, that attention given to the measurement of refractive errors or the correction of muscular anomalies which one sees in some French and in most English dispensaries. Still there is a peculiar fascination about the man and his teachings that seems very attractive to students and patients. At the same time one can not help wondering whether the enthusiastic hopes of these patients are more frequently realized than are the calmer prognoses extended to the *clientèle* of other dispensaries. The crowd at Galezowski's seems as large and expectant as when I first visited Paris in 1886. I do not intend by these words to depreciate the work which Galezowski has done for medicine generally, because that is valuable and forms a part of modern ophthalmology.

This ophthalmologic sketch would be incomplete without a reference to Dr. George J. Bull (4, Rue de la Paix, 2 to 4 daily) an American graduate, who has won a place in the front rank of Parisian oculists. He was associated for a number of years with Javal of ophthalmometer fame and that instrument probably owes more to Bull than he is willing to admit. At any rate his compatriots in medicine will always find him willing to advise them as to the best way to get about the Paris hospitals.

I regret that I was unable to visit Meyer, Oswalt, Darier or d'Espagnet as I intended, and will, consequently, say nothing about them, but the man who is interested in diseases of the eye ought, when time permits, look them all up.

Since I last visited this city, several surgical instrument makers and dealers in optical apparatus have come to the front. In addition to the well known firms of Collin, Nachet and Lüer (now at No. 6, Rue Antoine-Dubois) I have had satisfactory dealings with Roulot, 58 Quai *des orfeores* and Major et Genisson, Rue Racine 23. As the question of surgical appliances so frequently arises in the case of the medical traveler, let me give it to you as my opinion that London still retains her old preëminence as the place to buy most cutting instruments, but that in other respects New York excels. With the exception of certain *souvenirs de voyage*, which one picks up in every city, and the knives and scissors of London, I would not now buy a franc, a gulden or a mark's worth of office furniture. It can be better and almost as cheaply purchased in our own country. I believe that we shall be able, before many years, to say the same thing about our medical instruction. At least such is the impression made upon me, by comparing what I have, so far, seen of French, German and English methods. In my next letter I hope to give you my experiences of some Dutch and German hospitals.

(To be continued.)

NO BOYLSTON PRIZE AWARDED.—The Boylston Medical Committee of the Harvard Medical School awarded no prize this year:—*Boston Medical and Surgical Journal*.

The Reorganization of the Harlem Hospital of New York.

NEW YORK, Aug. 8, 1895.

To the Editor:—There have been some changes recently made in the medical management of the Harlem Hospital of New York, by the Commissioners of Public Charities and Corrections, and connived at by the faculties of two medical colleges, which every honest, fair-minded member of our profession must look upon as most reprehensible, harsh and unjust.

With the advent of those new officers who came in with the change in politics, in the early spring, a disgruntled member of the profession who had been expelled from the hospital service, through one of the newspapers made a savage attack on the entire medical staff of the Harlem Hospital. Shortly after this, without an intimation of any description beforehand, the Commissioners—a board of laymen—gave notice of a reorganization of the Harlem Hospital staff. This staff consisted of Dr. John G. Truax, visiting physician and executive president; Dr. S. T. Armstrong, visiting physician; Drs. Thomas H. Manley and C. B. White, visiting surgeons, and Dr. A. Palmer Dudley, gynecologist.

As soon as the medical board came into possession of the knowledge of the proposed changes, or reorganization, they appealed to the Commissioners for an explanation, who answered, that they proposed to transfer the medical management of the hospital over to the three medical colleges and the ex-collegiate of Bellevue, and that if the former members were renominated by the colleges, they—the Commissioners—would appoint them; at the same time the medical board being assured that there were no charges against them. Three members of the medical board were graduates from out of town; one, Dr. Truax, from Rush, of Chicago; Dr. Armstrong from St. Louis, and Dr. Dudley from Dartmouth, N. H. Dr. Manley was a graduate of the University of New York, entering the hospital service as an interne in 1875. Dr. Chas. B. White was a graduate of the Bellevue Hospital Medical College, entering the service through that faculty.

It therefore would seem certain that, under the circumstances, Drs. Manley and White, who were graduates of New York colleges, would be vindicated and returned to the service. In the meantime, the Commissioners enlarged the hospital staff from five to eight, abolishing the gynecologist and requiring the colleges and ex-collegiate to make each two nominations. And now comes the most despicable part played by the two medical colleges, who ignored their plain and imperative duty to defend their own alumni. Both Bellevue and the University took advantage of the opportunity to nominate four physicians, in spite of a strong protest from the County Medical Association.

The College of Physicians and Surgeons has alone stood out, and delayed nominating, until it is assured by an investigation, that no injustice is to be imposed on the medical board dropped out.

This, certainly, is a magnificent position for a faculty to take, not to be a party to, and not to connive at any scheme which has for its object the imposition of a serious injustice on a body of physicians who have performed their duty with fidelity and conscientious attention, over a period of several years and without a farthing of compensation.

It is reported that the matter is to be made the subject of a most thorough and searching investigation, in the early autumn, in the County and State Medical Associations of New York.

JUSTITIA.

A Case of Sepsis Simulating Disease of the Brain.

PAWNEE CITY, NEB., Aug. 10, 1895.

To the Editor:—The following case being so unusual as to the symptoms, I think worthy of a place in the *JOURNAL*. Mrs. M., was on June 14 delivered of a female child at term, Labor lasted only two hours, but placenta remained until my arrival six hours afterward. Placenta was easily delivered and everything went well until June 20, when patient com-

plained of severe occipital pain. A few doses of acetanlid comp. relieved the pain. I saw the patient the next day; she was feeling well; the lochia and lacteal secretion normal, temperature normal but pulse 90.

June 23, during my absence, Dr. Wright was called and found patient had been unconscious for a short time, with involuntary discharges from the bowels. At the time of his visit, consciousness had returned, but there was trembling and nervousness with some difficulty of speech. Temperature $99\frac{1}{2}$ degrees F. I saw the patient the following morning at 9 o'clock. Pulse 120 and small, temperature $98\frac{1}{2}$. Conscious but can talk only in monosyllables. Says "no" to nearly all questions; sighing respiration; abdomen flat; no tenderness; no disturbance of vision; tongue clean. June 25, had a restless night. Pulse, 130, temperature 100 degrees. Sighing respiration. Lacteal secretion free, but she pays no attention to babe when put to the breast. Answers all questions by saying, no. Is evidently embarrassed when she answers wrong. About 9:40 had a slight convulsion, limited to ocular muscles and the right side of face. This was followed by stupor and great prostration. Urine highly colored but contains no albumin. Treatment consisted in the use of pot. bromid and gelsemium with free stimulation. The uterus was thoroughly irrigated with 5 per cent. solution of creolin. Some clots with much prune juice colored material was washed out.

June 26, patient rested well, mind clearer, answers questions correctly but hesitatingly and in monosyllables. No pain, no tenderness. Abdomen flat. Has not full control of bowels and bladder. Temperature 99 degrees; surface cool and clammy. Sighing respiration; great weakness. Treatment continued as yesterday.

June 27, rested better, sighing less, pulse 100, temperature 99 degrees. Frequently makes pressure with both hands to forehead, but when asked if head aches answers, no. Never speaks unless questioned.

June 28, temperature 100 degrees, pulse 120. Rational; no pain; asks about the baby for the first time.

June 29, temperature 99 degrees, pulse 108. Rational, but dull. Has not full control of bowels and bladder. The patient continued to improve slowly to complete recovery. Iron, quinin and strychnin were resorted to after the acute symptoms were passed. This was undoubtedly a case of sepsis, although the symptoms were entirely different from any heretofore encountered in an experience of eighteen years. The convulsion, the aphasia, the sighing respiration, the occipital pain, the paresis with a low temperature are certainly anomalous symptoms, and but for certain other contradictory evidence would lead one to suspect clot or congestion of the brain.

The free secretion of mammary glands, with no stoppage of lochia, are also to be set down as unusual in a case of this kind.

A. B. ANDERSON, M.D.

Fibroid Tumors of the Uterus.

CHICAGO, Aug. 16, 1895.

To the Editor:—In his address before the Gynecologic Section of the AMERICAN MEDICAL ASSOCIATION (JOURNAL issue Aug. 10, 1895), Dr. Franklin Martin has grossly misrepresented my work and I beg a short space in our JOURNAL to reply.

Dr. Martin stated that I "still open the abdomen with the deliberate intention of removing the appendages for fibroids." On the contrary, it is my invariable custom to do hysterectomy for fibroid tumors of the uterus, and I only resort to the removal of the appendages when the condition of the patient makes it unsafe to subject her to the added risk of complete removal. It is true that when I do perform the "makeshift operation of removal of the appendages," I also tie the uterine arteries as they course through the broad ligaments. Dr. Martin's claim that this procedure is simply his operation applied "from above," is, to say the least, surprising. I employed this method before I ever heard of Dr. Martin's operation (vaginal ligation of the uterine artery), but had I followed him in the matter of time, the invention of new operations would, indeed, become a matter of difficulty if two such different procedures are to

be considered one and the same operation. Far from lagging behind in the matter of hysterectomy, I am convinced that I was one of the first in this city to follow the great step in advance made by the New York and other gynecologists in removing the uterus in bilateral diseases of the appendages. Indeed, if my memory serves me, Dr. Martin was one of those to oppose this procedure, but I warned him then, that it marks a new era in gynecologic surgery, and again I admonished him that he may not be left in the ranks of the "beginner and the timid."

And lastly, Mr. Editor, had Dr. Franklin Martin ever enjoyed a personal knowledge of the work of the "Birmingham sage" I doubt if he would have acquired the impression that he belonged to the ranks of the "beginner and timid." A man who has done nearly forty consecutive hysterectomies for fibroids without a death could hardly be considered an amateur, neither could he reasonably be suspected of being afflicted with that disease of youth, "timidity."

Far from desiring "to shake off entirely the teaching of the Birmingham sage," I am proud that it has been my good fortune to have been a pupil of so great a master as Mr. Lawson Tait.

Respectfully,
BYRON ROBINSON.

An Opinion of the Journal.

QUINCY, ILL., Aug. 9, 1895.

To the Editor:—The JOURNAL has been made so useful, its tone so excellent, and its articles so helpful to physicians and surgeons that none of them can afford to do without it. In the past, many many useful methods and facts have been lost for want of a public journal belonging to everybody, to permanently record them.

H. W. K.

BOOK NOTICES.

Publications du Progres Medical, Paris. 14 Rue des Carmes, Paris. *Bibliothèque d'Éducation Spéciale, tome IV. Assistance, Traitement, et éducation des enfants, idiots et dégénérés. Rapport fait au Congrès National D'Assistance Publique (Session De Lyon, Juin, 1894).* Par BOURNEVILLE. Vol. in 8vo, de 246 pages avec 28 figures. Prix. 3 fr. 50.

This is a report on assistance of idiot children and degenerates, by the learned and accomplished Bourneville. We have before mentioned, in one of our book notices, the appreciative mention by Bourneville of the labors of the lamented Séguin, and the same fairness and *noblesse oblige* is seen in this report. The volume begins with a historical review of assistance and treatment of idiotic and degenerate children in which our own country is given due credit for its work in this direction. The second chapter discusses the assistance to this unfortunate class in the departments of France. The number of admissions to each institution are given. Chapter 3 describes the private establishments devoted to idiot children, epileptics and degenerates in France. Chapter 5 contains a report on the assistance given this class in Europe. The age and capacity of each institution is mentioned, and as well their special features. Chapter 6 is devoted to the institutions of the United States. The works of Séguin, Woodward, Backus, Howe, Fernald, Wilbur, Browne, Richards, Knight and Miller receive appreciative mention. Chapter 7 takes up the condition of asylums for idiots in South America, and as might be anticipated there is little done. Bolivia, Colombia, Chili and the Argentine Republic are without special institutions. There is no report from Brazil. Chapter 8 discusses in detail the motives which justify assistance, treatment and education of idiots and degenerates and the form or methods of assistance.

The second part of this publication contains the discussion on the report which was held by the National Congress

of Public Assistance in June, 1894, under the presidency of Dr. Carrier.

The third part gives an elaborate summary of the existing state of medico-pedagogic treatment of the idiot. The illustrations show some novel gymnastic appliances.

After reading this work we can with much pleasure repeat the saying of the President of the Congress, that if Séguin were the "first of the first" in this humane work, Bourneville was easily the first of the second.

Twentieth Century Practice; An International Encyclopedia of Modern Medical Science. By leading authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D., New York city. In Twenty Volumes. Volume III. Occupation, Diseases, Drug Habits, and Poisons. New York: William Wood & Company. 1895.

This volume of this unsurpassed series contains: 1, an article on Alcoholism and Drug Habits by Norman Kerr, M.D., London. This article is exhaustive and occupies 137 pages of the work. The author in his treatment of alcoholism, declaims against alleged specific medication, and insists that special treatment is required for nearly every case. 2, a pithy article of thirty pages, by Geo. F. Shradly, M.D., on Shock and Collapse. 3, an excellent and highly entertaining article by Medical Director A. L. Gihon, U. S. N., on Sea Sickness. 4, an article by Georg Von Liebig, M.D., of Munich on Mountain Sickness. 5, on Ostemalacia, by W. T. Councilman, M.D., of Boston. 6, Heat Stroke, by Medical Director Gihon, U. S. N. 7, Frost-bite, by the same. 8, The Diseases of Occupations, by James Hendrie Lloyd, M.D., of Philadelphia. This is the most elaborate section in this volume and contains 186 pages. In the historical notes accompanying this paper, he begins with the classic work of Ramazzini and reviews the literature to date. There is some looseness in the manner of quotation; for instance, Lloyd in quoting Patissier, says, p. 512: "As an example of Patissier's method and acumen the following may serve: 'Pastry cooks,' he quotes, 'are less debauched than bakers, and more gentle and sociable! He thinks he sees in pie dough a mysterious influence that renders a man more sweet and companionable than his fellow who makes bread. This extravagant deduction is on a par with much that has been and still is being written on the influence of occupation on health.'"

Now nothing written by Patissier carries any such inference. The following is an exact translation from Patissier, p. 195-196:

"Diseases of Pastry Cooks.

"The pastry cooks are exposed to the same diseases as bakers; however, they are less intense. The flour often renders their eyelids bleared; as they always carry their hands toward the fire, it sometimes follows, that on the surface of the metacarpus, squamous herpes appears, the cure of which is very difficult. M. Cadet-Gassicourt said that these workmen are less debauched than bakers and more mild and sociable."

This is the entire reference of Patissier to the pastry cook, and the reviewer submits that Dr. Lloyd has unintentionally perhaps, misrepresented Patissier. The remaining portion of this section is excellent.

9, Poisoning, by Beaumont Small, M.D. of Ottawa. 10, Poisoning from Lead, Arsenic, Zinc, Copper, Mercury, Silver, and Phosphorus, by James Stewart, M.D. of Montreal.

As a whole, the volume is up to the high standard of its predecessors.

Skiascopy and its Practical Application to the Study of Refraction. By EDWARD JACKSON, A.M., M.D., Professor of Diseases of the Eye in the Philadelphia Polyclinic, etc., etc.

The author of this little book belongs to those who from the beginning have recognized the great practical value of the shadow test in the examination of refraction. He has given the subject special attention, and is particularly well qualified to write on it. His book, therefore, bears the stamp of personal experience and original observation, and can not be too highly recommended to every oculist and physician desirous of becoming thoroughly familiar with the theory and practice of skiascopic examination.

Syphilis in the Innocent, CLINICALLY AND HISTORICALLY CONSIDERED, WITH A PLAN FOR THE LEGAL CONTROL OF THE DISEASE. By L. DUNCAN BULKLEY, A.M., M.D. 8vo, cl., pp. 398. New York: Bailey & Fairchild.

This work is the result of ten years' work by the author, and is an extremely valuable contribution to the study of syphilis. The occurrence of the disease among the innocent is so frequent that the wonder is, so small a part of syphilography has been devoted to this branch of the subject, and the profession generally has been placed under obligation to Dr. Bulkley.

Over one hundred categories of transmission of the disease have been given. There are very full tables illustrating the proportion of genital to extra-genital chancres; epidemics of syphilis which have occurred from 1577 to the present time (of which there are over one hundred). From page 241 to the end of the work, the volume is entirely devoted to the analytical bibliography of syphilis insontium.

The author in his plea for the legal control of syphilis says, p. 205:

"The time has certainly come, when the dangers of syphilis, and especially the dangers to innocent persons, should be fully recognized. It is too late in the history of science and of humanity to stigmatize the disease as 'venereal,' and on that account to withhold scientific protection from thousands of innocent sufferers. Among babies, nursing women, persons infected in dental or surgical operations, and in dozens of other manners, syphilis can no more be described as a 'venereal' affection than any other contagious disease. The time has come to place it under the control of the proper health officers, and make it quite as *criminal to transmit syphilis wittingly* as it is to communicate smallpox, scarlatina or diphtheria."

As a reference book it will be found the most complete of any on this subject.

Contribution à l'Étude de L'Atrophie musculaire progressive type Duchenne-Aran. Par le Dr. J. B. CHARCOT. Volume in 8vo, de 176 pages, avec 6 figures et 4 planches hors texte. Prix 5 fr.

This work, which is dedicated by the son to Charcot, père, does not profess to be a monograph on Duchenne-Aran muscular atrophy, but is intended to clear up some points hitherto doubtful or obscure, from a clinical or anatomic point of view. The author says:

"This disease was first described by Duchenne (of Boulogne) and Aran as follows: 'An atrophy which develops in the adult age, comes on insidiously, and which begins in the small muscles of the hands, and slowly and progressively invades the periphery. . . . The muscles of the arms, the trunk, and finally the lower extremities become involved. Only rarely do the muscles of the tongue, pharynx and larynx become involved.'"

The author, after an exhaustive historical account of the affection, gives illustrations showing microscopic appearances of sections, and furnishes details of many original experiments. It is apparent that the son possesses much of the keenness of observation of the distinguished father.

Exercise and Food for Pulmonary Invalids. By CHARLES DENISON, A.M., M.D. Pp. 71, cl. Denver: The Chain & Hardy Company. 1895.

This little book contains an excellent system of rules for the guidance of the consumptive in the selection of articles of diet, and the performance of suitable exercise. Few can speak with more authority on this subject than Dr. Denison, and none with more practical common sense. The book is well written and deserves a wide circulation.

The Retrospect of Medicine. A half yearly journal containing a retrospective view of every discovery and practical improvement in the medical sciences. Edited by JAMES BRAITHWAITE, M.D., London, etc., etc. Volume III. Cl., pp. 411. January to June, 1895. London. Simpkin, Marshall, Hamilton, Kent & Co. Limited.

This well known volume continues to be issued, although the limited scope of the work prevents the editor from using more than a very scanty portion of the current literature.

PUBLIC HEALTH.

Typhoid Fever at Stamford, Conn.—Late reports from Stamford show that three hundred and thirty cases of fever have been reported, and twenty cases are under treatment in hospital. There are a few secondary cases. There are thirty trained nurses employed, under the relief fund, for families not able to engage them. The fund collected for the relief of the poor is \$2,000. Dr. Edward J. Meeks was taken to the Presbyterian Hospital, New York; he is believed to have contracted the disease in the care of his own child. There are suspicions on the part of many of the residents that the eating of raw oysters has had its share in the development of the scourge. The health authorities do not vary from their original ground that the epidemic is one of "milk typhoid."

Alleged "Impossible" Death Rates.—Dr. F. W. Reilly, Assistant Health Commissioner of Chicago, recently quoted Deputy Surgeon-General John S. Billings, whom he styles the highest authority on vital statistics in this country, to the effect that a death rate of less than 18 in the thousand was incredible for a city so large as Chicago claims to be. The deaths reported in that city for 1894 were 23,892; the claimed population—that determined by the official census of April, last year—was 1,567,727 and the death rate on this basis was, consequently, 15.24 per 1,000. But at the minimum rate fixed by Dr. Billings—18 per 1,000—the population must be only about 1,327,000. This is by no means palatable to the civic pride of the Western metropolis, and a movement is on foot to secure an "authoritative" census, superintended by the Census Officer of the Department of the Interior. Meanwhile, Chicago should take what comfort may be got out of the fact that the Registrar-General's returns for the city of London recently showed a death rate for one week of only 15.5 per 1,000 in that city.

Sanitation of Flooded Regions.—A disaster somewhat similar to that at Johnstown, Pa., occurred this spring at Bouzy in the Department of Vosges, France. A dam of masonry, 500 meters long, 22 high and 20 wide, forming a reservoir containing 7,000,000 cubic meters of water, suddenly gave way and flooded the valley of the Avière for a distance of 20 kilometers, overturning houses, uprooting trees, and carrying away the inhabitants and domestic animals. When the waters subsided there was left on the land, beside ooze charged with organic matter, *debris* of all sorts, cadavers, and masses of slime and vegetable detritus. These deposits rapidly gave off disagreeable odors, and the survivors feared an epidemic. The General Hygienic Council of the Department, acting under the supervision of the French Consulting Committee on Hygiene, took measures to prevent this. The cadavers of animals were buried in deep trenches after being covered with quicklime; *debris* of all sorts was collected in heaps, sprinkled with sulphur and buried. The trees clogging up the river bed were removed and the stagnant water led off into trenches. The wells were condemned for the time being. Dwelling in the inundated houses, filled with slime, was forbidden. The walls were scraped, washed and calcimined, the floors washed and the furniture and hangings disinfected.

Spread of Cholera.—Recent cable advices indicate that from very small beginnings in the Russian province of Volhynia, cholera has suddenly made an expanding break in several directions, notably to the south and west. Various dispatches from Cracow, Lemberg and other points show that it is spreading rapidly in Austrian Poland. Still more circumstantial stories come from southern Russia, where the epidemic has reached the vicinity of Kiev, and even, it is rumored, in the city itself. As usual, there is much activity in the line of quarantine restrictions, and it is probable that this extension will renew interest in the recent strictures of Inspector-General Proust of the French Sanitary Service on the English indifference to quarantine *per se*. Dr. Proust has

declared that the refusal of Great Britain to apply the decisions of the International Conference is absolutely criminal, and that if Europe is invaded with cholera this summer, Great Britain will be to blame for it. Dr. C. W. Chancellor, U. S. Consul at Havre, says, however, that the attitude of Great Britain in ignoring quarantine and relying mainly on sanitation to restrict cholera is having its effect on international cholera policy; and again points out, as the late Dr. Rauch was wont to do, that "cholera quarantine, if ever it could be satisfactorily carried out, would be of no use excepting with regard to the one disease—cholera. Sanitation, on the other hand, even if primarily attended to for the special prevention of cholera, is, in its measure, useful in preventing other infectious diseases conveyable by similar means, such as typhoid fever, yellow fever, etc., and is useful also in raising the general average of health in every community." This is the lesson of the situation for the United States. If cholera should spread throughout Europe this year we may not be able to shut it out from our shores by quarantine, but we can and should make our environment so wholesome and cleanly as that it shall be fatal to cholera as well as to all other of the filth diseases.

Never Again a Cholera Panic.—A newspaper interview of some of the New York health officers, regarding the delayed approach of cholera to these shores this year, has excited much interest. Hopeful and optimistic views prevail. Among others, Dr. Roger S. Tracy of the City Department was interviewed. He gave it as his opinion that there will never again be a cholera scare in New York like that of 1892, and that there is safety for that city so long as sanitary laws are well enforced, and wholesome water is abundantly supplied. Even if a few infected immigrants were to reach quarantine, there would be hardly any danger of the disease becoming epidemic, for the means of stamping it out are at the command of the governing powers. The health authorities of Germany, France and England are now confident of their ability to deal with cholera promptly and successfully. The Germans have this year had experiences even more satisfactory than those of last year, and have been able to guard their country by methods as scientific as they are easily applied. Dr. Tracy, in discussing the subject, applies to it the germ theory of disease with that fullness of confidence which is derived from long familiarity with it. "No cholera scare hereafter," he says. There can be merely guesses as to the extent to which the disease prevails in China. In the dispatches there are occasional references to its existence in the Liao-Tong peninsula, and in the kingdom of Corea, and there is every reason to believe that it has been very destructive in these regions. From the trustworthy statistics that are kept by the Japanese authorities, it is learned that up to the close of July there had been 9,500 cases of the disease in Japan, more than one-half of which had proved fatal. This fatality may be regarded as part of the price paid by Japan for her victory over the Chinese. In some other countries beside those here mentioned, including Mexico and Cuba, there had been cases of cholera during the year, but it has not been epidemic in any of them. It has been estimated by good authorities that the average yearly number of deaths from cholera, the world over, is close upon a quarter of a million. It is now known that in Russia alone last year there were nearly 100,000 cases of the disease, about 45 per cent. of which proved fatal; but the ravages of the disease among the Russians are light as compared with the losses among Asiatics.

Health Reports.—The following health reports have been received by the Supervising Surgeon-General, Marine-Hospital Service:

SMALLPOX—UNITED STATES.

Michigan: Battle Creek and Detroit, July 26 to August 3, reported existing.

Tennessee: Memphis, August 3 to 10, 1 case.

Texas: Eagle Pass, July 29 to August 9, 115 cases, 6 deaths.

SMALLPOX—FOREIGN.

Buda-Pesth: July 16 to 23, 2 cases.

Cairo: July 2 to 8, 3 deaths.

London: July 20 to 27, 1 death.

Madrid: July 15 to 22, 4 deaths.

Moscow: July 6 to 13, 1 case.

Mexico: Nogales, July 26 to August 3, 1 death.

Prague: July 13 to 20, 2 cases.
St. Petersburg: July 6 to 20, 10 cases, 3 deaths.

YELLOW FEVER.

Havana: Month of July, 84 deaths.
Santiago de Cuba: July 13 to August 3, 124 deaths.
San Juan de Porto Rico: July 6 to 27, 104 cases, 67 deaths.
Santos: June 30 to July 6, 5 cases, 1 death.
Rio de Janeiro: June 30 to July 13, 22 deaths.
Vera Cruz: July 24 to August 1, 12 cases.

CHOLERA.

Hiogo: July 6 to 13, 104 cases, 87 deaths.
Yokohama: June 14 to 21, 1 death.

SOCIETY NEWS.

Mississippi Valley Medical Association.—*To the Editor:*—I inclose you the preliminary program of the Mississippi Valley Medical Association, to be held Sept. 3, 4 and 5. The first evening, Tuesday, September 3, Dr. Theodore A. McGraw will deliver an address on Surgery at Strassburg's Hall, the place of the meeting, and after this there will be given a reception by the profession of Detroit at the Cadillac. Wednesday evening an address on Medicine will be given by Dr. William Pepper of Philadelphia. Thursday evening the Association will be given a boat ride on the river. The profession here are very enthusiastic in their efforts to make the meeting a success.

HOTELS.—The Cadillac will be headquarters, \$3.50 to \$4 per day; Russell House, from \$3.50 to \$4 per day; Normandie, from \$2.50 to \$3 per day; Wayne Hotel, from \$2 to \$3.50 per day. H. O. WALKER.

Detroit, Mich, Aug. 8, 1895.

Patrick, Chicago; Wounds of the Peritoneum Due to Perforation of the Rectum by Pitchfork Handle, by Weller Van Hook, Chicago; Tubercular Peritonitis, by L. H. Dunning, Indianapolis; The Surgical Treatment of Local Disorders in Insane and Neurotic Women, by W. H. Manton, Detroit; The Treatment of Paralysis by Mechanico-Therapeutics, by E. H. McCullers, St. Louis.

Arrangements have been made whereby those attending the meeting can secure a round trip ticket on the certificate plan for one and one-third fare. Be sure and secure certificates of the local agent where you buy your ticket, which will be signed here by the Secretary, Dr. F. C. Woodburn.

NECROLOGY.

CHAUNCEY M. FIELD, M.D., died July 17, at Plainfield, N. J. He was a native of Bound Brook, in the same State, about 45 years of age. He was a graduate from the Medical Department of Columbia College in 1875.

W. A. BETTS, M.D., one of the best-known physicians in eastern New Jersey, died at Red Bank, on Sunday, the 4th inst. He was 61 years old, and was graduated from the College of Physicians and Surgeons, New York, in 1861.

WILLIAM E. NEWING, M.D., of Long Branch, N. J., died July 11, aged 29 years. He was a native of New Jersey, the son of William S. and Margaret W. Newing, and was educated in medicine at the College of Physicians and Surgeons, New York, of the class of 1888.

MISCELLANY.

Charitable Donations in New York City.—The executors of the late Hugh Reilly, of New York city, have distributed \$9,500 among eighteen Hebrew charitable institutions and societies. The distribution was specifically provided for in the will of the deceased.

Sulphuric Acid.—From the action of sulphuric acid on the gas from cleveite, M. Deslandres has obtained in the extreme red of the spectrum, the third of the four lines in the solar spectrum that had not been found on the earth. This

leaves only one permanent ray from the solar atmosphere, the green line, known as "the line of the crown," yet to be discovered in earthly substances. It probably belongs to some gas lighter than hydrogen.—*Scientific American*.

Eligibility to Office of Physician in Benevolent Society.—Membership in a mutual aid and benefit society, the Supreme Court of Rhode Island holds, in the case of State v. Boucher, decided May 10, 1895, is not necessary to render a person eligible to the office of physician for the society where the by-laws thereof do not require it.

New Health Commissioner of New York City.—Dr. George B. Fowler, of New York city, recently received his appointment as Health Commissioner, *vice* Dr. Edson, resigned. He is about 50 years old, a native of Alabama. He is a member of the Union League Club, the New York and Racquet Clubs, the County Medical Society, Academy of Medicine and the Society of Medical Jurisprudence, and is a visiting physician to Bellevue Hospital and Infant Asylum. He was formerly connected with the Health Board as medical inspector. He has practiced his profession in this city since 1871, at which date he was graduated from the College of Physicians and Surgeons, of New York.

The Hodgkins Prizes of the Smithsonian Institution.—In March, 1893, the Smithsonian Institution announced that the income of a fund, the gift of T. G. Hodgkins, of Setauket, N. Y., would be expended in prizes for the best articles and original researches on the nature and properties of atmospheric air in relation to the welfare of man. Three prizes were offered, one of \$10,000 for the most important discovery, a second of \$2,000 for a treatise on the relations of air to the various sciences and the best lines of direction for future research, and a third of \$1,000 for a popular essay on atmospheric air. Wide publicity was given to the announcement, with the result that when the period allowed for the competition closed on Dec. 31, 1894, papers had been received from all parts of the civilized world. It is officially announced that 218 contestants submitted papers in competition for the three prizes. The subject must have been discussed thoroughly in this symposium; and the members of the Committee of Award may be regarded as on the advanced line in this direction of scientific inquiry. The committee consisted of: Dr. S. P. Langley, Chairman, *ex-officio*; Dr. G. Brown Goode, appointed by the Secretary of the Smithsonian Institution; Deputy Surgeon-General J. S. Billings, U. S. Army, by the President of the National Academy of Sciences; and Prof. M. W. Harrington, by the President of the American Association for the Advancement of Science. These were assisted in their work by a foreign Advisory Committee, composed of the late Professor Huxley, of M. Janssen, of the French Academy of Sciences, and of Professor Wilhelm von Besold, Director of the German Meteorological Service. The committee announced Aug. 6, 1895, the following decisions:

First prize, of \$10,000, for a treatise embodying some new and important discoveries in regard to the nature or properties of atmospheric air, to Lord Rayleigh, of London, and Prof. William Ramsey, of University College, London, for the discovery of argon, a new element of the atmosphere.

The second prize, of \$2,000 is not awarded, owing to the failure of any contestant to comply strictly with the terms of the offer.

The third prize, of \$1,000 to Dr. Henry de Varigny, of Paris, for the best popular treatise upon atmospheric air, its properties and relationships. Dr. de Varigny's essay is entitled "*L'Air et la Vie*."

Honorable mention and silver medal: Mr. A. L. Herrera and Dr. Vergara Lopez, of the National Museum, Mexico, "*La Atmosfera de las altitudes y el bienestar del hombre*;" Geo. L. Madsen, Esq., Villa Bregnehög, Helsingör, near Copenha-

gen, Denmark, "*Thermogeographical Studies*;" F. A. R. Russell, Esq., Vice-President of the Royal Meteorological Society of Great Britain, "*The Atmosphere in relation to Human Life and Health*."

Honorable mention and bronze medal: Dr. Franz Oppenheimer and Dr. Carl Oppenheimer, of No. 4 Eichendorff Street, Berlin, "*Über atmosphärische Luft, ihre Eigenschaften und ihren Zusammenhang mit dem menschlichen Leben*;" Mr. Alexander McAdie, of the United States Weather Bureau, "*The known properties of atmospheric air considered in their relationships to research in every department of natural science, and the importance of a study of the atmosphere considered in view of these relationships; the proper direction of future research in connection with the imperfections of our knowledge of atmospheric air and the conditions of that knowledge with other sciences*;" Dr. O. Jesse, of Berlin, "*Die leuchtenden Nachtwolken*;" Mr. E. Deberaux-Dex, and Mr. Maurice Dibos, of Rouen, France, "*Études des courants aériens continentaux et de leur utilisation par des aérostats long-courriers*;" Mr. Hiram S. Maxim, of Kent, England, "*Natural and Artificial Flight*;" Dr. A. Loewy, of Berlin, "*Untersuchungen über die Respiration und Circulation unter verdünnter und verdichteter Sauerstoffarmer und sauerstoffreicher Luft*."

Honorable mention: Surgeon Charles Smart, U. S. A., "*An Essay on the Properties, Constitution and Impurities of Atmospheric Air, in relation to the promotion of Health and Longevity*;" Dr. A. Marcuse, of the Royal Observatory, Berlin, "*Die atmosphärische Luft*;" Dr. F. J. B. Cordeiro, U. S. N., "*Hypsometry*;" Dr. A. Magelssen, of Christiania, Norway, "*Ueber den Zusammenhang und die Verwandtschaft der biologischen, meteorologischen und kosmischen Erscheinungen*;" Prof. C. Nees, of the Polytechnic School, Copenhagen, Denmark, "*The use of kites and chained air-balloons for observing the velocity of winds, etc.*;" Prof. F. H. Bigelow, of the United States Weather Bureau, "*Solar and Terrestrial Magnetism and their relation to Meteorology*;" E. C. C. Baly, Esq., of University College, London, "*The decomposition of the two constituents of the Atmosphere by means of the passage of the Electric Spark*;" Dr. F. Viault, Faculty of Medicine, Bordeaux, France, "*Découverte d'une nouvelle et importante propriété physiologique de l'Air atmosphérique. (Action Hématogène de l'air raréfié.)*;" Prof. Dr. S. Geisler, Bonn, Germany, "*Mittlere Tagstemperaturen von Bonn, 1848-88*;" Prof. Emile Duclaux, of the French Institute, Paris, France, "*Sur l'actinométrie atmosphérique et sur la constitution actinique de l'atmosphère*;" Dr. J. B. Cohen, Yorkshire College, Leeds, England, "*The Air of Towns*;" Dr. Ludwig Ilsvay von Nagy Ilsvay, Professor in the Royal Joseph Polytechnic School, Buda-Pesth, Hungary, "*Ueber den unmittelbar oxydirenden Bestandtheil der Luft*."

Philadelphia Notes.

DR. ROBERT I. HARRIS, the well-known correspondent, and statistician of Cæsarean section and of symphyseotomy, has been very ill during the past fortnight with an attack of hemiplegia, the results of which threaten to be serious.

The weather during July was much cooler than it has been for years and the hospitals had little opportunity to put to practical test their appliances for treating sunstroke. The health of the city has been exceptionally good, largely owing to the cleanliness of the streets; the Director of Public Works having had his efforts in this direction greatly stimulated by the Health Protective Association composed of public-spirited women, who have ideas on the subject of clean streets and do not care who knows them.

The Pennsylvania Legislature, at its session which recently closed, passed an act "prohibiting the exhibition of insane, idiotic, deformed or imbecile persons in any public hall, museum, theater, tent or building for a pecuniary consideration or reward." The offense is punishable by a fine not exceeding \$1,000 or imprisonment not exceeding six months. The police lieutenants of Philadelphia have just been furnished with copies of this act of Assembly and have been directed to secure its enforcement.

The physicians in charge of the State Hospital for the Insane at Norristown, in a communication to the managers last week, reported an epidemic of dysentery and bowel disorder in both departments, the cause of which has not yet been ascertained.

Washington Notes.

HEALTH OF THE DISTRICT.—The death rate continues to fall. According to the reports received at the Health Department during the last week there were 103 deaths, and the annual rate was 19.79 as compared with a rate of 20.06 for the week previous. So far as the range of diseases is concerned, the week's health history indicates very slight variation from the several immediately preceding reports. None of the dangerous contagious diseases present a phase causing anxiety to the medical profession. The four deaths from typhoid fever reported in the former week were followed by three more fatal cases last week. There were but twenty-eight deaths from this malady in the first six months of this calendar year, while since the first of last month twelve deaths therefrom have been reported. In other respects the condition of the public health is favorable; infant mortality is on the decline, and the rate of mortality is 3 per 1,000 inhabitants below the normal.

DISPENSING MEDICINE TO THE POOR.—The Health Officer has decided to abolish the old plan of having prescriptions for the poor filled at the drug stores. The new system provides that all standard medicines be purchased in tablet form direct from the pharmacists, to be kept in stock and supplied to physicians in pocket cases as needed. In treating a case the physician is not to write a prescription and send to the druggist for it to be filled, but will deliver the medicines at once, thus saving much time. It is not intended to have this new system superseded by the old one entirely at present, but it is to be tried to determine its utility and saving of money.

PHYSICIANS TO THE POOR MUST PASS MEDICAL EXAMINATION. Directly in line with their intention to apply civil service to the District government as far as possible, the Commissioners to-day approved a recommendation of the Health Officer, which takes in the physicians to the poor, and compels applicants for such positions to pass a competitive examination. The Health Officer's recommendation, which has been approved by the Commissioners and issued to-day as an order, says: "That the board to examine practitioners of regular medicine, seeking appointment as physicians to the poor be composed of the attending physician to the Washington Asylum, the medical sanitary inspector of the Health Department, one member of the Board of Pharmacy and one member of the Board of Police Surgeons. The questions should be prepared and answers examined and marked by this board. The examination itself should be conducted by clerks from the Health Department. Candidates passing successfully the written examination should be required, as a practical test of their ability, to examine and to diagnose and outline proposed treatment for one or more patients at some public hospital or dispensary.

THE DOCTORS FOR SENATOR GORMAN.—The medical profession is watching with great interest the political fight of Senator Gorman in Maryland. He is sure to be successful and the doctors are with him. Senator Gorman has always been the friend of the medical profession and enthusiastic in all important medical and sanitary questions. As a member of the Appropriations Committee of the Senate, his good offices have always been exerted in the direction of the most liberal expenditures for the extension of the influence of the Marine-Hospital Service, and he has always appreciated the importance of ample appropriations to guard against the inroads of yellow fever and for the extension of quarantine regulations. To his effort was due the passage of the Congressional appropriation bill which, at the last moment, made the First Pan-American Medical Congress a grand success. Apropos of the success of his exertions, was the brilliant reception to the delegates to the Congress, by the Maryland profession, at Baltimore, on the occasion of their visit to that city.

SENATOR GREY AND A NATIONAL BUREAU OF HEALTH.—Another matter of considerable interest to the medical profession, is the gossip which connects the name of Senator Grey, of Delaware, with the next Democratic nomination to the Presidency. It is now well known, as a fact already

communicated to the nearest friends of the President, that the latter does not expect, and in fact will not accept a re-nomination for a third term. It is also more or less certain that the friends of the President will control the action of the next Democratic National Convention. This being the case, it may be possible for these Cleveland Democrats, as they are known, to virtually name who shall be the Presidential nominee. If it shall be impossible to nominate either Secretary Carlisle or ex-Secretary Whitney, and the latter says he will not accept the nomination, it is known that the President would be glad to see Senator Grey receive the honor. Mr. Grey has always been a steadfast friend of the administration, and as far as the President can aid him, his ambitions will be advanced in the convention. This being the case, it is interesting to note that Senator Grey has been one of the few national legislators who has always been favorable to the creation of a National Bureau of Health. A bill looking to the formation of such a bureau was introduced in the last Congress by Senator Grey and was advocated by him, although in the press of other important matters it did not receive the attention it deserved. Should he be nominated and eventually elected, the medical profession would have an enthusiastic friend in the White House, and the creation of a Bureau of Health with a possible cabinet officer at its head, would be a possibility.

THE PUBLIC SERVICES.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from August 3, 1895, to August 9, 1895.

First Lieut. CHARLES F. KIEFFER, Asst. Surgeon U. S. A., is granted leave of absence for two months.

Major EZRA WOODRUFF, Surgeon (Ft. Keogh, Mont.), is granted leave of absence for one month.

First Lieut. WILLIAM F. LIPPITT Jr., Asst. Surgeon (Ft. Leavenworth, Kan.), is granted leave of absence for two months.

A board of officers, to consist of; Col. DALLAS BACHE, Asst. Surgeon-General; Major HENRY MCELDERY, Surgeon; Major JOSEPH K. CORSON, Surgeon, is appointed to meet at Ft. Robinson, Neb., on Friday, Sept. 6, 1895, for the examination of Capt. LOUIS W. CRAMPTON, Asst. Surgeon, with a view to determining his physical fitness for promotion.

A board of officers, to consist of; Major PHILIP F. HARVEY, Surgeon; Major GEORGE H. TORNEY, Surgeon, and Capt. CHARLES F. MASON, Asst. Surgeon, is appointed to meet at West Point, N. Y., Aug. 15, 1895, or as soon thereafter as practicable, for the physical examination of the cadets of the first and third classes; the cadets of the second class on their return from furlough, and such other cadets of the U. S. Military Academy, and candidates for admission thereto, as may be ordered before it.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending August 10, 1895.

Surgeon C. G. IERNDON, detached from Bureau of Medicine and Surgery, to duty on the "Lancaster."

P. A. Surgeon F. C. BATHWAITE, detached from naval hospital, Norfolk, Va., to duty on the "Lancaster."

P. A. Surgeon E. R. STITT, detached from special duty, and ordered to the "New York."

P. A. Surgeon J. F. URIC, detached from the "New York," and granted two months' leave.

P. A. Surgeon L. W. KITE, detached from the monitors, to duty on the "Franklin."

P. A. Surgeon L. L. YOUNG, detached from the "Franklin," to duty at naval hospital, Norfolk, Va.

ORIGINAL ARTICLES.

VAGINAL HYSTERECTOMY FOR PELVIC SUPPURATION.

Read in the Section on Obstetrics and Diseases of Women at the Forty-sixth Annual Meeting of the American Medical Association at Baltimore, Md., May 7-10, 1895.

BY EDGAR GARCEAU, M.D.

BOSTON, MASS.

In an old edition of Thomas' work on gynecology, the following sentence occurs: "A guarded prognosis should always be made as to the time of recovery in pelvic cellulitis, for no amount of experience can foresee the course of the affection; whether the effused *liquor sanguinis* will disappear by absorption in three weeks; whether the discharge of one abscess will end the patient's suffering; or whether a chronic induration will exist a great length of time."

The pathology of pelvic suppuration has undergone some modifications since this was written, but the prognosis, unfortunately, remains practically the same. Many women have the so-called "chronic induration" which makes them confirmed invalids, and in many instances bedridden. Various operations have been devised for their relief, and various treatments. Perhaps no branch of gynecology has received more careful attention than the one we are now considering. It has been made the subject of dispute and is now far from settled. What one surgeon approves of and practices, another derides and condemns, and yet the results of each may be the same. Under these circumstances it is apparent that any new method of dealing with this class of cases must of necessity be open to severe criticism before it is generally adopted. If to this is added the fact that such a method is attended with great technical difficulties the criticism becomes the more severe, and frequently it is condemned before it is even tried. Such has been the case with vaginal hysterectomy for pelvic suppuration. Inaugurated in France by Péan in 1886, it was received with opposition by the French surgeons, and it was only after repeated proofs of the efficacy of the method that it finally gained a foothold in Paris. At the present time it is the method of choice in cases of long-standing severe inflammatory disease of the appendages. The keynote of the operation is one word—drainage—good, free, unobstructed, surgical drainage. The abdominal route has been studied to the point of exhaustion. It was entirely overlooked that the vaginal route was the logical one, and why? Simply because it had never occurred to anybody to remove the uterus which was in the way so that there should be a large, unobstructed highway down which the pus could flow. So much care has been bestowed upon the appendages that the uterus escaped its share of attention. Not only is the uterus a mechanical obstruction in pelvic suppuration, but it also may be a constant source of

future danger to the woman by reason of germs which it may contain, and which may excite active inflammation at a subsequent period. Many a woman has been celiotomized over and over again for inflammatory trouble of the appendages without relief. Dr. Pryor, of New York, told me of a case in which celiotomy had been done seventeen times by various surgeons.

Jacobs' summing up of the operation and its indications is as follows: "Let us now review the indications for vaginal hysterectomy, beginning with the most difficult cases of suppuration complicated with adhesions. There is pus in the dilated tubes, in the ovaries, in the adjacent cellular tissue. The uterus is fixed, and the coils of intestines are glued together above these lesions like a solid roof. In such a case celiotomy displays the adhesions, which can not be separated without opening the bowels, with a chance that we may reach the purulent focus limited by them, open, empty and drain it; and the result may be that the woman will slowly recover, or that she will have an intractable fistula. Often we are confronted by a similar condition in which the pelvis is occupied by adhesions, in the middle of which the uterus is imprisoned, and yet without the presence of purulent foci. In such cases, owing to fear of accident, the surgeon is induced to relinquish the operation as an exploratory incision. It is, of course, always possible to finish the operation, but we have to consider the life of our patient. In just these cases vaginal hysterectomy gives results little short of marvelous—not wholly without danger, but with a security far greater than the abdominal. The collections of pus are opened into the vagina without infecting the peritoneal cavity; the adhesions are severed if possible, but should the finger encounter too great resistance they are abandoned and in a few days they will soften and become absorbed. In pelvic suppuration, and with extensive complicated adhesions, both equally formidable for the celiotomist, vaginal hysterectomy is triumphant."

Recently it has been the practice of many surgeons to remove the uterus as well as the appendages at their celiotomies, for suppurative disease, and the reason was because they found that their patients did not all get well when they removed only the appendages. Pathologic changes of the uterus certainly demand as much attention as those of the appendages. Possibly the reason they have been overlooked heretofore is the difficulty of recognizing their presence. A uterus affected with metritis, and not giving rise to any enlargement, is difficult of diagnosis. In comparatively simple cases the uterus and the appendages can be removed by the abdominal route very much more easily, and perhaps very much more quickly, than by the vaginal route; but to compensate for these advantages the degree of shock attending the vaginal operation is insignificant; added to

this is the fact there is no possibility of subsequent ventral hernia which makes the life of the patient so uncomfortable. In the operation of vaginal hysterectomy, the bowels are neither seen nor touched until the end. Special emphasis must be made in regard to the lesser degree of shock; it is one of the strongest arguments in favor of the operation.

In those cases in which pelvic suppuration is complicated with rectal, vesical or intestinal fistulæ, vaginal hysterectomy is the operation of choice. A celiotomy under such circumstances is always dangerous; but by the vaginal method the peritoneum is not soiled; the discharges flow down a natural incline, and the fistula closes by itself. The conditions are favorable for such a result, the healing being aided by cicatricial contraction of the pelvic contents *en masse*. It is rare that a secondary operation is needed. How great this cicatricial contraction is, may be inferred by the fact that in one of Ségond's cases, in which all the feces were passed *per vaginam*, complete closure of the fistula occurred spontaneously after a vaginal hysterectomy. But perhaps the most wonderful result of vaginal hysterectomy is the immediate disappearance of the inflammatory masses. There is no doubt whatever about this. The explanation is probably to be found in the excellent drainage and in the removal of the cause. There is no reason why cicatrization should be any different from that in any other part of the body. An almost analogous condition is to be found in appendicitis. Before operative methods were in vogue in treating this disease, its frequent recurrence was its most distressing feature; the appendix removed, the patient got well. Whether or not leaving behind the appendages, or parts of them influences the final result is perhaps at present unsettled; in most instances, however, it is feasible to remove them with the uterus.

And now a word in regard to the objections to the operation. It has been contended that it is unsurgical, that it is brutal, that it is blind, and that it is unsafe. Furthermore, it has been contended that hemorrhage is likely to occur during the operation; that the ureter and the viscera may be wounded. In regard to the first of these objections, it is not necessary to say much. They have been raised by men who know but little about it, and who have never seen it done properly. To see a skillful surgeon perform the operation is a pleasure. The steps are carefully followed; there is no embarrassment; there is no hemorrhage; and the operator sees exactly what he is doing at each step. The fundamental principle of the operation is never to work at haphazard. It is not a blind operation. If the operator has a hemorrhage it is his fault; if he makes a misstep he is lost, and he must be a skillful man if he would recover himself. The laws which govern the procedures must be as rigidly followed as an algebraic formula, otherwise there is no security against mishap. Heretofore, the operation of vaginal hysterectomy has been to get the uterus out in the best and quickest way possible, each individual operator having perhaps his own method, there being no special rules laid down, beyond the incision of the vaginal attachments and the securing of the broad ligaments. No one before Péan attempted to remove the uterus piecemeal, although the simplicity of the thing is evident on reflection.

In regard to wounding the bladder or rectum, it

may be said that this occurs not more often than in celiotomy with a skillful operator, probably not as often. Ségond has done the operation 400 times and he never lost a patient from hemorrhage. He opened the bladder three times; the wound was sutured at once and recovery followed. Nine times the rectum was opened; three times it was accidental, six times there was a preëxisting fistula; of these, two died several months after the operation from pulmonary tuberculosis; a third still had a small fistula, but it was a recent case; the other six recovered spontaneously without interference, notably the case already cited of the woman who passed all her feces *per vaginam* before the operation. Ségond in all his 400 cases never clamped the ureter once. He uses a special incision in incising the vagina, which gives more room and at the same time allows the ureter to slip away from the bite of the forceps. The viscera can not be injured if the retractors of the Péan model are used. They are long, flat blades which raise the bladder and rectum away from the cutting instruments, and if properly used are an absolute safeguard against accident.

Statistics are unsatisfactory and to many they are no proof; yet in what other way shall we judge the merits of a new method? Jacobs' are among the best. He has done the operation of vaginal hysterectomy for double inflammatory diseases of the appendages 166 times; he had 162 recoveries and 4 deaths—a mortality of 2.4 per cent. On analysis we find that in 113 there were double purulent collections; of these 111 recovered and 2 died—a mortality of 1.8 per cent. The bladder was perforated twice, the intestines once; the opening was closed and no fistula resulted. In ninety-eight of these recoveries the patient was followed for a period varying from one to four years; eighty-eight were absolute cures; of the others a few suffered somewhat from vesical disturbances due to adhesions, and a few from pelvic pain; a few were not relieved at all.

Péan's results are even better. His first 150 cases all recovered with but one exception; she was moribund at the time of the operation. But perhaps the most instructive cases are those of Landau's. He always does celiotomy when there appears to be a chance of succeeding, reserving the more difficult operation of vaginal hysterectomy for those cases of suppurative disease which, if attacked by the abdominal route, would prove perilous to the patient. "These are cases complicated with rupture of the tube into the bladder, rectum, or intestine; reference also is made to multiple abscesses which are intra- or extraperitoneal." He has done thirty cases of this sort without a single death. It is questionable if statistics of celiotomy can compare favorably with these.

In a short paper of this kind anything but a brief description of the operation is impossible. In the first place, a word about clamps. In a case of adherent uterus they must be used; ligatures will not do on account of the impossibility of securing them properly beyond a certain depth in the vagina. But in cases in which the uterus is low down, for instance, a retroversion with disease of both ovaries requiring removal, ligature holds the preference because of the greater comfort to the patient. Dr. E. W. Cushing, of Boston, has devised a method of ligating the broad ligament which I would like to refer to here because of its neatness, and because it avoids entirely a sloughing stump in the vagina. After amputating the uterus,

which in a simple case can be done in a few minutes, he draws down the broad ligament of one side into the vault of the vagina. Then he passes his needle through the upper edge of the vaginal incision near the outer angle, and then encircles the uterine artery, which has been temporarily held by a clamp; he then finishes the stitch by emerging at the lower edge of the vaginal incision. The uterine artery is thus firmly ligated, and at the same time the ligature closes over the stump of the broad ligament by approximating the lower and upper edges of the vaginal incisions. The rest of the broad ligament is secured in the same way, on each side, by additional ligatures, two or three more being required. The ovarian artery is ligated separately. By this means the vault of the vagina is closed with the exception of a small hole through which a piece of iodoform gauze is thrust for drainage. Necessarily this method is applicable only to those cases in which there is no pus. In cases in which the uterus is adherent and high up, and in which there may be pus on one or both sides, the following method of operating is the one to be adopted:

Briefly it may be described as having three stages; 1, removal of the inferior segment of the uterus; 2, removal by morcellation of the anterior wall of the uterus; and 3, eversion anteriorly of the stump.

The patient lying on the back, four retractors are put in position, one on each side, and one anteriorly and posteriorly. The cervix is now seized with a bullet forceps and a circular incision is made around the cervix; an additional incision is made on each side parallel to the lower border of the broad ligament, two-thirds of an inch long; it gives more room and protects the ureter. Directly the incision is made, the top of the anterior retractor is forced into the wound and pulled upward and backward along the cervix. The sectioned tissue yields a good deal—surprisingly so in fact—and it is just this maneuver that makes the Péan instrument of so great value. While the retractor is pulling back the tissue, blunt-pointed, curved scissors separate by short snips the attachments between the bladder and uterus; with each snip of the scissors the retractor takes a fresh hold, being introduced into the part just cut by the scissors. The finger will sometimes help a great deal in the dissection. Having separated as much as possible in front, the same should be done behind. The forefinger of the left hand is now placed on the anterior surface of the cervix and glides along outward toward the base of the broad ligament; it penetrates between the anterior peritoneal fold and the ligament proper and pushes aside the ureter. The same is done behind. Then two fingers grasp the broad ligament and serve as guides to the first forceps, which seizes the ligament at least an inch from its lower border. The ligament is then cut the whole length of the forceps close to the uterus; the same is done on the other side. The cervix is now split transversely from side to side up to the point of the forceps; two flaps are thus made, an anterior and a posterior. The posterior flap is now amputated and strong forceps seize the anterior flap and pull it downward; the uterus begins to roll anteriorly, thanks to the void which has been created behind by the amputation of the posterior flap. At the same time fresh separation is effected between the uterus and the bladder. The anterior flap is then amputated. If the uterus is not very adherent it may be pos-

sible to make two more flaps which are amputated in the same way after preliminary hemostasis of the broad ligament. But if the uterus is very adherent, the rest of the operation deals with the anterior wall of the organ. Placing a bullet forceps on each side of the canal, the stump is pulled down as much as possible and separation effected between bladder and uterus. After separating as much as feasible, the anterior uterine wall is morcellated in the median line in small pieces. The part removed should include all the tissue down to the uterine cavity. Two more bullet forceps are now inserted on the upper parts of the edges of the excavation; renewed traction is made, more denudation effected and morcellation carried higher up. By repeating the process the peritoneal cavity is reached. The uterus may now be hooked with the finger and everted anteriorly with ease. It is a simple matter to clamp the rest of the broad ligament and to remove the organ. In many instances the appendages are dragged into the vagina and are clamped separately.

If, during the operation, a pus sac has been opened, the operator waits until the flow ceases, then washes out the cavity and proceeds exactly as before. But if it has not been opened, it must be searched for with the finger, for, if undiscovered, it will cause further trouble.

When it is possible to remove the appendages it is proper to do so; otherwise they may remain behind and in the majority of cases will cause no trouble.

The dressing consists of iodoform gauze placed above the tips of the forceps and between them and the vaginal walls. The forceps are removed in forty-eight hours; the gauze not until the sixth day. Pain is controlled with morphin, and in three weeks the patient is up.

The following case which came under my notice is typically illustrative of the sort of patient that is cured by vaginal hysterectomy:

M. J., 29, 2-para, was admitted to the Broca Hospital Aug. 12, 1894. Ever since her last confinement, three years before, she had been suffering from inflammatory pelvic trouble which had confined her to bed most of the time. The longest period of quiescence was three months; the rest of the time she had been practically bedridden from pain and prostration. She had had four attacks of pelvic peritonitis which were severe, the last one eight days before entering the hospital. Examination showed a uterus which was fixed, immovable, and surrounded by inflammatory adhesions; on the right, a mass the size of a good-sized fist filling the pelvis and impinging on the rectum; on the left, a smaller mass. Vaginal hysterectomy was done by Pozzi's first assistant, Dr. F. Jayle. No pus was found. There was no shock to speak of, although the operation lasted over an hour. In three weeks the patient was completely well, suffering no pain and walking about.

I had examined the woman before the operation and easily made out the large masses; when I examined her again, three weeks after the operation, I was astounded to find that on the left side almost nothing remained, and that on the right side there was only a mass the size of a small hen's egg. She told me that she was perfectly well and she looked so, and yet both ovaries and tubes remained behind.

I can not refrain, in conclusion, from referring briefly to the further scope of the vaginal route in dealing with pelvic diseases. In the pre-antiseptic

days it was the only route, and the impunity with which ovaries could be removed through an incision in Douglas' pouch served to put Battey's operation on a sound basis. Not only were ovaries of normal size removed in this way, but also tumors of considerable size. Dr. W. H. Baker, of Boston, assures me that before the celiotomy period he had several times removed a dermoid or other cyst of the ovary through an incision behind the uterus. Perhaps the most prominent advocate of the vaginal route in this country is Dr. Polk, of New York. It was a pleasure, a few weeks ago, to see him operate on a woman who had a cyst of the right ovary the size of a hen's egg. Her left ovary had been removed some time previously by celiotomy and she was much averse to having her abdomen opened again. Most women would be. An incision was made in the posterior vaginal wall close to the uterus, and the peritoneal cavity was soon reached. By means of two large retractors, made after the Ségond model, the operative field was clearly exposed and the cyst brought into view. A few adhesions were readily freed with the finger and the cyst aspirated. The sac was then grasped with a fenestrated forceps and removed. It proved to be a cyst of only a portion of the ovary. Enough of the ovary was left behind to assure the continuance of the catamenial flow. A bit of gauze was thrust into the wound and the patient put to bed. The operation took perhaps fifteen minutes to perform.

Dr. Polk told me that he treats extra-uterine pregnancy in the same way. He never fears hemorrhage, for it is a simple matter to clamp the ovarian artery which supplies the sac. His method is to introduce his forceps along the finger as a guide; to pierce the middle of the broad ligament with one jaw of the forceps, while at the same time the forefinger seeks the top of the broad ligament and protects the intestines, preventing them from being caught in the forceps. The clots may now be turned out at leisure and the cavity washed out. There is no shock to speak of.

In the same way, Jacobs, of Brussels, has removed a very large ovarian cyst, tapping it through the vagina and tying the pedicle, very much as in a celiotomy. Fibroid tumors of the uterus can safely be removed through the vagina. Here the laws of morcellation as set down by Péan must be closely followed, otherwise the operator will be disappointed in his results. A skillful operator has a mortality of almost nothing. It has been shown that fibroids reaching even to the umbilicus may be safely removed by this method. The mortality in 400 cases of fibroids of all sizes was 1.7 per cent.

From these facts it seems as though, in the near future, there must be fewer celiotomies and more vaginal work. The technical difficulties encountered in performing operations through the vagina will perhaps delay the adoption of the method for a time at least, but as the experience of those who are firmly convinced that it is the route of choice in selected cases accumulates, the vaginal route will become more and more popular, and will finally be assigned the place which rightfully belongs to it.

POTABLE SEA WATER.—The salts may be removed from sea water by drawing it, by means of a vacuum pump, through a block of wood in the direction of its fibers.—*Western Druggist.*

THE TREATMENT OF THE STUMP IN OOPHORO-SALPINGOTOMY—A NEW METHOD.

Read in the Section on Obstetrics and Diseases of Women, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, May 7-10, 1895.

BY L. H. DUNNING, M.D.
INDIANAPOLIS, IND.

There are three serious objections to the method almost universally employed of treating the pedicle and stump in the operation for the removal of the Fallopian tubes and ovaries. They are:

1. In consequence of many adhesions of the tubes and ovaries and the inelastic condition of the broad ligament, it is not infrequently difficult, indeed, impossible to form a pedicle without producing so much tension upon the extremities of the stump as to render them prone to retract and thus loosen the ligature, or even to pull away so far as to leave unprotected a raw surface, which is liable to bleed, or if the tissues do not retract, the tension may be so great as to induce cutting of the tissues by the ligature and thereby lead to oozing or active bleeding. Again, by the *en masse* ligature it is sometimes found impossible to include the Fallopian tube near the uterine cornu.

2. The constriction of the nerves included in the *en masse* ligature is a source of pain, which will sometimes persist for many days or even weeks.

3. An incised surface is left exposed to engender adhesions, which, if formed, result in painful action or occlusion of the bowels. This is a grave objection to the method and one generally acknowledged. The milder forms of adhesions are a prolific source of pain and obstinate constipation, so serious indeed, in some instances as to demand a second operation for their relief, while not infrequently the intestine will so adhere as to lead to ileus and death, if prompt interference is not instituted. Three cases of obstruction of the bowels, the results of intestinal adhesions to the stump, have been reported to our local society within the last two years. One of the cases occurred in my own practice, one in the practice of a colleague in which I assisted in re-opening the abdomen, to find a coil of intestine so attached to the stump as to induce an acute flexion of the intestine and complete occlusion, and the third one resulted from an operation done by a member of this Section.

Various methods have been resorted to, to avert the danger of adhesions, such as the cauterization of the stump and cutting out a wedge-shaped piece from the distal end of the stump and turning the raw surfaces in by sutures. That cauterization is not efficient is demonstrated by the fact that in two of the cases above referred to this plan was adopted. It is seldom possible to turn in raw surfaces, because the ligatures can not be applied far enough away from the tubes and ovary to leave sufficient tissue beyond the ligature to make the procedure a safe one.

For two years the writer has been earnestly striving to devise some method that is safe and free from the objections of the *en masse* method. He does not claim to have found a method safe and applicable to all cases in which it is necessary to remove the tubes and ovaries. He does claim, however, that when the method he proposes is applicable it is far superior in its results to the older method.

The method is as follows: after proceeding in the operation in the usual manner until the adhesions

are so far broken up as to permit of the tubes and the ovaries being brought into view, the uterus is lifted up toward the abdominal incision by the instrument presented by the finger of an assistant making pressure through the vagina. A provisional ligature is thrown around the Fallopian tube, close to the uterus. With scissors, the tube is cut off beyond the ligature, the severed end is seized by the thumb and finger of the left hand, gentle traction is made upon it, while with a pair of blunt-pointed scissors or knife, the tube is cut away by severing the mesosalpinx close to the tube. After its removal, one or two small arteries will be found spurting. They may be caught with forceps and tied with fine catgut. The ovary may now be taken in hand and its attachments to the broad ligaments severed close to the organ. Here, if one or two small arteries spring, they should be securely tied. Now with a straight needle threaded with fine catgut, begin at the outer margin of the incised surface, and with a running stitch close in all the raw surfaces, using the Lembert stitch.

This completed, tunnel out the uterine end of the Fallopian tube and close in the raw surfaces by one or two stitches of fine catgut. Then remove the provisional ligature. Proceed upon the opposite side in a similar manner. A dextrous and rapid operator will require from five to eight minutes to accomplish this work, if both sides are treated in the same manner. The writer has effected it in three minutes upon one side. It requires a slightly longer time than the *en masse* method, and this may be an objection to it in some rare instances, when rapidity of work is demanded on account of the critical condition of the patient.

The method is not easily applied, when for any reason the uterus can not be brought up near the abdominal incision. This may be the case when the operation is done during the acute stage of pelvic inflammation. In these cases, I question the propriety of energetic efforts to elevate the uterus. In two instances of this kind I have employed the method with satisfactory results, though through a somewhat longer incision than is necessary by the *en masse* method. When there are gross adhesions of the appendages and the uterus, these should be broken up before the uterus is elevated. Ordinarily no difficulty is experienced in this procedure. The vagina should be disinfected before bringing the patient to the operating room. As a preliminary step, the stem may be introduced into the uterus by an assistant before beginning the section, and held in a position ready for use when the adhesions have been liberated.

A large-sized urethral sound may be used instead of the elevator, or the finger of an assistant may elevate the uterus. The elevator I show, however, is superior to these means, for the reason that it gives better command of the position of the uterus. In two instances, I have employed this method without elevating the uterus. In such cases more difficulty was experienced in tying the arteries and in closing in the raw surfaces. For the latter purpose, short curved needles were used, carried by a needle holder, whereas when the uterus is elevated, a straight needle carried by the fingers is the preferable and the quicker course to pursue. The advantages claimed for the method are, that by means of it, the pain following the operation is much less than by the old method and there are left no exposed surfaces to engender adhesions.

The writer has employed it now nine times with great satisfaction in each case. A brief history of four cases are given, to show that the method has a considerable range of applicability:

Case 1.—Mrs. A. was operated upon at her home near Frankton, Ind., with the assistance of Dr. Coverly, of Frankton and Dr. H. E. Jones, of Anderson, May 22, 1893. There were found on abdominal section, a small ovarian tumor upon each side, a pyosalpinx upon the right side and a malignant disease affecting the omentum and mesenteric glands. It was found impossible on account of dense adhesions to lift the tumors out of the pelvis or to discover a pedicle. A circular incision was made around each tumor near the base, but only through the outer coat of the cyst wall. This incised portion was pressed downward and finally the hand slipped under the tumor, when it was lifted out of the pelvis and the left one delivered without rupturing. The right one was ruptured in attempting to deliver it through the abdominal incision.

Two arteries spurted upon each side, and were secured with difficulty. The Fallopian tube upon the right side was severed near the cornu and was removed by cutting the mesosalpinx near the tube. Two small arteries were seized and tied and the raw surfaces turned in by two or three catgut sutures. There was quite an amount of oozing from surfaces caused by separating adhesions upon the right side, so strips of gauze were packed into the pelvis, effectually checking the hemorrhage. The malignant neoplasms could not be removed. The abdomen was closed in the usual way. The patient made an easy recovery from the effects of the operation. In this case the method greatly simplified the operation. It would, however, have been more difficult had we not employed a long incision.

Case 2.—Mrs. B., a colored woman, was operated upon by abdominal section at the regular Wednesday clinic Oct. 17, 1894, at the Indianapolis City Hospital in the presence of the hospital staff of assistants and about one hundred and fifty students. There were gross adhesions. After enucleating a small intraligamentous cyst from each side and a small fibroid tumor from the uterus, one Fallopian tube was found to be distended by pus. The tube was so bound down by adhesions as to make it difficult to form a pedicle, so the cornual end was tied with catgut, the tube cut off beyond the ligature, the severed end seized and the mesosalpinx severed near the tube throughout its entire length. But a single artery spurted. This was tied and the raw surfaces turned in as in the former case. The cornual end of the tube was tunneled out and the edges turned in and sutured. The patient made a good recovery.

Case 3.—Mrs. C., aged 32 years, was operated upon by abdominal section at my private hospital March 14, 1895, in the presence of Dr. Potter and my assistants. This was a case of recurrent diffuse pelvic inflammation of many years' standing. The uterus was retroverted and adherent. The tube and ovaries were prolapsed and adherent. After separating the adhesions the uterus was elevated by an assistant making pressure from below with a finger in the vagina. The appendages were examined and those upon the left side found so much diseased that their removal was deemed advisable. They were extirpated with ease and expedition by the method described above. The fundus was anchored to the anterior abdominal wall by two silkworm gut sutures passed through each horn of the uterus and up through the abdominal wall and fastened to a button upon the external surface of the abdominal wall. The ease with which the operation was done, the freedom from pain and the easy recovery of the patient were most gratifying.

Case 4.—Miss D., a young woman aged 23, was operated upon at my hospital April 24, 1895, in the presence of Dr. Mauk, of Cambridge City, Ind., and Drs. Pfaff and Ferguson, of Indianapolis. The case was one of diffuse pelvic inflammation of three months' standing. There were many firm adhesions. The right tube and ovary were liberated and brought up with considerable difficulty. But little difficulty was experienced in elevating the uterus. The method as described was employed in all its details except that interrupted catgut sutures were used to close in the cut surfaces, and with the addition that the uterus was tilted to one side by making traction upon the provisional ligature. This, to some extent, facilitated the work.

We found it necessary to tie but two arteries and they were small ones. The ease with which the complete removal of the ovary and the tube can be effected was well illustrated by this case. It would have been difficult if not impossible,

to have applied the *en masse* ligatures so as to have removed the whole of the ovary.

This proved to be a pus case (pyosalpinx), and the wisdom of the provisional ligature and subsequent tunneling of the cornual end of the tube was exemplified. The left Fallopian tube and ovary, though imbedded in adventitious tissue were when brought out of the incision and examined, thought not to be sufficiently diseased to demand their removal, so they were dropped back and the abdominal incision closed. The patient is making an easy recovery.

In conclusion, I wish to say, that my experience with the method in the nine cases in which it has been employed has been most gratifying. The pain experienced by the patients has been much less than it has been in other cases in which the old method has been employed. There has been no case of secondary hemorrhage or adhesion to the stump. In some instances, in which the patients are prone to hemorrhage, I should be cautious in employing it; indeed, I abandoned it in one case, where much hemorrhage resulted in cutting the mesosalpinx.

If the hemorrhage does not cease after tying the arteries, a pedicle can be easily made and the whole secured by the *en masse* ligature. In one or two instances after cutting away the tube, the mesosalpinx has retracted. Some trouble was experienced in securing the arteries. This occurrence may be avoided by seizing one edge of the severed mesosalpinx with a tissue forceps. I am sure if the method yields as good results in other hands as it has in mine, the *en masse* ligature will hereafter be employed only in special cases.

THE ETIOLOGY AND TREATMENT OF INFLAMMATIONS OF THE UTERINE APPENDAGES.

Read in the Section on Obstetrics and Diseases of Women, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY AUGUSTIN H. GOELET, M.D.

GYNCOLOGIST TO THE WEST SIDE GERMAN CLINIC, ETC.
NEW YORK.

For some years past the surgical tendency of the gynecologist has completely overshadowed the rational treatment of diseases of the uterine appendages, and may be regarded as a confession of inability to cure; for it can no more be claimed that ablation of organs so important to the female economy is a cure of the morbid process, than amputation of a limb is a cure of the injured or diseased member.

General surgery has passed this stage of wholesale sacrifice of useful members, and to-day the saving of an injured limb is more creditable to the surgeon than a skillfully performed amputation. Gynecology must soon pass this stage also, for the limit of extreme pelvic surgery has been reached and the sad plight of the woman (?) who has survived the removal of her ovaries, tubes and uterus is beginning to be realized. I venture to predict that the gynecologist who saves the greater number of tubes and ovaries within the next ten years will win greater renown than he who removes the most. Any one who has had experience with diseased appendages will admit that it is much easier to remove them than to attempt to bring about resolution of the morbid process and save them. The same is true of a badly crushed arm or leg. But which is the more credit-

able procedure and which would you prefer to adopt, if the patient was your own wife or daughter?

The contention is not that these inflammations of the tubes and ovaries can always be cured, but that it is frequently possible, and that unless immediate operative interference is actually demanded, the patient should be given the chance and the attempt should be made before submitting her to a radical operation. In view of the fact that treatment directed toward attaining this end does not militate against a subsequent operation for their removal, should it become necessary, but on the contrary, improves the chances of an ultimate successful result—it is a perfectly rational procedure and one which should always be adopted. Remember, that once removed they can not be replaced.

In the light of recent developments in the etiology and pathology of inflammations of the appendages, is not the removal of these organs without previous attempt at a cure or removal of the cause which may be operating to maintain such a condition, to be regarded as a serious error? It would certainly be more rational to institute measures, first, which will bring about a cure of any disease of the uterus or other pelvic organs which may be acting as a maintaining cause. It will be asserted that this is the course usually pursued and that no case is submitted to a radical operation unless it is absolutely certain that it is the proper procedure to be adopted. But is this strictly true? Is it not a fact that tubes and ovaries are being removed every day without any previous effort on the part of the operator to cure the disease or remove conditions which may be producing it? It may be true that not so many are sacrificed now as a few years ago, but they are still removed too often for disease which is amenable to patient and persistent treatment, or which may be cured by a minor surgical operation, involving no risk, such as curettage or repair of a lacerated cervix.

My purpose, in presenting this subject for your consideration, is to show how many of these conditions are curable where a radical operation is usually believed to be necessary, and I will relate briefly the histories of some cases, which are conspicuous examples, substantiating this statement.

It will not be possible, in a brief paper like this, to consider these conditions in other than a general way, for to go into the details of the different stages of the morbid process would consume too much time.

Clinically, inflammations of the uterine appendages may be divided into salpingitis and ovaritis, for though they are often so intimately associated as to render their separation impossible, yet it is sometimes true that either the one or the other (tube or ovary) is more distinctly involved and demands separate consideration. It is quite impossible to institute rational and successful treatment without first ascertaining both the direct and indirect cause of the morbid process. Usually, the cause of salpingitis is readily ascertainable, but that of ovaritis is often remote and obscure. It is evident, therefore, that it will be more satisfactory to consider them separately in outlining the plan of procedure to be adopted.

Salpingitis will be divided into catarrhal, and that due to septic infection from the extension of a similar inflammation from the endometrium. Catarrhal salpingitis may occur coincidentally with a catarrhal

endometritis without previous existence of the latter, and occurs as a result of imprudence which precipitates suddenly and frequently a marked pelvic congestion or engorgement. In this respect it differs from inflammation due to septic infection as well as in another very important particular; viz., that it is less virulent and it is consequently more readily controlled. I believe that it seldom occurs as an acute inflammation but that in the beginning it rather partakes of the nature of the, so-called, subacute process which is simply a hyperemia attended with hypersecretion from the mucous membrane. As a result of continued and repeatedly provoked hyperemia, a chronic inflammation of the mucous membrane is developed which may eventually involve the deeper tissues and produce structural changes. It is possible that the secretions may accumulate in the tube and produce distension, since the caliber of the uterine end of the tube becomes obstructed in consequence of edema and infiltration of the mucous membrane. The abdominal ostium must also become obstructed to permit distension and this occurs no doubt in a similar manner. Such tubes are frequently mistaken for pyosalpinx or hydrosalpinx and removed. I am satisfied that hydrosalpinx when formed on one side only, with the other tube in good condition and functioning, is frequently produced in this manner and is rather the result of chronic catarrhal inflammation than septic infection from the endometrium. Acute exacerbations may occur when the tube is the seat of chronic catarrhal inflammation which may readily be mistaken for a primary acute salpingitis. The process is rather a perisalpingitis due to an extension of the inflammation from the interior of the tube. Such cases may present to a most rigid examination all the appearances of inflammation due to septic infection, and the appendages are often found to be surrounded by exudation if the inflammatory process has been going on for some time. This is the difference, however,—it yields more readily to treatment. This may be due to the fact that the structural lesions are not so extensive.

As a proof of what has been said, we often find the appendages the seat of chronic inflammation and surrounded by more or less exudation in cases where there has been no chance for infection and there is no history of an acute stage having preceded it.

On the other hand, inflammation of the tubes, due to septic infection will be ushered in by an acute inflammatory process of marked severity which must occur sooner or later after infection of the endometrium and as a result deep structural lesions occur early. When they are extensive and especially when due to gonorrhoeal infection, there is little chance of producing resolution by any method of treatment. The inflammatory process, which first involves the mucous membrane by extension from the endometrium, rapidly spreads to the muscular structure of the tube walls, and even to the peritoneal covering. The abdominal ostium is obliterated early and drainage into the uterus is prevented by infiltration of both the mucous membrane of the tube and the uterus, and also of the muscular structure. This obstruction may or may not be permanent; this depending upon the extent of the lesions produced. Some authorities contend that the uterine end of the tube is seldom occluded, but that the obstruction due to infiltration may be overcome and the tube drained

into the uterus. I believe that when the inflammation has subsided in the tube and it has become distended, the obstruction at the uterine end is often maintained by hypertrophy of the endometrium, surrounding the orifices of the tubes upon its surface, and that it may be overcome by removing this condition. When this is possible and drainage can be maintained a cure is possible, though the function of the tube may not be restored. If, however, actual occlusion of the uterine end of the tube has occurred, drainage can not be established and a radical operation is imperative if there is much distension. Cases where the tube is bent upon itself, prolapsed and is adherent, come under this head.

Ovaritis exists as an acute or chronic inflammation and is frequently a sequence of salpingitis, though it sometimes occurs independently of this condition. The lymphatics may convey infection directly from the uterus to the ovaries and thus septic inflammation may result there independently and without involvement of the tubes, though this is rare.

The acute form may occur coincidentally with salpingitis, being produced by the same causes, but a condition of hyperemia and hyperaesthesia which is sometimes regarded as an inflammation, frequently results from imprudences during menstruation, too frequent and excessive coition, ungratified sexual excitement and constipation.

Structural changes, characteristic of chronic inflammation, may result from the acute stage, but chronic ovaritis does not often follow the acute process. Most frequently it begins insidiously and develops gradually from this condition of hyperemia. Probably one of the most frequent causes of chronic ovaritis is laceration of the cervix during parturition, with consequent infection through the medium of the lymphatics which are well known carriers of infection. It is a well established fact to my mind that this lesion, if unrepaired, is a constant source of irritation which reflects upon the ovaries and maintains in these organs a state of hyperemia and hyperaesthesia. Further on, I will relate several instances of this kind, where a cure was effected by repair of the cervix.

Chronic ovaritis may exist as a condition of atrophy, hyperplasia or cystic degeneration, but the term is most frequently applied to a condition of passive hyperemia which, if unrelieved, may result in hyperplasia. This may be produced by the causes mentioned above or by any other source of irritation of the uterus, such as endometritis or growths within the uterus, especially if located in the cervical canal, such as small polypi. Fissures of the anus, ulceration of the rectum and chronic proctitis are also frequent causes of ovarian irritation and hyperemia which are often overlooked.

Any treatment, which has for its aim the establishment of drainage of diseased tubes into the uterus, the removal of the hyperemia and infiltration and the absorption of the surrounding exudation may be regarded as a perfectly rational procedure, and one which should be adopted, when possible, in preference to their removal. If this object can be accomplished (and it is frequently possible), a cure may be effected and the woman will be restored to a life of usefulness and happiness.

If this much will be admitted, the principal thing to be considered is the best manner of accomplishing this result.

When salpingitis is found to be associated with a severe type of chronic endometritis, with an hypertrophied or granular condition of the mucous membrane, the first step in the treatment should be dilatation of the canal, thorough curettage of the cavity of both the body and the cervix, followed by packing with iodoform gauze to secure thorough depletion and drainage. Especial care must be observed in removing the hypertrophied membrane from the vicinity of the internal os and both cornua. This latter is best secured by using a small size curette which will reach up in the angle at the entrance of the tube and should be employed after the cavity has been gone over by an instrument of larger size. The removal of these granulations or hypertrophied elevations of the mucous membrane about their orifices facilitates drainage from the tubes in the same manner as removing the superfluous granulations about the entrance of a fistulous canal. They obstruct drainage in the same manner. A sharp curette may be required for removing the hypertrophied tissue at the internal os. The extent of dilatation required is not nearly as great as is usually considered necessary. A moderate dilatation under anesthesia gradually accomplished by means of the steel dilator, sufficient for the easy introduction of the curette, is all that is necessary. The gauze packing, if carefully done, will effect still further relaxation. Divulsion is unnecessary and should never be done.

The technique of the operation is important and is as follows: the vagina and vulva are first rendered aseptic, then after sufficient dilatation has been accomplished the double current irrigator should be introduced and the cavity thoroughly cleansed with either a solution of bichlorid (1 to 4000), or what I often prefer, a 1 per cent. solution of lysol (hot). Then the cavity is curetted and again irrigated with the same solution until all oozing has ceased. The cervix is now fixed by a double tenaculum and a strip of 20 per cent. iodoform gauze, the absolute sterility of which has been previously assured, is introduced by means of a long applicator forceps, here shown, and carried well up into both cornua, the cavity filled and the cervical canal also. The gauze is cut into strips one yard long, and three-fourths to one inch wide. Usually, the whole strip can be packed into a uterus of moderate size. The vagina is then filled with wider strips of the same gauze and an aseptic pad is placed against the vulva. The patient is to be confined to bed while the gauze remains in the uterus. Usually, a week is sufficient for this part of the treatment. Instead of permitting the gauze to remain undisturbed in the uterus for several days, which is the practice of some gynecologists, I deem it necessary to remove it every twenty-four hours, at least; for it ceases to drain when the gauze in the vagina becomes saturated. Upon removing it, the cavity of the uterus should always be irrigated with a hot 1 per cent. lysol solution and the gauze is re-applied as described above.

Let it be understood, both by the physician and the patient, that the operation and the subsequent gauze packing is only to be regarded as a preliminary step in the treatment, and that it is necessary to maintain free drainage from the uterine cavity and tubes, remove all sources of irritation and institute measures which will promote absorption of surrounding exudates and relieve the engorgement of the pelvic vessels. To accomplish the first end, a patu-

lous condition of the cervical canal must be preserved and the uterine cavity must be kept free from all *débris*, such as small clots and particles of mucus, which, if retained, would be a source of irritation. This is accomplished by the occasional introduction of a small (clinical) irrigator and washing out with a 1 per cent. solution of lysol; or Thiersch's solutions may be used if an astringent action is desired. I never use anything else and never employ iodine or carbolic acid in these cases. If the canal becomes too much contracted to permit the easy introduction of the irrigator, it is connected with the negative pole of the galvanic current as an electrode and about 10 milliampères turned on. This will facilitate its introduction and if the current is allowed to remain on during the irrigation it exerts a stimulating action upon the endometrium through the medium of the liquid projected through the irrigator.

The second object (the absorption of exudates and the restoration of the normal circulation of the pelvis) is accomplished by the persistent application of the faradic current of high tension, made sufficiently stimulating to suit individual cases. I know of no better way of accomplishing this end and nothing which I have employed has given such prompt and satisfactory results. It serves a double purpose in these cases, since it not only quickens the capillary circulation and hastens absorption, but by stimulating contraction of the tube walls and the uterus, it favors evacuation of the tubes into the uterus and empties the uterus as well.

In some of these cases it is better to institute some preparatory treatment before the operation which will relieve the extreme sensitiveness, lessen the surrounding congestion and remove the infiltration and exudation, and for this purpose I employ the fine wire faradic current to great advantage. At the same time, the bowels should be kept relaxed and the patient's diet and digestive apparatus must be regulated.

Under this plan of treatment it has frequently happened that tubes which were considerably distended have been evacuated while the gauze was in the uterus and they have not refilled. In other cases evacuation does not occur until after the packing has been discontinued and the stimulation of the faradic current is employed. The probable explanation is, that in some instances, the barrier to drainage from the tubes is infiltration of the tube walls, or the pressure of surrounding exudation, which is removed by this latter method of treatment. Faradic stimulation here promotes the evacuation of the tube into the uterus, by exciting contraction of the tube walls, which is vermicular and in the direction of the uterus.

When salpingitis is associated with a simple catarrhal endometritis, curettage is not needed. The occasional introduction of a conical dilating electrode connected with the negative pole of the galvanic current (10 to 15 m.) to render the canal free, and favor drainage from the uterus, together with frequent applications of the fine wire faradic current to relieve engorgement of the pelvic vessels and promote the removal of infiltration of the mucous membrane will give satisfactory results in the majority of cases. When the secretion is abundant and does

NOTE:—In a paper which I read recently before the New York Academy of Medicine upon the "Physiologic Effect of Periodic Induced Currents," the exact manner of their action in bringing about these results was clearly explained.—See American Medico-Surgical Bulletin, April 15.

not drain away readily, it will be better to irrigate the cavity twice a week with a warm lysol solution by means of the small clinical irrigator, followed each time by faradic stimulation with the fine wire current. This may be done at the office and after a short rest the patient may be permitted to return home. It is astonishing what immediate and lasting relief this treatment affords the patient. If she comes into the office with a dragging sensation in the pelvis and a tender painful condition about the uterus she is immediately relieved by washing out the uterus, because the source of the irritation, retained secretions within the uterus, has been removed. Frequently the symptoms do not return for several days.

Some care is necessary, however, in carrying out this treatment, to avoid provoking undue irritation in introducing the irrigator and washing out the uterus. No force should be employed, but first ascertaining the direction of the canal, the instrument is inserted as far as it will enter readily which is usually up to the internal os, then the current is turned on and it is allowed to slip in under very gentle pressure. The irrigation should be continued until it is absolutely certain that everything has been washed away and the cavity is clean. Then the inflow of the solution must be stopped and that remaining in the cavity of the uterus must be permitted to drain away through the return flow tube of the irrigator before it is removed. The cavity is thus left perfectly clean and empty.

The treatment of ovaritis consists in removing the source of irritation or the cause when ascertainable, as far as possible. When it is associated with and dependent upon an endometritis or salpingitis, these should be treated in the manner described above. When dependent upon an injured or diseased cervix it must be repaired or removed. If it is found that the rectum is the seat of disease, or there is fissure of the anus, it must be cured before we can expect to relieve the ovarian irritation.

Relief of the symptoms may be afforded by treatment directed to the ovary alone, but it will only be temporary and not permanent until the cause of the irritation is removed.

I recall many instances where patients suffering with ovaritis have been brought to me by their physicians who had employed electricity for months without permanent benefit, and it has been found that the cause of the condition has been disregarded and overlooked.

In employing this agent in the treatment of ovaritis, the preference is to be given to faradization in the majority of cases, because it affords quicker relief of the pain and the result is more satisfactory, especially if the condition is one of hyperemia with infiltration or exudation. In conditions of hyperplasia, galvanism or a combination of the faradic and galvanic currents is more appropriate and gives better results. In employing the galvanic current for these conditions a moderate strength continued for a longer time produces the best effect.

The importance of discriminating in the choice of the current to be employed in certain conditions of ovarian inflammation, as well as the necessity of removing the cause of the irritation, is well illustrated in the following case:

Case 1.—The patient, a young girl of 18, had been for over a year under the care of a prominent gynecologist in New York for ovaritis. During this time he had persistently em-

ployed the galvanic current, and failing to derive any benefit therefrom he suggested removal of the ovary as the only possible means of relief. She was then brought to me and began to show immediate improvement when the fine wire faradic current was substituted. But no permanent benefit was obtained until the rectum and anal orifices were restored to a normal condition. The cause of the ovarian irritation and hyperemia proved to be an inflamed rectum, with fissure of the anus, associated with obstinate constipation. Two years have now elapsed, there has been no return of the trouble and the patient is in excellent health.

The digestive apparatus is often at fault in these cases and constipation is frequent and annoying. There is no doubt that this is a prolific cause of ovarian irritation and inflammation which is often overlooked or disregarded.

Malnutrition, which may be attributed often to disorder of the digestive apparatus, brought on by improper food, is also indirectly a cause of ovaritis and is to be counteracted by careful attention to the diet and the state of the excretory organs.

A congestion of the ovary may be maintained by interference with its circulation, due to the pressure of an exudation in the broad ligament, which may be removed by stimulating absorption with the fine wire faradic current.

A condition of atrophy of the ovary is frequently produced by the pressure of exudation which interferes with its circulation and function, and is often associated with either absent or very scanty and imperfect menstruation. It may be cured if the exudation can be removed and the menstruation restored to normal activity, if it has not existed for too long a time.

Cystic degeneration of the ovaries is very rarely benefited by any form of treatment, and if the symptoms are persistent and are sufficiently annoying to warrant it they should be removed. This is a condition, however, which is difficult to diagnose without inspection.

If a septic inflammation of the ovary has progressed to that point where an abscess has developed, its prompt removal is the only course to be adopted, and neglect to do so is as unwarranted as a hasty operation in other conditions when it is not necessary.

Ungratified sexual desire has been stated as a cause of ovarian irritation and inflammation, and there is no doubt that it exists in some instances without the knowledge of the woman so afflicted. A case which serves as a forcible illustration of this was related to me by a gynecologist of some prominence in New York:

Case 2.—A lady of refinement and education who was left a widow after several years of married life, without children, developed a most intense ovarian irritation and inflammation which gave rise to so much suffering as to make her an invalid. Everything possible had been done for her by different specialists whom she had consulted but with no benefit. She was advised and urged to have her ovaries removed and finally consented to the operation, if after an anticipated trip and rest abroad she was no better. On the steamer going over she chanced to meet a gentleman of whom she became very much enamored. They became engaged and on her return to New York she hastened to ask her physician if her condition should prevent her from marrying, and if marriage would aggravate her condition and cause greater suffering. He discouraged her and advised against it, believing that it would be worse for her. He again urged her to have the operation performed. Much to his surprise, a month or two after this he received an invitation to her wedding. Meeting her there she explained that she had not taken his advice because she was so deeply in love with the gentleman that she had determined to take the chances and if she became worse, afterward, with his consent,

she would have the operation performed. Several months elapsed before he again saw her, during which time they were absent from the city. She then told him that from the time they were married she ceased to suffer and was now perfectly restored to health, which her appearance made quite manifest, and asked him if he could in any way explain her cure. He suggested the cause of her suffering which had been removed, but she disclaimed any knowledge whatever of the existence of any such cause.

The following case shows that an intractable inflammation of the ovary may be overcome by restoring a normal condition of the uterus and cervix which was the cause:

Case 3.—Mrs. B., age 35, married at 17, two children, the last 12 years old, came to my clinic in May, 1893, suffering with intense pain in the left ovarian region. The left ovary was enlarged to about the size of a walnut and there was chronic metritis and endometritis with an old laceration of cervix and cystic degeneration. The pain in this case was relieved temporarily by faradization, but returned with the same severity whenever treatment was discontinued. The patient's general health improved greatly while under treatment, but as no permanent benefit to the ovarian condition was obtained, I feared that I would be obliged to remove the ovary. Before doing so, however, I curetted the endometrium and repaired the cervix, being particular to remove all the diseased tissue possible. Upon getting up after the operation she was overjoyed to find that she no longer suffered pain in the ovary and there was no return of it. Within three months she became pregnant, though she had been sterile for twelve years, and subsequently was delivered at term. She has suffered no inconvenience with the ovary since and it is about normal in size.

The next case, one of fixed retroflexion, cervical laceration with metritis and endometritis, salpingitis and ovaritis resembling cystic degeneration, illustrates what may be accomplished by patient and persistent treatment and restoration of a normal condition of the cervix:

Case 4.—Mrs. T., age 33, married fifteen years, mother of three children, last 7 years of age, was sent to me by her physician in Columbia, S. C., October, 1893. Her ill-health dated from the birth of the last child, which was followed by pelvic peritonitis due to septic infection following labor. When she first came under my care, she could not walk a block without great fatigue and suffering; she was anemic and her general health was greatly impaired.

Examination revealed an immovable retroflexed uterus, surrounded by exudation, both tubes and ovaries involved, a bad metritis and endometritis with bilateral laceration of the cervix and laceration of the perineum.

Celiotomy had been advised, as the only possible means of relief.

The treatment instituted was fine wire faradization daily, and drainage from the uterine cavity, promoted by the application of negative galvanism to the canal. Later, when the uterus was rendered movable and could be replaced, a soft whalebone pessary was introduced. Six weeks after beginning treatment the cervix and perineum were repaired. The period occupied in the treatment was three and one-half months. At this time she was able to return home and was directed to have the faradic application continued twice or three times a week. She was able to walk a considerable distance without fatigue or without suffering any pain or inconvenience in the pelvic organs, and was then wearing a hard rubber pessary. She continued to improve and within a year after she had entirely regained her health and strength.

The next case shows how pelvic exudation may be removed by faradic stimulation unaided:

Case 5.—Mrs. L., age 37 years, one child twelve years before and one miscarriage, six years before, came to my clinic in 1893. Menstruation consisted only of a few drops and was attended with great pain. She could walk only with the greatest discomfort, the slightest jar giving her great pain. Examination revealed the pelvic organs absolutely fixed by surrounding exudation. The diagnosis was chronic metritis and salpingitis and ovaritis with exudation. There was an old laceration of the cervix with cystic degeneration. Under faradization alone, nothing else being employed, the pain was immediately relieved and within a few months the exudation had disappeared and the uterus was

movable. Subsequently the cervix was repaired, the diseased tissue being carefully removed. The patient is now in excellent health and menstruation is free from pain and more normal in amount. The uterus is freely movable. Examination under anesthesia at the time of the operation showed no abnormal condition of the appendages remaining.

Case No. 6, illustrates the benefit to be derived from curettage and gauze packing, in securing drainage of distended tubes into the uterus:

Case 6.—Mrs. H., age 28 years, married six years, consulted me in December, 1894. She suffered only slight dysmenorrhea until a miscarriage which occurred two years after marriage, when she began to have more or less pelvic pain and profuse leucorrhœa. Examination revealed an endometritis with salpingitis, left tube distended to size of the thumb with some infiltration about the tube and ovary. Dilatation, curettage and gauze packing secured evacuation of the tube after the third day. The subsequent treatment consisted of irrigation of the cavity twice a week. Drainage was maintained and the tube did not refill. Duration of treatment six weeks. The cure has been complete and so far permanent.

The next case, one of pyosalpinx, was drained into the uterus and cured without curettage, and pregnancy followed:

Case 7.—Mrs. A., age 23 years, married four years, sterile, consulted me in May, 1892, for a condition which began shortly after marriage. She suffered some dysmenorrhea before marriage. About a year after she became very much worse and began to suffer with pelvic pain, backache and leucorrhœa. Her general health was greatly impaired and she was anemic. Diagnosis: endometritis and salpingitis, the right tube being distended to about the size of a small egg. Celiotomy had been advised by specialists in Detroit and Pittsburg, but was declined. The tube was so much distended and obstructed, I feared that I would also have to advise an operation, and told the patient that nothing could be promised positively from treatment, but under the negative galvanic applications to the uterine canal and fine wire faradization the tube began to drain into the uterus within two weeks and eventually emptied completely. The discharge was muco-purulent in character. The walls of the tube contracted and it did not refill.

The duration of treatment was three months. She was then so well that she went West to join her husband. A year later on her return to New York, I found her pregnant. She was confined in October last, the labor being normal and easy. Her health has been good since.

In marked contrast with the foregoing case, the next illustrates a class of cases which can not be drained, though the symptoms may be relieved by treatment, when operative interference is prohibited:

Case 8.—Mrs. S., age 24 years, married six years, sterile, consulted me in August, 1892, for the relief of a constant dragging pain in the back over the sacrum, and pelvic pain referred more especially to the left side, associated with dysmenorrhea and at times with considerable leucorrhœa. These symptoms dated back several years, but had become more pronounced within the last two years. Examination revealed a smooth elastic tumor, posterior to the uterus in Douglas' pouch, which proved to be an adherent hydrosalpinx. The left ovary was sensitive and enlarged, the right could not be made out. The patient was told that the treatment would afford only temporary relief, that an operation for the removal of the diseased tube was advisable and would eventually be necessary. She objected to the operation, but asked that some treatment be instituted which would relieve the symptoms. The attempt was made to drain by means of galvanic application to the uterine canal and faradic stimulation, with the result that the endometritis was overcome and the pain relieved within two months. She then discontinued treatment but was advised to have the operation performed as soon as the symptoms recurred. She returned after four months, stating that there had been no return of the pain, leucorrhœa or dysmenorrhea, but for two weeks she had a return of the backache, and she made up her mind to undergo the operation. I operated March 26, 1893. The tumor proved to be a hydrosalpinx of the right tube and the ovary of the same side was cystic. The tube was bent upon itself near its attachment to the uterus, and was consequently occluded and drainage into the uterus was prevented. The tube and ovary of the other side were left

undisturbed. The patient made a good recovery and has enjoyed excellent health since.

Case 9.—Mrs. G., age 26 years, married seven years, consulted me in June, 1889. Examination revealed partial fixation of uterus and a mass to the left which proved to be the tube distended with pus and surrounded by exudation. There was also an endometritis with considerable erosion of the cervix. Celiotomy had been advised. Her trouble dated from a miscarriage and an attack of pelvic inflammation one year later which confined her to bed for eight weeks. The treatment instituted in this case, was drainage through the uterus, by means of negative galvanic applications to the endometrium and cervix, which acted by overcoming the endometritis and securing free drainage from the cavity, and faradization to promote absorption of the exudation and stimulate evacuation of the tubal contents. The treatment extended over a period of six months but her attendance was irregular, as is the case with many of these patients when they notice improvement.

The result obtained was absorption of the exudation, drainage of the tube into the uterus, disappearance of the tumor because the tube did not refill, cure of the endometritis and mobility of the uterus. The patient was in good health two years afterward.

The next case is one which illustrates how catarrhal salpingitis yields to this method of treatment:

Case 10.—Miss E., 19 years, consulted me in April, 1892. About eight months previously, after exposure to cold during menstruation, she began to suffer pelvic pain, backache and bearing down with profuse leucorrhœa. This continued some time before she consulted a physician. She improved somewhat under treatment, instituted at that time, but shortly afterward she got a wetting which precipitated an attack of acute inflammation, confining her to bed for four weeks. After being about for two weeks she was again taken sick and was sent to a hospital in this city. There she was treated by rest in bed, blisters to the hypogastrium and hot water vaginal douches with only slight benefit. Celiotomy, for the removal of the ovaries was then urged, which she refused.

At the time of consulting me she was the picture of abject misery, pale, anemic, haggard and was never a minute free from pain except when asleep. Walking or the least exertion greatly increased her suffering. Her appetite was poor and she did not sleep well. I found her so exquisitely sensitive to vaginal touch that a satisfactory examination was impossible. There was a profuse mucus discharge and the uterus was fixed by infiltration of the surrounding structures. The diagnosis was catarrhal endometritis, salpingitis and ovaritis.

The treatment instituted was fine wire vaginal bipolar faradization. The first application which was continued for twenty minutes dispelled all pain and rendered her perfectly comfortable for eight hours afterward. This was repeated every day. After the third application she remained free from pain twenty-four hours, and moderate exercise caused no pain. This plan of treatment was continued and supplemented later with mild negative galvanic applications to the uterine canal to facilitate drainage. At the end of two months and a half she was able to resume her occupation as stenographer and typewriter. Her health has been good since and there has been no recurrence of the trouble.

This is another case of catarrhal salpingitis, associated with ovaritis and endometritis, which yielded to treatment after celiotomy had been advised:

Case 11.—Mrs. E., age 21 years, married five years, was referred to me by Dr. R. W. Taylor of New York in April, 1894. Three years previous, according to her statement, exposure brought on ovarian trouble which resulted in inflammation. This did not yield to the usual treatment and celiotomy was advised, which she declined. The diagnosis, made at the time she came under my care, was catarrhal salpingitis, ovaritis and endometritis with ante flexion; some infiltration about right tube and ovary.

The treatment instituted was drainage of the uterine cavity, secured by negative galvanism to the canal, and fine wire faradic stimulation, which afforded prompt relief and resulted in a cure. The period of active treatment was about two and a half months. She was kept under observation for several months afterward but there was no recurrence of the trouble. The extreme ante flexion was

overcome. At the present time the patient is in excellent health.

Case 12.—Mrs. C., age 31 years, widow, one child 17 years old, was referred to me by her physician. Some years before, she had an attack of pelvic inflammation resulting from septic infection which caused fixation of pelvic contents. The uterus was retroflexed and surrounded by exudation which involved the appendages of both sides. Both ovaries were enlarged and exceedingly sensitive. The right tube was distended. The cervical canal was contracted and consequently drainage was defeated. Her menstrual period was accompanied with so much pain and prostration that she was compelled to remain in bed for the entire period. The attempt to dilate the canal and promote drainage by means of negative galvanism provoked so much irritation that it had to be abandoned. But the extreme sensitiveness was relieved by faradization and the uterus was rendered partially movable. Then under anesthesia the canal was dilated, the uterine cavity was thoroughly curetted and packed with gauze. Before the gauze was introduced, the uterus was replaced by careful manipulations which freed the adhesions. The vagina was then tamponed with iodoform gauze to maintain the position of the uterus.

The distended tube discharged into the uterus within a week, the fluid being thin and serous in character.

This treatment was followed by frequent irrigation of the uterine cavity with faradic stimulation and a pessary was inserted as soon as it could be borne.

Now (three months after the operation) the position of the uterus is maintained by a pessary which is worn without discomfort. The tube has not refilled. She experiences no pain, though she is constantly on her feet in attending to her duties as housekeeper. She menstruates without pain and does not remain in bed during the period. This patient can not be considered cured yet, but she is in a condition where improvement will continue and a cure will result. Celiotomy had been advised in this case and, at one time, I feared it would be necessary.

I could relate many more cases similar in character, but these will suffice to illustrate my point. Remember, they are selected cases, many of them being chosen because a radical operation had been advised by another operator before they came under my care.

351 West 57th Street.

DISCUSSION.

DR. CHARLES P. NOBLE, Philadelphia—said that the method of treating the stump, advocated by Dr. Dunning, was practically the same as that employed by Dr. Pratt, of Chicago. The only difference he saw was that the latter did not put in a provisional suture. With reference to Dr. Goelet's paper, while it was interesting, it did not contain anything particularly new in the treatment of inflammatory diseases of the uterine appendages.

DR. M. PRICE, of Philadelphia—wished to criticize the constant tendency to new methods, and calling them "my method." This is not necessary, because the rules laid down by the older surgeons, such as Tait, Keith and Bantock, answer every purpose. He agreed with the statement made by Dr. Goelet in his paper, that many patients with ovaritis and salpingitis are being operated on unnecessarily. During the past year he had turned away many women, telling them that there was nothing the matter with their tubes or ovaries, and yet nearly all of them succeeded in finding another surgeon to remove their appendages. In cases where actual tubal or ovarian disease exists, he regards simple curettage and drainage of the uterus as futile. In many of these cases the cervical end of the tube is entirely obliterated by the inflammatory condition.

DR. DUNNING had little to say in closing the discussion. With regard to the question of priority, he had nothing to say whatever, except that if Dr. Pratt, of Chicago, had been pursuing the method which he had proposed, he was not aware of it. Dr. Noble had, it seems, treated the subject in a very flippant manner and Dr. Dunning thought he would some day encounter a case of obstruction of the bowels, caused by adhesion of a loop of intestine to the raw surface left there, cutting off the tube and ovary, and then he would remember his paper and the method he had advocated.

CELIOTOMY FOR PUERPERAL SEPTICEMIA AND FOR PUERPERAL INFLAMMATORY CONDITIONS.

Read in the Section on Obstetrics and Diseases of Women, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY CHARLES P. NOBLE, M.D.

SURGEON-IN-CHIEF, KENSINGTON HOSPITAL FOR WOMEN, PHILADELPHIA.

The conditions under which it is desirable to perform an abdominal section in the treatment of the septic and inflammatory complications of the puerperal state are as yet not definitely determined. The problems involved are now pressing for solution, and the subject is receiving serious consideration by many members of the profession. So long as it continues to be a fact, that large numbers of women annually lose their lives from puerperal septicemia, this subject must be studied by the obstetrician and gynecologist, until the prevention and cure of puerperal septicemia are placed upon a thoroughly satisfactory basis. This paper has been prepared upon the invitation of our President, to serve as an introduction to the general discussion of the problems involved. As I have recently discussed this subject upon two occasions, my remarks will be based upon the papers referred to.¹

Cases of puerperal sepsis and of puerperal inflammatory conditions may be divided into two classes: 1, those in which some pathologic condition is present in the sexual organs before labor; 2, those in which these organs are normal at the beginning of labor.

The first class embraces those cases of sepsis and peritonitis caused by the bruising or rupture of tumors situated in the pelvis, or of purulent or other septic accumulations in the Fallopian tubes, or the adjacent pelvic organs. It is unnecessary to discuss this division of our subject at length, as there is little difference of opinion concerning it, and the nature of its treatment is reasonably plain. That puerperal peritonitis may be due to the bruising or rupture of tumors during labor has long been recognized. Any variety of pelvic tumor may be bruised, or have its blood supply cut off by torsion of its pedicle, and become inflamed and gangrenous, and thus set up a more or less serious peritonitis. Dermoid cysts are especially liable to undergo inflammatory changes when they form a complication of labor. The cardinal points to which attention should be called in this class of cases are, that the birth canal and lymphatics are not involved; hence the conditions present are very similar to those in non-puerperal peritonitis. Prompt operation, with the removal of the tumor, has been followed by a high percentage of cures.

Puerperal peritonitis due to the rupture or bruising of purulent or other septic accumulations in the uterine appendages, existing prior to labor, is not of frequent occurrence. This phase of the subject has not been very systematically studied. The references to it in the literature are very few. In 1891 I called attention to this subject², and reported three cases, in which the bruising of pus tubes during labor had set up peritonitis. I have personal knowledge of two other cases which occurred in this city. Of thirty-two eminent American gynecologists, from whom I

have received replies to a letter of inquiry concerning this, among other subjects, I find that but three have operated for peritonitis due to a pus tube, which had antedated labor, and each of these gentlemen has operated upon but one case.³ My other correspondents either had no personal knowledge of such cases, or at the most had merely suspected that the diseased tube may have antedated the labor, instead of resulting from infection after labor. Dr. Lusk⁴, of New York, states that he has seen three cases of puerperal peritonitis due to the bruising of diseased tubes during labor.

The fact that such a large percentage of my correspondents have not met with this variety of peritonitis, is conclusive evidence that it is not common, and therefore that its practical importance is not so great as was anticipated some years ago. The comparative infrequency of puerperal peritonitis due to this cause is explained by the fact, that women having even a single pus tube, or other septic accumulation in the pelvis, are usually sterile. The relative dangers of puerperal peritonitis of this variety and the results of operation done for it can not be determined at this time, because there are so few of such cases on record. Theoretically, the prognosis from operation should be relatively good, because the uterus and the pelvic tissues and lymphatics are not involved. The conditions are similar to those of operation for peritonitis in the non-puerperal state. I believe that the proper method of treatment to be pursued in such cases is prompt operation, irrigation and drainage.

The second class of cases, in which sepsis or inflammatory conditions result from infection of the birth canal, in women having normal sexual organs previous to labor, is a far more important one than that just considered. This is the common form of so-called puerperal fever. It embraces cases in which the infection is limited to the utero-vaginal canal, those in which the infection has spread to the broad ligaments through the pelvic lymphatics or veins, and those in which the infection has spread to the peritoneum, either by way of the Fallopian tubes or by way of the lymphatics. As a matter of convenience we will consider first the conditions under which it is advisable to perform an abdominal section for puerperal peritonitis.

Puerperal peritonitis may arise either through the spread of the septic inflammation by way of the Fallopian tubes to the peritoneum, or through the inflammation spreading along the lymphatics, either directly through the uterus to its peritoneal covering, or by way of the lymphatics of the broad ligaments. I am not aware of any investigations which have definitely determined the distinctions in the clinical history of the two varieties of puerperal peritonitis, to which reference has been made. My own opinion is, that in the first variety (by way of the Fallopian tubes) relatively speaking the inflammatory element is more decided and the septic element is less marked, whereas the reverse is true in the second class of cases (by way of the lymphatics). In the first class of cases, I believe it is the rule to have marked efforts at the localization of the peritonitis, by nature's method of pouring out inflammatory lymph,

¹ Puerperal Pelvic Cellulitis and Puerperal Peritonitis, American Gynec. and Obstet. Journal, January, 1895. Celiotomy for Puerperal Septicemia and Peritonitis, American Gynec. and Obstet. Journal, April, 1895.

² Salpingitis Considered in its relation to Pregnancy and the Puerperal State, Trans. Amer. Gynec. Society, vol. XVI., p. 480.

³ Dr. Edward Reynolds, of Boston, Dr. E. B. Davis, of Birmingham, and Dr. Hirst, of Philadelphia. Dr. Coe, of New York, reports that he has assisted at such operations.

⁴ Discussion before the New York Academy of Medicine, Feb. 28, 1895, on Dr. Noble's paper "Celiotomy for Puerperal Septicemia and Peritonitis."

and that where this result is accomplished, many of these cases go on to a natural cure, and that more of them result in the formation of post-*puerperal* pus tubes, and of circumscribed intraperitoneal collections of pus. On the other hand, in the cases in which septic lymphangitis is a marked feature, the element of peritonitis is merely an epi-phenomenon, the condition present being a general septicemia.

Puerperal peritonitis of the first variety may end in death or recovery within a few days, or it may continue for several or even many weeks, in those cases in which it is of mild type at its onset. Lymphatic peritonitis is of relatively short duration, many cases having a fatal termination after a course of a few days. The distinctions just made, I believe, represent the facts of the case from the clinical standpoint, and they are supported by the experience of those who have had large opportunities for observation. If the distinctions here made are correct, I find no evidence that abdominal section has been performed for lymphatic peritonitis in any considerable number of cases. The reports of celiotomies for *puerperal* peritonitis, with which I am familiar, show that the operations have been done in general after the end of the first week; in other words, at a time in which the subjects of lymphatic peritonitis have either died, which is the rule, or have begun to recover, which is the exception. As supporting this inference, I find that among the thirty-two eminent gynecologists already referred to, only four—Drs. Boldt, Polk, Carstens and Etheridge—have performed celiotomy for general peritonitis within seven days after labor; and only four—Drs. Smith, Etheridge, Polk and Baldy—have operated for localized peritonitis within the same limit of time.⁵

Lymphatic *puerperal* peritonitis is not amenable to treatment by celiotomy. I know of nothing, either in my own experience or in the literature, which gives the least encouragement for operating upon this class of cases. All who have been operated upon have died. It is not difficult to understand why operation done for lymphatic peritonitis should accomplish so little. A simple celiotomy, with washing out of the peritoneal cavity, does not influence the principal seat of the trouble, which is in the uterus and pelvic lymphatics, and necessarily can not influence the multiplication of germs which already may have entered into the general circulation. The more radical operation of hysterectomy offers but little in these cases, as by the time peritonitis has become a marked feature, either the patient is so reduced as to be unable to withstand the shock of a serious operation, or she is already suffering from marked general septicemia. If these patients are to be saved, they must be operated upon at a much earlier stage, before the development of peritonitis or of marked general septicemia.

Cases of *puerperal* peritonitis of a more decidedly inflammatory type, that is, in which the septic element is less marked, are more amenable to treatment by operation. In these cases, I believe that the peritoneum has been reached by the spread of the infection along the Fallopian tubes, rather than through the pelvic lymphatics, so that these latter structures are but slightly involved in the morbid process. Polk and Outerbridge have reported successful cases of celiotomy for localized peritonitis done within the first

week after labor, and many cases are on record in which celiotomy has been performed at a much later period. I have nothing new to offer concerning the indications for operation in *puerperal* peritonitis. So far as I know, patients operated upon for general *puerperal* peritonitis have died; hence, excepting the hope that the diagnosis may be wrong, one would hardly be justified in recommending operation with such a diagnosis. I am aware that certain cases are on record, which have been reported as operations for general purulent peritonitis, including some of the *puerperal* variety, but an analysis of these cases, I think, will convince the impartial investigator that they were really instances of circumscribed peritonitis, although involving a considerable area. In cases of localized peritonitis, during the first few days of the disease the abdomen should be opened if the attack be a severe one, and if it does not yield promptly to treatment. In cases presenting well marked local lesions, to be made out by bimanual examination, the indication for operation is more urgent than in those in which nothing can be determined by physical exploration. In my judgment such cases should be carefully studied, and operation be elected or rejected because of the conditions present—the symptoms and general course of the case—rather than in accord with any rules applied to such cases in general. Celiotomy is certainly indicated if the attack of peritonitis be a severe one, which does not yield promptly to medical treatment. Also, later in the course of *puerperal* peritonitis of a milder type, operation is indicated if the patient fails to improve, and is demanded should the case take an unfavorable course. In such cases, however, it should not be forgotten that bimanual examination will usually disclose marked local lesions.

At the present time it is safe to conclude that the prognosis of celiotomy done for general *puerperal* peritonitis is fatal. In localized peritonitis, the prognosis is best in those cases in which the inflammatory process has become well localized, and in which septic symptoms are slight, or else altogether absent—the case having resolved itself into one of pyosalpinx, of abscess of the ovary, or of pelvic abscess of *puerperal* origin. The prognosis is fairly good in cases of circumscribed peritonitis operated upon promptly, that is within two or three days of the beginning of the attack, which is equivalent as a rule to the fifth, sixth or seventh day of the *puerperal* period. Cases which have gone from bad to worse, and in which the operation is done as a last resort, usually terminate fatally.

Celiotomy is occasionally called for in cases of true pelvic abscess, located usually in the broad ligament or iliac fossa, and resulting from a lymphangitis, which has ended in suppuration of the pelvic connective tissue. It is at times difficult to determine whether or not the inflammatory process is limited to the connective tissue of the pelvis, or whether it is complicated with tubo-ovarian or intraperitoneal mischief. In such cases an exploratory celiotomy to determine the extent of the inflammatory trouble is desirable. If the broad ligament abscess is complicated by tubo-ovarian disease, or by intraperitoneal suppuration, the whole trouble can be dealt with through the abdominal incision. If, on the other hand, the morbid process is limited to the connective tissue of the pelvis, and has resulted in the formation of a true pelvic abscess, this can be

⁵ Seventeen of them have operated for *puerperal* peritonitis later than the seventh day of the *puerperal* period.

evacuated by a second, extraperitoneal, incision, made either in the groin or through the vault of the vagina, as may be best in the individual case. The personal experience of the writer with this method of treatment has been such that he recommends it highly in this class of cases.⁶

We have still to deal with cases of infection of the birth canal, fairly well localized in the uterus, in which the progress of the disease is from bad to worse, in spite of irrigation and curettement of the utero-vaginal canal. This class of cases logically should have been considered first, but because of the nature of the treatment which will be recommended in a certain percentage of them, it has been thought best to treat of it last. In these cases, septic intoxication or beginning septicemia are marked features, the absorption of ptomaines, or of microorganisms, taking place from the uterus or the vagina. Peritonitis, cellulitis or lymphangitis, are either absent or in their incipiency—the infected uterus is the nidus of the morbid process. In other words, we are considering these cases as a class distinct and apart, although it is recognized that within one or two days they would develop into cases similar to those already described. Some years ago a case belonging to this class would have been treated day after day by irrigation of the birth canal, and by internal medication, until the termination of the case either in death or recovery. Under this method of treatment, undoubtedly, a few cases have recovered, but in the great majority, when in spite of curettement and thorough irrigation of the uterus, the septic process increases instead of diminishing in intensity, the issue is a fatal one. The proposition to perform hysterectomy in such cases, and thus to remove the seat of the disease, has the merit of being logical. This proposition has been carried into effect by Kelly and Smith with a favorable result, and by Montgomery with a fatal issue. I have read of another successful case in the hands of a German operator—but am unable to find the reference. In these cases abdominal hysterectomy was performed. In Kelly's case there was a beginning lymphangitis, in Smith's a beginning peritonitis, and in Montgomery's pus was found in the uterine sinuses.

At the present time I am prepared to advocate the performance of hysterectomy for infection of the uterus, when in spite of thorough curettement, followed by copious irrigation of the utero-vaginal canal, and the use of an iodoform suppository and gauze within the uterus, the septic symptoms increase in severity. In general, the less radical measures of treatment should be employed for twenty-four or forty-eight hours (and longer in cases of mild type, in which the symptoms are not urgent), this time limit to be varied according to the severity of the septic symptoms. In such cases not only should the uterus be curetted and douched, but the patient should be purged with salines; and the use of quinin, baths and anodynes, should not be neglected. In all such cases the general condition of the patient, including the pulse, temperature, stomach and *morale*, is the best guide in deciding for or against immediate resort to hysterectomy. In other words, it is by no means proposed to do a hysterectomy because the patient has a septic endometritis or a septic metritis, but to do this major operation only in those

cases in which the methods of treatment, at present recognized as most efficient, fail to arrest the morbid process, which, in spite of the employment of these measures, goes on from bad to worse.

It will be observed that my advocacy of hysterectomy has been in cases of infection of the uterus early in the course of the disease. There is another class of cases entirely distinct from this, clinically speaking, in which it may be wise to add a hysterectomy to the removal of the uterine appendages, either because the suppurative process may include the uterus itself, or because the removal of the uterus as a technical point in the operation may facilitate the recovery of the patient. A number of such operations have been reported, but this class of cases must not be confused with that which has just been considered. In the one class of cases, the septic inflammatory process is acute, and a hysterectomy if needed at all, will be needed somewhere about a week after labor; whereas, in the other class of cases, the process is subacute, and results in suppuration late in the puerperal month. In the one class of cases, the removal of the infected uterus is the principal object aimed at; in the other class of cases, as a rule, the uterus is the least diseased of the pelvic structures.

At this time the great success which has been achieved in hysterectomy done by way of the vagina, for non-puerperal conditions, in the hands of the French school of surgeons, raises the question as to whether or not this method of operating should be selected in puerperal cases. Experience alone must determine this question. This is one of the problems of the future, as only a small number of cases have as yet been operated on by the lower route. Upon theoretical grounds, I am not inclined to advocate hysterectomy by the vagina for puerperal infection, as when it is employed we are precluded from inspecting, irrigating and widely draining the peritoneal cavity. This method would best fulfill the indications when employed very early in the course of the disease, as then the chances of peritonitis would be small, and the necessity for extensive drainage of the peritoneal cavity would be absent. The advocates of the vaginal route for removing the diseased structures from the pelvis, will probably take issue with the general position, that abdominal section is the operation indicated to deal with the various consequences of puerperal septic infection. I am prepared to agree with them that large pus accumulations can be more safely dealt with by way of the vagina than by operation from above, but with this exception, from my point of view, the preferable method of operating for puerperal septic inflammation and its results is by celiotomy.

The present status of the subject of celiotomy for puerperal septicemia and for puerperal inflammatory conditions may be summed up as follows; the cases may be divided into two classes:

a. Those having morbid conditions in the pelvis antedating labor, such as tumors, pus tubes, or other septic accumulations, the bruising or rupture of which during labor leads to peritonitis or septicemia. Prompt operation in these cases has given good results.

b. Those having normal pelvic structures at the onset of labor. The infectious process may spread through the lymphatics to the peritoneum, and give rise to peritonitis, cellulitis and septicemia. It may

⁶ Noble, Charles P., Acute Puerperal Cellulitis and True Pelvic Abscess, Amer. Jour. Obstet., 1893, XXVII, 427.

spread by way of the Fallopian tubes to the peritoneum, setting up peritonitis. Or it may be limited to the utero-vaginal canal. Celiotomy is not indicated in lymphatic peritonitis, as the morbid process is too widespread to be reached by operation. Celiotomy has been followed by a fatal result in cases of general puerperal peritonitis. The only ground for advising operation with such a diagnosis is the possibility that this may be erroneous. The prognosis is best when celiotomy is done for localized peritonitis, when the process has become well circumscribed and the element of sepsis eliminated; in other words, when the case has resolved itself into one of pyosalpinx, abscess of the ovary, or of pelvic abscess of puerperal origin. The prognosis is good when cases of localized peritonitis are operated upon promptly, that is within two or three days of the beginning of the attack, or at about the end of the first week of the puerperium. Cases which have gone from bad to worse, and in which the operation is done as a last resort, usually terminate fatally. Hysterectomy is indicated for those cases in which the infection is limited to the utero-vaginal canal, when, in spite of thorough curettement of the uterus, together with copious irrigation of the utero-vaginal canal, and the employment of proper systemic treatment, the infectious process increases in severity.

In dealing with the results of puerperal septicemia by operation, celiotomy affords the opportunity for satisfactory diagnosis and adequate treatment. The organs involved may be palpated or inspected, and when necessary the operation may be followed by irrigation and satisfactory drainage. The vaginal route for operation is indicated for large pus accumulations which are found late in the puerperium.

EXTRA-UTERINE GESTATION—ITS EARLY DIAGNOSIS AND TREATMENT.

Read in the Section on Obstetrics and Diseases of Women, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY S. L. JEPSON, M.D.

WHEELING, W. VA.

(ABSTRACT.)

The following were the author's conclusions:

1. Extra-uterine gestation is probably always primarily tubal; the ovarian is a possible rare exception.

2. Diagnosis before rupture may often be made with reasonable certainty. In some cases it is impossible.

3. Diagnosis after rupture can in most cases be made so certainly as to justify opening the abdomen.

4. Electricity—preferably galvanism—should be used when a diagnosis is made before rupture, unless the patient can and will secure the services of an expert operator.

5. Celiotomy by an experienced abdominal surgeon is always proper in early unruptured cases.

6. After intraperitoneal rupture with free hemorrhage, the abdomen should be promptly opened and the tube grasped near the uterus. The operation may be completed at once or delayed to restore the patient, as her condition requires.

7. After rupture into the broad ligament, abdominal section is not urgent, and often is unnecessary.

8. While condemning operations by the inexperienced in cases of no urgency, yet an emergency may arise after intraperitoneal rupture, when celiotomy by the inexperienced may become a duty, but this should never be resorted to without counsel.

DISCUSSION.

DR. A. H. GOELET, of New York—said that while Dr. Jepson had covered the subject pretty thoroughly, there were some points in the paper from which he wished to differ with the essayist, and first as to the necessity of operating upon every case of unruptured tubal gestation. In the first place, the necessity of the operation is the danger of rupture, and that danger is removed if the death of the fetus is accomplished. That can unquestionably be done by electricity. If rupture has taken place between the folds of the broad ligament, it is admitted by some of our best authorities that it is comparatively harmless and may be left alone. He has had several cases of this character, and they resulted very satisfactorily by leaving them undisturbed until the ruptured vessels had sealed up, and then, when necessary, emptying the sac through the vagina. In this way we avoid opening the peritoneal cavity. Statistics show that even when the hemorrhage occurs within the peritoneum it is seldom sufficiently severe to demand celiotomy for its arrest. No one would hesitate to open the abdomen in cases where the bleeding is very severe, but if it has ceased it is far safer to let it alone. When the danger of secondary hemorrhage has passed, we can open the sac through the vagina and empty it. This procedure is far safer to the patient, and it is our duty always to consider this point.

DR. RUFUS B. HALL, of Cincinnati—said it was very often difficult to decide whether rupture had occurred between the folds of the broad ligament or directly into the peritoneal cavity. In sixteen cases coming under his observation, a diagnosis of rupture into the broad ligament was made in fifteen cases, and they were treated as such for varying periods. Later on, in operating for the removal of the blood clot, it was proved in every case that the rupture had occurred into the peritoneal cavity. When we teach that rupture takes place into the folds of the broad ligament more frequently than it does into the peritoneal cavity, he thinks we do not treat our patients fairly. We should assume primarily in these cases that rupture has occurred into the peritoneal cavity and be governed by the condition of the patient, or the loss of blood, as to when we shall operate.

DR. CALEB R. REED, of Middleport, Ohio—said that these cases are not infrequently met with in small country towns, where the assistance of an experienced surgeon can not be readily obtained, and he expressed the opinion that in such an emergency, any physician who has an ordinary knowledge of the anatomy of the parts and who has the boldness to use the knife should not hesitate to operate. While he has had personally but little experience with the use of electricity in these cases, he would not advocate it unless he was reasonably sure that it would succeed in destroying the fetus, and according to his reading on the subject, electricity was in the majority of cases a failure.

DR. J. M. COBLE, of Dallas, Tex.—said he had had three cases of extra-uterine gestation come under his care. He regards the operation for extra-uterine pregnancy as a very simple one, and said a man who has any skill and knows how

to do it, should go ahead and perform it as soon as the diagnosis is made.

DR. A. LAPHORN SMITH, of Montreal—is in favor of operating for extra-uterine pregnancy as soon as the diagnosis is made. He also regards it as one of the easiest of the abdominal operations.

DR. J. M. DUFF, of Pittsburg, had had no experience with electricity in cases of extra-uterine pregnancy, but it occurred to him that it would be just as dangerous for one who is not skilled to attempt to use it as it would be for an unskillful operator to use the knife. A case came under his observation some three years ago in which he diagnosed extra-uterine pregnancy; there was a tubal abortion at about the third month. He could not get the consent of the patient to let him operate. The woman had a miscarriage about a year later; he was sent for, found her in collapse, and discovered that she had an extra-uterine pregnancy on the other side. He operated and found the product of the first pregnancy, which was almost as natural as that of the last one, which he knew to be of only eight weeks duration. There was no absorption.

DR. H. W. LONGYEAR, of Detroit—said if a case of tubal pregnancy is diagnosed before rupture has taken place, the physician should operate at once, or he should get the most experienced surgeon to do so. He cited a case in which the pulse fluctuated more or less for two months. At the operation the abdomen was found full of blood clots, partly organized and mixed up with the intestines, and it was with the greatest difficulty that the blood was removed from the abdominal cavity, and he believes that the length of time necessary to do this was the cause of death.

DR. JEPSON, in closing, insists upon the operation being done by an expert when possible. He said his remarks were addressed to the average country practitioner who is not competent to operate in these cases. There was in his town to-day a man who was doing a large amount of operative work. Two years ago this physician was called to a neighboring town to operate upon a case of ruptured tubal gestation. He opened the abdomen, and before he could find the ruptured tube, the abdomen was full of blood. He was horrified. He filled up the abdominal cavity with towels and let his patient die. This man was a post-graduate student.

With reference to hysterectomy, the expert surgeon who stands up before a Section composed largely of general practitioners and asserts that it is a trifling operation creates a false impression, and it may be the means of leading other men to do operations that are grave, although to him they may be comparatively easy.

THE VALUE OF SYMPHYSIOTOMY.

Read in the Section on Obstetrics and Diseases of Women at the Forty-sixth Annual Meeting of the American Medical Association at Baltimore, Md., May 7-10, 1895.

BY HUGH HAMILTON, M.Sc., M.D.

HARRISBURG, PA.

Operative obstetrics is an essential part of a physician's education. The process of natural birth is merely an incident, but a birth may become eventful and ultimately tragic. Cases demand action in the order of their occurrence, namely: detention from want of maternal power; due to fetal malposition; arising from deformed fetus; by deformed maternal parts. Nature makes an effort to sacrifice upon these occasions the child for the mother, because her preservation is the conservation of the species—following this guide, accoucheurs strive to do this and more; therefore the highest aim of the art of midwifery is to save both, through the application of therapeutic remedies and other means. More Madden questions if we have an emmenagogue in the special sense in which we use it. Recently I had a letter from a Philadelphia physician, stating that brown sugar was an excellent uterine tonic! Upon this question at present it is not necessary to enter. When medical aid fails, recourse must be had to manual or instrumental skill or surgical relief, bearing in mind the simple classification, a birth is detained through lack of ma-

ternal power. The reflexes having been used to stimulate these powers and failed, turning may be resorted to, or the forceps, or both consecutively. Forceps do not always fit and will often slip; to overcome the difficulty, contrivances have been made to secure the necessary force in the proper axes of expulsive power. (Demonstrated clamp.)¹

2. Malposition of the fetus may be regarded as all but the four vertex ones, *i. e.*, dexter et sinister; anterior et posterior. For although breech presentation gives less risk than others, for all that, the after-coming head is not always a problem of easy solution. Presentations may be modified by manual dexterity and expediency; even then they do not result in living infants.

3. Should the deformity of the fetus prevent birth, then instrumental function asserts itself; if possible, only upon the lifeless infant, but not reprehensible upon the living one, under certain restricted conditions. (Demonstrated my great forceps.)

4. When dystocia comes from deformed maternal parts, then modern surgical technique renders pronounced aid. These are divided by the anterior-posterior diameter of the pelvis. Then means for accurate measurement becomes of great moment. The most recent and complete pelvimeter is that of my friend Dr. Philander A. Harris, of Paterson, N. J. (Demonstrated.)

A. Pelves of a conjugate vera of less than 7 c.m.

B. Pelves of a conjugate vera of more than 7 c.m. modified by symmetrical contraction. In class A section is the only method advisable. In class B, symphysiotomy, etc., are the proper operations. (Demonstrated by charts and my new symphysiotomy knife.)²

Recent statistics³ covering the year 1891 before symphysiotomy, and during the subsequent years in that period, at the Clinic Baudelocque in Paris: there was, in 1892, 13, in 1893, 14; in 1894, 22 symphysiotomies; total, 49. The maternal mortality was four from those undergoing the operation. The infantile mortality attributable to those whose mothers underwent the operation was five. To go into more details in these years, Pinard reported at the Baudelocque in 1891, a total of 1,654 cases treated, of which number there were 140 deformed pelves, being 8.456 per cent. on 1,654; of this number natural delivery took place in 18, or 4.89 per cent. upon 1,654, or 57.85 per cent. on 140, the whole number of those with deformed pelves. The remaining fifty-nine were delivered by artificial means (including premature artificial births, high and low forceps operation, version, Basiotripsy and conservative Cæsarean operation.) Or 3.55 per cent. on 1,654; or 42.15 per cent. on 140. The maternal mortality was 4, or 0.241 per cent. on 1,654; or 2.85 per cent. on 140; or 6.77 per cent. upon 59, the whole number operated on. The infant mortality was 31, or 1.87 per cent. on 1,654; or 22.14 per cent. on 140; or 52.52 per cent. on 59.

At the Royal Dresden Clinic⁴ during the period from Jan. 1, 1892 to July 1, 1893, eighteen months, there were 2,512 cases of confinement. Of this number 610 or 24 per cent. had deformity of the pelvis; however, there were 146 of these whose deformity was so slight as not to demand any anxiety whatever, so that the number is reduced to 464 or 19.40 per cent.

¹ Ann. Gynecol. and Pediat., Vol. viii, p. 103.

² Amer. Gynec. and Obstet. Jour., Vol. v, p. 624.

³ Ann. Gynecol. et D'Obstet.—Tome xliiii, 1895.

⁴ Arb. a. d. Kgl. Frauenkll., Bd. I and II, 1893-95.

upon 2,512; 424 of this number were fortunate in having unassisted births, or 16.87 per cent on 2,512; or 88.98 per cent. on 464; the revised number of deformed pelves. Those requiring assistance (in procedures as follows: forceps, version, Basiotripsys, premature births, Cæsarean sections, symphysiotomy) were 89 or 3.54 per cent. upon 2,512; or 11.01 per cent. upon 464. Those who were subjected to operations other than symphysiotomy were 83 or 93.85 per cent. on 89 of those totally operated on, or 3.30 per cent. on 2,512; or 9.72 per cent. on 464. Consequently there were six symphysiotomies performed, giving rise to the following comparative proportions: 0.23 per cent. on 2,512; or 1.29 per cent. on 464; or 6.7 per cent. on 89.

In the published account there was a mortality of mothers, due to operative interference, of 4, being 0.159 per cent. upon 2,512; or 0.864 per cent. upon 464; or 4.49 per cent. on 89. It is but fair to state that out of this number there were 5 deaths in 194 primipara which were expected to give birth naturally although their pelves were deformed. They really do not belong to operative statistics; yet they should have been operated on by symphysiotomy and the lives saved. This would make the percentage more than double. It is difficult to make tabular statements to represent at a glance all we wish, although the Paris figures include *all* deaths and the comparison is more favorable than it seems to the Clinic Baudelocque. The infantile mortality was 43 of which there is 1.70 per cent. on 2,512 cases; 9.48 per cent upon 464 deformed pelves; and 48.30 per cent. upon all operations, 89. The same parenthesis can be made in this respect as upon the mothers' mortality, in there being an additional loss of infants of 9, making in all when added to 43, 52. This would increase the percentage to beyond 10 upon 464.

The maternal mortality in operations other than symphysiotomy was 3 which gives 0.119 per cent. upon 2,512; or 0.646 per cent. upon 464; or 3.37 per cent. upon 89 operated cases; or 3.53 per cent. upon 83 operations *not* symphysiotomy. The mothers' deaths in symphysiotomy were only 1 *i.e.*, 0.037 per cent. upon 2,512; or 0.21 per cent. upon 464; or 1.23 per cent. upon 89; or 16.66 per cent. upon the operation (symphysiotomy) 6 itself. No deaths of infants were due to symphysiotomy.

The Clinic Baudelocque in 1894 gives the most recent report and presents the following: the whole number of confinements were 2,147; of this number 94 were deformed in the pelvis; the measures were taken by the pelvimeter, being 4.37 per cent. on 2,147; even of this number 64 gave unassisted birth, being 2.98 per cent. of 2,147 cases; or 67.97 per cent. upon 94, the number of deformed pelves; allowing 30 to be artificially assisted (these consisted in Basiotripsys 6, Porro operations 1, symphysiotomies 22, Vec-tis 1) being 1.39 per cent. upon 2,147; or 32.03 per cent. on all cases operated on. Those cases in which symphysiotomy was not used being 8 or 0.37 per cent. upon 2,147; or 8.51 per cent upon 94, all deformed pelves; or 26.66 per cent. upon 30, all the cases operated on. There was performed 22 symphysiotomies, being 1.22 per cent. of all cases, upon 2,147; or 23.41 per cent. upon all deformed cases, 94; or 73.33 per cent. upon all operations, 30. The total operative maternal mortality was 3, which upon 2,147 is 0.139 per cent.; 3.20 per cent upon 94; or 9.99 per cent. upon 30. The total infant mortality was 8, being

0.37 per cent. upon 2,147; 8.51 per cent. upon 94; or 26.66 per cent. upon 30. The maternal mortality with operations other than symphysiotomy was 2, being 0.0925 per cent. of all cases, 2,147; or 2.13 per cent. of deformed pelves, 94; or 6.66 per cent. of 30, the operated cases, or 25 per cent. of the operations other than symphysiotomy, 8. The maternal mortality under symphysiotomy was 1, being 0.046 per cent. upon 2,147; or 1.07 per cent. upon 94; or 3.33 per cent. upon 30; or 4.55 per cent. upon 22, the operation (symphysiotomy) itself. The infant mortality was *nil*.

[A comparison with American statistics may be made from the admirable paper by R. P. Harris, in American Gynecol. and Obstet. Jour., Vol. iv, p. 788.]

The results are that symphysiotomy relieves the peritoneum from being disturbed; does not divide the uterus; becomes as easy of reparation as any section or re-section of the long bones; permits the passage of a head, frequently without forceps; beside making a perineal rupture less probable; the time required for union of the symphyses allows the uterus time to become completely involuted. Its disadvantages are non-union at the symphyses, which affects locomotion.

tion; at any rate it offers much in attracting attention to accurate pelvimetry which will exercise caution in prognosis, and facilitate the progress toward scientific obstetrics.

1. Creating no necessity for premature artificial confinement.

2. Giving up all application of forceps and of all operations implicating the force of the head against the bony resistance of the pelvis (when it is developed or remains in the superior strait, in the excavation or in the inferior strait).

3. The absolute abrogation of embryotomy upon the living baby.

4. The enlargement of the size of the pelvis (by symphysiotomy, pubiotomy, ischio-pubiotomy, coccygotomy) in all the cases where the osseous resistance is not overcome by the uterine contractions, the position of the head being well determined, and together with its size, where the calculation demonstrates that when section of the pelvis is made, its enlargement will not be under 7 c.m., allowing the passage of head of the fetus at term.

5. Where absolute contraction of the pelvis is present (under 7 c.m.) the section serves for the Porro operation.

SUSPENSIO UTERI—THE PROPER METHOD OF PERFORMING IT, AND ITS RESULTS.

Read in the Section on Obstetrics and Diseases of Women, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY HOWARD A. KELLY, M.D.

BALTIMORE, MD.

(ABSTRACT.)

Dr. Kelly refused to accept the name of ventrofixation or hysteropexy. The uterus is not fixed. He prefers the name of suspensio-uteri as more accurately describing the condition. In the past five years he has performed this operation one hundred and seventy times and thirty-seven times in the past year. The indications for the operation are extreme local discomfort associated with uterine displacements, and neurasthenia, with backache and headache. In the first class of cases, with local symptoms but no general symptoms, the operation is plain. In the last series of cases it is difficult to say just when the operation is indicated. The most brilliant cures, however, have been in this class of cases. He is willing to take the chances and fail in four cases in order to get one good cure. Of the 132 cases reported, 90 were married; and of the 78 per cent. had borne children, and 14 of them had had miscarriages. Not one died or showed bad symptoms. Transient mania has occurred in three cases, pneumonia in one case, and stitch-abscess in three cases. Cystitis and frequent urination had occurred in four cases only, and had been but transient.

The operation is simple. The pelvis should be slightly elevated, and a small incision made just above the symphysis pubis about one and a half or two inches in length. The peritoneum is incised and drawn out with forceps. Two fingers are inserted to the fundus, and the uterus hooked up. Adhesions are stripped off with the fingers or cut with scissors or knife, and the uterus anteфлекed. The abdominal wall is lifted on the left side until the peritoneum can be seen for one inch away from the line of the incision. A needle is then carried through the peri-

toneum, but not entering the muscular tissue, and then through the posterior uterine wall just below the fundus, taking in about one-fourth of an inch in length, and extending about one-eighth of an inch in depth. The suture is then carried to the opposite side of the abdominal wall. Another stitch is passed just above the first, near the incision, and inserted into the uterus below the other, and then carried back to the opposite side of the abdominal wall. This increases the anteфлекion. A third suture may be inserted. The peritoneum is then closed by a continuous suture; then the fascia is closed and then the skin incision. The distance between the uterus and anterior abdominal wall is about one or one and one-half inches. The organ is attached by a strong fibrous cord which contains the sutures close to the abdominal wall. Pregnancy is not seriously interfered with. In only one case, and that after two years, did the uterus drop back.

THE TREATMENT OF HEMORRHAGIC CONDITIONS OF THE UTERUS BY ZINC-AMALGAM ELECTROLYSIS.

Read in the Section on Obstetrics and Diseases of Women, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY G. BETTON MASSEY, M.D.

PHILADELPHIA.

The use of a soluble metallic electrode as the positive pole of a galvanic current is specially avoided in the usual applications to the uterine and other mucous cavities whenever the pure action of the electricity alone is desired. To avoid this disintegration of the electrode and the consequent local action of the nascent metallic salt produced by its erosion, it has been necessary to employ non-oxidizable electrodes with this pole; platinum and carbon being the only practicable materials. It has however, been more recently discovered that the nascent salts produced by the corrodible electrodes have a distinct value in certain cases, particularly those in which a local alterative and antiseptic action is desirable. The salts produced by this erosion of a base metal anode are oxychlorids, produced by union of the free oxygen, and chlorin developed by the electrical action, and being in a nascent condition are particularly active. Copper, zinc and iron have been the substances employed by Onimus, Gautier (who has especially studied the method), Morton, Goelet, Cleaves and others, under the designation of interstitial electrolysis, metallic electrolysis and cupric electrolysis.

My own work has been almost entirely with zinc, and was originally directed exclusively toward the treatment of incipient malignant conditions, in which the nascent zinc salt has been a most valuable adjunct to the lethal action of a concentrated current. Owing to the practical difficulty that at times resulted from the adhesion of the electrode to the surface after a prolonged application, and also on account of the roughened surface rapidly attained by the electrode, I was led to amalgamate the zinc freely with mercury before using, and am convinced that the expedient is a valuable one. Not only does this keep the zinc surface always smooth, lubricated and non-adhesive, but a new value is attained in the use of a nascent oxychlorid of mercury in addition to the oxychlorid of zinc and a far more efficient alterative and antiseptic action results.

The additional effect given by this process to the galvanic treatment of hemorrhagic endometritis is shown in the following case histories:

Case 1.—Mrs. J. F., aged 54, was referred to me by Dr. H. W. Elmer, of Bridgeton, N. J., April 17, 1894. For three or four years she had been suffering from an almost continuous hemorrhage, resulting in great prostration. Shortly after the beginning of the hemorrhages, a tumor of the uterus was discovered, which was the size of a large fist when I first saw her. She was placed under the Apostoli treatment, which produced considerable improvement in the hemorrhages but did not even after six months' occasional treatment entirely correct the hemorrhagic tendency. Fearing that the case was a malignant one in spite of the absence of marked pain, I decided to substitute an amalgamated zinc electrode for the carbon one previously employed. It was found that the applications with this electrode were better borne, enabling them to be used more frequently. Six applications were made in a period of two weeks in December last, completely checking the dribbling, and since then there has been no real hemorrhage and the patient has been restored to health. The tumor was materially reduced in size.

Case 2.—Miss C. F. H., aged 31, had been under treatment for some time for a uterine fibroid of large dimensions, accompanied by profuse and exhausting menorrhagia. Under the ordinary Apostoli treatment the tumor had been reduced somewhat and the menorrhagia lessened, but she still had periods that were too profuse for her impaired strength. In January and February of the present year the electrode for intra-uterine treatment was changed from carbon to amalgamated zinc, the same current strength, 150 milliamperes, being employed. All periods subsequent to these applications have been absolutely normal.

Case 3.—Mrs. F., aged 47, had also been under treatment for a hemorrhagic fibroid of smaller size, with a similar history of decrease and partial control of the hemorrhagic feature. The metal of the intra-uterine anode was changed from platinum to amalgamated zinc about the same time, a current strength of 60 being employed. Up to this time her periods had always anticipated by several days, notwithstanding her age, but the first period after the changed treatment was postponed a week, and they have been delayed and normal in amount since.

AËRO-URETHROSCOPY.

Read in the Section on Surgery and Anatomy at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY WILLIAM K. OTIS, M.D.

ATTENDING SURGEON TO THE CITY HOSPITAL, NEW YORK; TO ST. MARK'S HOSPITAL, NEW YORK, ETC., ETC.
NEW YORK.

Notwithstanding the very great improvements made in urethroscopic instruments during the past few years, the urethroscopic field, in point of size, is still far from being entirely satisfactory. Since the invention of the original illuminating apparatus, little if any change has been made in urethroscopic tubes, though they have borne various names and been constructed of many different materials.

Glass from its transparency seemed especially adapted to this purpose, but the reflections from its surface and the changes produced by pressure on the mucous membrane, together with the danger of fracture if used in the deeper urethra, render it practically valueless. The discovery in 1870 of the great underestimation of the normal urethral caliber permitted the use of much larger tubes, with a corresponding increase in the size of the field; but the practical urethroscopic tube remained and still remains a simple straight tube.

In the year 1887 the late Geza von Antal, of Buda-Pesth, in the endeavor to extend the urethroscopic field, evolved the ingenious idea of distending the urethra with atmospheric air. He invented an

instrument for this purpose which was eminently successful, consisting of a tube with a well-fitting obturator, 6 cm. long, with a concave metal shield at its proximal end which fitted over the glans penis, the urethral orifice being drawn upward against this so as to prevent the escape of air. After the introduction of the tube an ocular portion, rendered airtight by a glass plate, was attached by a sliding joint. By means of a small tube entering the ocular portion at right angles, the urethra was inflated with a rubber bulb and an inspection of its mucous membrane obtained by a beam of light reflected from a head mirror¹.

This instrument, however, failed to attract much attention and the method met with but little favor among urethroscopists in general.

The examination of the inflated urethra was taken up, independently of von Antal's work, in this direction, by Heule of New York (1890) who devised a simpler but equally effective instrument for accomplishing the same results.

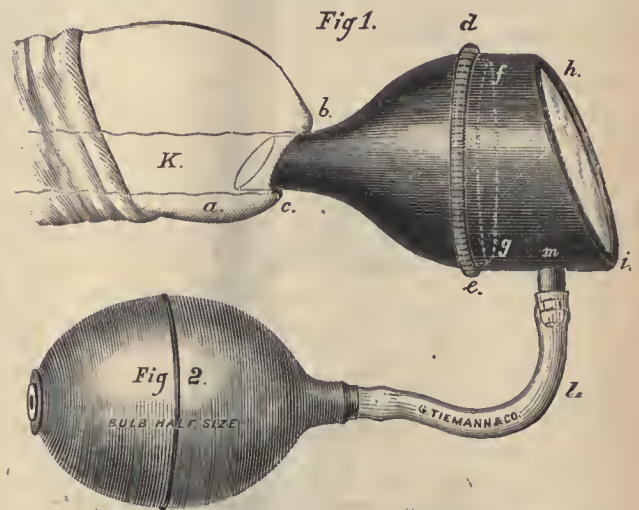

Fig. 1.—Heule's Aëro-urethroscope.

Heule's instrument consists of two parts, viz., "the speculum, *a, b, d, e*, and the cover, *f, g, h, i*. The speculum is made of rubber, glass or metal, shaped like a truncated cone, with the end *a, b*, cut obliquely to facilitate its introduction into the urethra without the aid of a stilet. At the other or proximal end is a flange, *d, e*, which is useful in separating the cover from the speculum. Into this proximal end is closely fitted the removable cover, *f, g, h, i*, having at *h, i*, a transparent glass crystal, fitted airtight, and at *m* an attachment for a rubber tube with bulb (Fig. 2) for forcing atmospheric air into the endoscope.

"To prevent the glare of reflected light, the glass crystal at *h, i*, is placed at an obtuse angle to the line of vision, and the inside of the instrument is blackened. The specula at *a, b, c*, are made of various sizes to fit small and large openings, but at the proximal end, *d, e*, are all adapted to one cover, *f, g, h, i*.

"In using this instrument the flaccid penis is grasped between the ring and middle fingers of the left hand, the lips of the meatus being opened with the index finger and thumb of the same hand. The endoscope held in the right hand by the flange, *d, e*, can now be readily introduced into the urethra by means of the oblique end, *a, b, c*, until the thicker portion of the speculum, near *d, e*, fills the opening. Air is now

¹ Vierleijerssch, f. Derm. u. Syph.

forced in by the rubber bulb in the hands of the surgeon or patient until the requisite distension of the urethral canal is obtained. In case there should be too much distension, the air may be allowed to escape from the meatus at the side of the speculum by slightly withdrawing it."

Two years later, (1892) E. Hurry Fenwick, of London, having followed the work of von Antal and Heule, induced Leiter to add an aëro-urethroscopic attachment to his electro-urethroscopic illuminator and was thus the first to combine the source of illumination with the air apparatus in a single instrument.

This instrument consists, as I have said, of the well-known Leiter illuminator arranged with an inflation apparatus. The nose piece is closed with an obliquely set glass diaphragm, so that air forced into the canula by means of an India rubber ball can not but distend the penile urethra up to the commencement of the deep urethra (the compressor urethræ muscle). The cup at the proximal end of the canula receives the convex glans penis, and effectually prevents the indriven air

from a concave mirror (reflected light) is inferior to that obtained by means of a plano-convex lens.

Fully recognizing the advantages which at times must be derived from an examination of the inflated urethra, I have designed an aëro-urethroscopic attachment to my "perfected" urethroscope which obviates the objections pertaining to previous instruments of this character.

This consists of a hard rubber disc, one and three-fourth inches in diameter and one-sixteenth of an inch in thickness, backed with metal. In the center of this disc is a circular aperture, one-half inch in diameter, to the inferior edge of which is soldered a metal rim one-fourth inch in depth, forming the male half of a sliding joint by which the different sizes of urethral tubes are attached to the instrument. On the superior surface of the disc, a glass diaphragm, held in a metal collar and placed at an oblique angle to prevent the reflection of light, is arranged on a pivot so as to swing over the aperture, hermetically closing it; or, when desired, instrumental applications through the tube beneath may be made by simply swinging it in the opposite direction. A slight projection on the side of the cap, locks under the outer end of the metal shoulder, by means of which my illuminator is fastened to the plate in exactly the same manner as it is to the Klotz tube. A small metal tube extends from the edge of the plate into the

Fig. 2.—E. Hurry Fenwick's Aëro-Urethroscope.

escaping from the urethra, unless a great pressure is exerted. The diaphragm, fastened in a collar, is held in place by means of a sliding joint with a bayonet catch, so that when a granular patch, ulcer, or tumor is discovered by means of inflation, the end of the canula is held firmly in position, the diaphragm is removed, and the operation proceeds through the open tube under the direct control of the electric light.

While this instrument is sufficiently effective to accomplish very excellent results, at the same time it presents several marked disadvantages, so that it can by no means be considered as the ideal instrument for this purpose. It is heavy and cumbersome, the distance between the glass surface of the diaphragm and the meatus is over two inches and a quarter (a decided consideration when we remember that the intensity of the illumination diminishes as the square of the distance). In making an application the diaphragm must be removed and laid aside, then found and replaced, making an annoying break in the rhythm of the operation, while it is not always easy to immediately connect the bayonet catch. The illumination

Fig. 3.—W. K. Otis's Aëro-urethroscope.

movable cap. To the outer end of this tube is fastened a piece of rubber tubing with double India rubber bulbs, like those used in the Paquelin cautery, by means of which the urethra is inflated. Urethral tubes of any length or caliber may be used with this instrument. To prevent the escape of air from the urethra the proximal ends of the urethral tubes are made conical so that they may be firmly wedged into the meatus urinarius, though if the metal cap covering the glans penis is preferred, tubes of that pattern may be adopted. The advantages of this instrument over others designed for a similar purpose are:

1. Ready access to the urethral field for the purpose of making local applications under the direct control of the light.
2. Minimum distance between the eye and the urethral mucous membrane, hence a better and clearer view of the field.
3. Extreme lightness.
4. Simplicity of construction and moderate cost.

Aëro-urethroscopy is undoubtedly a valuable addition to our means of obtaining a visual inspection of the urethral mucous membrane and will, in many

cases, render a diagnosis possible which would otherwise be obscure, nevertheless the field of vision, even in this method, is limited and by no means as perfect as some observers would lead us to believe. The manipulation of the inflating apparatus slightly complicates the technique of the examination, and the occasional escape of air into the bladder is unpleasant to the patient and annoying to the surgeon. The clouding of the glass diaphragm by the exhalations from the moist, warm mucous membrane sometimes renders the view hazy and unsatisfactory. The pressure exerted by the air also adds an element of uncertainty in correctly diagnosing the exact condition of the mucous membrane, while the view of the walls of the urethra is indirect; as when looking down a gun-barrel, flaws may escape notice which would be readily observed if we were looking directly at the surface of the metal, so lesions of the mucous membrane may escape detection by this method of examination. We are, however, able to obtain a direct view at any point by removing the diaphragm and allowing the air to escape. When the diaphragm is not in place this instrument practically becomes a simple urethroscope and the same view is obtained of the urethral mucous membrane as through the ordinary tubes.

The difficulty in obtaining a thorough appreciation of the morbid conditions present in the many obscure cases which present, when the urethra is implicated, renders any additional assistance to our present methods extremely desirable, so that despite these drawbacks the aëro-urethroscope furnishes us with a new means for investigation and an aid to diagnosis which no urethroscopist of the present day, no matter how skillful, can afford to ignore. Aëro-urethroscopy does not supplant the older method of visual urethral examination, but rather is a powerful ally, by whose aid we are enabled to increase our appreciation of the conditions existing in the urethra by obtaining more extensive pictures from different points of view. The advantages of ocular examination of the inflated urethra have already been demonstrated, and the simplicity and facility of manipulation of this instrument, it is hoped, will add to the growing popularity which the method already enjoys among those who have given it a practical test.

VAGINAL FIXATION IN RETRODEVIATIONS OF THE UTERUS, WITH SOME REMARKS ON VAGINAL CELIOTOMY.

Read in the Section on Obstetrics and Diseases of Women at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY N. O. WERDER, M.D.
PITTSBURG, PA.

The newest addition to our operative treatment of the backward displacements of the uterus is vaginal fixation. It is the result of a gradual evolution of Schücking's method, and its modifications by Zweifel and Sänger, and has been developed to its present form by Dührssen and Mackenrodt, each of whom claim priority, and is known by their respective names, their methods varying very little from each other.

The technique of Dührssen's operation, which is the simpler of the two is as follows: the cervix, having been seized by a volsellum forceps, is drawn down toward the vulva; a transverse incision is

made through the anterior vaginal wall close to its attachment to the cervix, care being taken to avoid the bladder. The latter is then dissected away from the uterus just the same as in vaginal hysterectomy. It is important to push the vesico-uterine fold as far up toward the fundus, by the finger, as we can, in order to expose as much of the body of the uterus as possible. If thereby the peritoneum should be opened accidentally, no attention is paid to it; the important point upon which the success of the operation depends being to be able to secure the uterus by the fixation sutures at or near its fundus. A stout silk ligature is now passed through the anterior uterine wall at its highest visible point; traction on this enables us to catch the uterus a little higher up by a second provisional suture. If drawing on this does not bring the fundus into the vaginal wound, a third similar suture usually accomplishes this. It is now fixed by silkworm gut sutures to the edges of the vaginal wound; two such sutures being generally employed. The provisional sutures having been removed, the rest of the vaginal wound, which is usually converted into a longitudinal one, especially when there is a shortening of the anterior vaginal wall, is now closed by a continuous catgut suture. The patient is returned to bed and kept there about ten days. The fixation silkworm gut sutures are removed about six weeks after the operation. In my last eight cases I have employed buried silkworm gut sutures and have found no harm resulting from them thus far. After the operation the uterus is found firmly fixed to the anterior vaginal wall and is, I believe, in about as nearly a normal position as any fixation operation can possibly bring it.

Mackenrodt's operation differs from the one just described only in the method of vaginal incision. Instead of separating the anterior wall of the cervix from the vagina by a transverse incision at the cervico-vaginal junction, he makes a longitudinal incision extending from the center of the cervix to within an inch of the meatus urinarius, dividing the anterior vaginal wall into two equal flaps which are dissected off the bladder; the dissection is carried up along the anterior wall of the uterus until the entire bladder is separated from it. The fixation is done in the same manner as in Dührssen's operation.

Failures in both of these operations have been due to the fact that the fixation sutures were inserted too low down in the body of the uterus. In order to guard against a return of the malposition the fundus must be sutured to the vagina. In the only case, my first one, in which I followed this method, and which was at least a partial failure, the uterus returning into the position of slight retroversion shortly after removing the sutures, I no doubt made the mistake of fixing the uterus below the fundus. It is rather difficult to strip the vesico-uterine fold up to the fundus without tearing through the peritoneum. This probably induced Dührssen to open the peritoneum as soon as the bladder has been separated from the uterus in all of his more recent cases, as it allows the operator to see the exact point where he wishes to insert his sutures, which is at the fundus, between the cornua—the fundus is reached and drawn down in this *intraperitoneal* method in the same manner as described above; that is, by climbing up along the anterior wall of the uterus with provisional sutures. This is preferable to seizing the body of the uterus by

means of tenacula or volsellum forceps, which tear out very easily.

In the thirteen cases in which I have performed vaginal fixation, in twelve I have operated by the intraperitoneal method and regard it as much preferable to, and more satisfactory than, the older ones. Thus far I have not seen a single failure in these twelve cases, though they are all too recent to justify an opinion as to the permanency of the results, they all having been operated upon within the last seven months.

In all cases the operation of vaginal fixation should be preceded by a thorough curettage, not only because an endometritis is present in nearly all the cases requiring an operation, but because it is advisable to have an aseptic uterine cavity, should any of the sutures pass through the endometrium. If an operation about the cervix is required, it should be performed before fixation is undertaken. In most of my cases, in addition to a curettage, trachelorrhaphy or excision of cervical erosions, or an amputation of the cervix was done previous to fixation and followed by an Emmet's perineum operation, all at one sitting. An anterior colporrhaphy can easily be combined with this operation, especially when Mackenrodt's method is employed; the only additional step being required is an incision of a crescent-shaped piece from each vaginal flap before bringing them together by the continuous catgut suture.

Pregnancy has occurred only in one of my cases, the first one, who went to term and was delivered without any difficulty. Dührssen says in regard to this point: "Pregnancy continues to term without any disturbance and no harm has resulted during labor which can properly be attributed to the preceding operation. By observing a few precautions, the uterus will remain in the position secured by the operation after pregnancy and labor."

The intraperitoneal method of vaginal fixation termed "vaginal celiotomy," by Dührssen, has, beside permitting of a more satisfactory fixation of the uterus, the great advantage that it allows the fundus to be drawn down to the vulva and outside of it, and with it the adnexa, which can then be carefully examined both by touch and visual inspection, as I have repeatedly been able to demonstrate in my cases. When necessary, diseased ovaries and tubes can, as a rule, be removed with ease in this manner. Adhesions about the uterus and appendages can be separated with little more trouble than by abdominal section. Small fibroid tumors have been enucleated from the body of the uterus during this operation^{2,3}, and A. Martin⁴ has divided the anterior wall of the uterus by a median incision up to the fundus and after removing small growths from the uterine cavity, closed the uterine incisions and re-attached the bladder to the uterus. From this we can see what a large field is hereby opened to the conservative pelvic surgeon.

In two of my cases the retroflexed uterus was adherent with its appendages and the adhesions were broken up during the operation. In one of my cases an ovary and tube was removed. In two others, cystic ovaries were punctured, once with the thermocautery. In all cases the convalescence was that

following an ordinary curettage, excepting one in which some complications delayed the recovery, and the patients were usually up on the tenth day.

The only precaution necessary in the cases in which we wish to bring the uterus and adnexa out of the vaginal incision before the vulva, is to provide a free vaginal incision and to make the opening through the peritoneal fold connecting uterus and bladder, just as large as that through the vaginal wall. A neglect of this precaution may lead to serious difficulties in returning the uterus, with its appendages, as I experienced in one case. Since then I have been in the habit, when I wish to examine the adnexa, or to separate adhesions, to connect the transverse vaginal incision with a longitudinal one; in other words to combine Dührssen's and Mackenrodt's incisions, which gives ample room for any operations indicated.

From what has been said we can place the indications for vaginal celiotomy or the intraperitoneal methods of vaginal fixation on the same level with ventrofixation. Its advantages over the latter operation, however, are:

1. The avoidance of an external incision, which is always regarded with more or less fear by the patient, and which is liable to be followed by stitch and mural abscesses, fistulae and hernia, accidents not common, but always within the range of possibility.

2. Less danger from septic infection, as there is no manipulation of intestines, which hardly ever come into view during the vaginal operation, and less exposure of the peritoneum.

3. The shorter and smoother convalescence with absence of the distressing symptoms usually following laparotomies, such as intense thirst and flatulence.

To this I may add another advantage, which is, that patients with retrodisplacements, who require operation for some other lesion about the cervix or vaginal outlet, will readily consent to an operation correcting the malposition of the uterus, provided this can be done by some vaginal operation without increasing the risk or time of convalescence; while the operator frequently hesitates to urge, and the patient is loth to consent to an operation requiring some external incision. Many patients, however, as I have learned from experience, are very much disappointed after recovering from some plastic operation, when they learn that they still have a displacement of the uterus for which they may require the use of a pessary. In most cases in which a displacement complicated other lesions requiring plastic operations, I have advised vaginal fixation and this explains in a measure, the comparatively large number of cases operated upon within a short period of time.

The only contra-indication to the operation is a very narrow vagina, though my list includes two unmarried patients, in whom, however, the operation proved rather difficult. It may be said in favor of ventrofixation, that it is easier than vaginal fixation, which is, no doubt, true; but the gynecologist who has been trained in plastic work and has had experience in vaginal hysterectomies will find no difficulty in its technique.

A REMARKABLE CASE OF VISCERAL ANOMALY AND INVERSION.

BY G. E. CRAWFORD, M.D., PH.D.
CEDAR RAPIDS, IOWA.

A very remarkable and interesting case of congenital deformity and anomaly of the heart and other viscera came to my notice a few days ago at the autopsy of a young girl of 16, who had suddenly died of heart disease after a brief incidental illness of a couple of days.

I had had the child under observation for about five years. Her people are ignorant Bohemians and I was not able to get much history of the case previous to that time. Though a delicate child she had not been sick much; had measles when 3 years old. They had no knowledge of her heart trouble, and did not know that there was anything the matter with her until her chest became much deformed, and this they did not notice until she was 10 years old and then attributed it to a fall, but there was no evidence that she had had any fall.

I mention these trivial matters in the absence of a better history, merely to show how mild the symptoms must have been not to have attracted any attention until she was 10 years old.

When I first saw her, about five years ago, she was suffering from some febrile disturbance, probably having no causative relation to the heart trouble. The heart at that time was much enlarged and beating tumultuously, with a loud mitral murmur. Dyspnea and cyanosis were marked; I expected her to die, and told her parents that she was liable to die at any moment. But the fever passed off and she soon recovered and was as well as usual again. A year ago she had a similar attack, which was followed for a time with pain in the chest, dyspnea and very bad heart action. I prescribed two or three times for this, and then saw nothing more of her until the day she died. Her father told me since that for some time past whenever she stooped over she would spit up some blood. On the evening of June 17, they sent to me for something to stop vomiting; the girl wrote the note herself. I prescribed for that symptom. Two days after I was called to see her and found her with quite a high fever and in a restless, excited state bordering on delirium; the heart beating violently, the pulsation seen and felt on the right side. The impulse was so strong that the concussion of the chest could be seen across the room. I called again at noon, found her extremely cyanotic, pulseless at the wrist, though the heart was still beating violently. She soon afterward died.

I made a post-mortem at 5 o'clock in the presence of several of my medical associates. The form was tall and slender—rather above the average height of a girl of 16, with a marked deformity of the thorax, which was narrow and protruding in the front—a marked condition of pigeon-breast; also protruding posteriorly in a posterior curvature of the spine—a veritable visceral hump or dome. The heart, immensely enlarged, was found to fill the entire left side of the thorax; it was turned half over to the right, with the left ventricle to the front, extending diagonally across the chest downward and to the right, bringing the apex well over in the right side. The pericardium was greatly thickened and abnormally adherent, both to the heart and the diaphragm; contained no fluid. The left side of the thorax was thus entirely filled with the heart; there was no left lung whatever.

On the right side of the thorax, behind the apex of the heart, was a double lung, consisting of two long narrow lobes, side by side, connected in the middle for about two-thirds of their length. This anomalous lung was healthy, and seemed to have about the capacity of one normal lung.

The heart as it was taken out with the pericardium, with the auricle collapsed, measured nine inches in length and six inches in greatest breadth, and weighed three and a quarter pounds. There was but one common auricle, which was greatly dilated, which opened into each ventricle. It would probably hold a pint and a half of blood when distended. The auriculo-ventricular valves were very defective, especially the mitral, which could have offered very little resistance to regurgitation. The ventricles were greatly hypertrophied, especially the left. The aortic and pulmonary valves were intact, and this alone made it possible for any circulation to be carried on. The arch of the aorta was dilated, but beyond this it was remarkably small. The pulmonary artery was short, dilated and bifurcating about an inch and a half from its origin, passed into each side of the double lung.

The liver was also enlarged to several times its normal dimensions, extending entirely across the body, with the gall-bladder on the left side.

The stomach was long, intestinal shape, having scarcely any of the form of the normal stomach.

The spleen, or rather three distinct spleens, were situated in the right side, also enlarged. The larger one measured seven inches in length by three inches in breadth; the second one, which is about the size of the normal spleen, is three inches by two inches; and the smallest one two inches by an inch and a half. These glands are entirely distinct, but connected by large blood vessels, about two inches in length.

The kidneys were about double the usual size.

The other abdominal and pelvic organs were healthy and in their normal relations.

All who saw the case were agreed that it was the most remarkable of its kind of which they had any knowledge. And it is especially interesting to know that a child could live in this condition to be 16 years old, and nearly all the time in quite a comfortable degree of health.

PERITONEAL SUPPORTS—(LIGAMENTUM PERITONEI).

CHICAGO.

(Continued from page 152.)

The omentum colicum Halleri is the right lower border of the great omentum. It can be distended with air driven through Winslow's foramen. If one follows the peritoneum from the right kidney upward and outward over the pars descendens duodeni, upward to the anterior part of the transverse colon, it will be noticed that this layer of the peritoneum passes into the anterior layer of the great omentum. This is Haller's omentum and it will extend along the ascending colon for a considerable distance; the point of its lower end may reach the cecum in some embryos which I have examined. This same process of peritoneum which I traced from the right kidney until it was lost in the anterior layer of the great omentum, can also be traced up to the ligamentum hepato-duodenale with which it may blend and form

what is known as the ligamentum hepato-colicum. This fold of omentum reaches from the hepatic flexure of the colon to the liver. It seems to be often no more than an increased projection of the ligamentum hepato-duodenale. In quite a number of cadavers I have actually noted the gall bladder lying in this coli-hepatic ligament. There was a mesentery of over an inch between the liver and the gall bladder, and also a mesentery reaching from the gall bladder to the hepatic flexura of the colon. The gall bladder lay in this ligamentum hepato-colicum exactly as the pancreas lies in the great omentum between the stomach and colon (in embryos). This hepato-cystocolic ligament is of great importance in subjects of gall stone. For it will serve two valuable purposes, viz.: 1, it will conduct an hepatic calculus ruptured through the gall-bladder toward the colon external to the peritoneum and induce it to enter the colon on a portion not covered by peritoneum; 2, this ligament, when large will especially aid in circumscribing pus which arises from rupture of the gall bladder. It will form a barrier against infectious invasion. By the peculiar ligamentum hepato-colicum, there is formed a more or long distinct cone-like sac in the right border of the great omentum, just as there is formed a sac in the lower left border of the ligamentum phrenico-colicum. Any evaginated peritoneal sac is liable to obliteration, so this sac no doubt is more or less obliterated by coalescence or readjustment.

Bochdeleck asserts that Haller's omentum gradually loses the capacity of being distended with air being blown through Winslow's foramen toward the fifth embryonal month through coalescence. Yet some embryos at five months allow a large sac to be distended by air in the omentum colicum Halleri. I have observed in adults that the omental sac is frequently limited in various directions by adhesions. In an adult male which I recently examined, I tore through the gastro-colic omentum to make careful observations of the lesser omental cavity for two reasons: 1, because the case possessed a mesenterii commune and I wished to note the existing omental relations; and 2, the remnants of ancient peritonitis were quite general and I wished to note its effect on the omental cavity. In this case the omental cavity was chiefly limited toward the left by approaching adhesions or coalescence of the walls where the sac was prolonged between narrow layers and peritonitic bands stretched across the space, and the lesser omental bag lacked the space of an adult form encroaching adhesions on the margin of the sac. I could find no constricted off sacs, but could find depressions constricted off, which could easily become constricted off sacs by further coalescence due to inflammations. I have found peritoneal pockets or sacs constricted off by inflammation frequently along the colons. Such sacs or peritoneal pockets appear to be lined by genuine peritoneum and are of various sizes, from that of a hazel nut to that of an apple. The only typical lesser omental sacs are those of embryos under seven months of intra-uterine life. For in adults I find the lesser omental sac, especially at its left end, variously limited in size by various kinds of encroaching adhesions at its margins. In short, the encroaching adhesions or coalescence of the lesser bag is apt to occur on the left, adjacent to the ligamentum phrenico-colicum and at the right in the omentum colicum Halleri. Bochdeleck gave

a splendid illustration of the relations of the ligamentum hepato-colicum by noting that it will distend with air driven through the Winslow's foramen and also that in some cases the distension will actually reach to the neck of the gall-bladder, along the descending part of the duodenum and even in front of the pancreas. All the above distensions are in direct communication with the lesser omental bag. The lesser omental cavity becomes partially obliterated at different periods of existence, without any rule I can formulate. However, my examinations report that the chief variations arise at the extreme right or left of the omental sac. Now to retrace the steps by which the great omentum becomes the mesocolon is impossible so far as it relates to Meckel and Miller's views. Coarse instruments will fail, and even air driven through Winslow's foramen is insufficient to note the original boundaries. One can not tell what his instrument has divided or what the distending air has separated, and I am sure that much manipulation does not bring one to the goal of primitive structures. I must state, however, that embryos show very distinctly that the origin and method of formation of the mesocolon transversum as well as the circumference of the bursa omentalis vary very much as regards individuals and time.

It may be summed up as follows: from the ligamentum hepato-colicum to the ligamentum phrenico-colicum, the peritoneum consists of one membrane, *i. e.*, one blade of the great omentum at its lower border. It may be said that the lesser omental cavity is the diverticle of the mesogastrium posticum. The lesser omental cavity may consist of diverticulæ constricted off at either right or left ends or both, *i. e.*, closed off sacs may exist in the ligamentum phrenico-colicum or in the omentum colicum Halleri.

THE GREATER OMENTAL CAVITY, THE GREATER CAVITY OF THE PERITONEUM, THE GREATER BAG OR SAC OF THE PERITONEUM.

The greater sac of the peritoneum is that one placed between the viscera and anterior abdominal wall. It comprises all the peritoneum except that of the lesser sac. The greater or lesser sacs are not placed in regular order, but may be compared to an hour-glass with one end smaller than the other, and also the smaller end bent over the greater end, *i. e.*, the hour-glass is not in the same straight line. The smaller sac lies almost wholly within or below the greater sac. The greater sac with its posterior layer lies on and faces the anterior surface of the viscera. Its posterior layer lines the anterior abdominal wall. The posterior layer of the sac lies on the surface of the viscera and sends back folds and tucks into the clefts between the viscera. The various diverticulæ which the greater bag projects between the viscera not only line the visceral clefts, but pass back in places to most the projections of the lesser bag, *e. g.* one diverticle passes back between the liver and diaphragm to meet the lesser omental bag. Another projects between the stomach and liver to meet the lesser bag at the transverse fissure of the liver. Still another pouch of the greater bag passes to the dorsal wall between the transverse colon and the small intestines. This pouch comes in contact with the lesser bag at the under surface of the upper blade of the mesocolon transversum. The long, wide, pendulous, pars colico-omentis hangs freely into the greater omental sac. In short, the greater sac almost sur-

rounds the lesser sac. The anatomic fact is that the two sacs greater and lesser, are not and should not be separated. They are one and the same membranous bag simply constricted at the foramen of Winslow, lying between the portal vein and the inferior vena cava. At the lower end of the great omental sac there are some smaller diverticulæ. There is one between sacrum and rectum, one between uterus and rectum and one beside the omental sac envelopes the viscera lying along the dorsal wall and in the pelvis, and then its anterior layer lines the anterior abdominal wall. The great omental flap consisting of four layers (the pars colico omenti) hangs like a veil in the middle of the great bag.

Figure 36.

At this place the figure of Cruveilhier (See JOURNAL, p. 149.) can be referred to as it is an apt cut in illustrating some of the views of coalescence. It will be observed by this figure that the two blades of the mesogaster, one from the posterior and the other from the anterior surface of the stomach, converge at the greater curvature of the stomach and pass downward below No. 5, whence the two blades return on themselves, passing upward entirely in front of the transverse colon, onward to the dorsal wall of the abdomen. Now, the posterior blade of the great omentum ascends on the dorsal wall of the abdomen, while the anterior blade descends on the dorsal wall for a short distance, thence it passes forward to form the upper blade of the transverse mesocolon. When this upper blade arrives at the transverse colon it passes around the bowel and forms the under blade of the transverse mesocolon, whence it descends to form the mesentery of the small intestines. The dispute between the coalescence and displacement theories concerns the pouch No. 2. The coalescence theory claims that the peritoneal pouch No. 2 becomes obliterated by adhesion. The displacement theory claims that the pouch No. 2 is drawn out and readjusted so that no part of the serous layer lining the peritoneal pouch is destroyed. v. Hansen wrote a treatise on the physiology and anatomy of the peritoneum in 1839 in Latin, in which he claims that in the fetuses there are five peritoneal layers in front of the transverse colon (as in the figure) and not three as in (Fig. 21, JOURNAL, p. 108.) In the adult the adhesions of the layers forming pouch No. 2 and the dotted line into one single layer obliterates pouch No. 2 and produces conditions observed in grown persons. But the readjustment or displacement theory allows of no coalescence or obliteration and insists on the dragging out of peritoneal pouches during the progress of visceral development. The displacement theory readjusts the serous surface over the viscera during their varying vicissitudes of growth and fluctuations of size. The displacement theory is a very elastic and widely applicable affair. It allows viscera to appropriate serous membrane to the disadvantage of other organs. It

is an evolutionary theory, a survival of the fittest, *e. g.*, the growing cecum steals away from the atrophying appendix its covering, appropriating it to its own needs.

In regard to the great omentum, it may be said that not all the mesogaster is involved in the formation of the lesser omental cavity. Only that part of the mesogaster which is in contact with the stomach itself is involved in making the smaller peritoneal bag. That part of the mesogaster which is attached to the duodenum does not enter into the formation of the lesser sac.

The mesoduodenum, minus the serous epithelial layers which originally faced both sides, lies against

Fig. 37 (after Deblierre, 1890, modified) represents a horizontal section of the body on a level with the umbilicus to show the disposition of the peritoneum. 1, white line; 2, round ligament of liver; 3, rectus abdominalis muscularis; 4, aponeurosis of external oblique; 7, parietal peritoneum; 20, kidney; 21, psoas munda; 22, vena cava; 23, aorta; 24, pillars of the diaphragm; 25, left descending colon; 26, right ascending colon; 27, small intestine; 28, right blade, 29 left blade, of the mesentery; 30, mesocolon, left. It must be observed that the vertical colons in this diagram are represented as possessing each a mesocolon, which long investigation in the viscera has convinced me are abnormal. The normal vertical colons appear to me to possess no mesocolon. The arrow points to Petit's triangle.

the left dorsal wall and does not engage in forming the lesser sac. It may be allowed that a small part of the left serous surface of the mesoduodenum enters into the formation of a small part of Haller's omentum, but that is not settled. Hence only the gastric portion of the mesogaster is involved in the formation of the lesser sac of the peritoneum.

As regards the views of the coalescence of the peritoneal surfaces or displacements of the same,

Fig. 38 (after Deblierre, 1890, modified) represents diagrammatically the development of the greater and lesser cavities of the peritoneum. 1, greater cavity; 2, lesser cavity of the peritoneum; 3, hiatus Winslowii; E, stomach; F, liver; I, intestine; C, colon; U, uterus; V, bladder.

considerable has been said by only a few authors. Those who support the coalescence theory must present reasonable grounds, especially, to show why it applies to distinct localities of the peritoneum as, *e. g.*,

the great omentum. The view of coalescence must be based on: (a), local peritonitis whereby the epithelium of the peritoneum is destroyed and the two bared, denuded surfaces simply unite as in any other wound; (b), the advocates of peritoneal coalescence must show that the epithelial cells of the serous layer are not genuine epithelial cells or that they are another structure—endothelial; (c), they must show that these endothelial cells are of such a character that they will coalesce and disappear in a physiologic manner, *i. e.*, the peritoneal surfaces are of a connective tissue type and hence a normal physiologic coalescence may arise; (d), such advocates must show why this "physiologic coalescence" occurs in local places in the peritoneum, as the great omentum, and not anywhere and everywhere in the peritoneum.

As far as regards the first view of coalescence by local peritonitis, all agree that it is correct; that coalescence of peritoneal surfaces is an actual and frequent occurrence. But the theory will not fit when it only applies to a particular locality and not to all parts of the membrane alike. Why the anterior blade of the great omentum should be subject to a peritonitis and blend with the superior blade of the transverse mesocolon by peritonitis in intra-uterine life, is not tenable because, under the same circumstances any other part or the whole of the peritoneal surfaces might be endangered to peritoneal coalescence. In this theory no adequate reason is offered why the great omentum alone is attacked with the process of coalescence.

The second theory of coalescence comes, so far as I am aware, from the venerable pioneer, Professor His of Leipsic. This theory advocates the idea that the serous epithelium is not genuine epithelium, that it is endothelium, or rather nothing but connective tissue cells. Therefore as connective tissue cells it can coalesce at any other point as any other connective tissue surface. If this were the case it may be asked why coalescence, especially in the great omentum and not everywhere on the serous surface; why this predilection for the great omentum and not any and all the peritoneal surface. If the epithelial cell on the serous surface is only connective tissue, a person is in constant danger of having his whole peritoneal sac obliterated at any time.

This theory does not explain any more than the first, its selective affinity for the great omentum to the exclusion of other serous localities. So far as regards "physiologic coalescence," it does not differ from the second theory. We would not know when and how it began, nor its method of progress nor when or where it would end, so that the coalescence theory has no especial favor, except a local peritonitis. In that case the whole matter rests back as to what induces local peritonitis. Will the passage of the right end of the bowel over the mesoduodenum create sufficient friction to arouse a (plastic) peritonitis and consequent destruction of epithelium which will be followed by cohesion of surfaces?

(To be continued.)

Trustees of Insane Asylum to Receive No Compensation.—Section 3, of chapter 330, of the Wisconsin Laws of 1889, entitled, "An act relating to the maintenance and care of the chronic insane in counties having a population of more than 100,000, and an asylum therefor," is amended by adding a provision that "such trustees shall receive no compensation."

SOCIETY PROCEEDINGS.

The Ohio State Medical Society.

Annual Meeting held at Columbus, May 15, 16 and 17, 1895.

SECOND DAY—MORNING SESSION.

DR. JOHN A. THOMPSON, of Cincinnati, Ohio, read a paper on

DEAFNESS FROM INTRANASAL DISEASE.

Diseases of the ear are more intractable to treatment than those we encounter in any other department of medicine. Late cases of chronic catarrhal otitis media in either of its forms, are regarded by experienced otologists as being almost hopeless by modern methods of treatment. From this hopelessness arises the constant suggestion of new procedures directed to the ear itself, in the hope of at least partially restoring the function which is so important to the happiness and success in life of the individual. A few observers, notably Swineburne, turning from the attempt to cure the already established condition, have sought to lessen the number of hopelessly deaf by seeking the cause, and method of prevention. Swineburne examined the nose and throat carefully in a thousand cases which presented themselves at the Harlem Eye, Ear and Throat Infirmary, complaining of deafness. Where deafness resulted from disease of the middle ear, his conclusions are that in 95 per cent. of all cases the primary lesion is in the nose or naso-pharynx.

Just how disease in these organs produces chronic inflammation in the tympanic cavity, has been a question of dispute. Some experienced writers assert it is due to the direct extension of inflammation by continuity of tissue. In structure, the tympanum is only one of the accessory sinuses of the nose, though it differs entirely from that organ in function. Others have thought we could trace the resultant ear disease, secondary to obstructive lesions in the upper respiratory tract, to imperfect aeration of the middle ear. Still other authorities have thought that the interference with the circulation in the internal and middle ear by the inflammatory and neoplastic changes in the nose or nasal pharynx, was the cause of the secondary disease. It is probable that each method plays a part in the production of secondary diseases in the middle ear.

While I have seen many cases where the secondary deafness could be accounted for, and the cure understood from the well-known relations of nasal and aural diseases, I have encountered others that are not susceptible of explanation by any of the known facts in rhinology or otology. I wish to report three of these cases, chosen because they are dissimilar in many of their features. They suggest that there is a relation not yet understood, between the healthy condition of the nose and naso-pharynx, and the sense of hearing. In all of these cases there has been a serious and irremediable impairment of the organ of hearing, yet in all, the ability to hear has been greatly increased by restoring the nose and throat to their normal condition.

Mrs. S., aged 31 years, married when 16 years old, has suffered from diseases of the generative organs since the birth of her first child. She is very nervous, weak and anemic. She suffered from pains in the chest, headache, cardiac palpitation, rapid pulse and dyspepsia. These symptoms could not be relieved by ordinary constitutional treatment. She was referred to me by her physician, Dr. W. H. DeWitt, for the treatment of the upper air passages, with the hope of relieving these intractable symptoms, which he believed were secondary to the local disorder.

The patient had marked hypertrophic rhinitis with a deflected and thickened septum. The thickening was in the right nostril. There was also marked naso-pharyngeal catarrh. The right ear was deaf to all ordinary tests. She could not hear the watch on contact. She could not hear the conversational voice. She could hear loud voices only as an indistinct noise. She gave a history of this ear as follows: seven years before, while suffering greatly from her uterine trouble, the ear became inflamed and was intensely painful for several days. The drum was finally perforated;

the pain diminished with the free discharge of pus from the ear. She had had occasional attacks of acute suppuration in the middle ear from that time. Inspection of the ear showed a cicatricial drum membrane with evidence of old perforations. There was no suppuration at this time. The ossicles were firmly bound together by old inflammatory adhesions. The condition revealed by inspection was so bad that no attempt was made then or subsequently to improve the hearing by treatment of the ear. The hypertrophic rhinitis was treated by the usual method and the spur on the septum was removed March 13, 1894. The headache and neuralgia of the chest which the patient had supposed were all due to her uterine trouble, were entirely relieved within six weeks after this operation. The rapid pulse and cardiac palpitation yielded to the combined effect of the operation and heart tonics administered internally. The patient began to improve in health and strength and in a short time felt better, weighed more, and was better able to do her work than she had been for years. About ten months after the operation, she discovered that the hearing had returned to the supposed incurably deaf right ear. A careful test of this organ in April, 1895, shows that the patient is able to hear the conversational voice fairly well, and hears the watch, which was not heard on contact before the operation, two inches from the ear.

F. J. H., aged 18, had scarlatina when he was 13 years old. The scarlatina was complicated by purulent otitis media in both ears. The drum membrane and ossicles of the right ear were completely destroyed. In the left ear three-fourths of the drum membrane was destroyed and the ossicles remained bound together by cicatricial adhesions. With every cold the patient caught, there would be suppuration from one or both ears. I saw him first in March, 1894. At that time he heard a conversational voice one foot, could not hear a watch on contact, and could not hear a whisper at all. There was no appreciable difference in the hearing powers of the two ears. He was about to lose his situation as clerk, because of his inability to carry on a conversation with customers in the store.

Examination of the nose and throat showed hypertrophic rhinitis and a large spur on the septum in the left nostril. There was a complicating naso-pharyngeal catarrh. After treating the acute inflammation that was present when I saw him, for a few days, I removed the spur and cauterized the hypertrophied turbinated bodies so as to give him free breathing room through the nose. The left ear was suppurating when I first saw him, but this suppuration readily yielded to the dry treatment. The patient was under treatment six weeks and was dismissed with the ability to hear a whisper three feet and to distinguish ordinary conversation so readily that he still retains his position as clerk. Dec. 1, 1894, he caught a severe cold, and with the resultant swelling and inflammation of the nose and throat, his hearing became again seriously impaired. Ten days of local treatment cured this attack, and with the return of the nose to the normal condition, the hearing distance for the whispered voice again became three feet for either ear.

Mrs. F. L. J., aged 35, has been deaf from childhood. I can get no distinct history of the cause of this deafness. She had repeated attacks of acute purulent otitis. In her earlier years she was treated by a number of good otologists who succeeded in checking the suppuration, but did not prevent the total loss of hearing power in the right ear. She had been constantly under the care of a competent man for three years before I saw her. She had visited him once or twice a week all this time to have the left ear inflated by the Politzer method. This inflation gave temporary relief from the tinnitus aurium and improved the hearing temporarily. In spite of this treatment, the deafness was progressive and at the end of the three years she was worse than at the beginning of this period. Examination of the ears showed the right ear with only a perception of loud sounds. Inspection of the drum showed only a mass of cicatricial tissue, through which nothing could be seen to throw any light on the condition of the middle ear. The left ear showed a badly retracted drum membrane with cicatrices where old perforations had healed. Loud voice heard only one foot, watch not at all, in left ear. Examination of the nose showed a bad hypertrophic rhinitis, and in the right nostril at the junction of the perpendicular plate of the ethmoid with the triangular cartilage, there was an enchondroma with a broad base nearly an inch in diameter and so thick that it completely filled the upper and anterior portion of the right nostril.

As all known methods of direct treatment had failed to benefit the deafness, I decided to remove the enchondroma

and to restore the lumen of the nostril by cauterization of the hypertrophied tissue in the turbinated bodies. The operation was made under chloroform Oct. 11, 1894. I cut the nasal branch of the ophthalmic artery in the first incision for the removal of the tumor. This complicated very much an operation always difficult to perform on account of the free bleeding hiding the field of operation. I removed the tumor as rapidly as possible and packed the nose with cotton saturated with McKenzie's styptic solution. Recovery was further complicated by an attack of follicular tonsillitis which began three days after the operation. The patient was already weakened from loss of blood and from the shock, so the attack of tonsillitis was unusually severe and prolonged. The immediate effect upon the hearing was disastrous. As soon as the patient was able to resume her visits to the office, the hypertrophied tissue in the turbinated bodies was destroyed by the galvano-cautery as rapidly as this could be done without exciting severe inflammation. The patient remained under treatment for four months and was dismissed with hearing distance for the watch, left ear, of nine inches. She hears the ordinary conversational voice with ease. Up to the present the improvement has continued, and I have no doubt the hearing will be better a year from now than it is to-day.

These three cases present a few similar features. There was in all marked nasal obstruction from hypertrophy of the normal tissues and from the growth of abnormal structures. The condition of the ears in all was such as to offer no hope of cure by treatment of the ear itself. All were benefited so they could hear ordinary conversation, the best test of hearing power, by treatment of the nose.

In the first case reported the ear was never treated, either before or after the operation on the nose, yet as a result of this operation, hearing was restored to an ear which to all appearance was hopelessly deaf.

In the third case, the patient had been under the constant care of competent men from childhood to mature life. In spite of this care, the hearing power was entirely lost in one ear and so far diminished in the other ear that common conversation could not be heard. Yet, in this case, the hearing power is restored to the ear by restoring the normal lumen of the nostrils. During the time she was my patient, the ear received no treatment. It might be said the result in these cases was due to the fact that normal respiration and aeration of the middle ear through the Eustachian tube was restored. While this is a possible explanation, I do not believe it to be the true one. In the third case the Eustachian tube had been kept open by constant treatment, yet the deafness was increasing. The tube remaining open, no attention was paid to it while I was treating the nose, yet there was a remarkable gain in hearing power. It certainly will not apply to the second case, where in one ear there was no drum membrane at all and in the other ear only a remnant. The recurrence of the deafness months afterward when the nose became inflamed and swollen, and the prompt restoration of good hearing power by treatment of the nose, is an additional demonstration of the controlling influence that, in this case at least, the nose has, on the power of hearing.

While I do not pretend to explain the influence which brought about the deafness or the cure in these cases, there is a practical conclusion to be drawn, upon which we can act, even if we do not understand thoroughly the theory or the principle on which our action is based.

This practical deduction is that no case of supposed incurable deafness is really so, unless the nose and naso-pharynx have been examined and treated, if necessary, by a competent rhinologist.

DR. A. H. HEWETSON, of St. Clairsville, Ohio, read a paper on

COMPLICATIONS AND SEQUELÆ OF EPIDEMIC INFLUENZA (LA GRIPPE), AND THEIR PROPHYLAXIS.

ABSTRACT.

Of complications, undoubtedly pneumonia and bronchitis are more often present, but there is a dispute among observers as to which of these occurs more frequently. A recent French writer believes that the complex pathology of these chest complications is explained by the presence of different microbes in different forms. There are thus congestive, inflammatory and suppurative pneumonias; these produced by pneumococci and those caused by streptococci.

It is an admitted fact that the virulence of microorganisms is raised to the highest degree in all forms of influenza and its complications.

The important duty is to remember the depressing nature

of the original affection. Especially remember the importance of sustaining and energizing the cardiac and respiratory nerves. In my limited experience I have found nothing that can compare with strychnia and digitalis; full doses of digitalis and much larger than the ordinary dose of strychnia. We are too timid in our dosage of strychnia. In those cases where the influenza is still active, I add to the above, fl. ext. aconite in small doses. This may appear heterodox, but I believe it to be a sensible combination. Phenacetin and its companions of the coal-oil group, with codein, may be continued in some cases from the original influenza to the complicating pneumonia and bronchitis. An early recourse should be had to cod-liver oil and syrup of hypophosphites or similar tonic remedies.

Pleuritis is a complication which is not very frequent, nor is there any particular management required except to remember the nature of the previous trouble. A more frequent complication, as well as more troublesome, is pleurodynia. In our part of the State it has been of very frequent occurrence the past season. The pain is often severe, resembling pleuritis or pleuro-pneumonia. Pressure along the course of the intercostal nerve will promptly locate the trouble. It is usually located on the left side. Great alarm frequently results from the feeling that the heart is or would be involved.

At certain times in some epidemics, rheumatism is a complication. Disorders of digestion are frequently complications; they constitute a very troublesome form of the disease. Fortunately, however, the stomach is, as a rule, only functionally affected, the disturbance of digestion being due largely to the effects of the general disease upon the nerve centers.

Of complications we must view those having a nerve origin as the most important and perplexing. Post-mortem examination of a patient who had died of influenza, revealed serious injury to the brain. Althaus, of London, refers to the results of a series of eleven post-mortem examinations. In every case intense hyperemia of the pia mater at the base of the brain was present. The arteries were distended and the consistence of the brain and spinal cord was increased. In two cases by Fürbringer, the autopsy revealed capillary emboli and hemorrhagic foci in the lobes of both hemispheres, involving the white and gray substance. Mills, of Philadelphia, classifies the organic nervous lesions occurring in the wake of influenza in the following order; neuritis, meningitis, myelitis and cerebritis. He considers no single affection so common as neuritis, occurring in every form as to location and diffusion. By some authors, meningitis is said to cause more deaths in influenza than heart failure.

To name, number, classify and explain the nervous consequences of la grippe is a task too great to be undertaken. While their number and variety is legion, still we believe a careful consideration will show that they result from the exhaustion of the power of the nerve centers, due to the effect of the essential poison upon nerve structure. Cephalalgia, trigeminal neuralgia, insomnia, loss of memory, cardiac weakness, indigestion—in a word, functional derangement of all the organs, can in a vast majority of cases be traced back to a neurotic origin. If a careful examination does not reveal any central cause, then the task may be wonderfully simplified by regarding all as forms of exhausted nerve force or vital power. I do not believe we can do better than place our main reliance upon our friends of other years, strychnia, iron, quinin, cod-liver oil and phosphates. These cases in their multitudinous characters will afford opportunity for the largest experience. There is change of location, out-door life and exercise; there is the rest treatment, massage and electricity.

I wish to name one simple remedy I have found of great benefit, especially in the case of patients in advanced life when the waste products are becoming more and more retained; the coatings of the vessels filling gradually; in these cases I urge the patients to use hot water freely—to drink all the stomach will retain. It is frequently surprising how soon improvement appears. Having applied the teaching of modern scientific hygiene in an intelligent manner to the case, and given careful attention to the mucous lining of the nose and throat, the medical attendant has about performed his duty. For a scientific prophylaxis we must look to the faithful pathologist and bacteriologist.

DISCUSSION.

DR. E. B. FULLERTON, of Columbus—I think there is no doubt as to microbial origin of influenza. There is not that proof which would have been satisfactory some years ago;

but there is proof, that, after the discoveries or proofs in regard to the bacillus tuberculosis, is conclusive I think to reasonable men. There have been a number of experimenters in regard to this. You all have knowledge of the various experimenters, from Pfeiffer, Kitasato, Canon, onward.

There are some very interesting allied diseases. Among animals, the epizootic must have a microbic origin also. The epizootic sometimes attacks men. Influenza, I believe never attacks animals in the ordinary state, although it may be communicated. A remark about the character of the condition in the different years of its prevalence in this epidemic, seems to me not out of place. I should say the typical epidemic we had in Ohio was in 1889-90. Then we had the typical season, and I think since then the disease has been more likely not to be typical. During the last winter I have rarely seen a typical case of grip. There have been more mild cases, which would pass almost for bad colds.

In regard to complications—and that is the matter to which really this discussion should be limited—I think the Doctor has spoken of the most of them. One of the most obstinate cases of brachyalgia I have ever seen was undoubtedly of this origin. I have seen several cases of sciatica that were unusually obstinate as the result of this disease. I have seen one case of cruralgia, also. In regard to the treatment of the complications and sequelæ, this of course merges into the treatment of the disease.

As to the treatment of grip. There has been one treatment I adopted in the typical cases in the beginning that I have seen very little of in the journals, and have heard only little of in discussions, and that is the treatment by the tincture of aconite, one or two drops every hour. This will quiet the fever and the pulse, and relieve the catarrhal conditions about as much as any of the new remedies. Dr. Whittaker, in his very valuable work on the "Practice of Medicine," mentions salipyrin as almost a specific. Whether others count it so, I do not know. I know in my practice I have found it to have no more prompt control than other remedies commonly used; phenacetin, the so-called anti-febrin, acetanilin, aconite and the bromids. And, gentlemen, there is no remedy like full doses of the bromids. Where the patient is complaining of pain, interfering with his rest, full doses, 30 grains, of the bromid of potassium will answer like a charm.

DR. CALDWELL—The most disastrous complication I have had to deal with is the tendency of old people to take on degenerative processes. Weakness comes on from the exhaustion of the disease. This has not occurred in the last year or two that we have been having the grip. And I would rather agree with the last speaker, it has become rather a popular name, and as physicians we are prone to use the term a little recklessly.

DR. NORTH—I have seen within the last few years quite a number of cases of influenza; that is, the form of grip called influenza, attacking the respiratory tract. I believe this disease to be of microbic origin. It has become quite a fad with the profession. I do not know how we would get along without the grip. We are in the habit of calling everything we do not understand, "la grippe." Now I believe it arises from the presence of a microorganism, and this microorganism develops or generates a ptomaine, and this ptomaine enters the system and affects the ganglionic system. Why it affects one ganglionic system in one person and not in another, I can not explain. Sometimes it affects the celiac axis and sometimes other ganglia. I want to protest against the use of quinin in this influenza in any form. The paper read gave an account of post-mortem examinations, where hyperemia and inflammation had taken place in the membranes of the brain. I believe I have treated a number of cases of deafness, due to quinin given in influenza. It is one medicine that should never be given in influenza. I am a great friend of quinin, but would not use it in influenza. It causes hyperemia and inflammation of the brain. If you study the cases which go on to insanity, you will find the majority of them have been treated with quinin. I have used in these cases a combination of salol and phenacetin. It has acted almost as a specific. I combine two and a half grains of salol with an equal quantity of phenacetin. If you go into the decomposition of salol and phenacetin, you will find a physiologic reason for its action. You will find some of these patients blue from paralysis of the heart, due to the action of coal-tar products. But with the quantity in these pills, it takes only a few hours to get good results.

(To be continued.)

Chicago Pathological Society.

(Continued from page 111.)

Regular Meeting, May 13, 1895.

DR. WELLER VAN HOOK, President, in the chair.

DR. ARTHUR R. EDWARDS read the first paper on the program, entitled

REPORT OF CASE OF CHRONIC FIBROUS MYOCARDITIS PRODUCING
A RELATIVE AORTIC REGURGITATION.

The patient was 54 years of age, drank hard and had rheumatism. For four weeks he had suffered from dyspnea, edema, tympany, anorexia, coughing and occasional vomiting. On examination, there was orthopnea, ascites and anasarca. The heart was enlarged, especially the left ventricle, to which were added the signs of hypertrophy of the same chamber, as evidenced by the quick pulse and heaving apex beat. The physical findings were those of aortic regurgitation; weak second aortic tone, soft protracted blowing, diastolic aortic murmur heard over the second left intercostal space near the sternum, the alterations in the left chamber as already mentioned, and appropriate sphygmographic and auscultatory arterial phenomena. While the clinical diagnosis was aortic insufficiency, the autopsy disclosed an extensive fibrous myocarditis with secondary ventricular hypertrophy and dilatation. The cause of the myocarditis was atheroma of the coronary arteries and coronary thrombosis. Relative insufficiency is very rare and myocarditis has never been described as one of its causes. A complete review of the literature of this variety of relative insufficiency gave but twenty-five cases.

Two main etiologic agents exist: 1, ventricular dilatation; 2, dilatation of the aorta. Ventricular dilatation producing relative aortic leakage has resulted from muscular exertion, myocarditis, idiopathic cardiac hypertrophy, arterio-sclerosis, aortic atheroma, increased arterial tension, synechia cordis, and parietal endocarditis. Aortic dilatation is caused by atheroma, aneurysm, trauma and acute inflammation.

The clinical diagnosis is involved. Groedel's "distance" murmur and percussion of a dilated *arcus ascendens* have made diagnosis *intra vitam* possible. Accidental venous diastolic murmurs may complicate the diagnosis. Murmurs, even diastolic, do not constitute a valvular lesion. Renvens has demonstrated the intimate connection between the walls of the left ventricle, the auriculo-ventricular ring and aortic valves, whereby ventricular dilatation may render the aortic valves incompetent.

DISCUSSION.

DR. JOS. M. PATTON—This is certainly a very interesting subject, because it brings before us the diseases of the heart which are very difficult of recognition in a clinical way. Fraentzel congratulated the profession a year ago on the fact that diagnoses of myocarditis were much less frequently made than formerly. Virchow has always maintained that myocarditis was a rare affection, and has always been inclined to deprecate the freedom with which this diagnosis was made. Certainly, so far as clinical signs are concerned, it is very difficult to make a diagnosis of myocarditis. There are four forms of myocarditis which it is claimed can be observed clinically with more or less distinctness, viz: the acute circumscribed myocarditis, acute diffused myocarditis, chronic circumscribed myocarditis, and chronic diffused myocarditis. The two first mentioned can probably never be diagnosed of themselves, but may be suspected on account of the associated conditions with which they may appear. The third mentioned might be diagnosed by a physical examination in case of a localized area of degeneration, where resultant dilatation from the area would present in such a way as to be perceived by palpation or percussion (a so-called cardiac aneurysm), otherwise it could not be diagnosed. The fourth is the most interesting one, because we will meet with it as we become acquainted with these ill-defined cardiac diseases. Chronic fibrous myocarditis occurs most often on the left side of the heart. It is associated with many other conditions of the vessels and of the other internal organs. It may affect small portions of the cardiac muscle; or the cardiac muscle may be excessively changed by the aggregation of these cicatricial patches and deposits, as described by Dr. Edwards. The clinical interest centers in our ability to formulate some class of symptoms, by which we could deduct this condition in life. There are no symptoms which are in any degree pathognomonic to chronic myocarditis. The symptoms which do present are essentially those of either uncompensated valvular lesion,

or of failure of the lesser circulation. The symptoms of marked ataxia of the muscle are the same. They may take the form of severe dyspnea, or there may be symptoms of pulmonary infarction or edema. The dyspnea may simulate that which accompanies advanced sclerosis of the peripheral vessels, but even if it is associated with infarction or edema, the condition is transient, and it is doubtful what part this might play in the production of symptoms. The physical examination of the heart will reveal nothing, except the enlargement of the left cavity in the earlier stages of the disease, and that dilatation may disappear later on. Very often there is marked enlargement, as in the case presented by Dr. Edwards. There is one symptom that is practically always present, and that is cardiac arrhythmia, very often amounting to the condition known as tremor cordis, with a pulse of 200 or upward, the pulsations being almost inappreciable; but then this condition is associated with so many others that it is difficult to place the responsibility for its occurrence. The fact remains that a rapid and arrhythmic heart is an almost constant clinical sign of chronic myocarditis. Then again, there is a distinctive feature in regard to the character of the heart sounds. The second sound is usually weak, and that is somewhat indicative, because in a great many conditions of weakened heart muscle we have a relatively louder sound as compared with the bulk—the volume—of the first sound; whereas, in advanced conditions of chronic myocarditis the second sound is usually weak. The principal feature in regard to the sounds is the variation that occurs in the character of the tones, a few tones being loud, sharp and snappy, and then a few following being weak and indistinct, a regular tic-tac, there being a greater variation of the force and volume of the tones than in any other condition of which I am aware. The report is certainly very interesting, particularly so because it is by just such clinical histories, accompanied by pathologic specimens, that we are to learn more of these very imperfectly defined cases, as we understand them at present.

DR. J. B. HERRICK—One of the lessons that is brought home to me by the very interesting and very instructive paper of Dr. Edwards, is the lesson that has been impressed upon me more and more, as I have studied heart cases, particularly in the light of autopsies—and that is the lesson that the murmur we hear from the heart does not always tell us the condition of the valve over which we hear the murmur.

Fraentzel, from whom Dr. Patton has quoted, makes the statement that of the physical signs of the heart that lead us to diagnose valvular disease, the murmur is the least important. I am sure that we have, all of us, more than once been deceived by an anemic murmur. It seems to me that we do not pay enough attention to the other evidences of cardiac disease that are really open to examination. For instance, the very inspection of a patient will often enable us to make a fairly accurate diagnosis. We can, by inspection and palpation, alone, almost make an accurate diagnosis of aortic regurgitation. We have in such cases diffuse apex-beat with heaving impulse, tortuous, pulsating temporal and brachial arteries; and we have the peculiar water-hammer pulse of aortic insufficiency. We can find, too, the tones that are peculiar to the latter lesion in the peripheral vessels, so that we could, without even listening to the heart, make a diagnosis of that variety of valvular disease. What Dr. Patton has said with regard to the second tone of the heart is, I think, worth a great deal. We frequently make mistakes because we do not pay enough attention to the condition of the second tone. We all know how valuable the second aortic tone is in cases of cardiac hypertrophy due to renal diseases, and, again, the value of the second tone as an aid in estimating the muscular tone of the heart itself is not to be underestimated. It seems to me then, that one of the lessons of this case is that we should examine, not alone for the murmur of the heart, but examine as well for the enlargement of the heart; examine the second tones, the first tone, the peripheral arteries; in a word, make a complete examination and not rest entirely upon a discovery of a murmur. I do not think it possible in this case to have made the diagnosis during life. All the typical signs of aortic insufficiency were present; no cardiac irregularity to suggest myocardial trouble. But the lesson remains that every cardiac murmur is to be considered in the light of other cardiac findings, before an estimate is to be made of its importance as an evidence of primary valvular disease.

DR. A. R. EDWARDS, in closing, said: One thing is suggested to me by what was said about increased pulse rate. In myocarditis the pulse may be increased, of normal frequency, and there is still another group in which there is a decreased rhythm. In this case we watched throughout for

any irregularity and it never appeared in the clinical course of the disease. Regarding the value of murmurs: it is one of the four cardinal rules of Fraentzel that a murmur does not establish a lesion at a valve, and that applies most especially to systolic murmurs, and the converse has usually been taken as true of diastolic murmurs, the latter always indicating a valvular lesion. I omitted in reading the paper, on account of its length, to state that diastolic murmurs may occur, due to inorganic causes. They have been demonstrated to be due to venous bruits in the jugular vein, in the cavæ superior and inferior, and furthermore they have been found in the cases which I have cited, nearly all of which have been diagnosed as organic lesions during life. As to the specimen, there is nothing on the slides, as they are shown, that are not found in specimens of myocarditis from other causes—simply, the broad masses of cicatricial tissue, some long cells, and few foci of round cells.

DR. T. A. OLNEY, of Chicago, read

A REPORT OF A CASE OF AMOEBIC LIVER ABSCESS.

Patient was admitted to the medical ward, where a diagnosis of liver abscess was made. This was confirmed by exploratory punctures with an aspirating needle, following his transference to the surgical ward. Drainage was secured by a rubber tube inserted in the posterior axillary line at the seventh rib, and a considerable amount of yellowish pus discharged. Death occurred in a few days following a further exploration by puncture of liver, dullness in front and behind having failed to locate other abscesses. At the autopsy several irregular large abscess cavities were found, one of these occupying the posterior and upper part of the left lobe—which the drainage had not reached. These were all surrounded by a marked zone of necrotic liver tissue and contained thick grayish pus which contained chocolate colored lumps and granular necrotic liver tissue. In the caput coli two or three small ulcers were found. There was no history of dysentery.

DISCUSSION.

DR. A. R. EDWARDS—I saw this case on the medical before it went to the surgical side, and afterward with Dr. Olney on the surgical side. When the pus was drawn from the thorax with the needle, the color of the pus was invariably white and very thin. There was none of the chocolate color in that cavity, at least. And then when it was transferred to the surgical side after free drainage, and the symptoms of sepsis were not abated, Dr. Olney put needles into the liver. The needles were inserted into the area of dullness beneath the hypochondrium on the right side, and once only was pus obtained in something like thirteen punctures. The pus in this instance was quite creamy. The interesting point, clinically, is that the largest abscess of all was concealed by the peritoneal adhesions which bound the lower surface of the left lobe of the liver to the upper surface of stomach, thereby entirely concealing a large abscess by the gastric tympany. If we had pushed the needle through the tympany, we would have reached the liver abscess which caused his death. There were at the post-mortem, other small abscesses, too small for clinical detection.

DR. E. R. LECOUNT—I happened to see the autopsy conducted in this case, and it is interesting from several standpoints. First, the small amount of intestinal involvement. Only three ulcers were found in the caput coli, and those were very small. The amount of liver involvement was very large. Another interesting point in connection with cases of this character is that, as a rule, the pus is chocolate colored, due to the necrotic liver substance contained in the pus. Another interesting feature—the pus was brought into the laboratory from the morgue, placed on a slide and a drop of warm salt solution added, when amœbæ with amoeboid movements were seen by a number—Dr. Weaver, Dr. Williams, Bishop and myself, and some of the assistants. As soon as it was found that the amœbæ were active, they were fixed with 2 per cent. Fleming's solution, and in this way they were positively differentiated from the necrotic liver cells.

In the examination of pus from the liver, while the patient is still living, it is frequently very difficult to distinguish possible amœbæ from necrotic liver cells, on account of the vacuoles that will be present in both of them, the amœbæ being frequently dead as well as the liver cells. A 1 per cent. osmic acid solution was used to differentiate fat from vacuoles of the amœbæ and fulfilled expectations. Notwithstanding the small amount of mucous membrane involvement of the colon, the amœbæ coli were very numerous in the mucous membrane and were found down between the

mucous follicles and beneath the mucous follicles lying upon the muscularis mucosæ.

DR. JAS. W. WALKER presented specimens from an ancient empyema, and made the following remarks: I regret that I can do nothing more than offer these specimens. I know nothing of the history of the patient but that he was a man of 60 years, admitted to the hospital for an operation on a neoplasm of the right eyelid which was to be performed to-day. He was in the hospital a few days and died suddenly on Saturday. Unfortunately, no careful history of the patient has been recorded, so I can only show you the result of the post-mortem made this morning. The neoplasm of the right lower eyelid, growing for one year on the site of a pigmented mole, is presumably an epithelioma.

In the ileo-cecal valve (the rest of the intestinal canal was negative) was a small tumor projecting into the lumen of the valve. On section it has the appearance of a fibroma.

The heart is enlarged. It measures over 12 cm. for the left ventricle, and the right ventricle 10 cm. There is a thickening of the aortic valve, but no deformity. There is also myocarditis of the columnæ carnæ of the left ventricle, and most interesting of all is the very marked atheromatous place in the mitral valves, and a few at the beginning of the aorta. The only clinical record is the fact that there was a mitral systolic murmur.

In the left chest the lung was negative, except that the pleura immediately over the apex was markedly thickened. The pleura was much thickened and there were white scars on the pleural surface of the same lung, but the lung substance was entirely negative. The apex of the right lung is quite firm, just as firm as in pneumonia. I have not been able to find anything like tuberculosis in it but it is perfectly solid, and seems to be an old unresolved pneumonia. The pleura was not adherent to the apex, and the lower part of the lungs was normal. In the right pleural cavity, in the lower half of it, laterally and posteriorly and adhering to the diaphragm below, was a bulging mass covered by a yellowish membrane resembling very much the inside of the aorta, calcareous in consistency in many places; with pin point nodules which grated under the finger, and slightly fluctuating on pressure. There was nothing abnormal in the appearance of the ribs on that side of the chest. The covering was so firm that fluctuation was quite obscure. On cutting through it a thick greenish-black fluid oozed through the opening, and on cutting into it more deeply I found this mass. It has a clayey appearance; it is brittle like a piece of blue earth; it has no odor whatever, and the under surface of this is the part that was projecting toward the pleural cavity. I think this clay-like material was between the two surfaces of thickened pleura. I would suggest that an old empyema was the disease leading to the conditions found. The ribs were sufficiently soft to allow my cutting through them with an ordinary morgue knife.

The stomach is not specially interesting. The gall bladder contained thirty-eight small gall stones. The kidneys were both quite small, and the markings of the cortex almost absent, glomeruli distinct, proportion of pyramids being 1 to 5. Spleen small in size, firm in consistency; shows nothing in cut section but its surface had a corrugated, alligator skin appearance, and shows a number of pin-head size, white patches. The liver in places was a cloudy gray color, with entire absence of markings of the lobules around the periphery of the convexity; distinct nutmeg appearance is very sharply defined.

Uterine Flatus.—According to the *Medical Press and Circular* July 26, an interesting instance of "phantom tumor" of the uterus due to tympanitis of that organ, has been reported by Dr. Lichtenstein, of Liegnitz. On account of a chronic metritis, a patient was successfully treated by tamponment with iodoform gauze. A considerable time afterward she suffered from violent pains in the abdomen. On examination the abdomen was found much distended, and the uterus three finger-breadths above the umbilicus. On examining with the sound it passed into a large empty cavity, and air escaped out of the uterus with a distinct pop. The patient was frequently troubled in this way, the uterine tympany always coming on when the stomach or bowels were disordered. A few days after the attack described there was still pain at the side of the uterus. Massage and rhubarb and charcoal still further improved the condition.

W. H. LOWDERMILK & CO., WASHINGTON AGENT.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proofs sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 86 Fifth Avenue, Chicago.

SATURDAY, AUGUST 24, 1895.

PATHOGENY OF DERMOID CYSTS.

In *L'Union Médicale*, July 13, ult., is an excellent article by M. PIERRE DELBET, the Parisian surgeon, giving a resumé of the pathogeny of heterotopic tumors (dermoid cysts), which is abstracted from the large work on clinical and operative surgery by PROFESSOR LE DENTU and the same author. The oldest theory seems to be that of GEOFFREY SAINT-HILAIRE—that of diplogenesis by inclusion. This author arranged these tumors in a long series, beginning with the most simple forms, as those of the eyebrow, and going through the more complex varieties in the ovary and sacro-coccygeal region, and ending with parasitic and autositic monsters. In other words, he believed that simple dermoid cysts are to be considered as the "prodigiously incompletely developed" remains of a primitively distinct individual. This theory was strongly combated by LEBERT and BROCA. The latter pointed out that all dermoid cysts do not contain authentic fetal *débris*, while others contain too much,—as those with 300 teeth, etc.

Again, it is difficult to comprehend how one embryo can penetrate the abdomen of another, to lodge, for instance, in the ovary. LEBERT has shown that it is not rare to find dermoids in both ovaries, which, if we adhere to SAINT-HILAIRE's theory, necessitates believing that two distinct embryos have penetrated a third. "It takes," says LANNELONGUE, "a great effort of the imagination and much good faith to recognize the representative of a distinct individual in a simple dermoid, a simple small sac formed by the skin, and often without papillæ or sudoriparous

glands." This theory, however, offers the only satisfactory explanation of these tumors of the jaws, the sacro-coccygeal region and the scrotum where we find fetal *débris*.

LEBERT, in his theory of plastic heterotopics, has taken a diametrically opposite stand to that of SAINT-HILAIRE. He compares dermoids with other neoplasms and admits their autogenous and spontaneous formation. They develop by virtue of "a particular aberration of nutrition." This author did not extend his theory to the more complicated forms and, as DELBET remarks, it is not worthy of discussion.

The theory of inclosure of REMAK and VERNEUIL supposes that a part of the integument is nipped off during growth and buried in the surrounding tissues where it continues to develop. This theory readily explains the formation of simple cysts; moreover, these are always observed in regions with a complicated development—around the branchial clefts, orbits, in the sternal, abdominal and perineal regions, where the ventral and dorsal plates fuse. It may be objected that the structure of these cyst-walls is not the same as that of the skin, for the papillæ and sweat-glands are generally wanting; but these two structures are precisely those parts of the external tegument which are the last to appear. This hypothesis is utterly inadequate to solve the problems of the more complex tumors.

DELBET dismisses the theory of extra-uterine pregnancy, which presumes that these tumors are the result of extra-uterine fetation, with the remark that it will hardly answer for those in the eyebrow and the testicle, and, moreover, it does not suffice for those in the ovary which are to be seen in the newly-born and in virgins.

BARD has proposed a peculiarly unique theory, that of "nodal cells." This author is a great partisan of the absolute nature of the cells; but this must evidently be primitive. The ovule and the first few cells developed from it have the property of giving rise to daughter cells, differing from the mother-cell and from each other. These first cells must, then, be extremely complex, for they may give rise to the most diverse tissues. These are the cells which he calls nodal cells. With increasing stages of development these cells become less complex and finally they become fixed and incapable of producing cells differing in character from themselves. But, according to BARD, some of these nodal cells may persist in the adult tissues and it is the proliferation of these cells which forms dermoid cysts. DELBET remarks that while the contemplation of this theory affords a certain sense of satisfaction, the presence of these nodal cells in adult tissues is absolutely undemonstrable.

The theory of parthenogenesis next claims attention. This, as is generally known, is the develop-

ment of an embryo from the ovule without the intervention of the male element. This form of asexual generation has been shown in some of the lower animals (parthenopinea) where it produces normal individuals. BUFFON and SAINT-HILAIRE believed that possibly this might occur accidentally in the higher animals and give rise to rudimentary monstrous individuals.

REFIN and MATTHIAS DUVAL attributed the formation of ovarian dermoid cysts to parthenogenesis. The former author concludes that all dermoid ovarian cysts contain vestiges of organs and that they represent imperfect beings which can only be of ovarian origin. The possibility of segmentation of a non-fecundated egg has already been shown. DUVAL says we may even say that parthenogenetic segmentation is an ordinary, almost normal, process, but it is quickly arrested by fatty degeneration and does not proceed as far as the formation of a blastoderm, much less that of organs however rudimentary. STEINLIN has seen a very young dermoid, the size of a hemp seed, in the interior of a Gräafian follicle. While this parthenogenetic origin is not directly demonstrated it is very likely. It has two facts in its favor—the frequent segmentation of non-fecundated ovules and the intra-follicular seat of these cysts in their beginning.

DELBET sums up the evidence as follows: the widely different characters which dermoid cysts present and the nearly constant relation between their location and their degree of complexity lead us to believe that they are not of the same nature and are due to different pathogenic conditions. It is very probable that the simple dermoids are produced by inclosure, while the complex cysts, containing fetal *débris*, have two different pathogenic causes according to their situation—first, those which we may call external, in the jaws, sacro-coccygeal, perineal and scrotal regions, are due to diplogensis; they are double monsters, joined to their hosts like parasites; these double monsters are considered, since the researches of FOL, to be due to polyspermia, that is, the penetration of several spermatozoa into the same ovule, in other words, diplogensis is uniovular. Second, the complex tumors which we may call visceral, those of the ovary or testicle, are, on the contrary, very probably due to parthenogenesis.

Is this theory satisfactory? Some details are still obscure, especially those of the mediastinum. Most of these tumors are simple cysts which may be explained by inclusions, found at the expense of the front gut or by invagination of the bronchial tree; but there are complex cysts, also, such as that reported by GORDON,¹ which contained bones and seven teeth. The causes of this almost unique case are still unknown.

SIMULATION OF INSANITY.

The case reported in the daily press, of a leading German actor, who, after repeated impersonations of the character of a lunatic became himself insane, is one of some psychologic and medico-legal interest. It is not altogether unique; the same story has been told before, and a somewhat parallel case in this country has been published recently, but it is worthy of attention as evidence that continuous dwelling on, and practical adoption of, insane acts and ideas, even though with full consciousness of their abnormal nature, has a naturally bad effect upon the mental health. It is probable, it is true, that most of those who thus succumb to insanity in this way, were already somewhat predisposed to it, but absolute mental equipoise can be claimed by no one, and the danger is not to be disregarded even by those who are best equipped and fortified mentally.

In a medico-legal point of view it has some importance as bearing on the question of simulation. Some high authorities, among whom we may count SCHUELE and SANDER, assert that protracted simulation is itself pathologic, or, at least, that it becomes so after long continuance. Such instances as the one referred to would seem to support this view, and it has in its favor the well-known psychologic phenomenon expressed in the common saying that habit becomes a second nature. The actor who tries to realize his conception of the character he represents, is moreover, in far less danger than the man who for a purpose endeavors to continually act as a lunatic. His conception may be an imperfect one and his attempt clumsy in execution, but however this may be, he runs a risk of sooner or later making it natural enough if he persists.

On the other hand, actual simulation of insanity does not exclude the possibility of co- and preëxisting mental disease. This has been repeatedly demonstrated, notably by KIERNAN, HUGHES and others in this country, as well as abroad, and marked cases are within the experience and recollection of most observing asylum physicians of long experience. This point is one that ought to be well considered by jurists, and, with the other, may not infrequently have important bearings in cases before the courts.

THE NEW ILLINOIS PHARMACY LAW.

Illinois has what is practically a new pharmacy law. It purports to be only the old one amended, but the differences are more numerous and striking than the samenesses. The indications are strong that it was prepared and passed for the benefit of the pharmaceutical profession rather than the general public. The latter will undoubtedly indirectly gain by it on some points, but only incidentally, and not without loss. For what good it contains, the Governor

¹ Med. Chir. Trans., XIII, p. 13.

apparently did not care to veto it, but let it become a law without his signature.

Its scope can be somewhat judged of from the section headings, which are as follows: "None but registered pharmacists to dispense, etc.; Who may be employed in drug store; Meaning of the words "drug store" or "pharmacy;" Registered pharmacists; Who may be registered pharmacists; Assistant registered pharmacist—who may be; Permits to persons in villages; Duty of registered pharmacist; Annual registration—fee—certificate to be posted; Board of pharmacy—how appointed; Organization of board—duties of officer—place of meetings; Salary of officers—report; Label with name of article—penalty; False representation to procure registration—penalty; Adulteration—penalty for—expert—board to prosecute; Suits for penalties."

To begin with, this law seeks by multiplying descriptive terms and incorporating a definition to specifically cover, not only pharmacies and stores, but also dispensaries, "drug stores," apothecary shops and any "store, shop or other place of business where drugs, medicines or poisons are compounded, dispensed or sold at retail." However, the board of pharmacy is authorized, in its discretion, to issue permits to persons, firms, or corporations engaged in business in villages or other localities, empowering them to sell the usual domestic remedies and proprietary medicines under such restrictions as the board may deem proper, such permits to specifically state just what the holders thereof are allowed to sell.

But nothing in this act is to prevent any person or persons owning a drug store or pharmacy who shall employ and place in active and personal charge of the same, a registered pharmacist, nor interfere with the exclusively wholesale business of any "wholesale druggist," whereas it was before of "any dealers."

Neither is it, any more than did the old law, to apply to or in any manner interfere with the "practice" of any physician or prevent him from supplying to his patients such articles as may seem to him proper, substituting, as above, the word "practice" for "business." It also omits the proviso in this connection of the former act "that no part of this section shall be so construed as to give the right to any physician to furnish any intoxicating liquor as a beverage, on prescription or otherwise."

Not only must appointees to the board of pharmacy be such "competent registered pharmacists in the State, as have had ten years' practical experience in the dispensing of physicians' prescriptions," as heretofore, but they must be persons "who are actively engaged in the practice of their profession."

Other changes require that registered pharmacists must be 21 years of age; prescribe certain qualifications for them; make the original registration fee in

all cases \$5 and the subsequent annual fee not to exceed \$1.50; fix the cost of "permits" at \$1 in the first instance and 50 cents a year thereafter; impose upon registered pharmacists who take into their employ apprentices, to report to the board such facts regarding their schooling and preliminary qualifications as the board may require; empower the board of pharmacy to refuse registration or suspend the certificates of registered pharmacists, or assistant pharmacists, who are proved to be so addicted to the excessive use of stimulants or narcotics as to render them unsafe to handle or sell drugs, medicines and poisons; require the conspicuous exposure of certificates, and display over the door or department the name of the registered pharmacist who conducts the drug store or pharmacy.

What concerns the public yet more, and is to be deplored, is the change with respect to the selling of poisons. The new law on this point, in full is: "No person shall sell at retail any drug, medicine or poison without affixing to the box, bottle, vessel or package containing the same a label bearing the name of the article distinctly shown, with the name and place of business of the registered pharmacist from whom the article was obtained: *Provided*, That nothing herein contained shall apply to the dispensing of physicians' prescriptions. Any person failing to comply with the requirements of this section shall be liable to a penalty of \$5 for each and every such offense."

This, it will be readily seen, opens the gates wide for careless and unscrupulous dispensers and criminal and suicidally-disposed purchasers—if it is not a broad invitation to crime and self-destruction. What protection is there in a registered pharmacist's name affixed as prescribed, when he is neither required to exercise caution in making sales of deadly drugs, nor to mark same "poison?" The old law was infinitely better in this respect. It required all this and the distinctly marking of poisons as such, beside forbidding the delivery of the commonly recognized poisons to any person under 15 years of age, or to any person, without the seller satisfying himself that such poison was to be used for a legitimate purpose, although the penalty for a violation thereof was fixed at the ridiculously small sum of \$5 for each offense.

Comparison with the Wisconsin Legislature at its last session, when it revised the law of that State on this subject, is to the decided credit of that State. It requires paris green to be marked "Paris Green, Poison," and has added to the list of specially proscribed articles: oil of savin, oil of tansy, oil of cloves, phosphorus, sulphuric ether, or any mixture containing any of the specified poisons or of any combination of them sufficient to kill a person taking the same. When lawfully sold, a label bearing the name "Poison" distinctly shown, together with

the name and place of business of the seller must be affixed to the box, bottle, vessel or package containing the same, and to the wrapper or cover thereof. "And every person who shall sell or retail any such poison shall keep in his place of business a book, in which shall be entered an accurate record of the sale of all poisons; such record shall contain the amount purchased, the date, for what purpose purchased and the buyer's name and address. This record shall be at all times, during ordinary business hours, subject to the inspection of the district attorney of the county in which such store is located, or of any authorized agent of said board. Any person failing or neglecting to comply with any of the provisions of this section shall be guilty of a misdemeanor and upon conviction be punished by a fine not exceeding \$50 nor less than \$5."

When the Illinois Legislature meets again, it should certainly "amend" the pharmacy law once more, and restore it in this particular to what it was before, if it can not be induced to emulate the example of the law-makers of an adjoining State and throw still stronger safeguards around human life.

THE DUTY OF URGENT EXIGENCY.

The railway companies are finding themselves held to the strictest accountability in their humane or politic—as different persons consider it—arrangements to furnish their unfortunate employes with medical attendance. In the case of the Ohio & Mississippi Railway Company v. Early, decided April 12, 1895, the Supreme Court of Indiana reverses a judgment for damages obtained in the circuit court. It says that while a railroad company is under no legal obligation to furnish an employe, who may receive injuries while engaged in the service of the company, with medical or surgical assistance, yet where a day laborer or employe has, by unforeseen accident to him while engaged in the line of his duty as such employe, been rendered helpless, the dictates of humanity, duty, and fair dealing would seem to demand that it should furnish medical assistance. This duty could not rest upon the master in ordinary cases, in the absence of a contract to do so, but should rest upon him only in extraordinary cases, where immediate medical or surgical assistance is imperatively required to save life, or avoid further serious bodily injury.

This duty on the railroad company only arises out of strict necessity and urgent exigency, where immediate attention thereto is demanded in order to save life or prevent great injury. The duty arises with the emergency, and with it expires. This duty does not clothe the master with the power to dictate to the injured servant what particular physician or surgeon shall treat him, nor does it deprive such injured servant of the right of making a conscious and delib-

erate choice, while in the possession of his mental faculties, of the time, place and person, and by whom and when and where he will be treated. And if the master, yielding to such right complies with the request to be so treated, and at the same time promptly places before him ample medical and surgical assistance, ready to be rendered to meet the emergency, which he declines, then such emergency has ceased, and the duty with it; and if the choice thus made, in the conscious exercise of his own free will, turns out to be a mistake, the company is not liable, because the duty ceased with the expiration of the emergency.

ASSOCIATIONS AND THEIR JOURNALS.

"The journal is the Association," says DR. THOMAS M. DOLAN, editor of the *Provincial*, speaking of the *British Medical*. He ascribes the wonderful growth of the British Association during the past twenty-five years largely to its journal, and says: "When we come to analyze the work of the Association, and what it is doing for the profession, we are more than ever convinced that without the journal the Association would be a very powerless machine, and that were the journal to cease, the Association would rapidly diminish. The influence of the press has, during the last twenty-five years, been a constantly increasing one, and we need not wonder that the medical press has shared in the general benefits. The *British Medical Journal* has been ably edited. Still more, MR. FOWKE has been able to secure for it that which brings in grist to the mill—viz., advertisements. Without the journal you can hardly imagine an Association. What does the journal do? It brings all the members into communication; it publishes letters on every conceivable kind of subject; it lays down the law on ethics; it publishes long reports of the scientific committees; and it also gives the results of the annual meetings, the papers read furnishing material for the year. Its editorials and all that comes under the "we" are, we believe, alone paid for, and at a very cheap rate. The *British Medical Journal*, then, is the key-stone of the Association, and we hope it will flourish."

It seems hardly necessary to comment upon the foregoing, or to seek to apply its obvious lesson to the AMERICAN MEDICAL ASSOCIATION and its JOURNAL. We will only observe that the "grist to the mill" of the current issue of the *British Medical* is eighty-four pages of well-paid advertisements—netting more than enough, probably, to cover the entire cost of the number.

LET THE GOOD WORK GO ON.—In the last six weeks nearly two hundred Chicago physicians, have added their names to the subscription list of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION. Many of them have joined the ASSOCIATION, and others have signified their intention. The physicians of Chicago know a good thing when they see it.

CORRESPONDENCE.

Letters to My Hospital Internes, Past and Present.

BY CASEY A. WOOD, M.D., OF CHICAGO.

111.

UTRECHT, July 22, 1895.

No better situation could have been chosen for the largest Dutch ophthalmic hospital than Utrecht. The city is about the geographical center of Holland and is the seat of a university founded in 1636 whose medical department is attended by a large number of students. Ophthalmology, as well as other branches of medicine, owes much to the Utrecht school.

It was the celebrated treatise of Donders on physiologic optics (translated into English) that opened the way for a clear understanding of the refraction of the ocular media, the mode of accommodation and the action of the extrinsic ocular muscles. All these and many other important matters have been elucidated by his worthy successor, Prof. H. Snellen. Two years ago the building of the new ophthalmic hospital (*Nederlandsch Gasthuis voor ooglijders 49 Bleijenburgstraat*, seventy beds with over five thousand outdoor patients and five hundred operations yearly—daily clinic 8 to 12, operations at 11) was opened. This is a very handsome eye hospital with wide corridors, high ceilings and cheerful indoor walks for the patients. It is built so that there is plenty of light where a good illumination is required, while convalescents can go about in covered ways suited to their condition. In this building Snellen gives the regular university courses for students. Here, too, other teaching is done by the Professor's sons, Drs. H. J. and W. Snellen and the other assistants. All the operators follow the Professor's example in making the corneal incision (in cataract extraction) extend slightly underneath the conjunctiva. Snellen thinks that if this is done so as to avoid the sclera, that no bleeding will take place into the anterior chamber and so render the subsequent steps of the operation uncertain and difficult. This is, as you know, the chief objection to the conjunctival flaps. Its chief advantage is that such a wound heals in a few hours and binds the edges of the cornea closely together. When he does an iridectomy, as part of cataract removal, he favors the preliminary operation and performs it some six weeks before. When there is increased intra-ocular tension, a sluggish pupil, posterior synechiæ or an unripe lens he would advise it. At the time of the operation a 4 per cent. solution of pilocarpin is instilled, instead of eserine which is often very painful and irritating. After dressing the eye, subsequent to any operation where the eyeball has been opened, a thin oval aluminum shield (about 4 x 3 inches) is placed over the ocular region and this is kept in place by adhesive straps. The patient is now carried to bed on a litter made of poles and side-pieces run through folds made in the under operating sheet. He is allowed to sit up the next day, when the lids are also opened for examination.

I was courteously allowed to examine a large number of cataract cases operated upon at various dates, and was greatly pleased with their appearance and the absence of complications. The Dutch people are notoriously clean and live in well-ventilated houses. I was consequently not surprised to learn that they are pretty free of diseases of the lids and conjunctiva. Dr. Snellen informed me that in Utrecht, with a population of 100,000, he sees barely 6 or 7 cases of trachoma yearly. On the other hand, among members of the large Jewish colony in Amsterdam (most of whom work in factories and live in dirty, ill-ventilated tenements) granular lids has been endemic for over a century, and has apparently resisted all attempts to eradicate it.

Professor Snellen is at present engaged in perfecting the ophthalmometer and believes that the University optician (office in the Physiologic Institute) has succeeded in grinding the prisms and other lenses connected with the instrument with a precision not attained by Parisians or other workers. He also showed me a new scheme for testing the color vision of railway employes. This consists, essentially of illuminated colored discs of glass which are exposed for a second or less, to the view of the person under examination, by means of the rubber ball and shutter used in the ordinary photographic camera. The size of the disc and its distance from the eye correspond to the visual angle for which the Snellen test types are arranged. The short exposure and artificially illuminated test color make it more difficult for the color-blind person to escape detection than when the Holgren wools are alone employed. Moreover, the Snellen apparatus can be used at night time and the illumination does not vary, as does that of any other method that depends upon daylight.

It seems to me that at least a portion of the post-graduate student's stay in Europe might profitably be spent in one or more of the smaller university towns like Utrecht. He would in this way escape the over-crowded clinics of larger cities like Vienna, and be able to get nearer both patients and teachers. It is true that in the case of Utrecht, for example, the average student does not know and would not care to give time to the study of Dutch, but since both Professor Snellen and his assistants speak admirable English, and many of the patients understand a little German, this drawback is not a serious one. I think, also, that it is a mistake for the student of German medicine to give all his time to Berlin and Vienna, where he often has to take his chances with the members of a large class in getting partial views of operations between the heads and over the shoulders of numerous assistants who crowd about the operating table. In smaller places, like Prague, Königsberg, Göttingen, Kiel, Buda-Pesth, etc., the American student will generally have the advantage of personal instruction from as good teachers as he will find in Vienna, and will secure advantages and opportunities which he can not hope for even in the much-vaunted and more costly courses of the Austrian capital.

BERLIN, July 30, 1895.

There have been remarkably few changes in the *personnel* of the Berlin medical faculty during the past eight years. It would require more space than I have at my disposal even to mention all the celebrities at whose feet students, both graduate and undergraduate, might sit at this great teaching center. I renewed my acquaintance with so many of them as I could find in town. This is, however, the time of the midsummer vacation which every North German keeps who can.

Virchow is still working away, pretty much as usual. His celebrated early morning (*Pathologisches Institut, Charité*, Mon., Wed. and Sat., 8 to 10 A.M.) demonstrations in pathologic anatomy and microscopy is just ended but will begin again, like all the other university classes, with the winter semester about the middle of October and last until March. Virchow's former assistant, now Professor Isräel—well known friend of the American—also gives courses on pathology in the same place.

Berlin, when the convenience of the post-graduate student and the opportunities for study are concerned, is, to my mind, superior to London, while equivalent courses are much less expensive than those of Vienna. In the latter city every thing medical practically centers about the large *Allgemeines Krankenhaus*; there is no running about to distant hospitals or lecture rooms for instruction or to witness operations. Both the regular University lectures and the other Vienna

courses (which go on month after month with little change) on the same or allied subjects, are generally so arranged that one can constantly pursue even a single line of study without much conflict of lecture hours. The proportion of teachers who speak English is probably greater in Vienna than in either Paris or Berlin.

Although Vienna is perhaps the best place for the student who has but a short time for study abroad, yet Berlin and other German cities occasionally offer superior advantages in most departments of medicine to the physician or surgeon who can remain for a year or two. A prolonged stay will enable him to learn the language thoroughly and he will be better able to mentally digest what he sees and hears. He will also cultivate the acquaintance of teachers (a numerous class here) who follow their particular studies with an eye single to the service of science—not always casting furtive glances at the pocket books of the class before them. The University issues an admirable calendar (to be had at every book store) and time table of lectures—a pamphlet that will be appreciated by those who have studied in London and Paris. Armed with this, and having chosen a centrally located lodging somewhere near the *Charité*, he can profitably set to work at almost any time. Berlin should, however, be avoided by the new arrival during the months of July, August and September unless he has previously arranged to act as *locum tenens* for some assistant or chief of clinic who has gone for the usual holiday. Moreover, unless he wishes to follow some special advanced course or courses it would be wise for him to begin at the commencement of one of the semesters (the next begins October 26), or one of the *Ferien course*—vacation courses—for practicing physicians. The latter can not be too highly praised and should be attended by every post-graduate student who can conveniently reach Berlin toward the end of September. Full information regarding each course with the address of the clinic where it is held, name of teacher, honorarium, etc., is given in an announcement to be found in most medical bookstores or at the “Langenbeck house” (10 *Ziegelstrasse*).

The lecturers and instructors in the *Ferien* courses are not confined to the professors and *privat docenten* of the University—although these are in the majority—so that several competent and popular instructors outside the sacred precincts are afforded an opportunity to display their merits.

As many of these courses are limited, an early application is usually desirable before September 30, when certain of them begin. They all come to an end on October 26, each single course lasting four weeks. The fees are usually 40 marks (\$10) but range from 20 marks—*e.g.*, Westphal's class in mental diseases, limited to five, twice a week—to 150 marks for Baginsky's practical course in otology, limited to three, and held daily. No department or departmental subsection of medicine or surgery seems to be forgotten in this scheme. For instance, there are thirteen courses, no two of which cover the same ground, in bacteriology, normal and pathologic anatomy; seventeen in internal medicine; eleven on the eye and ear; eight on gynecology and obstetrics; two on physiology; six on medical jurisprudence, toxicology and hygiene; eight on nervous diseases and electro-therapy; five on general surgery; fourteen on diseases of the ear, nose and throat; seven on syphilis, skin diseases and diseases of the genito-urinary organs, and one on medical photography.

Berlin has for us rather a melancholy interest in presenting most of the sanitary advantages that our large towns lack, and but few hygienic shortcomings, of which American cities furnish such conspicuous examples. Every medical visitor should inspect as part of his studies, the extensive municipal slaughter houses and their laboratories, where every animal is examined, macro- and microscopically before its flesh is used for food. And woe unto the butcher who dares

expose for sale a carcass lacking the proper sign of examination! He should also inquire into the system by which a *daily* and thorough (I had almost said non-political) examination is made of the milk sold within the city limits, and by which a careful search is instituted for adulterations in other forms of food. These matters are fully gone into by Meyer in a little book (*Das Gesetz betreffend den Verkehr mit Nahrungsmitteln*) published by Springer in Berlin. During this study of municipal hygiene, he will find that smallpox is practically unknown in Berlin and that everybody is, without exception, vaccinated. Finally, not to further expand this letter, he will discover that the sewage of the town does not pollute the Sprey, but is pumped out to, and spread upon a municipal farm of some 1,200 acres where it is used as a fertilizer. This estate is thus made to pay, over and above current expenses, more than 3 per cent. on the original outlay for the land.

The Code—Once More.

CHICAGO, ILL., Aug. 1, 1895.

To the Editor:—Will you grant me a little space to consider three questions which in the midst of all the present discussion upon the Code of Ethics, I do not remember to have seen presented in print in exactly the same way they have presented themselves to me. A clear, precise answer, devoid of all eloquent circumlocution, to each one of them will, I believe, go far toward establishing the value of the Code in the minds of many doubters in the profession. These questions stated briefly are as follows:

1. Is any written Code of Ethics compatible with free competition?
2. Is any code which does not assume the form of law with penalties attached, likely to have more than a poetic influence upon competing men?
3. Is the medical profession free from the “commercialism” so much condemned by the Code?

Upon principle and policy I will confess that I am a rigid code man, but I nevertheless fail to see the advantage of a written code of ethics for the medical profession or any competitive avocation and I am without hope of such a code ever being universally practiced though it may be universally admired. The weakness of the Code in the matter of personal competition and want of provision for appropriate penalties, I can best show by a couple of illustrations:

A young man, industrious and well-trained, honorable and talented, graduates at the head of his class and then begins the practice of medicine upon a limited capital. He expends a large part of his surplus cash fitting up his office and otherwise equipping himself for his life work. Like all beginners, he has but few patients, and these far between. Some morning while wearily waiting in his office, an individual walks in to consult him in regard to a small tumor. The young physician recognizes the nature of the growth, is fully cognizant of the ability and willingness of the individual to pay him a handsome fee for removing it, and has furthermore, every confidence in his own surgical skill gained by hospital experience. The patient, however, suddenly informs him that he has just come from Dr. X, whom the young man knows by repute and personal knowledge to be a man of inferior attainments. He furthermore learns that Dr. X has been in charge of the case, and for the last three months has been endeavoring to remove the tumor with all sorts of internal and external medication. Dr. X, being a regular physician, a confrère and personal acquaintance as well as a near neighbor, the young man at once thinks of the Code of Ethics. He also thinks of his own sore need of money to meet his coming rent, and of this rare opportunity afforded him to reveal his superior skill and experience. To send the patient back to Dr. X, would not bene-

fit the patient but would merely turn him away to some other physician. It would moreover, probably bring down upon his own head all the jealous wrath and backbiting of an angry rival—a result which he is likely to bring about whatever course he may pursue.

What, Mr. Editor, is the young man to do in the light of the Code of Ethics? One specific answer in such instances which are so common, is worth a volume of general platitudes.

Permit me to relate an actual occurrence, for these are the cases that are troubling many honorable men in the profession who admire the Code and yet seem strangely opposed to it:

A young friend of mine was treating satisfactorily several members of a well-to-do family. One of the daughters of this family suffered from excessive dysmenorrhea, the attacks of which were so severe as to resemble hysteria. A consultation was proposed and a popular gynecologist summoned. Glancing at the patient, the latter at first declined to make the examination, saying that the case was merely one of nervous dysmenorrhea so frequent among young girls and that marriage would relieve her of all her trouble. The family physician, however, insisted upon a physical examination, stating that the family expected it. It was made. The consultant still declared that nothing was the matter except general neurasthenia which was to be treated upon general principles, and with electricity to the spine, notwithstanding the fact that he had been told the girl had undergone such treatment for about two years at the hands of one of the best neurologists in the city. This was in the spring of the year. The gynecologist went to Europe, and the young physician not having made an examination himself, carried out the consultant's suggestions to the letter. There was not a particle of improvement, but rather the reverse. In the fall, the gynecologist returned and the attending physician after much earnest persuasion got the patient to go and see him. She did so, but note the result! The great man now said she had "inflammation of the womb," that she always had had it and that it was the inflammation which had given her all the trouble in the spring and while he was away. She was told to visit his office (the gynecologist's office!) once or twice a week to receive local applications, for which she paid him \$5 a visit. To complete the story, she went regularly, still continues to go, so far as I know, though much dissatisfied with the result obtained, as she seems but little better than she always was.

The family physician who graduated with intense enthusiasm for the Code, told me he was astounded at two things: first, that the gynecologist whom he had often heard speak glowingly and eloquently before medical audiences in behalf of the grand Code of Ethics, should have so ignored his rights; and second, that he should have played him so false as to recommend a line of treatment in the spring so utterly at variance with the requirements of the case. The family physician being still in attendance is asked all sorts of questions in regard to the gynecologist's sudden change of opinion, line of treatment, results obtained, etc. To preserve his own credit and to act up to the spirit of the Code how, Mr. Editor, should the attending physician reply to these questions?

A simple answer in such a dilemma is worth a dozen generalities. I wish space was permitted me to cite from actual occurrences even more glaring than these; and I furthermore wish that the valuable space of our better journals now filled with "sweet talk" and "platitudinous nonsense" about the grand old Code were used to report specific instances of flagrant misdemeanors. We would then secure some perceptible light upon many a dark problem haunting the minds of honest would-be high code men.

Mr. Editor, when a man's living is at stake, it is not in the power of human nature for him to make a martyr of himself. One may be persuaded at times to sacrifice one's personal ambition for an ideal principle, if by so doing he does not cause himself or family to starve; but it is perfectly useless to talk to a man about declining to receive certain patients when he is dependent upon these patients for his daily sustenance. It is simply Utopian. Competition exists in the practice of medicine as in every other walk of life. Endow a man with a life competency and he may rise above the spirit of competition except as a means of personal gratification. He may then live up to the letter of the Code or any other divine rule of conduct. On the other hand, while

it may not be a glorious act of martyrdom, neither is it a form of dishonesty for a man to accept all that the world chances to send him and all that his superior talent and education entitle him to enjoy. The socialistic notion is a dream of the imagination; it is neither desirable nor practicable in this intensely human world of ours. It is not to be expected or commended in human nature to hide its light under a bushel. It is a fact, all too apparent, that the one hundred and forty medical colleges of our country turn out doctors of widely varying abilities. The spirit of the Code, if not the actual words, seem to require that every doctor should defer and bow to every other doctor, which as a matter of Chesterfieldian courtesy is all right, but as a matter of a competitive struggle for existence is simply impossible. The medical profession consists of *men* having all the various feelings, unequal talents and differing ambitions of *human beings*. The practice of medicine being almost universally the means of earning a livelihood is a matter of pure competition, and competitors in the very nature of the case can not afford to be self-sacrificing for one another.

It has been said by some of our rigid code friends that the preceding argument is an ancient one and in a few words amounts to this: because "men do not live up to an ethical, religious or even a legal ideal, therefore the ethical, religious or the legal law or ideal should be abolished." In reply, I must recall to our friends the fact that unanswered and unanswerable arguments, only, become ancient, otherwise they would cease to exist at all as arguments; and secondly, that ethical, religious and legal laws or ideals are totally free from the influences wrought by competition. To speak of ethical, religious and legal ideals in the same category as the medical code is a willful misconception or lamentable ignorance of them all. Ethics has to do only with a man's own conscience and is largely a matter of education. A disregard of ethics may injure the man himself but he has only himself to answer for it; when a disregard of an ethical question amounts to a positive injury to one's neighbor, the law steps in and takes charge of the question which has now ceased to be one of pure ethics. Law, however, knows that its ethical enactments must be enforced with appropriate penalties. A man may lie, if he wishes, to his neighbor and he may even become an habitual liar, which is unethical and may prove unprofitable, but at all events the man is free to do as he likes and from his particular point of view may even reason that it is right to lie. If he commits a forgery, however, he injures another beside himself and the law then takes charge of him and punishes him.

Ethical questions are all controversial. They range from questions of mere self-preservation to questions of heroism and martyrdom. A Hottentot's ethics differ from the ethics of the North American Indian. In all sincerity each will act in accordance with his own conscience. Two men and their families watch a burning house. A child belonging to neither of the men has been left in the house and it is positive death for either one of them to attempt to rescue it. One man says: "My family is dependent upon me. I will not risk my life"—(self-preservation); the other says: "I will try and save the child if I lose my own life." He rushes in and does lose his life—(heroism). The ethical question in the case of each man was answered by his own conscience. A man steals for his starving little ones at home; another lets them starve rather than steal. They both know it is wrong to steal, but their respective reasoning leads them to different results.

So illustration after illustration might be given to show that ethical questions are, as a rule, controversial, and are usually answered according to a man's *individual* conscience. Recognizing this fact, common law strives to eliminate the controversial element out of the ethical questions it takes in hand, by assigning penalties for their disregard. It says to both men who steal: "I care not what reasons you may have had for stealing, reasons perhaps conclusive to your own mind. Stealing is wrong and you must be punished for it." That is just where the Code of Ethics of the AMERICAN MEDICAL ASSOCIATION is at fault. It is a mere code of ethics and is therefore controversial; on the other hand, it is not law and therefore without the force which law with its penalties usually exercises.

Religion is so absolutely a matter of private opinion and so utterly free from all shadow of human competition, that I marvel any rational being should have compared it and its teachings in any way with the practice of medicine. Jew and Gentile live most harmoniously together so far as their particular religious opinions are concerned, but may fight like the Killkenny cats when bartering over a piece of silk. I am ashamed that any one in this nineteenth century and

in this tolerant land should even so much as insinuate that religion and religious tenets enter as a part of the competitive scheme of life. Religion is a matter of the soul, and has to do with man's relation to his Creator. The nature of that relation may and does influence in one way or another the man's actions in life, but for those actions he is responsible only to his Creator from the *religious* standpoint. A Moham-medan with his dozen wives, a Jew denying the Messiahship of Christ, an Atheist and a Christian may buy and sell, practice medicine upon each other and do a thousand other things mutually needful in life, and yet never know one another's religious opinions.

Let us not lose sight of plain common sense in our discussions. The Code, therefore, while theoretically a most commendable set of rules, just as Plato's "Republic" and More's "Utopia" are theoretically admirable governments, is practically valueless because it can not overcome (nor would it be desirable for it to overcome) the worldly spirit of competition, and because it offers no appreciable deterrent against its own infringements.

Why, Mr. Editor, it seems almost absurd that it should ever have been thought that such rules would be effective. Every organization that I know anything of, such as militia companies, literary societies, clubs and beneficiary bodies, impose fines for misdemeanors or delinquencies against their rules, and yet these delinquencies and misdemeanors, while involving more or less disgrace, do not involve a man's livelihood. On the other hand, the AMERICAN MEDICAL ASSOCIATION adopts a set of rules utterly devoid of all punitive provisions and then expects it to be effective against misdemeanors and delinquencies that are not only at times irresistibly tempting but, occasionally, seemingly necessary for a man to commit in making his living.

I verily believe, sir, in that as a profession we injure and belittle ourselves in the eyes of the people, with all this shallow, ineffective nonsense of the Code, and with the effort to set ourselves up as superhuman beings, too good for this terrestrial existence with its sharp competition and intense rivalry. I wonder that lawyers, statesmen and legislators, leaders of men and all those who have to do with men *en masse*, do not laugh at us more than they are in the habit of doing, for our refreshing gullibility in expecting laws without penalties attached to have any very profound or extensive influence.

Let me say emphatically right here, sir, that for one, at least, I disclaim all such slurs upon our great merchants, bankers and commercial houses as are insinuated in the cant frequently appearing in our journals to the effect that, as a profession, we are too good to stoop to commercialism and commercial methods. We do stoop to commercialism and when honorably done we need not be ashamed of it. We exchange or *barter*, if you like, our skill, learning and particular experience for a price. Our prices vary with our skill and reputation, just as the merchants' prices vary with the quality of their goods. We advertise too, and it can not be gainsaid. Our successful cases are our advertisements. College and hospital appointments are eagerly sought after by most reputable men for the advertisement such positions give them. We join social organizations and enter clubs, unions and all forms of corporate life for the advertisement we get therefrom. We solicit patronage by seeking for examinerships in insurance companies, railway offices, beneficiary unions and other associations. If we are specialists we are not averse to accepting office in special societies and even giving banquets and receptions to the medical profession in our own homes. As editors of reputable journals, we publish our names in full at the head of the editorial columns. Our libraries groan with the accumulated weight of books in which positively the only new thing is the author's name with a long string of self-laudatory honors attached. Perhaps 50 per cent. of our periodical literature is written for mere advertisement. Is it from the simple love of speechmaking and a self-sacrificing devotion to poor humanity that some of the best of us give lectures upon medical topics before Young Men's Christian Associations, popular institutes and other public assemblies? If we are rich enough to drive a team and keep a luxuriously appointed office with an extra maid in attendance, do we not do so? Show me the doctor who, in dress, manner and mode of living does not endeavor to put himself in the best light (professional light, I mean) before the community, and I will show you a man who has ceased to be human.

And what is this all done for? Legitimate advertisement, call it by what other name you please. Let us not ostrich-like hide our heads in the sand and chuckle to ourselves that we are unlike other men. Let us, for our own credit's

sake, at least, not try to parade around in the masks of angels, in the hope of making a shrewd world believe that we are something more than human.

No, sir! I, for one, most honestly believe and aver that doctors as a class are no better, no worse than any other class of men. Pray, who does not know that the entire commercial world has an unwritten code of ethics? The great and honorable merchants deal courteously, gentlemanly and diplomatically with one another as all men should do; they compete for customers in a legitimate manner; and they strive to surpass one another by availing themselves of their respective superior opportunities. They are charitable in their way just as we are in ours. They give of their wealth as we give of our skill. It is high time that we should cease the cant phrase and vulgar insinuation that we as a profession are something better than the commercial world. We are what we are, solely because we are the *men* we are. I believe if we acted less superciliously, and met the laity on their own footing, there would be less friction between hospital boards and medical attendants, between courts and experts, between public functionaries and physicians in public places.

Let us have done, then, with all this unbecoming, childish, self-laudatory, namby-pamby nonsense about the angelic qualities of the medical calling. It is a practical, very practical profession in a practical world among practical men. An unwritten code will always exist among medical gentlemen, just the same as an unwritten code exists among gentlemen in other walks of life. For the other fellows of the medical profession, as well as for the other fellows of the other avocations, the only code that will be of any avail at all will be the code that has some effective punishment provided against its infringement. AMERICUS VERITATIS.

BOOK NOTICES.

Gunshot Injuries. A New Edition of Sir T. Longmore's Work.—Gunshot Injuries; their History, Characteristic Features, Complications and General Treatment; with statistics concerning them as they have been met with in warfare. By SURGEON-GENERAL SIR T. LONGMORE (Retired) C.B., O.H.S., F.R.C.S., etc. Second edition. London and New York: Longmans, Green & Co.

Surgeon-General Longmore, although on the retired list of the Army, has not given up his active work on behalf of the medico-military profession. There has just been issued a second edition of his volume on gunshot injuries. The first, published in 1877, contained 686 pages; the second is a solid volume of 821 pages. In the intervening years, radical changes have been made in the firearms of military nations which will alter the character of the gunshot wounds of future wars and modify the relations which medical officers will bear to the fighting line; meanwhile, also, changes have taken place in methods of treatment. The object of the present volume is to give an account of these changes and to bring the information contained in the former edition on many other topics up to date. The reader will, however, find it a work of much difficulty to sift out the new matter, as it is scattered throughout the many sections and chapters in interpolated paragraphs and sentences and even in modifications of the sense of sentences that are found in the old edition. In fact, the whole work has evidently been rewritten with the utmost care.

In bringing up to date the many other topics to which he refers in his preface, the author has made free use of the third part of the "Surgical Volume of the History of the War of the Rebellion," which was issued subsequent to the publication of his first edition.

In Chapter 2, a paragraph is given to smokeless powder; a second to the special explosive, cordite, authorized in the British service for use with the Lee-Mitford rifle, and a third to the use of compressed air as an agent in the production of gunshot wounds. In Chapter 4, the article on red hot shot gives place to one on machine guns and another on "fougasses." The latter are stated to have been employed largely, under the misapplied name of "torpedoes," in the

defense of places during the War of the Rebellion in the United States. In Chapter 5, the leading features of the principal military small bore magazine rifles and their projectiles are described, including the Lebel, Mauser, Krag-Jorgensen, Berthier, Mannlicher and Lee-Mitford; and this chapter closes with a paragraph which constitutes the text of most of the new matter in the volume: "The alterations that have occurred during the last three or four years in military rifles and their projectiles, the reduction in caliber of the firearms, the introduction of compound projectiles and the use of new explosives in place of gunpowder, have led to extremely important changes in the general aspects of war, as well as in the characters of many of the wounds which are likely to be inflicted in the future at remote distances. So far as Europe is concerned the effects of the new weapons have only been observed, with a few accidental exceptions, experimentally; they have not happily been experienced in actual war. The reports which have been published regarding the results of their partial use during the civil war in Chili have been contradictory. But it is beyond question that the changes referred to have caused a very great increase in the velocity both of translation and rotation of the bullets, in their accuracy of flight over extended ranges, and in their penetrative capacity. The increase in hardness of the surfaces of the projectiles, at the same time the fact of their weight being sufficiently maintained by the core of heavy lead within, effect results which not only increase the power of penetration of these narrow missiles, but also enable them to maintain this power over distances at which the rifle bullets in previous use had parted with considerable portions of their energy. Another important consequence of the great reduction in the diameters of rifle projectiles, surgically regarded, is the fact that, with the narrowing, there has been a proportionate exclusion of air, and of all the irritant and morbid germs which air contains, from the openings and interior surfaces of wounds caused by them. When, therefore, the wounds are confined to some of the soft and yielding tissues of the human body, they become nearly analogous to subcutaneous wounds."

The various properties, as defined by experiment, of the small bore armored bullets are described. Their destructive energy up to 500 or 600 yards is in excess of that possessed by any rifle projectiles that have preceded them, while their penetrative energy up to 2,500 yards, and beyond, is such that no bodily structure is able to resist their passage. There is little difference in the amount of comminution of bone and general damage produced by them at short ranges and the .45 inch bullets in previous use, the main difference between them being that the destructive effects of the small bore bullets are met with at distances considerably beyond those at which they result from bullets of wider diameter. The damage done by the narrow bullets at medium ranges to the shafts of bones is always very great, but has been observed generally to be less than in wounds at similar ranges by old style bullets; while at very long ranges, at which a greater amount of velocity and higher penetrative power are preserved by the narrow bullets, the comminution and splintering are generally greater from the narrow than from the broader projectiles.

In discussing the conveyance of septic germs by bullets the experiments of Captain La Garde, U. S. Army, as published in the Report of the Surgeon-General for the year ending June 30, 1893, are cited, and a synopsis is given of the conclusions deduced from his experiments.

The survivals among patients with penetrating wounds of the chest will probably occur in a much larger proportion in future wars. The slight resistance that can be offered against the passage of the new bullets will cause perforat-

ing wounds of this region to be more common than hitherto; while the narrowness and other physical qualities of the bullets will render their effects less fatal by limiting the areas of the lesions inflicted by them. Penetrating wounds of the abdomen will also be more frequent; while the difficulties in the way of applying the remarkable improvements that have taken place in abdominal surgery in civil life, to military, practice after important engagements in the field, will probably prevent any considerable reduction in the large ratio of mortality which has hitherto attended them.

Professor Longmore refers to the rarity of erysipelas in gunshot wounds since the use of antiseptics has been adopted. He speaks of the presence of pyogenic cocci in pyemia and of the special microorganisms and their septic products which give rise to hospital gangrene; but he doubts the connection of tetanus with a bacillus, considering the difficulties insuperable when endeavors are made to reconcile the agency of this reputed cause of tetanus with all the clinical conditions under which the disease has followed gunshot injury on different occasions in naval and military practice.

In the paragraph on examination by the finger, he has introduced a new sentence: "It seems hardly necessary to observe that when making an exploration of the kind in the field, where sources of impurity are so abundant, very strict care has to be taken to prevent the introduction of septic matters into the wound by the explorer's finger or by the fingers of assistants." A paragraph on antiseptic dressings, not found in the old edition, discusses the use of sublimate solutions, sublimate wool, iodoform and the double cyanid of mercury and zinc.

In the old edition, the chapter on inflammation began with the enunciation of the principle: "Every gunshot wound, the most trivial as well as the most severe and complicated, is naturally followed by inflammatory action." In the new work, inflammation is not recognized as an essential consequence of a gunshot wound. The following sentence does not appear in the new volume: "The amount of suppuration has been reduced by the greater attention which is now being generally given to hygienic arrangements and especially to cleanliness in the manipulating of wounds; but I fear the day is still far distant when suppuration will not be met with during the process of cure in a very large proportion of severe gunshot wounds."

In referring to the prevention of muscular contractions and stiffness of joints during the healing of wounds, the Continental practice of sending the patient to some of the thermal springs is favorably mentioned.

Lastly, in speaking of the 1:4 ratio of killed to wounded in battle, the following is inserted: "If we may judge from the experience gained down to the present time, such may be regarded as an approximate average of the proportion of killed to wounded likely to be met with in battles. It is generally surmised that the employment of small bore bullets will lead to the proportionate number of men killed in battle being lessened and that of the men wounded being increased, so far as regards rifle fire; but even if this surmise should prove to be correct, when the uncertainty which prevails regarding the probable effects of the new artillery fire is considered, it seems evident that the general ratio of killed to wounded among troops in wars of the future can not now be forecast with any approach to accuracy."

A German English Medical Thesaurus, or TREASURE OF SINGLE AND COMPOUND MEDICAL WORDS AND TERMS; with Dialogues, Idiomatic Phrases and Proverbs, etc., and German and English Indexes for Physicians and Students. By REV. HENRY LOSCH, M.D. Pp. 323, cl. Philadelphia, 1895. Published by the Author. Price \$2.50.

This manual contains over twenty thousand words relating to medicine, and is distinguished by its conciseness in

definition and its simplicity in the arrangement of the vocabulary for rapid reference. The book is divided into three parts, of which the first is devoted to the systematization of simple and compound medical terms; the second, to hygienic, medical, surgical and domestic affairs; Part 3, consists of dialogues, idiomatic phrases and proverbs, a schedule of the termination of each declension, and a list of irregular verbs. Medical students will find much of value in this volume, and it should find a place upon the shelves of every reference library.

SOCIETY NEWS.

Southwestern Iowa Medical Association.—The semi-annual meeting of the Southwestern Iowa Medical Association was held in Red Oak, Iowa, August 15. Attendance sixty.—The physicians of Douglas County, Kansas, met at Lawrence, Kan., August 10, and formed a society. The following officers were elected: President, W. S. Bunn; Vice President, J. I. Doughart; Secretary, H. Ernest.

Mississippi Valley Medical Association.—The secretary of this Association desires to announce that the railroad rates for the Detroit meeting September 3, 4, 5 and 6 will be one and one-third regular fare, on the certificate plan. In purchasing ticket to Detroit full fare will be paid. On request, the local ticket agent will furnish purchaser with certificate which will be handed to the secretary at Detroit. This certificate when signed and vided by the agent of the Central Traffic Association will entitle holder to a return ticket at one-third regular fare.

FREDERICK C. WOODBURN,
Secretary.

American Academy of Railway Surgeons.—The second annual meeting will be held in the parlors of the Auditorium Hotel, Chicago, Ill., on Wednesday, Thursday and Friday, Sept. 25, 26 and 27, 1895. Motto: "The higher the order of Railway Surgery, the greater the protection to the Employee, the Passenger and the Company." Officers: President, C. K. Cole, Chief Surgeon, Mont. Cent. R'y, Helena, Mont.; First Vice-President, C. M. Daniels, Chief Surgeon, W. N. Y. & P. R'y, Buffalo, N. Y.; Second Vice-President, W. H. Elliott, Chief Surgeon, Cent. R'y of Georgia, Savannah, Ga.; Secretary, Webb J. Kelly, Surgeon, Erie & Big Four R'ys, Galion, Ohio; Treasurer, C. B. Kibler, Surgeon, Erie R'y, Corry, Pa.; Editor, R. Harvey Reed, Consulting Surgeon, B. & O. R'y, and Surgeon, C. S. & H. R. R., Columbus, Ohio; Chairman of Executive Board, John E. Owens, Chief Surgeon, C. & N. W. R'y Chicago, Ill.; Chairman of Committee on Transportation, W. J. Galbraith, Chief Surgeon, U. P. R'y, Omaha, Neb.; Chairman of Committee on Arrangements, A. D. Bevan, Chief Surgeon, Iowa Central R'y, Chicago, Ill.

FIRST SESSION—WEDNESDAY.

Subject unannounced, R. D. Mussey, Chief Surgeon, C. H. & D. R'y, Cincinnati, Ohio.

Some of the Benefits to be derived from the Higher Order of Railway Surgery, W. J. Galbraith, Chief Surgeon, U. P. R'y, Omaha, Neb.

Subject unannounced, A. D. Bevan, Chief Surgeon, Iowa Cent. R'y, Chicago, Ill.

Subject unannounced, M. Cavana, Surgeon, N. Y. P. & O. R'y, Oneida, N. Y.

Subject unannounced, W. H. Buechner, Surgeon, Erie R'y, Cleveland, Ohio.

SECOND SESSION—WEDNESDAY.

President's Address, C. K. Cole, Chief Surgeon, Mont. Cent. R'y, Helena, Mont.

Report of Secretary, Treasurer and Standing Committees. Registration of Fellows and payment of dues. Consideration and disposal of applications for fellowship. Miscellaneous business.

THIRD SESSION—THURSDAY.

Subject unannounced, J. W. Perkins, Surgeon, U. P. R'y, Kansas City, Mo.

Fractures of the Forearm Complicated with Dislocation, E. Griswold, Surgeon, Erie R'y, Sharon, Pa.
Subject unannounced, Wm. T. Dalby, Ass't Surgeon, U. P. R'y, Salt Lake City, Utah.

Subject unannounced, F. H. Peck, Surgeon, N. Y. P. & O. R'y, Utica, N. Y.

FOURTH SESSION—THURSDAY.

Address on Medico-Legal Surgery, Hon. Tracy C. Becker, Buffalo, N. Y.

A Practical Way of Testing Railway Employees for Color Blindness, D. C. Bryant, Oculist, U. P. R'y, Omaha, Neb.
Traumatic Neurosis, Henry W. Coe, Surgeon, East Side R'y, Portland, Ore.

Verdicts Obtained Through Perjury, C. B. Kibler, Surgeon, N. Y. P. & O. R'y, Corry, Pa.

What Should Disqualify Applicants for Railway Service, John E. Owens, Chief Surgeon, C. & N. W. R'y, Chicago, Ill.

Personal Experience in Spinal Injuries, J. M. Pritchard, District Surgeon, C. & N. W. R'y, Manitowoc, Wis.

Intra-Venous Injection of Neutral Salt Solution in the Treatment of Desperate Injuries. Exhibition of Apparatus, C. B. Parker, Surgeon, L. S. & M. S. R'y, Cleveland, Ohio.

A Word on the Modern Use of the Terms Infection and Contagion, R. Harvey Reed, Consulting Surgeon, B. & O. R'y, Columbus, Ohio.

FIFTH SESSION—FRIDAY.

Railway Sanitation, W. M. Bullard, Ass't Surgeon, Mont. Cent. R'y, Wickes, Mont.

Sanitary Regulations Governing Railways, L. E. Lemen, Division Surgeon, U. P. R'y, Denver, Colo.

The Use of Gold Foil in Fractures of the Cranium and Resulting Hernia Cerebri, W. L. Estes, Chief Surgeon, L. V. R'y, S. Bethlehem, Pa.

SIXTH SESSION—FRIDAY.

Transportation of Injured Employees, F. H. Caldwell, Chief Surgeon, S. F. & W. R'y, Sanford, Fla.

The Use of Cocain in Minor Amputations, C. M. Daniels, Chief Surgeon, W. N. Y. & P. R'y, Buffalo, N. Y.

Concussion of the Brain, W. H. Elliott, Chief Surgeon, Ga. Cent. R'y, Savannah, Ga.

Wounds that Open the Knee-Joint—Treatment, C. D. Evans, Surgeon, U. P. and B. & M. R'y, Columbus, Neb.

Treatment of Wounds of Face and Scalp, Charles B. Fry, Surgeon, Big Four R'y, Mattoon, Ill.

Injuries of the Hands and Fingers, John McLean, Chief Surgeon, P. P. C. Co., Pullman, Ill.

How to Differentiate Between the Use of Heat and Cold in Railway Injuries, Wm. Mackie, Surgeon, C. M. & St. Paul R'y, Milwaukee, Wis.

Best Method of Obtaining the best possible Aseptic Condition during Operation done at places other than Hospitals, J. F. Reger, Surgeon, B. & O. R'y, Littleton, West Va.

SEVENTH SESSION—FRIDAY.

Selection of next place of meeting. Miscellaneous business. Introduction of officers elect. Adjournment.

The managers of the various railroads that have already reported, have very cordially agreed to furnish the necessary transportation to enable the Fellows of the Academy to attend the coming meeting. Those who need transportation will apply for same at once *through their proper officers*.

Very respectfully submitted,

W. J. GALBRAITH, Chief Surgeon, U. P. R'y, Omaha, Neb.

Medical Society of Virginia.—The twenty-sixth annual session of the Medical Society of Virginia will be held in Wytheville, Va., beginning Sept. 3, 1895. After prayer, Address of Welcome by COL. R. E. WITHERS, M.D., Report of Committee on Applications for Fellowship, etc., the Address to the Public and Profession will be delivered by DR. LEWIS G. PEDIGO, Shawsville, Va.

Report of Committee on Prize Essays: Dr. Hunter McGuire's prize of \$100 for essay on "The Present Status of Serum-Therapy;" conjoint prize of Drs. Joseph Price and Herbert M. Nash of \$200, for "The History of Surgery and of Surgeons in Virginia."

Wednesday, September 4, Dr. Ro. J. Preston, of Marion, Va., will deliver the Annual Address of the President.

After the elections, etc., the call for papers and discussions will be continued as the order of business. The following Fellows have complied with the terms of their appointment by the President last fall:

Z. V. Sherrill, Bland Court House, Vesical Calculus in

Females; James N. Greer, St. Paul, Laparotomy, with Report of Cases; C. K. Kernan, Lebanon, Strychnia as a Heart Tonic; W. S. Sayers, Wytheville, Convulsions; George Ben. Johnston, Richmond, Treatment of Cholelithiasis; J. W. Long, Richmond, Pelvic Inflammations; T. W. Simmons, Martinsville, Uric Acid as a Gynecologic Factor; Wm. F. Drewry, Petersburg, State Provision for Epileptics; Hugh M. Taylor, Richmond, Obstruction of Bowels; Paulus A. Irving, Richmond, Puerperal Sepsis.

The following have promised papers: Honorary Fellow Dr. Hunter McGuire, Richmond, Seventeen Operative Cases of Chronic or Relapsing Appendicitis, with One Death—Remarks; B. C. Keister, South Boston, Varicocele; J. Allison Hodges, Richmond, The Galvanic Current in Treatment of Pelvic Pain; Honorary Fellow Dr. Joseph Price, Philadelphia, Pa.; R. M. Slaughter, Theological Seminary, Abscess of the Liver in Children; James L. Kent, Bertha, Long Survival of Injury of the Spinal Cord in the Cervical Region; Charles M. Blackford, Lynchburg, Pathology and Treatment of Gonorrhoea; Honorable Fellow George Tucker Harrison, New York, The Symptomatology, Etiology and Treatment of Endometritis; M. J. Payne, Locust Grove, A Case of Cerebral Trauma, Indistinct and False History—Remarks on Diagnosis and Treatment; Jos. A. White, Richmond, Eye Troubles in their relation to Diseases of Other Organs.

The following have responded favorably: J. McFadden Gaston, Atlanta, Ga., Pyemia and Septicemia in their Surgical Aspects; D. Mayer, Charleston, W. Va., Rigid Os; Edwin Ricketts, Cincinnati, Ohio, Some Recent Work in Gall-Bladder Surgery.

LANDON B. EDWARDS, M.D.

Recording Secretary, etc. (for the Executive Committee).
Richmond, Va., Aug. 3, 1895.

PUBLIC HEALTH.

To Prevent Blindness.—Two laws precisely alike were passed by the last General Assembly at its regular session and signed by the Governor of Illinois, namely, House Bill No. 51 and Senate Bill No. 57. They provide that should any midwife or nurse having charge of an infant in this State notice that one or both eyes of such infant are inflamed or reddened at any time within two weeks after its birth, it shall be the duty of such midwife or nurse having charge of such infant to report such fact in writing, within six hours, to the health officer, or some legally qualified practitioner of medicine in the city, town or district in which the parents of the infant reside. Any failure to comply with the provisions of this act shall be punishable by a fine not to exceed \$100 or imprisonment not to exceed six months, or both.

Right Denied to Boards of Health.—A health ordinance providing that no cows shall be kept within two hundred feet of any dwelling without a special permit obtained from the board of health, the general term of the Supreme Court of New York holds, in the case of Village of Flushing v. Carraher, decided May 13, 1895, is not authorized by a statute which gives local boards of health power to make and publish all such orders and regulations as they may deem necessary and proper for the preservation of life and health and the execution and enforcement of the public health in the municipality, and to make, without publication thereof, orders and regulations for the suppression of nuisances and concerning all other matters in their judgment detrimental to the public health in special or individual cases. Under the statute, if the matter is such that a general ordinance can be passed upon the subject, the court says that then such ordinance should be enacted. If not susceptible of general regulation, then the board should proceed by special order in the particular case, when the person attacked may defend himself in the courts. The board of health, by the ordinance under review, did not forbid the keeping of cows within two hundred feet of a dwelling house, but so keeping cows without a special permit. In other words, the board took to itself the power of licensing cow stables. No such power was granted by the Legislature.

French Degeneracy from Alcoholism—Absinthe Condemned.

The Paris correspondent of the *Press and Circular*, for the issue of June 26, writes that Dr. Lannelongue, who is a member of the House of Deputies as well as professor at the Academy, has made a vigorous appeal against the lax laws of France concerning the manufacture and sale of alcohol. "Among other statements made by Dr. Lannelongue, he said that 'alcoholism, at the present day, was not only endangering the public health, but also threatening the very existence of the species; it filled the hospitals, the asylums, the prisons, and populated the penal settlements. Previous to 1850, alcoholism was almost unknown, or rather it had not the same character; the effects were temporary because the drink taken was pure and natural. But four years afterward, alcohol of vinous origin failed, and immediately it was replaced by that derived from molasses, beet-root, and potatoes, which poisoned the race. In 1830 the number of suicides from alcoholism were 5 per 100,000 persons; they were 21 in 1881, while 46 per cent. of homicides, 74 per cent. of grievous wounding, 54 per cent. of domestic quarrels, 77 per cent. of outrages against public decency were due to drink. Against the many afflictions which attack man, against the large number of contagious maladies, epidemic or other, the characteristic of the healthy individual is his organic resistance, which enables him to triumph over all the assaults from his most terrible enemies—microbes. The drunkard, on the other hand, has lost all resistance, and falls an easy prey to disease. At 40 he is already an old man; his tissues are degenerated, so that he makes the worst of patients. It is not the richer classes in France who saturate their bodies with alcohol, because they know better, but the lower classes, and especially the workmen, who are ill-fed, clothed, and lodged. In Brittany, however, women of good position give themselves up to alcohol. Out of 107 young married women who died from drink 8 were sterile, and of the 99 others there only remained as posterity 6 sickly children. On the other hand, these same women had 28 children before having taken to alcohol who are very healthy, showing what the others might have been if the mothers had led a sober life. What is still worse,' continued Dr. Lannelongue, 'is the fact that the passion of the parents is transmitted to the children. The drunkard engenders an offspring with the same tendency, be they girls or boys, and curious to say, they begin to drink at the same age that the father began to drink.'" Dr. Lannelongue, who spoke for nearly two hours, interrupted by frequent applause, concluded by appealing to the government to take under its own control the manufacture of alcohol, and to forbid entirely all those liquors made from essences, and more especially from absinthe.

Health Reports.—The following health reports of infectious diseases have been received by the Supervising Surgeon-General of the Marine-Hospital Service:

SMALLPOX—UNITED STATES.

New York: Brooklyn, August 10 to 17, 1 case.

Texas: Eagle Pass (smallpox camp), to August 18, 143 cases, 35 deaths.

Tennessee: Memphis, July 1 to August 7, 10 cases; Shelby County, July 1 to 31, 17 cases.

Philadelphia: July 17 to August 16, 18 cases, 1 death.

SMALLPOX—FOREIGN.

Antwerp: July 20 to 27, 2 cases.

Buda-Pesth: July 22 to 29, 2 cases.

Calcutta: June 30 to July 6, 6 deaths.

Guayaquil: July 19 to 26, 3 deaths.

Madrid: July 22 to 29, 1 death.

Nogales: August 3 to 10, 5 cases, 1 death.

Odessa: July 20 to 27, 7 cases.

Rio de Janeiro: July 13 to 20, 40 deaths.

St. Petersburg: July 20 to 27, 1 case.

CHOLERA.

India: Bombay, July 2 to 9, 1 death; Calcutta, June 30 to July 6, 22 deaths.

Japan: Hiogo, July 13 to 20, 85 cases, 74 deaths; Nagasaki, July 5 to 12, 29 cases, 20 deaths.

Russia: Volhynia, June 9 to 22, 57 cases, 20 deaths.

Turkey: Mersine, June 18 to July 16, 410 cases, 235 deaths;

Tarsus, June 18 to July 16, 293 cases, 143 deaths; Adana, June 18 to July 16, 660 cases, 305 deaths; Sis, July 1 to 10, 4 cases, 2 deaths; Karszulcadric, July 9, 10 cases, 2 deaths; Hatchiu, July 1 to 8, 14 cases, 7 deaths; Karatasch, June 30, 23 cases, 27 deaths; Messis, June 29 to July 11, 17 cases, 8 deaths; Alan Sinar, June 30, 12 cases; Pajas, July 1 to 9, 26 cases, 24 deaths; Bulanik, July 1 to 13, 35 cases, 22 deaths; Jumurtalik, July 10 to 13, 7 cases, 5 deaths; Marasch, June 30 to July 14, 25 cases, 15 deaths; Padzardjik, July 8, 7 cases, 7 deaths; Hadji-Bil (Lazaretto) July 7, 3 cases, 3 deaths; Gok-Sun, July 8, 8 deaths; Karahissen, July 7 to 11, 11 cases, 7 deaths; Husu Mansur, July 8 to 10, 10 cases, 4 deaths.

YELLOW FEVER.

Cuba: Cienfuegos, August 4 to 11, 1 case; Sagua-la-Grande, August 3 to 10, 4 cases; Havana, August 1 to 8, 70 cases, 25 deaths.

Brazil: Rio de Janeiro, July 13 to 20, 14 deaths.

Mexico: Vera Cruz, August 1 to 8, 7 deaths.

NECROLOGY.

J. R. BRANDT, M.D., of Chicago, August 18, aged 57. He was born in New York and after graduation at Oberlin College taught school in Kentucky, becoming State Superintendent of Public Instruction in that State. In 1886 he came to Chicago and began the practice of medicine, and in 1890 was appointed a member of the county hospital staff. He was elected county commissioner in 1890. Only three weeks since, Dr. Brandt, in company with Dr. E. F. Wells and the editor of this JOURNAL, called on President Healy and urged the appointment of specialists to the control of the Cook County Hospital for the Insane at Dunning. That President Healy did not see fit to adopt the suggestion, was no fault of Dr. Brandt's. He then seemed in his usual health and spirits, and no one would have supposed him to be so near his end. His last public work was directly in the line of his profession and in the service of humanity.

JAMES GORDON, M.D., of Carlyle, Ill., August 11, aged 77 years. He was born in Huntsville, Ala., and began the practice of medicine in 1838. Thomas McKennan, M.D., of Washington, Pa., August 8, aged 70.—Rees Davies, M.D., of Wilkes Barre, Pa., August 10, aged 58.—D. L. Manchester, M.D., of Waupaca, Wis., August 11, aged 62.—William S. Battles, M.D., of Wooster, Ohio, August 9, aged 69.—Samuel C. Metcalf, M.D., of Fort Wayne, Ind., August 10, aged 51.

MISCELLANY.

Aid for Industrial Home for the Blind of Chicago.—The Illinois Legislature has appropriated for this institution for working capital to be permanently employed, \$10,000; for completion of third and fourth stories of dormitory, \$7,000; and for expenses, per annum, \$10,000.

Surgeon-General James B. Tryon, of the Navy, has been elected a member of the Red Cross Society of Venezuela. He has also been awarded the bronze medal of that Society in recognition of the services he rendered the wounded at La Guayra during the revolution of 1892, when Dr. Tryon was attached to the flagship *Chicago*.

Liability in Michigan of Married Woman to Pay Physician.—In Michigan a married woman who lives with her husband is liable for medical services and medicines furnished to her and to her daughter by a former marriage, the Supreme Court of that State holds, in the case of *Goodman v. Shipley*, decided May 21, 1895, when it was done at her request, the charge made against her, and she promised to pay therefor.

In the Interests of Science.—Among the appropriations made by the State for the University of Illinois in which the medical profession is more or less interested, are the following: for the increase of scientific cabinets and collections, \$1,000,

per annum; for improvement in the chemic laboratory, \$5,000; for a laboratory for vegetable physiology, \$2,000; for a small temporary building and equipment for work of the biologic experiment station on the Illinois River, \$2,500, and for half of the operating expenses of said station, \$1,500 per annum.

Illinois State Laboratory of Natural History.—Among its other appropriations, the Illinois Legislature has set apart \$1,000 for the improvement of the library of the State Laboratory of Natural History; \$1,500 per annum for the experimental investigation of the contagious diseases of insects, and \$1,500 per annum for one-half of the expense of the Illinois Biologic Station.

Provision for Insane of Illinois Soldiers' and Sailors' Home.—Members of the Illinois Soldiers' and Sailors' Home who are now insane, or who hereafter become insane, the Illinois Legislature has enacted, may be committed to any of the State hospitals for insane persons, except the hospital for the criminal insane, and, being wards of the State, they shall not be credited to any county, but to the State at large.

Provision for Rebuilding the Southern Hospital for the Insane at Anna.—For rebuilding in a thoroughly fireproof manner the south dormitories and wings, and the administration building of the Southern Hospital for the Insane at Anna, Ill., recently destroyed by fire, including the costs of the improvements, removing *débris* and repairing the damage done by fire and cost of repairing the same, the Illinois Legislature appropriated the sum of \$171,970, or so much thereof as may be necessary, payable to the trustees on their order, or their order approved by the Governor, in sums not exceeding \$35,000, as the work progresses.

A Physician Entrapped and Robbed.—Dr. George Drury, a Brooklyn physician, was the victim of the most audacious as well as well-planned robbery that has been experienced by any practitioner in many a day. He was decoyed to a vacant house, gagged and securely bound, and then stripped of his valuables and money while a knife was held at his throat. The robbers carried out their plot without a hitch, and had taken flight more than half an hour before Dr. Drury recovered consciousness and released himself from his bonds. The telephone was the instrumentality of the summons in this case. Dr. Drury remembered that he recently had a patient whose name resembled that which was used over the telephone, and made reply that he would give the case his immediate attention. Whether the robbers knew of Dr. Drury's attendance upon a patient bearing the same name as that which they employed, or whether they chanced upon the resemblance, it shows a possible danger that lurks in telephone calls. Look out for the unknown telephone caller, whether the name used has a genuine ring or not! It is very easy for a designing rogue to work in with a coachman or other physician's employe and worm out the name of some patient that will fit in with a scheme of robbery. It may safely be predicted that we have not heard the last of this branch of thievish enterprise. Other cities beside Brooklyn will be its field of experiment. The telephone is a great labor saver, but it may be the means of loss of life to some medical practitioner as well as being the tool of assault and robbery.

Illinois Vaccine Laboratory.—The sum of \$3,000, was appropriated by the Illinois Legislature at its last general session for the purpose of establishing, equipping and maintaining a laboratory in connection with the State University at Champaign, for the propagation of pure vaccine virus. The trustees of the University, it is provided, shall have the management of said institution, though the State Board of Health is to exercise supervision of the methods of propagation and shall certify to the purity of all products. All physicians and health officers within the State are to be furnished with the product of the laboratory at the cost of

propagation. A report of the management, together with a statement of the receipts and disbursements is to be made and included in the annual report.

Typography a Roman Art.—It is stated on the authority of the *Foia Diecessana*, the official paper of the Greek-Roman bishopric of Carausebes, in South Hungary, that unmistakable evidence of the art of typography has been discovered among the ruins of Bersovia, in Dacia, an old province established as a colony by the victorious Romans on territory then acquired by them. The discovery is attributed to the architect and archaeologist, Adrian Diaconu, who, it is said, found evidence of the use even of movable type by the Romans at this colony, and particularly by those of the fourth legion, Flavia Felix. Two members of the Bucharest Scientific Academy confirm Diaconu's opinion, having examined the evidence and declared the discovery to be of the utmost importance. If these facts be really true, the honor of inventing typography will no longer reside with the Germans nor with the Italians, who attributed the discovery to Panfilio Castaldi.—*Scientific American*.

The Upas Tree.—During his recent stay in Java, Professor Wiesner ascertained some interesting particulars with reference to the celebrated Upas tree, *Antiaris toxicaria*. Contrary to the general impression that this tree is not uncommon in Java and the Sunda Islands, an impression manifested by the statements in the leading text-books, Professor Wiesner learned that the original specimen described by Leschenhault has been felled, and in the whole of Java there were but three individual trees belonging to the genus and closely allied to *A. toxicaria*. Of these three one was found by Dr. Greshoff to be innocuous, and was therefore *A. innoxia* Blume, a species supposed by many botanists to be only a variety of *A. toxicaria*. The second tree proved to be poisonous, one drop of the latex being sufficient to kill a dog; the third has not been examined. The tree has, however, been cultivated in the botanical garden, and there are in the plantation at Tjikomoh about seventy specimens. Neither in the botanical garden nor in the plantation could any ill effects be observed, even after a person having been for some time in the neighborhood of the trees; so the accounts of the poisonous nature of the exhalations from it are much exaggerated. Dr. Burek has shown that the plant gives off no injurious vapors, and that the latex is poisonous only when it passes through a wound into the blood.—*Scientific American*.

Cost of Caring for Some of the Illinois Unfortunates.—There was appropriated by the Illinois Legislature for the purpose of defraying the ordinary expenses of the following institutions, for the year beginning July 1, 1895, as follows: the Northern Hospital for the Insane, \$150,000; the Eastern Hospital for the Insane, \$308,000; the Central Hospital for the Insane, \$165,000; the Southern Hospital for the Insane, \$125,000; the Asylum for Insane Criminals, \$26,000; the Institution for the Deaf and Dumb, \$100,000; the Institution for the Blind, \$52,000; the Asylum for Feeble Minded Children, \$80,000; the Charitable Eye and Ear Infirmary, \$26,000; or a total of \$1,032,000. Beside this amount, there was appropriated, for these nine institutions, some \$241,300, to be expended in certain specified directions, but principally for repairs and improvements.

College of Physicians of Philadelphia.—The William F. Jenks memorial prize of \$500, under the deed of trust of Mrs. William F. Jenks, has been awarded to A. Brothers, M.D., of 162 Madison Street, New York, for the best essay on "Infant Mortality During Labor, and Its Prevention." The Prize Committee also reports as highly meritorious the essay on the same subject bearing the motto "Vade Mecum." The writers of the unsuccessful essays can have them returned

to any address they may name, by sending it, and the motto which distinguished the essay, to the Chairman of the Prize Committee, Horace Y. Evans, M.D., College of Physicians, Philadelphia.

Trustees of the Wm. F. Jenks Memorial Fund.

British Medical Association.—Our contemporary, the *British Medical Journal*, grows enthusiastic in speaking of the recent meeting of the Association of which it is the organ. It says that Sir Russell Reynolds has presided at the greatest assembly that our profession has ever known, and in saying this it does "not forget the great International Congresses either in our own country or abroad; in mere numbers, for aught we know, some of these meetings may have surpassed the Association meeting of this week. English medicine, has, however, this week shown itself in numbers vast enough to fire the most sluggish imagination; while on the other hand, the age, standing, and prosperity of our Association give a unity, a dignity, and an impressiveness to its chief assemblies which are wanting to the more or less motley and fortuitous gatherings which have not a national character." The parallelism between the 1895 meetings of the two great national Associations is matter for congratulation.

Women Doctors in Russia.—Women desirous of studying medicine in Russia were formerly obliged to gain their special knowledge in founding homes, lying-in hospitals and convents. Later on, they were granted access to the university courses and the schools for assistant surgeons. It was not until 1872 that more complete courses of four years were instituted in connection with the Academy of Medicine for the instruction of midwives. In 1876 a fifth year was added and the studies somewhat assimilated to those for men. In this field the women soon acquired a brilliant and well merited reputation. During the time of the war of 1877-78 the services they rendered were generally recognized and the Emperor decreed them the title of "women doctors." In 1877 the first class of women doctors was turned out; after this, the medical courses having passed from the control of the Academy of Medicine to that of the Saint Nicholas Hospital, many hundreds of women were enabled to pursue their studies and are now successfully practicing in country communities and in the urban hospitals. Notwithstanding their incontestable utility, these courses were suppressed by the military administration in 1886, and then the women begged support from the municipal province of St. Petersburg. The municipality answered that it saw no hindrance to assuming charge of these courses for women on condition that they relinquished the urban hospitals, that the outlay for the courses did not exceed 15,000 roubles annually, and that the Minister of War would grant a certain sum for their maintenance. These conditions were all complied with and a sum estimated at 700,000 roubles has accumulated, yet the courses for women are not yet re-opened. However, it is expected this will be done shortly.¹

Hospital Notes.

THE German Society in charge of the Protestant Deaconess Hospital, at Indianapolis, Ind., announces that the new hospital will soon be ready for occupancy.—Plans have been prepared for the construction of a new contagious hospital at Paterson, N. J.—An effort is being made in Buffalo, N. Y., to establish a German hospital in that city.

Philadelphia Notes.

SMALLPOX.—There are about twenty cases of smallpox in this city, all in the Municipal Hospital. The local Board of Health has directed that hereafter all patients suffering with variola in this city shall be removed to the hospital, where a special isolating pavilion has just been erected for the exclusive treatment of such cases.

FIRE IN A HOSPITAL.—Fire occurred August 14 in the out-buildings used as a storage house and laundry at the Phila-

¹ Jour. de Med. de Paris, 1895, No. 27.

delphia Hospital (Blockley) in the Female Department. By the prompt action of the attendants, the patients were removed from the adjacent wards to a remote wing of the building. Good service was rendered by the well-trained fire crew composed of resident physicians and attendants and owing to the care of the nurses no panic occurred and no patient was injured. The damage to the buildings and storehouse was about \$30,000; the hospital proper was not injured.

THE STATE HOSPITAL FOR THE INSANE for the Southeastern District at Norristown has purchased adjoining property of about eighty-five acres for a sewage farm, to protect the Schuylkill River from pollution by that source.

Washington Notes.

HEALTH OF THE DISTRICT.—The report of the Health Officer for the week ended August 10, is as follows: number of deaths (still-births not included): white, 66; colored, 74; total 140. The effects of the extremely warm weather are manifest in the increased death rate during last week. From 103 as reported by the Health Department week before last, the number of deaths increased to 140. This gives a death rate of 26.9 as against the annual normal of 23.05. Diseases of the brain (11), heart (10), and diarrheal complaints (32), compose mainly the increase. Nearly one-half of all the mortality was of children under 10 years of age, 58 of whom were 1 year old. From the dangerous contagious maladies there were two fatal cases of diphtheria, one of scarlet fever and one from whooping cough. Four deaths from typhoid fever occurred and two from heat stroke. In other respects the health of the city is favorable for this season of the year.

FINED FOR VIOLATING GARBAGE RULES.—A number of persons have been fined in the police courts for failing to provide the regulation "slop tub." The penalty is a fine of not less than \$5 nor more than \$50 or imprisonment in the work house for from five to thirty days.

FELL FROM THE WINDOW OF THE CHILDREN'S HOSPITAL.—The coroner was called upon to investigate the circumstances attending the death of the child who fell from the second story window of the Children's Hospital on the 12th instant.

A NEW WAY OF BEATING THE DOCTORS AND DRUGGISTS.—An enterprising gentleman has invented a new trick for securing money without working for it, and has victimized a number of physicians and druggists here. He calls on the doctor, has him prescribe, and in payment presents a check, the amount of which is larger than the fee. The doctor, anxious for the fee, accepts the check and pays the patient the balance. The gentleman takes the prescription to the druggist, who fills it, and accepts a large check in payment, advancing the balance. The banks on presentation declare the checks worthless.

WASHINGTON NEEDS A MORGUE.—Possibly no city in the United States is less provided with a morgue than Washington. Particular attention was called to the fact last week, when the decomposing body of a young man, in a rude ice box, permeated the neighborhood with foul odors. The present morgue is a small room about 10 x 15 feet, poorly lighted and ventilated, adjoining the stables of the sixth precinct police station. It contains but one table and the above mentioned old-fashioned ice box. One spigot furnishes cold water. The room next, is far superior, but is used for the storage of the patrol wagon. It is well remembered that at the time of the Ford's Theater disaster, the dead were placed on the concrete floor, presenting a most disgraceful and shocking scene to those who called to identify the bodies of their friends or relatives.

ENFORCEMENT OF GARBAGE REGULATIONS.—The time allowed by the Commissioners to the housekeepers to comply with the garbage regulations has elapsed, and within a few days proceedings will be instigated in the police court against those who have failed to comply with them. These regulations have been neatly printed on a card and distributed throughout the city. A perusal of them at this time will be of benefit. Among other things, the householder must provide a suitable receptacle for garbage, pro-

vided with a tight cover, and keep the same in repair. It must be placed between 7 o'clock in the morning until 6 o'clock in the evening in a place convenient and easily accessible to the collector. Another important provision is that each householder having a street and alley entrance shall place at the alley entrance the street and number of the house. Failure to comply with these regulations makes the offender liable to a fine of not more than \$50, nor less than \$5, and in default of payment, imprisonment in the work house for not more than thirty days.

CLOSING THE WELLS.—Gradually the public wells of the city are being abandoned and filled. There has been no sweeping order, but each day or so, an order goes forth closing a well. There are comparatively few left, and it is believed before another summer comes, not one of the old original wells will be open. The Commissioners, however, believe in pure water, and a determined effort will be made at the next session of Congress to get an appropriation sufficient to sink a number of deep wells all over the city. The experiments recently tried upon these deep wells were so satisfactory that the Commissioners became convinced that deep wells were the only proper ones for Washington. There are two of these wells in the city at present, and more would have been sunk if there had been sufficient appropriation.

THE PUBLIC SERVICES.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from August 10, 1895, to August 16, 1895.

The leave of absence granted Capt. JUNIUS L. POWELL, Assistant Surgeon U. S. Army, is extended one month.

The extension of leave of absence on account of sickness granted Major CLARENCE EWEN, Surgeon, is further extended two months on account of sickness.

The leave of absence for seven days granted to Captain R. J. GIBSON, Assistant Surgeon, is extended twenty-three days.

Capt. LOUIS S. TESSON, Assistant Surgeon, is relieved from duty as Attending Surgeon, at Headquarters Department of the Missouri, and Examiner of Recruits at Chicago, Ill., and ordered to Fort Ethan Allen, Vermont, for duty, relieving Capt. AARON H. APPEL, Assistant Surgeon. Capt. APPEL, on being thus relieved, will report for duty as Attending Surgeon and Examiner of Recruits, Chicago, Ill.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending August 17, 1895.

August 14, Assistant Surgeon M. S. GUEST to the "Minnesota."

Marine-Hospital Changes. Official list of changes of stations and duties of medical officers of the U. S. Marine-Hospital Service, for the fifteen days ended August 15, 1895.

P. A. Surgeon EUGENE WARDIN granted leave of absence for ten days, Aug. 1, 1895.

P. A. Surgeon L. L. WILLIAMS, to proceed to South Atlantic Quarantine Station on temporary duty on being relieved by Assistant Surgeon E. PROCHAZKA, Aug. 6, 1895.

P. A. Surgeon W. P. MCINTOSH, granted leave of absence for thirty days from Sept. 1, 1895, Aug. 5, 1895.

P. A. Surgeon G. M. MACRUDER to assume command of smallpox camp, Eagle Pass, Texas, Aug. 10, 1895.

P. A. Surgeon H. D. GEDDINGS, granted leave of absence for thirty days on being relieved by P. A. Surgeon L. L. WILLIAMS.

P. A. Surgeon B. W. BROWN, to proceed to New London, Conn., as Inspector, Aug. 15, 1895.

P. A. Surgeon M. J. ROSENAU, to proceed to Eagle Pass, Texas, for temporary duty, Aug. 4, 1895.

Assistant Surgeon JAS. A. NYDEGGER, to assume charge of Detention Camp, Waynesville, Ga., in addition to other duties, Aug. 14, 1895.

Assistant Surgeon E. PROCHAZKA, to proceed to Charleston, S. C., for temporary duty, Aug. 6, 1895.

The Journal of the American Medical Association

Vol. XXV.

CHICAGO, AUGUST 31, 1895.

No. 9.

ADDRESS.

CHAIRMAN'S ADDRESS.

Read in the Section on State Medicine, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895

BY LISTON HOMER MONTGOMERY, M.D.
CHICAGO, ILL.

While in attendance at the forty-fifth annual meeting of the AMERICAN MEDICAL ASSOCIATION, which was held in that great metropolitan city located at the entrance of the Golden Gate where the commerce of all nations enters that wonderfully progressive and healthful State, the honor was conferred upon me in being elected chairman of this model Section for the year 1894-95. In accepting so much honor I am not unmindful of the responsibility that has devolved upon me. On the other hand, I am profoundly cognizant of my inability to discharge the duties as your chairman in as efficient a manner and to such an eminent degree of satisfaction as did my immediate predecessor, and others who have been chairmen of the Section prior to this time.

As your presiding officer, I desire most cordially and sincerely to return my heartfelt thanks to the members of the Section, and to earnestly request your kind and courteous indulgence in what may be my apparent or real shortcomings.

It is with pardonable pride that I am permitted to congratulate you on the presence of so large an attendance of ladies, delegates and members, and the unprecedented number of essays and papers announced to be read by the official program for this Section.

History records the fact that this is the third time the annual gathering of the ASSOCIATION has convened at Baltimore, but it is the first time that the Section on State Medicine has met in this city since its organization.

Not one of the great men are alive to-day who were officers of the ASSOCIATION at the time the first annual meeting was held in this city, and not to exceed two of the officers of the ASSOCIATION in 1866 are living. One of these was First Vice-President of the ASSOCIATION at that time, whom it affords me sincere pleasure to greet and welcome to-day. I refer to our venerable professional colleague and friend, ex-President James F. Hibberd of Indiana, of whom I can say, to know him is to love and esteem him.

(After a glowing tribute to Baltimore and all its belongings the speaker continued): During the past few years, much has been written upon public health, preventive medicine, State medicine, domestic sanitation and the science of public hygiene, almost synonymous terms, I believe, for us to discuss at this time. Not until recently, however, has this department, or branch of medicine become so

prominently recognized before the public. And each year it is being recognized to a greater degree in its broad field of usefulness. Its scope is widening to such an extent that State medicine not only embraces the subjects of general sanitary supervision of the country, including quarantine in all its details, domestic hygienic laws which embrace the pure-food question for the people; and should, in the main at least, include the topic, which well may be termed the physiological and medical uses of alcohol.

Isolation hospitals is another very important subject that will be discussed at this meeting of sanitarians. Bacterial life and microorganisms of various kinds will receive due consideration by the authors of the various essays and papers bearing upon those subjects and will be ably discussed by the learned gentlemen of the Section.

While there are a great many other subdivisions which you, as scientists, are familiar, with that very properly belong to and should be classified with this Section, your chairman will scarcely more than enumerate a portion of them, nor will he enlarge upon them in this address.

PHTHISIS PULMONALIS.

The field of study of the habitat and insidious ravages of microbes, micrococci, bacilli, etc., is a vast one, too marvelously comprehensive for me to do more than give the subject a passing review. Like the subject of electricity in all its intricate and various ramifications, the most marvelous discoveries of which may be looked for in the future, so, too, will the study of this form of life lead to hitherto unknown discoveries in the treatment of disease. That germs oftentimes do their work insidiously, slowly but surely, is evident, where, for instance, in some of the prisons and eleemosynary institutions of the country, subjects when they enter them in robust health sometimes within a few months become emaciated and physical wrecks. In this respect, phthisis pulmonalis takes the lead and fastens its tentacles upon this class of unfortunates, and as tuberculosis is the greatest scourge the human race has ever encountered, it is the most prevalent type of disease that criminals or the indigent class are subjected to in the institutions named. Notwithstanding, as in the past, scientific advancement in the future bacteriologic investigation of this intractable malady will, we believe, surely bring its ravages and destructive agents under a more certain degree of control. Sanitaria throughout various parts of the country are being established for the prevention, care and treatment of phthisis. Each of these sanitaria have a well equipped gymnasium, tennis courts, lawns, etc., and otherwise are provided with facilities necessary to combat this destroyer of human life.

The newest and latest therapeutic agents used in the rational treatment of phthisis are pilocarpin and

protonuclein. The former remedy was introduced by Dr. Louis Waldstein, of New York. At Berlin he has practiced the hypodermic method by successive injections of minute doses of it into the tissues of tuberculous subjects. As a result of this, there seems to be a gradual stimulation of the lymphatic system. In this connection I may add, that it is claimed also, that cases of lupus vulgans of many years' standing are relieved by using the remedy subcutaneously. Its activity, or pathology of action, as in tuberculosis, is the promoting, or increase of the secretions of the lymphatic glands.

Personally, I am not yet an enthusiast upon this so-called new discovery in the treatment of a disease that has baffled science for so many centuries, and to my mind their therapeutic value is overestimated, while pilocarpin may possibly do all that is claimed for it in the absolute cure of consumption, its action, if what is claimed for it is true, might be regarded more in the nature of a prophylactic, or preventive to a certain degree if used in the earliest stages, of phthisis, or even retarding the reinfection of a patient by fortifying his blood against subsequent inroads, or further invasions of the tuberculous difficulty, than as a curative agent of the disease after it has thoroughly manifested itself.

Toxalbumin, or antiphthisin of Klebs, is another of the so-called toxins used by that eminent German bacteriologist as a preventive as well as curative agent of tuberculosis when used in the early stages of the disease, and it is reported by Dr. Karl von Ruck, of Asheville, that he has practiced upward of twenty thousand inoculations of antiphthisin and has uniformly derived beneficial results. If this is true, it seems to me it should be more generally known.

While it is our duty to be ever on the alert to perform and suggest anything that will ameliorate the physical condition of our fellow-man, climatic conditions must be studied (everything else being equal) in the prevention and treatment of this class of our patients at any stage of the disease. That altitudes of moderate height, where the ozone of pineries in the mountain regions should be selected for at least a certain class of those afflicted in this manner is to my mind a *sine qua non*. That nature's ozone is a germicide and antiseptic is a well-known fact, which doubtless all of you have personally observed. Its prophylactic and hygienic properties will have the tendency to augment the oxyhemoglobin in the circulatory system, and I believe it is the opinion of conservative men also, that this potent remedy, in addition to its healthful tissue strengthening properties, through its action as above outlined, will sterilize the alimentary tract. In following these directions a goodly percentage of patients will result in complete recovery.

Other suggestions occur to us as to the prevention of phthisis, and especially where the disease is in its incipiency, which belong more properly in the treatment of the disease. A movement is on foot by those who are philanthropically inclined to erect sanitarium for the gratuitous treatment of consumptives in some of the southwestern portions of our country, notably in Texas, New Mexico and Colorado. Homes, or sanitarium of this kind for the indigent worthy class are a step in advance in our Christian Republic, to rescue them, as it were, and thus prolong many valuable lives.

Especially will these institutions be erected for the outdoor treatment of the more desirable class. Doubtless you all have heard of this proposition from other sources, but to me the topic is of so great interest that you will pardon me for reiterating it, in the hope perhaps that great benefit will be the result, if even the life of but a single case is prolonged or saved. While pure milk, along with strict attention to a well regulated meat diet, including fats that are easily combustible, and the judicious use of carbohydrates are helpful. In addition to the foregoing suggestions, there is a special value to be attributed to systematic physical exercise in cases of those disposed to phthisis. Psychologic therapeutics, or psychical sanitation, if I may be permitted to use this word, may very properly, I think, be classified or considered an important factor in the prevention as well as treatment of a not inconsiderable number of this class of patients. In a word, tissue metamorphosis of the ascending or building character is a much sought for result in the treatment of this malady. The prognoses, of course, will depend mainly upon the fundamental disease and the inroads it has made in a particular case.

LEPROSY.

At the meeting of this Section in San Francisco in June, 1894, my friend, Dr. Henry S. Orme, of Los Angeles, read an elaborate paper upon leprosy. The author therein stated that he believed there were more cases of the disease in California and elsewhere in the United States than was known. Your chairman fully indorses those views. To his mind there no doubt are isolated cases of leprosy in various parts of the country, notably in the States of New York, Louisiana and California, and possibly, also in the central, northwestern and other southern portions of the country, that are not publicly known. And while the Mosaic laws directed that all lepers be driven out of their homes, and their effects burned, such a general mandatory law if enacted throughout our civilized land would seem at first glance to be cruel and inhuman. But when we recall Biblical lore and the awful dread of what leprosy was to Moses and his people, or is to the Hawaiians and the inhabitants of the Philippine Islands, and of the Chinese Empire today, and which conditions actually exist among our own people where leprosy prevails, it appears to me that a pronounced movement should have long ago been inaugurated to establish at some remote point in the United States one or more leper hospitals, or one or more colonies for the lepers of this country to dwell. Recently, the secular press as well as various medical journals published an account or report of the death of a leper in New York city, and that there were many more cases of leprosy in the State of New York. That judicious and humane laws should be enacted for the compulsory segregation of this class of human beings is no longer a mooted point in my opinion. A colony for this class of afflicted people where they could live by themselves, should be established and maintained by the United States government. Treatment should be afforded them, and their condition ameliorated by every means that sanitary science can devise.

Any person who is suffering from a well defined stage of leprosy should be required to live there. Call these places what you will, sanitarium, or leper hospitals, a suitable institution should be provided for them, that the balance of their lives may be as

enjoyably and as profitably spent as possible, exercising great care that the intermingling of the sexes be prohibited. In this connection I may state that more than one year ago a movement was inaugurated for the establishment of leper hospitals, penal or reformatory institutions, at New Orleans and San Francisco. I am a firm believer in the segregation of this class of patients under the provisions or an analogous one to that just outlined. By so doing, the carrying out and adopting this plan judiciously in a thorough and painstaking manner, State medicine will be the means within the next two generations of banishing leprosy from our land, in the meantime, preventing foreigners who have the disease from landing upon our shores.

In the matter of the United States government having control of this class of people, I quote the following extract from the pen of Dr. Albert S. Ashmead, of New York city, in our JOURNAL of April 13, 1895: "I take in such affairs a higher ground than that of reporting a certain case to the local board of health, and according to my opinion, such cases should be reported to a United States health officer, and that the State or city board of health should have nothing to do with them."

While I agree with the Doctor in the first part of his remarks, I should not be willing to go on record as accepting the latter portion of his theory in this class of cases—no more than such theory would apply to the ordinary contagious or infectious class of diseases.

With reference to the presence of bacilli in leprosy, Dr. R. H. L. Bibb last year reported having examined thirty cases of tuberculous and five cases of macular leprosy covering a period of ten years, and never failed to find them in the secretions of tubercles, in blood drawn directly therefrom, in discharges from leprosy ulcers, and occasionally in the sputum and the secretions from the nose. In the treatment, he and others have used Chaulmoogra oil, internally and externally. While this remedy is not regarded as a specific, if the treatment is begun early and persistently and unremittently continued, associated with proper food and hygienic measures, many cases will recover, while many other cases, probably the majority, will receive no benefit.

Regarding Morvan's disease, scleroderma, Raynaud's disease, syringomyelia, etc., as being merely varieties of leprosy, these are hardly within the scope of this address to discuss, except to state that the preponderance of clinical and bacteriologic evidence goes to show that such is not the case, although these diseases in certain stages may have symptoms closely analogous to those of leprosy.

There is not one of us, I doubt, but entertains the view that variola, diphtheria, scarlatina, syphilis, leprosy, tuberculosis, cholera, actinomycosis homines, la grippe, anthrax, yellow fever and other specific diseases, whether they are zymotic in character or otherwise, as well as possibly pneumonia and carcinoma, whether they be sporadic in origin or not; that these are contagious, infective, endemic, or epidemic in form under certain conditions, particularly where climatic influences and sanitary environments are unhygienic in quality and kind. I should like to include tetanus, trichinosis, myxedema, etc., if time permitted. Whether, according to Dunglison, zymotic diseases are produced by "some morbid principle acting on the system," or, as is at present recognized, that

each of them are of germ origin. I do not wish to be understood, however, as differing from able scientists and teachers in the belief that inoculation and transplantation of cancer from man to a lower animal will produce the disease. On the other hand, I believe this procedure rarely, if indeed, is ever successful in producing it, while it is asserted by various writers for myxedema, that this variety of tumor is successfully combated or treated by the oral administration of thyroid tablets or extract of the thyroid gland in some form.

SMALLPOX.

This disgusting malady should never be permitted to become epidemic or very rarely, indeed, of an epidemic character in any of the larger inland municipalities where there is a well equipped board of health. That it should be permitted to take such a course is, in my opinion, due to a lack of thorough and early measures to stamp out the disease; allowing that cases are sometimes concealed for a time from the authorities by ill-advised and unwise friends, this can not long remain so, and when discovered, thoroughness and radical means should be promptly adopted, in all that this term may imply, to suppress any further outbreak of the disease and to prevent its diffusion. Vigilance, promptness and efficiency should be the watchwords to characterize the executive health officer in any community. From him the people have a right to expect proficiency and competency, and if this servant of the people is unmindful of his duty it is little less than criminal negligence on his part, in not taking most thorough and prompt measures to quell an outbreak of the disease and use radical measures to stamp out the contagion that may be lurking in the premises.

Dr. Thomas Stevenson, of London, in his "Treatise on Hygiene and Public Health," says upon this topic: "Formerly, protection against smallpox once acquired was looked on as permanent and absolute; cases of secondary smallpox, usually very mild, we called horsepock, swinepock, etc., just as in Jenner's time the variolous nature of post-vaccinal smallpox, also very mild, as a rule was denied. From whatever cause obtained, the amount of protection varies according to the thoroughness of the protective procedures.

"Severe smallpox gives more enduring protection than mild smallpox. Smallpox inoculation gives most protection when followed by eruption, and a complete and multiple vaccination gives more lasting protection than does vaccination resulting in a single small vesicle.

"In the present century a second attack of smallpox is less frequent than formerly because, as a result of the practice of vaccination a primary attack of smallpox usually comes later in life, so that the protection it affords does not wear off in time readily to allow of a second attack.

"Protection by smallpox inoculation or variolation was introduced into general notice in England in 1721. The practice under the name of *buying* the smallpox seems to have existed in Wales from time immemorial, following the introduction of the practice in 1721. The simplicity of the eastern operation was discarded for a severe operation with untoward results, which soon brought inoculation, as a whole, into disfavor. After 1740 it began to revive, and in the hands of the Suttons and of Dimsdale it became

a mild and fairly safe procedure, with only one death in perhaps three or four hundred cases, but it perhaps tended to spread the disease by atmospheric infection, and it is a moot question whether in this way it did not do as much harm as good."

Under the heading, vaccination and revaccination, the historical methods so well known are dealt with, as also the relationship of smallpox to cowpox. The whole tendency of the evidence is to show that vaccinia is as Jenner had supposed it, variola of the cow, and that the virus of human smallpox is so attenuated in the bovine animal as to be deprived both of its quality and atmospheric connection and of its tendency to cause a generalized eruption, and that in this way the change in the calf from variola to vaccinia has the effect of removing the objectionable and retaining only the valuable part of the original disease.

DIPHTHERIA.

The prophylaxis and latest method of treatment of this oftentimes malignant malady scarcely needs mention, for this is already fresh in the memory of us all, and includes all that is implied in the new serum-therapeutics. That the antitoxin treatment in diphtheria, whether it is the use of protonuclein, previously alluded to, or the serum derived from the blood of the horse, is in antagonism to bacterial poisoning appears, to say the very least, philosophical, and while the present methods may not be those of perfection, like the study of electricity, as previously stated, the wonders of which already have been achieved are not to be compared to what hoped-for results may bring about. So that, what to-day may appear to be crude as regards electricity may, on the same principle, be regarded as imperfect in the treatment of diphtheria in future, as advances are made in the use of antitoxin diphtheriticus. Even admitting all that is claimed for antitoxin, I would not advise the discontinuance of the older time-tried remedies, but combine the two when necessary in that class of cases, particularly, where the toxicity of the disease is profoundly marked by staphylococci and streptococci.

Another powerful remedial agent has recently been introduced, and remarkable results have been already attained by its use in the treatment not only of diphtheria, but in scarlet fever and some of the milder classes of eruptive fevers. I refer to nucleinic acid. This agent has the effect of neutralizing or combating the poison diffused by the staphylococci. Its use is also recommended as a tonic, as well as to cope with or prevent the contagiousness of these diseases extending to others who may have come in contact with those already ill.

SYPHILIS.

I quote from the London *Lancet* of June 2-16, 1894, the following extracts:

"The disease is widely spread in all parts of Russia, and in some districts is a veritable scourge. In the Government of Tomsk in Siberia, the immigrant population is said to be decimated by it. The medical department has therefore commissioned three medical experts, Drs. Stepanof, Flitner and Tchapin, to proceed to Tomsk and to take what measures may be necessary to prevent the further spread of the disorder there.

"The attention of the Indian Government has for some time past been called to the large and increasing

amount of inefficiency caused by venereal diseases in the European army in India. The question is a very grave one from whatever standpoint it is regarded. Nor are the evils, bad as they are in India, restricted to that country, for the health of our troops in this respect is seriously affected at camps and garrison towns at home and abroad. It must be always borne in mind that the effects of these diseases do not fall exclusively upon the individuals contracting them, but are often extended to other and innocent persons, and some of their remoter consequences are manifested in succeeding generations. So far as the contagious disease acts are concerned, there can not be a doubt that they exercised a deterrent and restraining influence in regard to a number of thoughtless girls exposed to the temptation of urban life, and have brought fallen women within the sphere of moral and remedial influences, to say nothing of the beneficial effects of the acts on the outward aspect and decency of our (their) streets."

ERYSIPELAS, PUERPERAL FEVER AND BRONCHOPNEUMONIA.

Briefly, I may include that Dr. Marmarek, a Parisian physician, has discovered a *new* serum which he has named "antistreptococcique," for the treatment of those maladies. As this is not quite in the line of prophylaxis, I will omit further discussion of this "toxin" agent except to add that it has been used at the Pasteur Institute in Paris.

CHOLERA.

The destructive agency of the comma bacillus and its media in cholera Asiatica—or cholera nostra, by thoroughly neutralizing its surroundings has been the means of asphyxiating or stamping out through the various countries of Europe this depopulating malady. Whether the disease will start anew in Russia, or the pestilence breed again as a result of the Chinese war, is a thought worth considering at this time. For, during the hot weather months in China it seems as if there is almost always some kind of epidemic prevailing. Should intelligence of this not improbable prophecy be realized and reach America, well may the authorities throughout Europe, as well as here, take thorough and prompt precautionary measures in adopting stringent laws to guard against the spreading of cholera in these countries.

LA GRIPPE.

We read of la grippe intoxication, and the antitoxic effect of certain drugs over this affection. Quinin is a true antitoxin in their treatment, as well as prevention when suitably administered, for in la grippe, or if you prefer to call it influenza, there is a bacillus, and their infective activity is no doubt the cause of this oftentimes distressing malady. As to the sequelæ, these are very numerous: bronchitis, pneumonitis, nephritis, diseases of the nervous system, digestive tracts, etc. I dare not mention more of them at this time, although by your permission I may be pardoned if I very briefly consider one or two of these so-called sequelæ.

My observation in bronchitis, following an attack of la grippe is hygroscopically, when the temperature is lower than it normally should be, or when this condition is combined with moisture, it is most favorable for the development of germs causing the disease. That they become most active, grow, and develop at such periods, I am well satisfied. Condi-

tions exist also to favor this malady so that it may become endemic or epidemic in character due to atmospheric suspension. That the germ may become infectious in its nature I have no reason to doubt, or that the disease may even occasionally be transmitted to, or contracted by one person being in too close contact with another.

PNEUMONITIS.

Regarding the pathology of pneumonitis and the microbe that has been proved to be the almost constant concomitant of this disease, I have but a word to add. The bacillus discovered by Friedlander was thought to be by many the pathogenic organism responsible for exciting it, but the real "pneumococcus" is that discovered by Fraenkel and Talamon and studied by Drs. Sternberg, Weichselbaum and others, later developments of which show that experimentation upon animals with pneumococcal inoculation will induce inflammatory processes in various tissues and organs.

DEPARTMENT OF PUBLIC HEALTH.

Serumtherapy, including antitoxins, antituberculin, antihydrophoie, etc., are rapidly being introduced. That in their study and their use lies a great future there is no longer a doubt in my mind, when they can be obtained in a perfectly fresh state. When the governments of our municipalities and various commonwealths recognize the importance of bacteriologic research and of State medicine in general, and the establishment of laboratories in various cities of the country, this may be said to be a step in advance of what a few years ago was scarcely worth the thought for a moment's consideration. In a word, then; I believe that in serum-therapeutics and antitoxins, the use of which is almost in their infancy, we have added another boon to humanity and that greater developments await their coming. These discoveries are in line with the researches of Pasteur, Koch and other bacteriologic collaborators. In addition to what has just been said, it may be gleaned from the foregoing pages that they point directly to establishing another branch of our federal government, known as the Department of Public Health, with a medical secretary of the same. To my mind there is no longer room for doubt that this proposed additional portfolio should be created. The special committee of the ASSOCIATION first appointed in 1891, to petition Congress to create "a Department and a Secretary of Public Health," submitted the result of its deliberations at the Detroit meeting in 1892 in a most excellent and scholarly manner. At Milwaukee, in 1893, and last year at the San Francisco meeting carefully prepared reports upon this most vital question were submitted, and at all these meetings the report of the committee was unanimously adopted. Your chairman is a very humble member of this special committee, yet he has invoked the promise of several Illinois Representatives and one of its U.S. Senators to cooperate with us to favor the passage of the bill that has been so ably prepared by the committee, and which has been before Congress practically for two years. While the billion-dollar mark for appropriations of the last (LIII) Congress was passed, no small amount of which was for the improvement or deepening the channel of "Mud creek," "Swan lake," etc., nothing was done to promote the health of the American people in the matter of legislation or establishing this greatly desired branch of our government.

That sanitary work can be accomplished and exacted by national authority, of local and municipal boards of health, who do not, or will not at all times comply with that which best subserves the sanitary interests of a community, is a certainty which would require the latter to vouchsafe their stewardship to the people. That well-known maxim, "*Salus populi, suprema est lex,*" should have received the thoughtful consideration of every member ere the demise of the last Congress is something which only the ozone of forgetfulness will remove. Permit me to suggest, that we advise and recommend to the ASSOCIATION in general session, ere its final adjournment, that the perpetuity of the committee, clothed with additional substantial authority be continued, and with the request also from this Section that sufficient financial aid from the treasury of the ASSOCIATION be appropriated to defray the necessary expenses of this committee, which should not be less than \$1,000 for the ensuing two years.

And now, gentlemen of the Section, you will excuse me, I know, for inviting your attention for a moment to another topic which is not exactly within the province of this address. It is a subject of considerable interest to every member of this Section, if indeed, not to every member of our profession in the United States. I refer to the proposed statue to Dr. Benjamin Rush, to be erected at the capital of the Nation. When we reflect that the beautiful city of Washington is embellished with statues of patriots and presidents, painters and sculptors, generals and jurists, philanthropists and theologians, and numbers of others, all of whom are affectionately commemorated, this much we owe to the memory of that great physician, sanitarian and teacher, a member of the Continental Congress and signer of the Declaration of Independence; when we recall the success that has been achieved by the American Surgical Association, with its hundred members, in raising a sufficient amount of funds for the completion of their monument to Gross, and the prospective erection of a most magnificent monument to Hahnemann in Washington by the homeopaths, it should be a matter of great pride as well as a pressing duty on our part for us to enthruse our members in the matter of the ASSOCIATION monument to Rush. Let it be promulgated from the Section on State Medicine, that we heartily approve this commendable object, and loyally and earnestly and in a substantial manner heartily support the committee having this sacred duty in charge, and with renewed hope going out from this Section of sanitarians, encourage and sustain the committee to invite every member of the ASSOCIATION and the profession throughout the United States to contribute toward this laudable undertaking. That a testimonial in the form of a shaft of marble or granite, surmounted with bronze, enduring as the ages, may be erected eighty-two years after the heroic death of Dr. Rush, to crown his immortal name and perpetuate the memory of one of the grandest and most illustrious members of our profession that America has ever produced, will, I believe, be another historic event of our honorable profession.

In conclusion, I wish to renew my thanks for your indulgence thus far, and say that I am not unmindful of my obligations to you in this respect, and to furthermore state that a very large part of the success the Section on State Medicine has attained this year, is due to the loyal support of the efficient Sec-

retary, Dr. Charles H. Shepard, and to all the members who kindly responded to our invitation to read papers, which you will note by referring to the titles and authors in the program, are of unusual scientific interest.

ORIGINAL ARTICLES.

NOTES ON TWO CASES OF PELVIC SURGERY.

Read in the Section on Obstetrics and Diseases of Women, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY H. R. HOLMES, M.D.

PORTLAND, ORE.

These cases I report, as throwing some light on the philosophy of ventrofixation:

Case 1.—Mrs. K., age 46, married twenty years; 2-para; youngest child 18 years of age. Seen first in June, 1892. Complained of menorrhagia. Five curettements had been done without much, if any, benefit. Perineum had been attempted by Tait's method which had not given satisfaction. In fact, there was yet a pronounced flatus vaginalis. The first thing I did for the patient was to curette the uterus carefully and pack it with iodoform gauze, and at the same time do an Emmet operation to repair the pelvic floor. The latter was a happy success, in so far as it restored the function of the pelvic floor, but this statement may be questioned, when I admit that it did not raise the uterus as high as its normal place, nor change it from its position in the second degree of retroversion.

Within three months the menorrhagia was bad as ever, and following the menstrual periods there would be a mucoserous discharge so irritating in its character as to abrade the cutaneous surface of the labia and thighs and render the patient hyperesthetic.

Another time I used, I think quite thoroughly, the curette; very little if any improvement took place, and when three months had passed I again curetted somewhat vigorously, and yet no considerable change of the condition was effected. The bimanual examination showed the uterus to be of about normal size and the uterine sound added confidence to this belief.

For more than a year, patient was treated expectantly. In May, 1894, on examining the first time for six months, a tumor the size of a Tangerine orange was found at either side of the uterus, and patient was complaining of constant pain. Within a few days celiotomy was done, and the two cysts, ovarian, were removed, and ventrofixation of the uterus was done also. Convalescence was without remarkable event and my patient improved to an extent, as to say, she underwent a precipitate menopause and not suffering her accustomed waste of blood, began to improve in strength and general appearance.

But still there remained a doggedly persisting uterine discharge—mucoserous in character—which was so irritating to the woman, using her own language, as to render life a misery to her. The irritation, so to speak, was exquisite. It set up a nervous erythism which she felt at times was unbearable.

In November, 1894, I removed the uterus on account of this uterine discharge for which I had tried every other remedy that I could think might be of benefit. On account of the former celiotomy and ventrofixation, I decided to remove the uterus by the suprapubic method, and did a total extirpation. Just before operating, I made a digital examination *per vaginam*, and while the uterus was found to be in good position it was so movable that I supposed it was no longer in any way connected with the abdominal wall. On opening the abdomen, the uterus was found suspended from the abdominal wall by a ligamentous structure about an inch in length by an inch in width, bearing a close resemblance to the natural uterine supports, consisting of two layers between which were the sutures. Recovery, as in the former instance, was perfectly smooth and patient is very well.

Case 2.—Mrs. R., age 39, 2-para. Had secondary syphilis, cyst of broad ligament, lacerated cervix, endometritis, retroversion of uterus and ruptured perineum. As she was a county charge and the officials being highly esteemed for their "political economy," I felt that I should do all I could for her at one sitting, for it was quite certain that she would not again have the chance to enter the hospital for surgical

treatment at the county's expense. Accordingly, and as rapidly as possible, and yet it required about an hour and a half, I curetted the uterus, repaired the cervix and perineum, ligated the hemorrhoids after stretching the sphincter ani, opened the abdomen after carefully cleansing the hands, cared for the cyst of the broad ligament and did ventrofixation of the uterus also.

The convalescence was easy; the results were satisfactory.

In the early part of February of this year she visited me at the Portland Free Dispensary to say that she had not menstruated for three months. Examining her, I was convinced that she was pregnant between three and four months. I would like to remark just here that patient had been examined each month at the dispensary and the uterus had been found in good position and movable. I impressed upon her mind the importance of being seen frequently, and accordingly she has come to the clinic every week. About the first of March she had some pain at the point of ventrofixation. This troubled her but slightly for three weeks and ended. She seems to be passing along through her gestation naturally. I think she is pregnant about six and a half months, and have hopes that she may go on to full term smoothly. We are keeping her on 10-grain doses of potassium iodid three times daily.

In conclusion, I feel like stating that I have never been better pleased with the results of any of my gynecologic operations than those of ventrofixation. I believe that it is just as valuable for extreme anterior displacements as for the posterior variety; yet it might not be appropriate to do it more than once perhaps for the former while it is being done twenty times or more for the latter, for the reason that cases demanding it for anteversion or anteflexion are relatively so infrequent as compared to those demanding it for posterior displacements. In other words, cases of extreme anterior displacement are rare.

I now know of three prominent and highly qualified surgeons who have employed this means of suspending extremely anteverted and anteflexed uteri, during the past year, and they have reported satisfactory results.

Last year at San Francisco, I read a paper before this Section on ventrofixation for extreme anterior displacements of the uterus, reporting six cases so operated on with pleasing results. Since that time I have met with but one case of the kind sufficiently bad to require the operation, while during the year I have suspended the uterus perhaps a dozen times for retroversion. To be sure, retroversion is usually accompanied with some degree of decensus, which is the cause in part at least, of the attending symptoms, but I am not convinced that anterior displacements do not cause bladder and menstrual disturbances equally great in rare but occasional cases.

When I read my paper in San Francisco I was as well as now aware of the popular professional opinion regarding the clinical import of anteversion and anteflexion, and yet, results of the few operations that I reported were so satisfactory, as well as encouraging reports from others who have done the operation, that I am still under the persuasion that the procedure is one of value. While it is so absolutely safe, barring the possibility of accident or error, I presume its justifiability will hinge upon the question, Is there such a thing as pathologic ante-displacement of sufficient consequence to merit attention or treatment? If so, the operation which I have proposed deserves your consideration and trial; if not, I am laboring

under a mistake; a part of Dr. J. Marion Sims' valuable time was wasted, and Dr. Dudley, of Chicago, has perpetrated a joke upon himself.

If it be not asking too great a favor, I should be glad if those who believe in the existing importance of ante-displacements, would give this simple and safe operation a single trial.

While the immediate effect of the procedure suggests the term, ventrofixation, in view of that which takes place secondarily, I am willing to accept the name which Professor Kelly now is using as a better one, and certainly he has the right to christen his own child.

DISCUSSION.

DR. A. LAPHORN SMITH, of Montreal—said he was very much indebted to Dr. Kelly for this operation, which he has now performed twenty-six times without any mortality rate and with very gratifying results. He referred to the importance of scarifying the peritoneum and anterior surface of the uterus for the purpose of favoring adhesion. He employs a permanent sterilized silk ligature in stitching the uterus to the abdominal wall. The organ is quite movable after the operation. He considers it preferable to Alexander's operation. He had done the Alexander operation twenty-six times before he began this method.

DR. REUBEN PETERSON, of Grand Rapids—said the first operation that he attempted for suspension of the uterus by the ovarian ligament was devised by Dr. Kelly. Dr. Kelly was fortunate in getting a large number of cases upon which the operation could be done, and we must depend upon the record and the results of a large number of cases in order to determine the special method we shall adopt. In seventeen cases he has suspended the uterus by means of the ovarian ligament. Recently he had the opportunity of examining ten of the patients personally, and had a report of five others. In ten of the cases the anatomic result was perfect, and a cure has been effected in fifteen out of the seventeen cases.

DR. RUFUS B. HALL, of Cincinnati—thanked Dr. Kelly for his excellent work in this direction, and said he had made the operation a number of times and was very much pleased with it. He mentioned the fact that in a number of cases in which one ovary was removed and the uterus fixed to the anterior abdominal wall, the patients had borne children without inconvenience. One patient complained of considerable pain in the line of incision about the fifth or sixth month, after which she went along and was delivered without trouble. He is more and more convinced that time will prove that retroversion will be treated in this manner as a routine mode of treatment.

DR. J. HENRY CARSTENS, of Detroit—said that ordinary cases of retroversion of the uterus without any adhesions did not require ventral fixation. He believes that such cases can be treated by mechanical means. Some of these women do not complain of any symptoms whatever, while in other cases more or less pain and distress are complained of. He finds also in these cases of retroversion of the uterus that a diseased tube is generally at the bottom of the whole trouble, and as a result we have on one side the tube, ovary, uterus, and rectum matted together. In such cases we have to perform abdominal section and remove both the diseased ovary and tube. When we do that and break up the adhesions between the uterus and rectum, we may as well stitch the stump in the lower angle of the wound and keep the uterus anchored *in situ*, while the other side being perfectly healthy will go on and functionate and the woman may become pregnant. He claimed that all cases requiring ventral fixation are due to a diseased tube and ovary, and they must be removed in order to do any good. He was perfectly astonished in the light of modern surgery to hear that Dr. Kelly still employed silk for ligatures in these cases, and thought it would be better to employ some absorbable material for that purpose.

DR. BEVERLY MACMONAGLE, of San Francisco—has performed the operation a number of times with excellent results. With regard to scarifying the tissues, he does not think this is necessary if the sutures are passed as recommended by Dr. Kelly. The whole intra-abdominal pressure is on the back of the uterus, and while the tissue allows it to sink down it does not permit the abdominal viscera to come between the uterus and abdominal wall. He has had quite a number of patients who have declined the operation. The operation of vaginal fixation is coming forward and

being practiced by a neighbor of his very generally, and he was anxious to hear the different opinions on this subject.

DR. M. B. WARD, of Topeka, Kan.—felt certain that there was no operation in surgery that is equal in its results to the one described by Dr. Kelly. He does not agree with Dr. Carstens as regards the benefit of mechanical treatment in these cases. A gynecologist might treat a uterus for six years by trying to replace it by mechanical methods, and yet eventually would be forced to do this operation in order to effect a cure, and if Dr. Carstens could replace a uterus in these cases by manipulation with tampons and pessaries, he was more skillful than the speaker. He had had excellent results in cases of ventrofixation.

DR. G. R. FEIL, of Cleveland, Ohio—referred to a case in which fatal secondary hemorrhage followed the performance of the operation. The patient was a woman, 33 years of age, upon whom a double ovariectomy had been performed. The uterus was retroflexed, and the physician in charge performed the operation as recommended by Dr. Kelly.

DR. X. O. WERDER, of Pittsburg—was sorry that vaginal fixation was not more discussed than it had been. He saw Dr. Kelly do his operation of suspensio-uteri two years ago, and was well pleased with the method and had been using it until seven or eight months ago. He had operated twenty-five times by Dr. Kelly's method and his results had been very good until he encountered mural abscesses. Shortly after this he noticed that German operators were recommending vaginal fixation. He has resorted to this method in thirteen cases. One advantage of vaginal fixation over the abdominal method is the avoidance of the abdominal incision, and he knows from experience that with many patients this is an important matter. Many patients will submit to vaginal fixation in connection with a cervix operation, Emmet's perineal operation, or some plastic operation about the vagina when they will flatly refuse to have the abdomen opened for correcting a malposition of the uterus. Another advantage of vaginal fixation is that patients can leave bed in ten days. After the operation they do not complain of any pain, thirst, or any of the disagreeable symptoms that are frequently complained of after an abdominal section.

CONCERNING THE PRINCIPLES AND PRACTICE OF EPISIOTOMY.

Read in the Section on Obstetrics and Diseases of Women at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY FRANK A. STAHL, M.D.

DEMONSTRATOR OF OBSTETRICS, RUSH MEDICAL COLLEGE; FELLOW OF THE CHICAGO GYNECOLOGICAL SOCIETY, ETC.

Nature teaches that she endeavors to establish a favorable relativity in size, axes and diameters between those of the mother and her parts, especially the pelvis, and those of the fetus and its parts. Where this is, there is the normal. When this favorable relativity is present and with long fetal part diameter to long pelvic diameter given the proper parturient power, there will be natural, unassisted or normal labor, without destruction or harmful adaptation of part to part; where otherwise, as long fetal part diameter to a shorter pelvic diameter there will be unnatural or abnormal labor, requiring corrective assistance either natural or artificial, be it at the superior strait, in the cavity or at the outlet; be it upon the mother's part or upon the fetus' parts, and as a result of such deviation, necessity has invented operations, such as the forceps, turning, Cæsarean section, embryotomy, and yielding for a moment to the symphyophile, symphysiotomy. At the outlet, nature teaches episiotomy. At the outlet, the longest diameter is the antero-posterior, and to it must be apposed, and through it must pass the longest diameter of the fetal part, and this is usually the case. Unfortunately the antero-posterior diameters of the osseous and soft pelvic outlets are not equal in length, that of the soft outlet being shorter, so that often a fetal part will readily clear the osseous outlet, but

not so the soft outlet, and then with difficulty and traumatism.

Nature endeavors to overcome this difficulty and disproportion between fetal part and soft outlet by dilatation of the soft parts to encourage increase of their diameters and circumference; but where dilatation does not affect this favorable relativity, nature does so by establishing the equality of diameters through separation of the parts of the soft outlet, thus overcoming the disproportion. In the great majority of all cases where this natural separation occurs, be the case normal or abnormal, it does so in the midline through the perineum, a natural episiotomy, as it were, and central in character, though in some few cases the separation deflects to one side or the other. In this phenomenon there is an expression of a law of nature. When and where she finds it necessary to overcome an obstacle, nature chooses that direction and that method in which there is the least resistance, the least injury inflicted, the least expenditure of energy, and in which the necessary therefore the most good is accomplished. Though this assisting corrective principle of nature at the soft outlet is an old one and must have been appreciated by many before him, to Fielding Ould (1742) is given the credit of being first to call attention to this subject. He seems to have adopted nature's plan, suggesting central episiotomy. The records are not clear whether or not he performed episiotomy. Michaelis (1799) is accredited with having been the first to have performed the operation, and he, like Ould, advocated episiotomy in the midline. In 1836 Ritgen suggested scarification of the outlet, but this theory is lacking in efficacy, as well as in principle. In 1850, Eichelberg, and in 1852, Scanzoni brought out and recommended lateral episiotomy, the method as generally practiced to-day, lateral incisions from 1 to 3 cm. in length. More recently Cohen suggested subcutaneous myotomy of the sphincter cunni, a suggestion failing again in efficacy and principle. It savors much of a congenial library and a fragrant Habana. Its to have been anticipated impracticability quickly proved itself when attempted at the bedside. Since Ould's time more or less interest has been shown in episiotomy, yet more interest than practice; its principle has always been regarded with favor, not so the method.

In America renewed interest seems to have been awakened in episiotomy, following the appearance in 1878 of Dr. Anna Bromall's most excellent and exhaustive article which was soon followed by those of Credé and Colpe, Manton, Wilcox, and many others in close succession, one of the last to appear being by Dickinson, well illustrating his conception of the principles and the technique to be followed in lateral episiotomy. They, like our text-books, favored the lateral method and the consensus of opinion to-day is to favor the lateral method. The success with the lateral method has been such that although the writers above referred to have all warmly recommended lateral episiotomy, the success or perhaps the lack of success which this lateral method has met with in the hands of the general, as well as special practitioner of obstetrics, has been and still is such that opinion at the present time is less enthusiastic toward the operation than formerly, many discarding it altogether as without virtue or value. This feeling is quite plainly reflected in the words of Professor Parvin who, in reference to this operation, concludes

as follows: "It may be stated that episiotomy will very seldom be plainly indicated, and in private practice will rarely be done." Very similar in tone writes Professor Lusk: "It (episiotomy) is essentially the operation of young practitioners, the occasions for its employment diminish in frequency with increase of experience," and further, Chailly-Honoré, the most enthusiastic advocate of lateral episiotomy (Bromall), refers to it "as the excellent practice of Professor Dubois, who taught that incisions should be made, extend in an oblique method, not to exceed 2 cm. He admitted, however, that perineal ruptures can not always be avoided, etc.," an expression very clearly showing his doubt in its efficacy and that nature often assists post operationem.

Though, comparatively speaking, yet a younger practitioner, I have enjoyed a preliminary training in obstetrics granted to but few, and since then my experience in the obstetrical field has been rich in material, and yet richer in instruction, since this preliminary training enables me to properly appreciate each and every case as it occurs.

Episiotomy, I believe, meets with so little kindness not because episiotomy *per se* is at fault, but rather it is the method in which opinion dictates it should be performed. Opinion has misled, and instructs to adopt the lateral method. On the other hand, nature remonstrates and requests to elongate in the midline. It is opinion that has endeavored to misdirect, but nature, like truth, will assert herself. Still, I can readily agree with these gentlemen in their adverse conclusions, but only in so far as their remarks apply to lateral episiotomy, because lateral episiotomy is wrong in principle and lacking in efficacy. This is not so with nature's method, central episiotomy, which in principle, I believe, is correct, and that is to elongate and increase the circumference in the direction of the essential diameter of the soft outlet, the antero-posterior, thus equalizing the diameters of the soft and osseous outlets and establishing the natural favorable relativity.

Lateral episiotomy does not accomplish this. At the outlet it is to and through this shorter a. p. soft outlet diameter that the longest diameter of the fetal part must pass, therefore if dilatation be not sufficient and inequality of diameter exists, correction in this diameter becomes a necessity and occurs; observation teaches this, so does nature, and central episiotomy thus becomes the natural method. In my humble opinion at the present time there is no subject before obstetrical thought which attaches greater importance to itself than does this matter of episiotomy.

Society, as the accoucheur finds it to-day, has a tendency to gather in the cities, crowding itself within very narrow lines, and where formerly the mode of life was such that there was room and plenty of it to live and move in, there is now, and this tendency is growing, scarcely space in many quarters to breathe in, not to say anything of properly exercising in. This overcrowding and confinement are gradually having their effect upon the body of the species. The physical under these unfavorable conditions is certainly not gaining, nor even in many instances holding its own. As a consequence there is a loss of power, of strength, to overcome the resistances nature requires the physical to overcome. Statistical research and scientific inquiry will prove this to be true, and in all branches of medicine, namely, medi-

cine, surgery and obstetrics. I feel quite sure that there is not an accoucheur of experience present but who indorses the point made by Duncan as to the disproportion between fetal part and soft pelvic outlet. Duncan writes as follows: "That in the Darwinian progress of the head of the species, the head of the fetus has increased in size more rapidly than the orifices and passages, through which it has come, have increased in size and dilatibility." As man's tendency to gather in large bodies in small places continues, so will loss of the physical continue until better hygienic conditions obtain, and so will this disproportion between outlet and fetal part continue, and therefore will continue the necessity for some corrective assisting means to successfully overcome this unfavorable relativity of outlet and fetal part, or we must leave it to nature to correct. It is in consequence of this light, this experience, that I find I can not agree wholly in opinion with our masters of obstetrical thought, Professors Parvin and Lusk. Experience has taught me to adopt episiotomy, and then central, never lateral, where the disproportion between fetal part and soft outlet is plainly evident; this in an experienced sense.

In my hands, episiotomy is an instrument, *par excellence*, aiding as no other instrument can in the preservation of life and body, both in the fetal and maternal, and as I grow in obstetrics and since I find that the disproportion does not decrease, I am glad to know that there is so effectual and yet simple an instrument as central episiotomy at my command. It is in private practice especially where it has proved itself of such benefit, and has often assisted me in saving the life of the fetus and always in preserving the perineal body and other parts of the soft outlet.

In nearly all cases of accouchement forcé, as turnings, high and low forceps in the primiparæ and well-preserved pluriparæ, and in something like 20 per cent. of so-called normal deliveries this disproportion between fetal part and soft outlet exists. Especially in turnings in the primiparæ has episiotomy been of great value to me. Formerly in the after extractions, I found the greatest difficulty in dragging the fetus through the undilated vagina and outlet, greater difficulty indeed than in the intra-uterine turning itself. Even before the turning, in some cases, the power of the arm becomes neutralized because of the intense contraction of the undilated outlet and vagina about the forearm: and often because of this constriction, delivery was not accomplished until vagina and outlet were forcibly ripped apart from the disproportion between fetus and outlet and in the hurry to save life. Now with episiotomy, turning and extraction are far easier than formerly, with greater comfort and less danger to all three concerned—fetus, mother and accoucheur. The same in principle applies to high forceps and in a modified way to low forceps.

Of the four methods—lateral, central, scarification and subcutaneous myotomy, suggested to favor the establishing of the favorable relativity of longest fetal part diameter and longest pelvic outlet diameter and increase of outlet circumference, lateral and central episiotomy only are worthy of consideration. Lateral episiotomy is lacking in two cardinal points: 1, it is wrong in principle; and 2, the operation as recommended is sadly deficient in efficacy, and besides it is unnatural. To establish the favorable relativity, the essential diameter, the soft antero-

posterior must be equalized. Lateral episiotomy, as practiced, does not accomplish this; on the contrary, it elongates the transverse and oblique diameters and remains almost neutral toward the all-important diameter, the antero-posterior, therefore this ill success. My experience with lateral episiotomy has been, I believe, much that of others. In those cases where it seemed to have been of service, legitimate doubt subsequently arose as to whether or not the fetal part could not have passed without lateral incisions. But in those cases where the disproportion was plainly evident, as in nearly all cases of accouchement forcé, as in high forceps and turnings where though lateral incisions were made, observation decided that invariably nature assisted with central episiotomy. And why? As taught, lateral episiotomy is made with reference to length of incision from 1-3 cm. in a lateral direction. Scarcely any mention whatever is made of depth (a depth of a line or 5 m.m. is practically without effect). As stated, this will elongate the transverse and oblique diameters—diameters that need no corrective assistance. Unless lateral episiotomy be made with reference *primarily to depth of incision that the interval between the incisions may fall back as a tongue of perineal tissue, lateral episiotomy is absolutely without effect upon the essential antero-posterior diameter.* But such a practice compared to central episiotomy is excessive, requires greater efforts to perform and to restore, is more dangerous and requires a longer road to arrive at an inferior result.

One of the best physical explanations offered me in support of this lateral method is the so-called theory of the "parallelogram of pelvic outlet forces"; and is, so I understand it, as follows: The head, as it rides upon and over the perineum and through the parallelogram, as formed by the labiæ, does so in a manner like the segment of a sphere whose diameters are equal in all directions. As a segment of a sphere its greatest power would be exerted at its central axial point, diminishing in a radial manner from the central point. The parallelogram not being continuous, resistance is not met with or power expended at this central axial point, but in a circumferential and radial manner, thus receiving and expending the greatest resistance and power in a radial manner, therefore lateral or radial incisions.

This theory is weak in several respects:

1. The head does not descend upon the soft outlet, so that it acts as a segment of a sphere, nor are its diameters equal in all directions. It may appear so between the labiæ, but the head in its passage over and through the soft outlet acts upon it as a segment of an ovoid whose longest diameter is in the antero-posterior, and to be favorably related to the pelvic outlet must assume and clear that outlet in its longest diameter, its antero-posterior.

2. Radial incisions are wrong in principle, since they increase the circumference, but superficially, and then so as to increase the non-essential transverse and oblique diameters. To be of service, increase of circumference of soft outlet should not be superficial only and must be made so as to increase the antero-posterior diameter.

3. Radial incisions as implied above, regardless of *number* and *length* are without the essential corrective effect, unless made with regard *primarily to depth*. Such a practice compared to the single simple non-dangerous midline incision is seriously objectionable.

4. Nature herself disproves this theory since often, notwithstanding lateral incisions, she corrects even the artificer and separates in the midline, and not seldom exaggerates the lateral incisions both in length and depth; again in the fact that in the great majority of all spontaneous lacerations they are central in incipency and character; also in the fact that where rupture of the perineum solely occurs it is central, never lateral.

5. This theory is not applicable to other forms of labor than occipito-anterior, as in those of occipito-posterior, face and pelvic presentations, where the circumference of the advancing part is oval.

The floor of the pelvis is divided throughout nearly its whole extent by two outlets. In outline these outlets may be compared to a flattened unequally looped figure of eight. The anterior and greater loop ovoidal in outline corresponds to the parturient canal outlet; the posterior, smaller and more circular corresponds to the alimentary canal outlet and as connecting link between the two loops and encroaching upon the caliber of both canals is the triangular perineum. If the circumference of either loop be too small to permit a body to pass, and especially an ovoidal body through the ovoidal loop, the most simple and effectual way to increase that circumference is to overcome the uniting encroaching link, and this will be in a line with its central diameter. In the case of the ovoidal body passing through the ovoidal loop, the greatest resistance will be at the central point of the circumference of the invading link, diminishing in a radial manner from this point.

Separation of the soft perineal link in the midline increases the superficial and deep circumference of the parturient outlet and in a direction equalizing the essential osseous and soft pelvic outlet diameters, with less expenditure of energy to perform and to restore, with less danger to body and life, and is more practicable than in any other method.

So far as technique is concerned, I have nothing to add what is already so well known; all that is required is a pair of blunt-pointed scissors. In high forceps and turnings in the primiparæ and the well-preserved pluriparæ where the fetal parts have to be dragged through an undilated vagina and outlet, where disproportion between fetal part and outlet is always considerable, before applying the blades or attempting to turn, I stretch the undilated perineum between two fingers and sever in the midline through the whole perineal body, through vaginal, parenchymal and dermal parts, as far as necessary even to the sphincter ani, stop hemorrhage where any, then apply or turn. In low forceps or normal labor I sever, as recommended by B. Schultze, only then when "the commissure shows signs of yielding," following in both cases with immediate post-partum perineorrhaphy.

THE THERAPEUTIC ACTION OF CHLOROFORM IN PARTURITION.

Read in the Section on Obstetrics and Diseases of Women at the Forty-sixth Annual Meeting of the American Medical Association at Baltimore, Md., May 7-10, 1895.

BY BEDFORD BROWN, M.D.

ALEXANDRIA, VA.

The results of chloroform anesthesia in parturition constitute one of the most remarkable and interesting features in the history of medicine. During the past thirty-five years there have doubtless been mil-

lions of cases of parturition in which the agency of chloroform as an anesthetic has been called into requisition in the civilized world with the rarest report of fatal consequences.

Then too, when we take into consideration the manner in which chloroform is given in labor, often recklessly, carelessly, and copiously, we are still further astonished at the almost universally favorable results. Often administered by ignorant nurses, husbands, bystanders, even by the patients themselves, and not infrequently, recklessly and injudiciously by the attending physicians, it is wonderful that evil results are so rare. Thus chloroform is used in a manner in parturition that no surgeon would dare to do in performing an operation.

The profession has come to regard the use of chloroform in parturition as almost utterly devoid of danger, and it is this opinion based upon substantial facts that has given rise to its universal and careless, even reckless administration in labor. Why chloroform acts differently in the parturient and pregnant female from the non-pregnant person, or why it is comparatively harmless in the pregnant and is attended with a certain degree of danger in the non-pregnant is a question not devoid of interest or importance. To be enabled to determine what there is in the physiology of pregnancy that protects the woman against the dangers of chloroform would be to ascertain and establish a fact in the therapeutics of chloroform that would shed an infinite amount of light on its therapeutic action not only in labor, but from a surgical point of view.

During the process of pregnancy there are two systems which undergo manifest changes of a developmental order. These are the vasomotor and circulatory systems.

The developmental changes in these two systems are of a phenomenal character. The muscular structure of the left ventricle takes on increased nutrition and growth, that it may have increased force and power to meet the new emergencies of circulation and nutrition. A new being is to be nourished, developed, formed, and shaped in all its parts, and to do this a new force is to be created. The heart of the pregnant female not only acquires additional force, but the great vasomotor and sympathetic systems, with their ganglia and nerves take on new energy, more vigorous action and power to maintain that complex circulation of both mother, the placenta and fetus. Just in proportion as the growth of the placenta and fetus increase, these developmental changes in the circulatory vasomotor systems advance. Otherwise the pregnant woman would utterly fail to sustain her own strength and health, and at the same time nourish the placenta and fetus. Hence her vasomotor system and circulation reach a state of development in point of vigor, energy and power rarely attained in any human constitution.

Under these circumstances, arterial tension and blood pressure more than redoubled are indicated in the strong, vigorous, bounding and frequent pulse of the pregnant woman, which is familiar to all practical obstetricians. Such a state of arterial tension and blood pressure would be regarded in the non-pregnant as indicating a dangerous degree of plethora and congestive tendency. But in the pregnant woman we know there is a safety valve, a diverticulum for this increased circulatory force and volume found in the placental and fetal circulations.

Among the most interesting developmental processes of pregnancy is leucocytosis, a purely regenerative and restorative process. This seems to be the foundation upon which is constructed all other developmental functions of the vasomotor and circulatory systems, to enable them to bear the new duties and superadded labors of the emergencies of pregnancy and parturition. To what extent the immunity of the parturient female from the toxic action of chloroform is due to the restorative and sustaining process of leucocytosis can not be determined at present.

The process of pregnancy, the evolution and growth of the fetus require that every energy of the maternal system shall be bent singly to the accomplishment of those objects.

That the therapeutic action of chloroform in the parturient female differs widely from that in the non-pregnant person, there is abundant evidence to prove. We know that in surgical practice, chloroform anesthesia is attended with a certain proportion of mortality that renders extreme caution necessary, while a death or even unpleasant result in labor is a very rare occurrence from that cause.

In the obstetrical practice of the civilized world, the most careful researches have only brought to light a very small number of cases of death in the millions of instances where chloroform is resorted to.

We may safely say that in the practice of the world there are twenty cases of parturition in which chloroform is resorted to, to one of surgery, and yet there is not the one-hundredth part of cases of mortality in the former as the latter. I do not think that this is an exaggerated statement. The most careful investigation has failed to find more than forty deaths from chloroform in labor, in the practice of the world, from the time that this anesthetic was brought into use to the present time. Some high authorities place the number at only three deaths. This is, I think, a wonderful exhibition, particularly when we take into consideration the careless, unscientific, reckless manner in which it is given during labor.

And not only this, but its often prolonged use during protracted labors. I have seen it given in protracted labors every half hour for twelve, and in certain cases for twenty-four hours, where there were not only no evil results, but labor terminated naturally and favorably. I have seen in cases of obstetrical operations the patient kept in a profound state of chloroform anesthesia for two and three hours without the least indication of collapse of the circulation or suspension of respiration.

In a long experience in the use of chloroform, extending over a period of nearly forty years, I have yet to see my first case of the least evil result to mother or child. Yet I am opposed to its reckless and careless use in parturition and for fear that there might be an evil result, believe that the same scientific principles and careful method of giving it should guide us as in general surgery.

According to these statements, and I am convinced that they are sustained by the experience of the majority of the profession, pregnancy, particularly during the stage of parturition, does in a large degree render the woman immune from the evil effects of chloroform. This having been established as a fact in its therapeutics, it remains to be determined what is there in the state of pregnancy or parturition that gives the parturient patient this immunity.

The extraordinary development of the vasomotor and circulatory systems in the pregnant woman has been alluded to, with its wonderful arterial tension and high blood pressure. The pulse even of the most delicate pregnant woman is often as hard, full and strong as the most robust man. In a paper read last November before the Southern Surgical and Gynecological Association, on the action of chloroform on the exposed human brain, I showed very conclusively that the anesthetic action of chloroform on that organ was invariably to produce anemia of its circulation, reduction of arterial tension and diminution of blood pressure, so that always under full anesthesia the brain becomes anemic to a degree that in extreme cases there is an enormous and dangerous reduction of circulation preceding general collapse. I am therefore constrained to believe that in this wonderful development of force, strength and power of the pregnant woman in her vasomotor system lies her immunity from the toxic action of chloroform. Every degree acquired of additional strength in the vasomotor system gives her increased immunity. It is this newly acquired force of the vasomotor system of the pregnant woman which enables her to resist the toxic action of chloroform to an extraordinary extent, which prevents extreme depression of arterial tension, and consequently excessive and dangerous anemia of the brain and spinal cord.

In the cases alluded to, of extensive injury of the cranium and the brain in which, while chloroform was being used, I had a perfect ocular demonstration of its action on the functions of the brain during its administration of three or four times in each case, reduction of arterial tension, blood pressure and vasomotor force in the arteries invariably preceded a state of anemia of the brain, and this extreme anemia of the brain, suspension of pulsation and hemorrhage always preceded tendency to general collapse.

These facts, I think, indicate to us very clearly that in chloroform anesthesia, anemia of the brain to an extreme degree always precedes dangerous chloroform narcosis and collapse, and, at the same time, that so long as the vasomotor force remains intact in sufficient force to sustain the circulation in the brain and medulla, life will be sustained.

In my experiments with chloroform in the cases cited of injury of the brain, there were two occasions in one, and one occasion in the other, on which there was alarming collapse, with almost entire suspension of respiration and cardiac action. Preceding these symptoms in every instance there was marked reduction of vasomotor force, arterial tension and blood pressure, and diminution of cardiac power. In all my experience in the use of chloroform in parturition, I have never witnessed this extreme reduction of cardiac and vasomotor force, no matter to what extent the agent was pushed, that I have in general surgery.

The primary action of chloroform is on the cortex of the brain, the seat of consciousness and sensation. For the relief of the pains of parturition, all we have to do is to bring the cortex under a state of anesthesia, without extending its influence so far as to involve the reflex functions of the cord. This is equally true of anesthesia of general surgery. By watching the action of the remedy we are enabled to confine its influence to the cortex without infringing on the functions of the cord or vasomotor system. This is all that is desired to relieve pain and to render the

act of labor more comfortable and easy for our patient. On the contrary, if we desire to relax excessive rigidity of the soft parts, or in case of convulsive action, to control that, we must extend our anesthetic influence further, and bring under its power the reflex functions of the cord itself. So long as we confine our anesthetic to the cortex alone we can not accomplish these objects. But immediately the cord is brought under its influence, complete muscular relaxation follows.

We will now consider the question of anesthesia in its practical bearing and influence on the process of parturition.

Is the use of chloroform in parturition justifiable for the relief of pain alone?

This is the first question that presents itself for our consideration. I believe that it is, but not in every case. For instance, there are cases where the pains are slight, the conditions all favorable, the passages spacious, the labor rapid, in which it is unnecessary. But in every case where the labor is at all slow, painful, and not easy, I believe that it is not only justifiable, but that it would be inhuman to withhold it. This statement is based upon the fact that the mortality from chloroform anesthesia in labor is so very small, not probably amounting to one in millions, we certainly can risk so little for so much good.

I know that there are those who oppose its use in parturition *in toto*, but I believe without good and just reasons.

Pain is the great terror of parturition and if it could be robbed of this feature alone it would be converted into a very simple and easy process. For some years before I adopted anesthesia in my obstetrical practice, I have time and again sat by the bedside of women in the throes of parturition and listened often with anguish to myself, to their cries for relief from pain, heard their moanings from almost insufferable agony, for hours of such scenes that impressed themselves upon my memory in a manner never to be forgotten. With chloroform at hand, and with my familiarity with its action, I never have to pass through such painful scenes now. I have tried in past years many substitutes for chloroform to relieve the pain of parturition, but have never found one yet. I am convinced that it is *the anesthetic* of all others peculiarly appropriate to the parturient state. It is clean in its action, does not cause congestion of either the brain, the lungs or kidneys, but markedly diminishes the tendency to congestion of the brain.

Does the action of chloroform facilitate the process of parturition?

I believe that, as a rule, it does. I am convinced that in a great majority of cases it does shorten the duration of parturition. I know that it is the opinion of some that its action is to reduce the strength of uterine contraction and in this way retard the process of parturition. It has been my experience that while it relieves pain, its use may be so graduated as to not impair uterine contraction. Acting on the cortex of the brain alone and on the reflex functions of the cord are two different things. Thus we can abolish sensation without affecting reflex action. I believe that with care and judgment we can confine the action of chloroform to the cortex alone, the seat of sensation, and leave intact the reflex functions and the contractive force of the uterus.

I have no statistics to guide me in this matter, but my personal experience in the administration of

chloroform in parturition leads me to believe that it not only makes labor easier, but that in the average it shortens the duration of that process. If then, it is capable of rendering labor easier, more bearable to the patient, and can shorten its duration one hour, or even thirty minutes, its application is justifiable when we consider the very small risk incurred in giving it. In certain conditions I know that it can shorten the duration of labor. These conditions are rigidity of the soft parts, and irregular contraction of the uterine muscular fibers or spasmodic contraction of certain sets of fibers and relaxation of other sets; a condition that may protract labor indefinitely. The spasmodic contraction of certain muscular fibers of the uterus and relaxation of others is not an unfrequent state during protracted labor, and is a similar condition to that which produces the hour-glass contraction after labor. Chloroform is capable of equalizing uterine contraction and of preventing irregular spasmodic contraction, and in this way facilitating parturition.

Its well-known power to overcome and relax muscular rigidity no one can doubt. In illustration of this fact, I have repeatedly in my experience seen cases attended with rigidity of the soft parts where the process of labor was stationary, it might be for an hour or more, or even hours, but when chloroform was given in such quantities as to produce muscular relaxation, the labor would progress rapidly toward a termination.

At what stages of parturition is chloroform applicable?

To relieve excessive pain it is applicable at any stage. But to induce relaxation of muscular rigidity it is applicable in unusual rigidity of the os uteri, and in extreme rigidity of the perineum when the fetal head begins to press on that body. When the object of giving chloroform is to relieve pain only, it should be given in small quantities at the beginning of each pain and left off when the pain ceases. But when we desire to overcome muscular rigidity the patient must be subjected fully to its influence. In the case of extreme contraction of the os uteri, or great rigidity of the tissues of the pelvic floor, no half way procedure will accomplish anything. The patient then must be brought sufficiently under its influence to at least partially suspend reflex action when complete muscular relaxation follows, just as we would do in reducing a dislocation.

When there is perfect accommodation between uterine force and muscular relaxation in a normal pelvis, labor proceeds rapidly, easily and successfully. On the contrary, when this accommodation is disturbed, when, for instance, uterine contractile force is feeble, and perineal muscular tension is excessive, labor proceeds slowly and painfully. The action of chloroform in this class of cases is to bring this accommodation between uterine force and pelvic resistance to a more normal standard by reducing muscular tension. Leaving out of question congenital defects, or those caused by disease in the pelvic bones, the vast majority of tedious and difficult labor will be found to be due to rigidity of the muscular structures of the pelvis, or inefficiency of uterine contraction. We often see these conditions existing together. Nineteen out of twenty cases of instrumental delivery, in my personal experience, have been due to excessive muscular rigidity of perineum. In these particular cases the action of chloroform has

been to cause perineal relaxation, to reduce muscular resistance, to bring about accommodation between force and resistance without materially impairing that force on the part of the uterus.

Does chloroform tend to suspend uterine contraction?

There can be no doubt that chloroform may be given in labor in a manner either to relieve pain and to leave uterine contractile force intact, or to both suppress pain and uterine rhythmic contraction so as to suspend parturition for a time.

Rhythmic uterine contraction is an essentially reflex function and we know that the different nervous functions come under the influence of chloroform in consecutive order—sensation first, then reflex action and finally vasomotor action. Because of this fact we can, as a rule, relieve the pains of labor without impairing the force of uterine contraction. All practical obstetricians have observed in patients in labor when under chloroform, entire relief from pain while, at the same time, the rhythmic contractions of the uterus, and all the symptoms of active tenesmus were in full operation. I believe that this is the ideal state of chloroform anesthesia, in labor, and I am convinced that it may be so administered always as to relieve pain and leave the reflex functions unimpaired. Again, I believe that the reflex functions of the parturient patient are far more resistant to the toxic action of chloroform than in ordinary cases, and that it is more difficult to suspend them. This fact gives us a decided advantage in giving chloroform in labor, simply to relieve pain without interrupting the progress of parturition.

In my experience it has been seen that when the uterine contractions have been for the time suspended by the too free use of chloroform, when this influence subsided, uterine contractile force returned with renewed and additional vigor to perform the work to be accomplished. Also there have been occasions in tedious cases of labor, when the pains were irregular and insufficient in character, causing much needless suffering to the patient, that when the patient was placed under full chloroform narcosis for a time and was made to enjoy a prolonged sleep, the pains were renewed with vigor and force sufficient to terminate the labor.

Does the action of chloroform tend to promote or prevent post-partum hemorrhage?

This constitutes one of the most important questions connected with the therapeutic action of chloroform in parturition. If it tends to promote hemorrhage then this fact increases the dangers of its use in this condition. From my personal experience I can say this much relative to this question. Many times after its administration in parturition, when pushed to the extent of causing entire unconsciousness at the time of birth, in not a single case have I observed a greater tendency to hemorrhage or any greater difficulty in producing firm uterine contraction than when it was not used.

So far as this question is concerned, I can speak alone from personal experience, and any personal experience in a large number of cases extending over a long term of years, is of some value in settling important questions. High authority on the action of chloroform on the circulation is that it is a vasomotor contractor. In my surgical practice its action on the vessels rather tended to establish this view. Profound chloroform anesthesia certainly does dim-

inish surgical hemorrhage. In my cases of injury of the skull and brain, under chloroform anesthesia there was a marked diminution of cerebral hemorrhage in every instance. Then if it be true that chloroform is a vasomotor contractor, this, it appears to me, would decide this important question.

Does the action of chloroform in parturition tend to prevent or promote laceration of the os uteri or perineum?

Are lacerations more common under the present method of delivery under anesthesia, or under the old system of delivery without anesthetics? I have no reliable statistical data bearing on this subject to guide me, but I will state here that I have practiced under both the old system and the new, and am enabled to state positively that all of the bad cases of laceration of os uteri and perineum have occurred in cases where chloroform was not given. Many of the worst cases of laceration of these organs occurred in cases of rapid birth before my arrival. I am decidedly of opinion that thorough relaxation of the structures of the pelvic floor constitutes the best security against injuries of this kind, and I know of no agent that is as capable of producing that extreme relaxation of muscular tissue as chloroform, and therefore placing the patient in a condition most favorable for the prevention of lacerations.

I will briefly cite the case of Mrs. T., a young married woman who had an accidental abortion at five month of pregnancy. I was called to her about eight hours after and found her with a retained placenta. The perineum was intensely rigid and the ostium vaginae closely contracted. The vagina was narrow and the os uteri was rigidly contracted on a protruding umbilical cord. I determined to place the patient thoroughly under the influence of chloroform, with the hope that it would produce sufficient relaxation of the soft parts to enable me to insert the fingers into the uterus and remove the retained placenta. While the patient was under the influence, to my surprise I found complete relaxation of the perineum, vagina and os uteri. These tissues were in such an extremely flaccid condition that I was enabled with perfect ease to pass my hand, not only into the vagina, but into the uterus, which was equally as flaccid, grasp the placenta, detach it from its adhesions and remove it safely. Without the influence of chloroform this operation could not have been performed. During my past professional life I have had occasion to test all the various methods proposed by different authorities for the prevention of laceration of the perineum. I have found them more or less defective, some entirely unworthy. For some years past the method which I have adopted with the most satisfaction was to retract the perineum, with the fingers hooked into the vagina, back toward the rectum forcibly at each pain, so as to maintain a continuous relaxing influence of the perineum until the fetal head presses on that body. When it reaches that stage then the perineum will have been very generally relaxed. At this point the patient is kept under the influence of the anesthetic until the head begins to protrude from the vulva, when it is suspended. In my hands this mechanical dilatation of the perineum, combined with the relaxing influence of the anesthetic has been the means of preventing more lacerations than any other method that I have tried up to this time.

In conclusion, I can truly say that after a long and

favorable experience in the use of chloroform in parturition, that I have found it not only a blessing to the patient but to the physician also. Without the means of relieving human suffering what a dreary, unsatisfactory and repulsive life that of the physician would be. Yet for ages and ages the lot of the woman in the throes of parturition was to suffer, to bear, and submit to its terrible tortures, hopeless of relief until the end came.

For the past half century the achievements of medical science in the discovery and perfection of remedies to relieve human suffering, to improve human health, and prolong human life, have astounded the civilized world and are a source of pride to our profession. And one of the greatest of all of these achievements is the discovery of chloroform.

DISCUSSION.

DR. A. LAPHORN SMITH, of Montreal, said, that in order to lessen the cries of pain, when a woman is approaching the last stage of labor, he does not refuse to give her an anesthetic, and it is his practice to administer the A.C.E. mixture and allow the woman to give it to herself until within the last half hour; then the assistant administers the anesthetic.

DR. H. W. LONGYEAR, of Detroit, also favored the administration of chloroform in cases of labor, notwithstanding the fact that it is said to predispose to post-partum hemorrhage by inducing inertia of the uterus.

DR. BROWN, in closing, says he has had more than three thousand obstetrical cases, and about fifteen hundred of them were subject to chloroform in more or less degree, and he has not had a serious result.

SOME ORIGINAL STUDIES ON THE OBSTETRICAL FORCEPS, WITH MECHANICAL DEMONSTRATIONS.

Read in the Section on Obstetrics and Diseases of Women, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY J. J. E. MAHER, M.D.

NEW YORK.

The obstetrical forceps is essentially a conservative agent, and by saving two lives at once, becomes the most useful instrument in surgery. It therefore well deserves the immense amount of ingenuity that has been expended in attempts to eliminate the defects discovered in the common or ordinary forceps. I shall proceed in the simplest possible manner, and leave all abstruse calculations and "*Reine Mechanik*," to be read rather than listened to.

For a workman to understand the character of the tool he requires, it is absolutely necessary for him to be able to appreciate the character of the work to be done. He must learn the conditions and the exigencies of them, before he can calculate the amount of force to be expended and the manner of its application to accomplish the work in hand. By work, I mean the application of force to overcome resistance. To understand this resistance to the descent of the child's head, we must be ready to appreciate certain conditions which obtain in the head of the child, and the obstetrical canal.

In considering the obstetrical canal, we will take two points, the axis of the canal and the character of the resistance offered by the walls. Hodge says: "The axis of the canal has been variously delineated by authors, but by no one with sufficient accuracy."

The circle of Carus, A, (Fig. 1) consisted of a two and one-fourth inch radius, having its center at the middle of the posterior surface of the symphysis pubis, and extended not more than one inch and three-eighths directly below the subpubic ligament, in the direction b. g.

Hodge took the middle of the subpubic ligament as the center of a circle, B, with a radius extending to the axis of the superior strait. This circle might get rid of the difficulty at the outlet, but at the superior strait it was very faulty. Hodge did not believe a single circle could be described satisfactorily; for he, like Naegele, Velpeau, Pierre Dubois and Caseaux, believed, what is apparently true, that the head descended practically in a straight line in the axis of the superior strait.

The circle of the planes C is also faulty in approaching too closely to the pubis.

Dr. W. S. Gardiner¹, of this city (Baltimore) deviated from the ordinary manner of describing a circle on the intersection of the planes of the superior and inferior straits produced beyond the pubis. He very properly showed that the tip of the coccyx did not make any part of the inferior strait. For him, and correctly, too, the end of the sacrum and a point half an inch below the subpubic ligament constitute the proper extremities of the inferior strait. While I would admit this as perfectly correct, I can not accept a circle D with a radius of seven inches, and which is four and one eighth inches below the subpubic ligament, as representing the axis of the outlet.

Fig. 1.—a, b, c, d, e, represent an antero-posterior section of pelvis; c, a, the plane of superior, and e, b, that of so-called inferior strait; c1, e1, the intersecting planes of these straits; d, m, the produced plane of inferior strait, after Gardiner; b, g, vertical line measuring the various axes offered, at outlet; N, E, the axis of superior strait; A, circle of Carus; B, circle of Hodge; C, the generally accepted axis, or the circle of the planes; D, Gardiner's circle of the planes.

It is easy enough to obtain a single circle, a segment of which shall delineate the axis of the obstetrical canal in a very practical way, if we go about it right. The anterior and posterior walls must be observed separately. Taking the anterior wall, we find it offers a uniform unyielding resistance, and that it extends from the top of the symphysis pubis to about half an inch below the subpubic ligament, as demonstrated by Dr. Gardiner. Now, we can easily conceive this anterior wall of the obstetrical canal to form a segment of some circle of which we should find the center. Let us take this point half an inch below the subpubic ligament, and any two other

¹ American Journal of Obstetrics, p. 60, July, 1892.

points on the posterior surface of the symphysis, as any three points in a given segment of a circle, to find the center. By uniting these three points by two chords, then drawing two radii from the center of, and at right angles to, the two chords, and then describe a circle from the point of intersection of the two radii, as the center, passing through the three points on the anterior wall, we have consequently the true anterior wall and the circle *a, b*, (Fig. 2) of which it forms a segment. The posterior wall differs materially from the anterior. Instead of two inches, it is more like ten or twelve inches long. The intrapelvic portion of it, about four inches long, limited by the planes of the superior and inferior bony straits, offers like the anterior wall an unyielding resistance; this with the tip of the coccyx pushed back to its extreme limit, is all that need concern us in the study of the posterior wall; because this wall in the extrapelvic canal is so yielding that it offers no *point d'appui* on which to calculate.

Fig. 2.—Same section of pelvis as Fig. 1, but *d, f*, shows coccyx pushed back; *a, b*, segment of the circle, *a, b*, represents the anterior wall of the pelvis; *c, d, e, f*, the eccentric circle of the posterior wall; *c, d, b*, the concentric circle describing the same segment; *i, k*, the circle delineating the axis of the obstetrical canal, almost mathematically correct.

Now, if we take the promontory of the sacrum, the end of the sacrum, and the tip of the extended coccyx, as the three points necessary to find the circle of which the posterior walls form a segment, we shall have a circle passing through each of these points, *c, d, f*. This circle might be objected to on account of the eccentricity formed by the hollow of the sacrum that is not involved. The hollow of the sacrum conduces to the amplitude of the pelvis, is an advantage, and is therefore not to be taken into account when considering the disadvantages or the narrowness of the unyielding straits in a forceps operation. But when we come to consider this circle in its distance below the subpubic ligament, we find it unsatisfactory. This fact led me to concentrate the circles, which might readily be done by slightly increasing the sacral eccentricity, which really does not exceed one-fourth of an inch at the lower end of the sacrum,

and in the upper half means nothing. This deviation from the purely scientific procedure gives a more satisfactory result. We then have the circle *c, d', h*, representing the posterior wall. To find the circle of which a segment shall represent the axis between the two walls just described, we have only to take half the sum of the radii of the circles of the anterior and posterior walls, as the radius of the third circle *i, k*, which shall be the most equidistant between both walls of the pelvis, of all the axes I have ever studied.

Fig. 3.—*a, c*, body to which the forces *ba, dc*, are applied, and which is equally as well opposed to the central balancing or resulting force, *f, k*.

Having determined the most practical axis of any obstetrical canal, we should now consider the fact that, at the inlet, the resistances offered by the pubis and sacrum are uniform and equal; neither will yield; they are absolutely unyielding. Now, if these resistances are equal, they combine so as to be represented by a resultant or single resistance, whose direction is that of the axis of the superior strait.

It is well known that if the two equal and vertical forces *ba, dc* (Fig. 3) are opposed to the two extremities of the body *ac*, they can be replaced by a single vertical force *fR*, equal to their sum and passing through the center *R*, of the body *ac*.

The resistance *io eo*, (Fig. 4) opposed by the walls *ab, cd* of the pelvis are, in reality, obliquely directed upward and inward; but these oblique resistances decompose into the inward or horizontal *if, ef*, and into the upward or vertical *im, en*.

Fig. 4.—*ab, cd*, the antero-posterior walls of pelvic inlet; *io, eo*, the resistances or forces presented by (and at angles to) these walls to the body; *im, n, l m, e u*, and *if, e f*, the resistances into which *io, eo*, are decomposed; *fR*, the resultant resistances replacing *im, en, e u*.

These two latter, as we have already seen, have a common resultant *fR*, equal to their sum and vertical like them, passing through the center *o* of the body *mn*. The horizontal or inward resistance *if ef*, tend to effect the reduction of the cranium, while the vertical or upward resistances *im en*, represented by *fR*, oppose its descent.

If two oblique forces could be opposed directly to the two oblique resistances offered, say, by the pubis

and the promontory of the sacrum, *io, eo*, what would be the effect? The directions of the forces would be opposite to those of the resistances, that is, downward and outward; the downward force being directly opposed to the axial resistance *fR*, would be entirely useful in overcoming it, but while the inward resistances *if, ef*, are useful in producing reduction of the cranium, the outward forces *fi, fe*, opposed to them must produce the contrary effect, expand the cranium, and hence increase the resistance.

The oblique forces therefore would expand the cranium, increase the resistance, and thus tend to damage the soft parts of the mother. Supposing the oblique force hypothetically opposed to the oblique resistance *io* were omitted and the force opposed to the oblique direction *oe*, then there would be left the inward resistance *if* and the outward force *fe*, acting conjointly in the same direction, *i.e.*, toward the pubis, thus increasing the resistance at that point, and producing pressure injurious to the mother in direct proportion to the force applied. Hence the application of a force in the oblique direction downward and forward at the superior strait, tends to drive the head against the pubis, make the head rotate about this point, increase the antero-posterior diameter of the presenting part, thus increase the resistance to be overcome, and cause unnecessary pressure to the soft parts of the pubic structure of the mother and a positive loss of a certain percentage of force applied.

This is precisely the effect of the ordinary forceps applied at the superior strait in a difficult case. Any forceps, ordinary or not, in the use of which, force is expressed in an oblique direction, shows the same effect more or less. Hence it can be readily observed without further detail, that to overcome the resistance met with at the superior strait, with the least damage to the tissues of the mother, the force should be directly opposed to the resultant resistance and consequently traction must be made directly in the axis of the superior strait.²

If the obstetrical canal were a straight one, this would be a very simple thing to accomplish, but since it is curved forward in such a manner as to have the axis of the inferior strait produce, with that of the superior strait, an angle of about 130 degrees (Hubert), it becomes necessary to have an instrument whose curve will approximate as conveniently as possible to that of the canal. As direct force can only be expressed in straight lines, the application of direct force to such a curved instrument as the forceps, as Simpson's, of which the axes of the blades and shanks form an angle of about 160 degrees, when adjusted at the brim, not only produces a certain amount of injury to the mother, but increases the amount of resistance to be overcome; because the direction of the force thus expressed would be along an oblique line from the middle of the blades *f* (Fig. 5), to the point of the instrument grasped by the operator, say near the lock *p*.

This direction of the force is by no means directly opposed to that of the resistance *KR*, met with in the axis of the superior strait as necessary to overcome it, but is oblique, downward and forward. It is thus a composite force, that can be decomposed into a vertical or downward *fs*, and a horizontal or forward force *ft*. The downward force being directly opposed to the resistance, will be entirely useful in overcoming

ing it, but the forward force, by crowding the head against and even above the pubis, can only increase the resistance and injure the soft parts of the mother by compression. This compressive effect of the ordinary forceps, bears a direct ratio to the size of the angle *sfp* produced by the oblique direction of the force and that of the axis of the superior strait. The larger this angle, the greater the compressive effect. With Simpson's forceps, this angle is about 30 degrees, and consequently over 55 per cent. of the force applied, is exerted against the pubis.

I might here state that, in the paper already referred to, I termed the above angle, the *angle of compression* and the angle *pft* formed by the forward direction and the oblique direction, the *angle of extraction*. But, to render the subject easier of comprehension, I made the axis of the blades (or rather the longest chord drawn on the axis) coincide with the axis of the superior strait, thus rendering the

Fig. 5 represents the blade, shank and handle of an ordinary forceps; K, R, the axis of the superior strait or the direction of the resistance; *f, p*, the direction of the force applied to the center of head, *f*, from the handle near the lock; *P, ft, fs*, the two directions in which the oblique force *fp* is actually expressed.

angle of compression only about 15 degrees, which can rarely happen in practice, with a perfect perineum, and consequently the angle of compression is, in reality, twice as great as that given in the paper mentioned.

To eliminate the compressive effect in the ordinary forceps, much ingenuity has been spent in devising methods of using it. But these methods, such as that of Oseander and others, are effective to an uncertain extent and the success achieved is of an uncertain quantity; for such methods require, for any degree of success, a hand educated to their use—a hand that has become adroit and skillful by prolonged experience in the manipulation of three forces acting in

² For further details see article in Medical Record, June 10, 1893

three different directions at the same time. No wonder then, that such methods have not become popular, while other means have offered a more certain result.

This condition of affairs led to the development of forceps in which these three directions of the force were reduced to two. These forceps, among which are Hubert's and other similar models, I would term "method forceps," inasmuch as a method of manipulating these two forces is inseparably connected with their use. Then another class developed, in which ingenuity has endeavored to reduce the three directions of the force into one, and that one direction, that of the axis of the superior strait, hence the name, axis traction forceps. Of this class I have not found, in the market, a single positive representative. If we take the rule laid down by Milne Murray, of Edinburgh, as governing the construction of the correct axis-tractor, and published by him in the *Edinburgh Journal*, and republished by Dr. Keiller in the *American Journal of Obstetrics*, and examine it carefully, we shall find that no instrument made according to that rule is an axis-tractor.

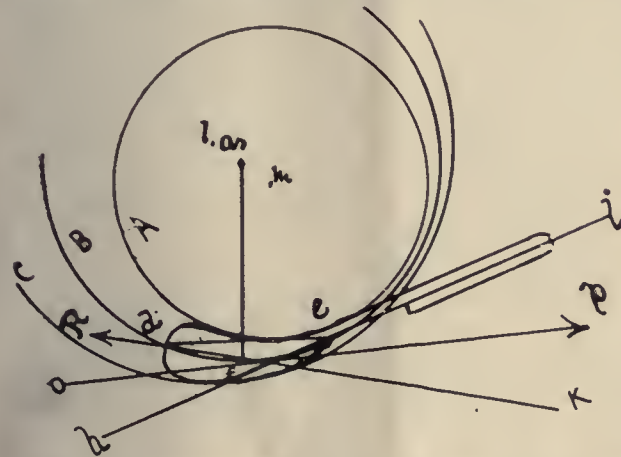

Fig. 6.—The central figure, d, f, e, i, represents an ordinary forceps blade, shank and handle; A, the circle of which a segment represents the smaller or anterior curve of the blade; C, the circle of which a segment represents the posterior curve; B, the circle of which a segment represents the axis of the blade; h, the axis of blade and shank; de, the cord of the arc forming the axis of the blade; f, is the center of the axis; Op, is a tangent to this arc drawn on the central point f, and parallel to the cord de; KR, represents the axis of the superior strait and the direction of the resistance.

Milne Murray draws a cord on the axis of the blade, and then draws a tangent line, passing through the central point of this axis, and parallel to the chord. He insists that, if the instrument is correctly made, the stud of the tractor handle lies along that tangent line.

If we take a Simpson forceps, and determine the axis of the blade by means of eccentric circles, made as before, we can readily prove this. The anterior or smaller curve of the blade is the segment of a circle A (Fig. 6), whose radius is five and one-fourth inches, and the posterior curve is the segment of another, C, with a radius of eight and one-fourth inches. Having the two circles, A, C, which do not intersect, it becomes an easy matter to find the third circle, B, whose radius is six and three-fourths inches, a segment of which represents exactly the axis of the blade, d, f, e. Murray and Keiller, by the way, determine their axis on the assumption of guess points, chosen where the curve of the blade is supposed to begin and end. If we draw the axis of the handles and shanks, h, i, its point of junction with

the axis of the blade, e, makes the beginning of the latter, and if we unite this point with that, at the intersection of the axis and the tip of the blade d, we shall have the longest possible chord drawn on the axis, which is five and three-fourths inches. If a tangent be drawn on the central point of this arc or axis, and parallel to the chord just described, we shall have the line along which Milne Murray tells us we must make traction. Now, if you will recall the fact that the axis of the superior strait is three inches behind the posterior commissure of the vulva, we can readily observe that since this tangent is not more than one and one-half inches behind the shanks, it is impossible to make axis-traction after Milne Murray's notion. On the other hand, the real axis of the superior strait is represented on the instrument, by uniting the highest point of the axis of the blade, d, and its center, f. Such a line produced, KR, would be three inches behind the shanks, near the handle. This, indeed, is the line along which the stud should lie and traction should be made, to be in the axis of the superior strait.

Having, to some extent, determined the character of the work to be effected at the superior strait, and having supplied the requisite tool in the axis-traction forceps, we may safely imagine the head of the child to have passed the superior strait and to rest on the

Fig. 7.—ac, body opposed by the two unequal resistances, ba, dc; oi, the force applied in the axis or middle of the body, ac; oe, the direction in which the force, of, is actually spent, i.e., in the posterior oblique; od, the anterior oblique representing of, oc.

floor of the pelvis. Now, we must consider that the conditions which obtained at the superior strait and necessitated axis-traction, being different from, and I might say absolutely contrary to, those at the outlet, the exigencies of the latter are of an entirely different character from those of the former; and consequently, when the direction of the force leaves that of the axis of the superior strait, the axis-traction instrument becomes a dangerous one. The conditions and exigencies of the outlet differ from those of the superior strait, in that the resistances are unequal and consequently can not be represented by a central resistance whose direction would be that of the axis of the canal—one part of the strait being composed of a fixed, bony, unyielding resistance, as offered by the pubic arch, and the other part composed of the yielding structure of the perineum, which offers much less resistance than the former. These two unequal resistances allow the balance of the force applied in the axis of the canal, to be spent on the perineum, as the point of less resistance, which can rarely escape rupture.

When all the resistances opposed by the walls of a canal to a body moving in it, are equal, they can be represented by a single resistance, expressed in the

center or axis of the canal, and overcome completely by a force exerted along that axis, as illustrated at the superior strait; but when the resistances are unequal and the force is applied in the axis of the canal, the body is arrested at the point of greatest resistance, and the force continuing, it is propelled in the direction of the lesser resistance, as well as in that of the axis of the canal. In fact, it rotates around that point of greater resistance, as around a pivot, thus producing extension of the head, and increasing the antero-posterior diameter of the presenting part.

If the two unequal and vertical resistant forces *b a d c*, (Fig. 7) be applied to the body, *a c*, they can be replaced by a single vertical force, not passing through the center *o* of the body *a c*, but through a point corresponding to its percussion point, approaching the greater resistance, *d c*, in proportion to the greater weakness of the resistance, *b a*. If, for example, the resistances were in the proportion of 1 to 3, these resistances would be equally overcome if the force were applied three times nearer the point of greater resistance. But, since this is impracticable, and an axial force, *o f*, tends to propel the body, *a c*, backward toward *a* and downward toward *f*, or along their any resultant *o, e*, in an oblique direction downward and backward; to relieve the strain on the

curity and uncertainty, for the muscular sense of the operator is always called into play the same as with the common forceps.

The perineum may be pushed back by the shanks of the instrument, without seriously altering the position of the blades, just as in the use of the common forceps. This, in some cases, is an absolute necessity, depending upon the situation of the posterior commissure of the vulva. This adaptability

Fig. 9.—Side view of forceps, with its mechanical effect; KR, direction of resistance as met with at the superior strait; f, center of blade; D, ball and socket joint. Notice that the socket piece and the ball end of the rod are in the same straight line. of the instrument to the canal is possessed by no other non-rigid forceps. There is, in fact, no other instrument that will permit of rotation during the traction, and allow of axis-traction in every case.

Bearing in mind the correction of the conventional error hereinbefore mentioned, a very adequate description of the forceps will be found in the *Medical Record* of June 10, 1893.

This instrument is manufactured by Richard Kny & Co., of New York city.

Fig. 8.—A, blade; B, shanks; C, handle; DD, detachable rubber side pieces; E, the axis traction attachment; a, socket between shanks for hook b, of traction rod; d, ball end of rod; e, clamp socket for d; f, thumb-screw for screwing the ball and socket joint; gg, the rubber cross bar; h, the ordinary Elliot wheel and threaded bar; l, an additional wheel with a half-threaded slot on opposite side, which both form the lock; KI, a quarter-circle slot and piece limiting the motion of lock-wheel or small knob on lock-wheel; n, n, metallic lugs which hold side pieces in place; oo, grooves in the metal for the reception of the lugs; pp, screws passing antero-posteriorly through the metal and flat where they pass through the grooves; a quarter turn of these screws, locks or unlocks the side pieces securely to the metallic portion.

weaker structure, the perineum, we have only to divert the oblique direction of the force *o e* into the opposite oblique direction, *o d*. Thus it will be observed that this anterior oblique direction of the force, *o d*, corresponds with the oblique direction of the force *f p* (Fig. 5) in the ordinary curved forceps, as demonstrated above.

Hence, the proper or perfect obstetric forceps is one in which the force can be expressed in the axis of the superior strait, and in the anterior oblique direction at the outlet.

The forceps which I have the pleasure of exhibiting to you, (Fig. 8) consist of the old familiar Simpson blades and shanks, the Elliott handles, and this simple traction rod, and an exceedingly practical lock, and permits admirably of just such expression of the force (Fig. 9). At the superior strait it is an excellent axis-traction forceps; at the outlet it is the most desirable model of the ordinary forceps. Though the fetal head is free to rotate, the instrument can not slip. It is not a Tarnier model, and possesses none of the defects of such; nor does it require an expert to use it. Whoever can use an ordinary forceps can use this as readily and as successfully as any expert. It does not produce that feeling of inse-

THE VAGINAL ROUTE FOR OPERATIONS ON THE PELVIC VISCERA.

Read in the Section on Obstetrics and Diseases of Women at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY D. TOD GILLIAM, M.D.
COLUMBUS, OHIO.

Everything indicates that we are about to have an epidemic of transvaginal surgery. Salpingectomy, cholecystotomy, nephrectomy and operations for appendicitis have ceased to be novelties and have therefore to an extent lost their charm. Men are merely boys grown up and, like boys, are fond of exploit and adventure. This in the main results in good by advancing knowledge, developing manual dexterity and evolving new methods. The pity is that in the name and guise of science and the legitimate pursuit of this noblest art so much is done for self, to the detriment of the patient. The surgeon should never aspire to a record; the best interests of his patient, the advancement of his art and the greatest ultimate good to his race should be the aim and object of his life. To such an one, fame, honor and confidence of the profession and people will come in due time, and will come to stay. From this standpoint let us look into the merits and demerits of this new fad; endeavor to prescribe its scope and limits, and by comparison with older and better known methods strive to affix its proper status in gynecologic surgery.

That many operations on the pelvic viscera through the vagina are practicable is well known to every one at all conversant with gynecologic history, and there are few gynecologists of long or extensive practice who have not essayed most of them. Some years

ago, indeed, it was the favorite and almost only method practiced, and there are doubtless elderly men in this assembly to-day who could give us pointers in vaginal surgery. We can all remember the time when abscesses and other fluid collections in the pelvis were attacked through the vaginal vault and when submucous and interstitial uterine fibroids, even of large size, were removed per vaginam. At a later period the uterine appendages and even ectopic gestation, ovarian cysts and the uterus itself were removed by this route. It remained for Péan and his collaborators to cap the climax by removing the fixed uterus by morcellation through the same channel. It is the latter, with its extensions to other conditions, that has given the wonderful impulse to transvaginal surgery that we witness to-day.

Let us briefly inquire into the advantages and disadvantages of the vaginal route, as compared with that by abdominal section, as it is between these that the issue lies. In the former we obviate section of the abdominal wall with its resultant scar. This scar is not only disfiguring and repulsive to the sensitive nature of the most sensitive of beings, but entails a feeling of weakness and insecurity, is at times painful and not infrequently the site of hernia. Furthermore, the omentum or bowel invariably becomes adherent to it and is liable to give rise to distressing, if not dangerous sequelæ. It is now generally conceded that the shock of the vaginal operation as compared with that of abdominal section is trivial, because the intestines, the most sensitive of the abdominal viscera, are not exposed or handled. This is far-reaching, for not only may the shock itself be dangerous to life, but by diminishing vital resistance it predisposes to sepsis and cripples the functions of important organs. Intestinal paralysis does not occur.

Sepsis, the bane of abdominal surgery, is less frequent in the transvaginal surgery: 1, because the pelvic peritoneum is better able to cope with germs; 2, because the route of invasion is less direct and against the tide of outflowing serum; and 3, because the germicidal powers of the splanchnic viscera are unabated. From a well-known fact that the vagina is the natural habitat of pathogenic germs of many varieties, that it is sometimes exceedingly foul, and from the supposed impossibility of rendering it surgically clean, I, with many others, had a dread of entering the peritoneal cavity by that route and always, when possible, refrained from doing so. I now have no more hesitation on that score. I believe with douches and a thorough scrubbing with creoline mollin we can render the vagina as aseptic as the skin. Again, in removing septic matters through the abdominal incision there is always a chance of peritoneal contamination and in many instances, as enucleating pus tubes, inundation of the cavity is unavoidable. This is always avoidable in the operation from below. Drainage through the vagina is incomparably more efficient than through the abdomen. The vaginal drainage is natural, perfect and with gravity. Abdominal drainage is against gravity. Not only so, but the animal fluids coating the tube or filling the meshes of the gauze afford an excellent culture medium for stray germs, which naturally make their way downward or inward. On the other hand, the outflow of fluids toward and into the vagina, not only prevents the accumulation of septic matter in the pelvis, but washes away any that may

be seeking entrance from below. So far the advantages are decidedly with the vaginal route, but it has its disadvantages. It is optional with the abdominal surgeon how much room he may make for himself. He can always keep the objective point under the eye or finger. He has ample facilities for seeing and knowing the position and surroundings, for avoiding important structures, ligating vessels and guarding against mischance. The ability to control circumstances and to advance with open eyes constitutes good surgery. Moreover his field is not abridged or limited. He can pursue the malady to the uttermost limits and he can preserve the healthy while eliminating the diseased. Should there be a mistaken diagnosis he can tack about and still be master of the situation. With the vaginal surgeon it is different. His field is limited; his operative space not amenable to optional extension. His facilities for meeting emergencies are meager. He is working in cramped quarters and ofttimes at a great disadvantage. It follows, then, that vaginal surgery has a sphere of its own. It can not aspire to supplant abdominal surgery nor yet in any large measure trench upon it. The possibilities of vaginal surgery will depend largely upon fortuitous circumstances. With a large, lax and shallow vagina many operative procedures may be feasible, but with a narrow, deep and unyielding one, even the more common of the operations may be rendered difficult or impossible. I speak knowingly on this subject, for I have had experiences in both directions. I have removed submucous fibroids, pelvic cysts and the malignant uterus as large as the fetal head, sometimes with comparative ease. I have signally failed to remove the fixed uterus on two occasions, on account of the narrowness, depth of the canal and unyielding structures about its outlet. In the first instance, incising the perineum failed to relieve the situation on account of the great depth of the canal. In the last, I was provided with Péan's retractors and all the appurtenances used by him. It was with the utmost difficulty that the retractors were introduced, and then, after prolonged effort it was found impossible to dilate the passage. As it is a cardinal rule never to go with the scissors or forceps where the eye or finger can not follow, I found it impracticable to complete the operation. Whether Péan or Jacobs could have done so, I know not, but I do know that the average surgeon would have failed as I did or done worse at a blind attempt at the impracticable. To my mind the field of transvaginal surgery includes hysterectomy of the normal or slightly enlarged uterus, the removal of the appendages when accessible, the drainage of the pelvic abscess, the morcellation of intra-uterine fibroids of moderate size and, possibly also, the extirpation of free cysts, low down in the pelvis.

It is unnecessary for me to say anything with reference to the technique, as this has been worked out so thoroughly as to leave little to be desired or expected. There are one or two points, however, to which I would like to call attention, and which I have found in my own practice to have been of material advantage. A modified Trendelenburg position contributed greatly to the facilities for operating, by giving a much better light and by preventing the prolapse of intestines, which at times are annoying. Should there be purulent or septic collections in or about the field of operation this position would

never be dispensed with. In many cases the short posterior retractor is vastly more efficient than the long ones used in Europe. It enables you to bring the vaginal vault within easy reach, and to follow the steps of the operation with much more ease and precision than when one has to work in the depths of a deep hole. Even in cases of fixation I have been able at times to use the short retractor to greater advantage than the long one, and I am so imbued with its value that I would be loth to attempt any of the more serious operations through the vaginal vault without having one at hand. Feeling the want of a self-retaining retractor, that was simple and efficient, I devised the instrument which I now show you. You will observe that it consists of two pieces. The holder which passes under the sacrum and is held firm by the weight of the body and at the extremity of which is a steel pin for holding, and a screw for adjusting, the blade of the retractor at any angle. The retractor has a short handle with notches on the inner aspect and a ring at the end. In adjusting the speculum it is introduced as any other, then the index finger of the left hand is placed on the blade where it curves inward, while the thumb is placed under the free end or screw of the holder. Now, with the finger of the right hand in the ring of the handle, the retractor is guided into position through the slot on the side, while the blade and holder are approximated by pressure between the thumb and finger. Once in position it is easy to secure the desired degree of perineal retraction by increasing the pressure when it locks itself automatically. Now by turning the thumb screw the inclination of the blade may be changed at will. The mechanism is very simple, the movements are easy, the result all that could be desired. Besides the instrument, as a whole, takes up very little space and can be carried almost as easily as a bivalve speculum.

REMOTE RESULTS OF REMOVAL OF UTERINE APPENDAGES.

Read in the Section on Obstetrics and Diseases of Women, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY E. E. MONTGOMERY, M.D.
PHILADELPHIA, PA.

The introduction of the operation for removal of the tubes and ovaries as advocated almost simultaneously by Battey, Tait and Hegar, though upon distinctly different lines, opened up an extensive field for the practice of abdominal surgery. The enthusiasm of their followers necessarily resulted in the practice of the procedure in many cases when it was of doubtful utility. Battey advocated the operation for intolerable dysmenorrhea; Tait for distinctly recognizable pathological lesions in tubes and ovaries, principally of an inflammatory character; Hegar to produce an artificial menopause in cases of uterine hemorrhage otherwise uncontrollable.

These distinctly defined indications soon became extended, so that pelvic pain of slight degree, whether associated with menstruation or not, has been considered an excuse for the removal of the organs. Ovaries and tubes have been removed in which careful macroscopic investigation has failed to disclose much, if any, evidence of disease.

The experience of over twenty years has afforded opportunity to study the immediate and remote effects of operations which, at least, must have a profound

effect upon the mental and physical nature of the individual in the interference with the procreative function.

It is a well recognized law of nature that unused faculties atrophy, so that it is not surprising to find that after castration of the unmarried female, the genital organs become smaller, the vaginal rugæ disappear and the mucous membrane is thinner and paler. In the married or those who subsequently marry, sexual desire becomes quiescent or even disappears, and to some the marital relation is painful and repugnant. Instead of being a willing and sympathetic partner in the act, she passes through the stages of indifference and passive suffering to disgust and distress.

If the condition just mentioned were the only unpleasant symptom, it would be a matter of but little moment. The most marked influence is upon the nervous system. It is generally recognized that the climacteric is a critical period in the life of every woman, one to which she looks forward with anxiety, realizing that hereditary traits and unpleasant phenomena are likely then to manifest themselves. If this be true when the woman matures and reaches the period undisturbed, how much more likely is she to suffer when the climacteric is abruptly and artificially induced, without nature having had an opportunity to prepare her forces for the changed relation.

Every operator is familiar with the flushing, vasomotor disturbances not unfrequently affecting the action of every organ of the body. These do not always disappear in a short period as in the natural menopause, but may continue for years, being a constant source of annoyance and discomfort. While it is true that many patients recover an appearance of good health who were previously great sufferers, in many this improvement will be found to be but temporary. Frequent attacks of neuralgia or neurasthenic pain in both ovarian regions as intense as prior to operation, in the uterus, in the intestines, the bladder, or the rectum; insomnia, restlessness and irritability of temper are not uncommon. Even if the individual may have had no desire for offspring, the assurance that motherhood is denied her frequently leads to intense longing for a child. When, however, she has been desirous for children and the possibility is precluded by an operation, the declining sexual appetite not unfrequently leads to a profound melancholy in which she feels life without solace or comfort.

Changes in pigmentation have been observed and it has been asserted that through menstruation certain material is eliminated which in its cessation is retained, producing splotches and discolorations of the skin, or the profound nervous manifestations.

The mental and nervous phenomena may be actuated or aggravated by the sequelæ of the surgical procedures, such as fistulæ, ventral herniæ, painful cicatrices, adhesions of intestines to the uterus, to the stumps, and to the bladder; cellular exudation, infection of ligatures, and the formation of abscess, immediately following the operation or years later.

A case recently came under my observation where, over four years after castration for bleeding fibroid, an abscess formed, which opened in the upper part of the cicatrix. An incision disclosed a large loop of silk in the abscess cavity.

Leucorrhœa and irregular profuse uterine hemor-

rhage not unfrequently follow the removal of both ovaries. Such an array of unpleasant phenomena, associated with the necessary mortality of the procedure when carefully and conscientiously done, should cause the surgeon to hesitate and weigh the condition of each case carefully before resorting to surgical procedure.

I would by no means wish to be understood as denying the necessity and wisdom of operative procedure in necessary cases, but would demand that careful study of the case should determine that the determined procedure was the necessary course for relief.

A careful survey of the immediate and remote influences of pelvic surgery justifies the following conclusions:

1. No mutilation or sacrificial operation should be done, where there is a reasonable probability of relieving the inflammatory condition through vaginal incision and drainage.

2. Efforts should be made to preserve portions of an ovary and a tube through resection, where partially diseased.

3. Where the ovaries and tubes are diseased, to such a degree as to require their complete removal, the patient is less likely to suffer from profound nervous phenomena if the operation be associated with hysterectomy.

4. Castration should be done for neuroses, only after it has been demonstrated by the experience of capable neurologists that the operation is the *dernier ressort*.

DISCUSSION.

DR. HENRY P. NEWMAN, of Chicago—said the subject under discussion was one of vital interest not only to the operator, but decidedly so to the patient. He had never seen a case in which removal of the uterine appendages produced insanity or an outward physical change in the patient, nor had he seen it result in any sexual deterioration to any great extent. In some instances, possibly that had been complained of. He expressed the opinion that before the operation is performed, its possible ill results should be carefully placed before the patient. Furthermore, it should only be performed for actual structural changes in the appendages, and not for mere pain.

DR. M. B. WARD, of Topeka, Kan.—said that where healthy ovaries are removed in young women, very marked nervous symptoms are produced—indeed, so marked that we ought never to do the operation if we can avoid it. He has never seen insanity result from it, however, nor a loss of the sexual appetite. The operation is sometimes followed by a very troublesome leucorrhœa. In all cases it is well to postpone the operation as long as possible. Nervous and hysterical patients have greatly improved after the operation.

DR. RUFUS B. HALL, of Cincinnati—had frequently seen patients suffer mental depression following operations for removal of diseased appendages. With one exception he had never seen insanity follow the operation. This exception was a woman, two of whose sisters had previously died in an insane hospital, and who showed a strong history of hereditary insanity. She died some time after the operation had been performed. There was a large suppurating ovary, and the woman had had gonorrhœa. He does not operate for reflex symptoms. Accumulation of fat usually occurs after the operation, this disappearing, however, at the menopause. He has never seen a growth of hair following celiotomy. So far as blunting of the sexual appetite is concerned, he had seen a few instances where this feeling was blunted. In no instance had it entirely disappeared.

DR. G. BETTON MASSEY, of Philadelphia—remarked that his experience on this subject was possibly somewhat peculiar, in view of the fact that the cases he had seen had been operated upon by other men, and his experience fully corroborates the large number of instances mentioned by Dr. Montgomery, of physical and nervous disorders that follow the removal of the ovaries. In one case a form of melancholia undoubtedly resulted from the operation. In many cases, after the removal of the ovaries in young girls,

their moral nature is greatly changed; the sexual feeling is not extinguished, but is largely limited by the operation. He has never seen an extra growth of hair on the face or elsewhere result from the operation.

DR. HOWARD A. KELLY, of Baltimore—had encountered six or eight cases of insanity after operation, one case after an abdominal operation, and one after curettement. All of the abdominal cases got well. When a woman asks him what bodily changes will follow the operation he tells her that she will get stouter and recover her health. The possible loss of sexual power does not militate against the performance of the operation, because these patients are usually in such a condition that they have not enjoyed sexual intercourse for years. On the contrary, the operation often restores family relations which have been impossible for years.

TREATMENT OF CONTRACTIONS OR STENOSIS OF THE UTERINE CANAL.

Read in the Section on Obstetrics and Diseases of Women, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY WILLIAM A. B. SELLMAN, M.D.

PROFESSOR OF OBSTETRICS AND DISEASES OF WOMEN, BALTIMORE UNIVERSITY, BALTIMORE, MD.

Contracted condition of the uterine canal has been treated by various methods. The slitting up of the cervix is a very unsatisfactory operation, as well as a dangerous one. The enlargement of the canal by means of the sharp curette is uncertain in its results, as the instrument merely scrapes furrows in the tissues and the part soon returns to its previous small caliber. I have attempted to obviate this by imparting a circular motion to the instrument during the operation and, by this means, reaming out the dense tissue at the point of contraction.

Hundreds, yes, thousands of women suffer from dysmenorrhœa on account of the uterine canal being contracted at some point. The condition may be acquired or congenital. After amputation of the neck of the uterus, the external os frequently contracts to such an extent that we fail to pass our smallest probe. I intend in this paper to speak more definitely as to the stenosed condition that we find existing at the internal os. These contractions are generally formed of tissue of a denser nature than normal mucous membrane and many times it is of a decidedly cicatricial character. This density of the tissue and this cicatricial character is frequently the cause of the displacement of the organ that we find existing in many of these cases. The fundus of the uterus is pulled over one way or the other, and after the caliber of the canal has been increased we find that the displacement has also been corrected.

I desire at this time to call your attention to a new instrument to remove this condition of stenosis. I call it my reamer.

This reamer is intended to be used to take the place of the slitting up operation and also to supersede the use of the curette. Dysmenorrhœa persisting on account of a narrow and, at times, an almost impervious condition of the uterine canal, or due perhaps to the existence of a ring of dense cicatricial tissue at the internal os, which dams back the flow of blood or secretions—these call for the use of the reamer. Rapid dilatation in many cases gives but temporary relief, as the parts return to their previous condition soon after the stretching operation has been performed. The dilator does not remove the dense tissue; it only lacerates it. The curette merely scrapes furrows in the tissue and the contraction remains.

With the use of the reamer, this tissue is reamed out or cut away by the knives placed upon the sides of the instrument. They are made in three sizes; begin with the smallest and gradually enlarge, and when you have accomplished all that you can do with this size, withdraw it and introduce a larger size.

The blunt probe-pointed end is introduced first and pushed in the constricted canal, a circular motion is imparted to the handle, and a moderate amount of pressure is exerted to cause the knives to engage upon the tissue, which at times is so hard that even the keenest knife has difficulty in making an impression upon it. The instrument works very much like a pencil sharpener paring away the tissue in slices. At times the constriction is so great that a small dilator has to be made use of, before the expanded portion of the instrument can be made to enter the narrowed uterine canal. As a rule, if the operation is properly carried out, a second operation will not be required. The patient should be under the influence of an anesthetic, if there be much tissue to be removed, or if she be of a nervous temperament.

The operation is frequently performed at the surgeon's office and the patient allowed to go about her accustomed duties; this is in cases of slight stenosis. When a large amount of tissue has been removed, it is prudent to place your patient in bed from four to seven days. After removing the tissue, swab the part operated upon with pure carbolic acid, and introduce a strip of iodoform gauze to the fundus uteri, allowing the free end to extend down into the vagina to the lips of the vulva. This insures thorough drainage and prevents the raw surfaces from uniting

by first intention. Allow this drainage tape to remain until the evening of the second day, then the nurse or patient removes it and a carbolized douche is given. The surgeon introduces another drainage tape at noon of the following day. Continue this treatment for ten days. These reamers will not remove fungous growths from the walls of the uterus, neither are they intended to remove retained membranes from the uterine canal.

Donations to New York Charities.—Under the will of Mrs. Bertha May, late of New York City, a property valued at \$23,000, has been donated to four charitable institutions in that city and Brooklyn. She leaves her property to the Mount Sinai Hospital, the Home for Aged and Infirm Hebrews, the Hebrew Orphan Asylum in Brooklyn, and the Home of the Little Sisters of the Poor.

A NEW SELF-RETAINING PERINEAL RETRACTOR.

Read in the Section on Obstetrics and Diseases of Women at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY A. E. ROCKEY, A.M., M.D.

PORTLAND, ORE.

The first requirement in operations on the uterus is that the organ should be exposed and held in such position that it may be accessible. The perineal retractor of Sims was a great step forward, but its narrowness and length of blade and the inconvenience of the prone position have at the present time consigned it to a rather minor place as an instrument for examination.

The retractor of Simon or some of its numerous modifications, with their shorter and broader blades, have almost universally superseded Sims' instrument in operations on the uterus. My own preference has been for that of A. Martin. It has essentially the Simon blade, with a broad outer flange, and a long, heavy handle. The perfect command of the field of observation given by this instrument, when held by skilled assistants, leaves but little to be desired.

The marked advantage of a short intravaginal portion is that it offers no obstruction to the ready descent of the uterus when drawn by the tenaculum forceps.

For vaginal hysterectomy, high amputation of the cervix, ligation of the uterine arteries, or any operation requiring full command of the vaginal vault, no self-retaining or purely mechanical device can ever take the place of trained assistants. In this way only, can that ready change of tension or position be obtained by word or sign, that facilitates so much the work of the operator.

Numerically speaking, however, operations of this class form but a small part of the work of the practitioner. It is a matter of common observation in practice that conditions requiring dilatation and curettement or simple trachelorrhaphy outnumber those mentioned five to one. Indeed, in general practice they outnumber all other operations on the female organs.

Hospital experience can not be taken as perfectly representing private practice in this respect, and yet the most extensive reports substantiate the truth of this statement.

The second Report in Gynecology from Johns Hopkins Hospital, covering a period of nearly three years, contains a table of 815 general gynecologic operations not involving celiotomy.

On examination of the table we find that 416 operations involved the cervix or cavity of the uterus. They may be divided into three classes, as follows:

1. Dilatation and curettement for stenosis, endometritis fungosa, pyo-physometra and retained products of conception—265 operations.
2. Trachelorrhaphy for lacerated cervix—103 operations.
3. Curettement of cancerous cervix and removal of polyp of cervical canal—48 operations.

The considerable preponderance of these minor operations and the difficulty or inconvenience of always obtaining suitable assistants, and, sometimes the embarrassment of their presence in private families, has made it desirable to have some purely mechanical device for exposing the uterus.

The limited field of operation has also made it possible to accomplish this with a greater or less degree of success. For these reasons a considerable number of such instruments have been devised.

Prominent among them is Emmet's self-retaining perineal retractor. The perineal portion is shorter and wider than Sims' and the point of resistance is an oval frame to rest over the dorsum of the sacrum. It was designed for use in the semi-prone position. By reason of the extremely various contour of this part, the frame does not always fit well and is liable to slip. To obviate this difficulty, the modifications of Cleveland, Hunter and Erich have shoulder straps or bands to hold them in place. These contrivances have proven awkward and cumbersome and are, consequently, but little used.

The Edebohl retractor, which is held in place by a bucket of shot or other weight, would be efficient when the conditions of its use are well complied with, but it must be inconvenient in private practice.

The most recent instrument of this class, and, I think, the best yet presented to the profession, was devised by Dr. Samuel C. Beach, and was exhibited at the June meeting of the Chicago Gynecological Society.

The retractor is an ordinary perineal retractor, but has the handle forked and turned at right angles to the plane of the blade. The retaining mechanism consists of a flat band of metal, hinged at its center for convenience in carrying. In use, this band is slipped under the body of the patient, lying in the dorsal position, with the thighs flexed, thus making a fixed point of attachment for the retractor, which slips into the inlet ring in the retaining bar and is held by a thumb-screw. The legs are held by a McBride-Packard yoke.

With the same object in view, I have devised an instrument which, unlike any other of its kind, utilizes the under surface of the pubic arch as a more convenient and uniform point for the support of the retractor. This instrument consists of two pieces—a perineal retractor and a sub-pubic rest.

The perineal retractor has a blade like Martin's, and also a long, heavy handle, but with the hook placed posteriorly at the lower part of the swell, thus affording a very firm grasp and at the same time a rest to the hand of the assistant. By examining Martin's retractor it will be seen that the hook is placed at the end of the spindle-shaped part of the handle, and is always about two inches below the firm grasp given by the large part of the handle.

To a considerable extent I am indebted to a remark by one of Martin's assistants for this improvement. It was after a long clinic, where two vaginal hysterectomies and several minor operations had been performed, that I tarried to speak with the assistant, who referred to that feature of the otherwise perfect instrument as, "*Nicht bequem für ein assistent.*"

The perineal part may be used alone to be held by an assistant in major operations on the uterus, and possesses all the merits of Martin's with the addition of a better grip on the handle. It is also an admirable retractor for use in abdominal work.

The heavy handle has been objected to by some who have examined, but not tried, the instrument. This is one of the decided advantages. It gives the assistant an easier command of the perineum,

not only for its retraction, but with the instrument I have devised for its shortening by upward pressure as well, when occasion requires it.

The distinctive feature of my instrument is the sub-pubic rest from which retraction is maintained. The blade is short, well curved on the top to fit the under side of the pubic arch, and corrugated near the tip to prevent slipping. It is attached to the perineal portion by a notched bar, sliding in hooks on the side of the blade; the compression of the parts locking it firmly in position without intervention of screws. It is easily adjustable, and may be placed or detached without removing the perineal portion. This piece has been cast from phosphor bronze to give it greater strength.

Fig. 1.—The author's self-retaining perineal retractor.

In use, the perineal portion should be first inserted and well retracted, and then the subpubic rest introduced and pushed to place. If the directions of this sentence are carefully followed there can be no difficulty in its use. The perineum should be retracted by a strong pull on the handle and but little upward pressure will be required on the subpubic rest. In fat women the thickness of the external parts make it necessary to push the upper part of the instrument well in between the labia in order that the curve of the short blade may rest upon the pubic bone. By the observance of these precautions there will be no slipping, and the command of the field of operation is almost as great as that obtained by manual retraction by good assistants and surely superior to timid makeshifts that must sometimes be resorted to in emergency. The blades being short, the cervix is not always exposed at once. The vaginal fold should then be pushed aside with the finger and the cervix seized with the tenaculum forceps and drawn down.

In connection with operations of this kind, I desire to refer to two adjuncts, viz., leg holders and tenaculum forceps. A most convenient and efficient leg holder may be made from a strip of muslin half a yard wide and two yards long, with slits through the center through which the arms and shoulders

are passed. The thighs are then fixed and the bandage placed around well under the knee and fastened with a large safety pin.

The heavy American bullet forceps, with lock, has proved not only the best instrument for holding

Figure 2.

down the uterus but a superior tenaculum and tissue forceps in many general gynecologic operations as well.

In the year that has elapsed since my instrument was devised, I have used it in many operations on the cervix and cavity of the uterus and the requirements have been admirably met. It was constructed for me by Charles Truax, Greene & Co., of Chicago.

THE SERUM TREATMENT OF DIPHTHERIA.

Read before the Michigan State Medical Society, at Bay City, June 6, 1895.

BY CHAS. T. McCLINTOCK, PH.D., M.D.

ANN ARBOR, MICH.

There can be no reasonable doubt that the larger part of the ill-effects of diphtheria, are due to the soluble poisons (toxins) formed by, or during the growth of the germs of the disease. The paralysis, the albuminuria, the necrosis in the various organs can all be produced at will with these poisons. Here is a diphtheria toxin. This was made by inoculating a flask of alkaline beef tea with a virulent culture of the diphtheria germ. This germ was obtained in December last from a child in Harper Hospital, Detroit. After the flask had been in the incubator, at the body temperature, for several weeks, the germs were killed by the addition of carbolic acid. The beef tea, or as we now call it, toxin, was filtered, first through paper, and then through porcelain. The latter removes all the germs. On testing this, we find that one-tenth c.c., or a large drop, is sufficient to kill a half grown guinea pig within thirty-six hours. Had we cared to study this, as has been done over and over again, we would have given a smaller dose, one sufficient to kill the animal in five or six days. Then had we studied this animal clinically, we would find all the essential phenomena noticed in a fatal case of the disease in a child. We would have the fever, more or less albuminuria, the paralysis, and on section we would find the necrosis.

From such studies, and the like is not true of this disease alone, there is but one conclusion—the toxin is the cause of the fever, the paralysis, the necrosis, the death. I need only mention that when the system is weakened by this poison, it is often preyed on by the pus germs, streptococci, etc., and that these may hasten and modify the uncomplicated disease. This poison, the diphtheria toxin, is produced by the germs of the disease which are generally confined to

the upper air passages. The poison is absorbed, and circulating throughout the body produces its harmful effects, it may be, in every organ.

The above being true, it follows that when we have a natural recovery from the disease, the body must in some way dispose of or destroy this poison, and the thought is at once suggested that, knowing the cause of the disease, it may be possible to find an antidote, an anti-toxin, a something which when introduced into the body may destroy, or so aid the cells of the body that they can destroy this poison. Such a substance we have in the antitoxic serum of Behring and Roux. And here may I say, that it was not a happy thought, not a revelation, not a happening, that led Behring to antitoxin. Ever since Pasteur's work in 1880; away back in the ancient history of bacteriology, we have been gradually approaching antitoxin; a fact here, a theory there, step by step, scores of observers aiding in the work, until at last this worker, placing together all that had been done before him, saw how it might be completed. It had been shown: 1, that the disease was due to a toxin circulating in the blood and lymph; 2, that the animal body had more or less power to neutralize, destroy, or dispose of this toxin; 3, that this power varied with the age and species of animal, an older animal or one of a certain species having much more resisting power; 4, by appropriate treatment this poison-destroying or antitoxic power could be increased; 5, that this power could be borrowed by taking the blood, or blood serum of the resistant animal, and loaned to the one with less resistance. These experiments on animals having shown the possibilities in the work, Behring began his work of perfecting the methods. Before it could be applied to the cure of diphtheria in the human being, the poison-destroying or antitoxic power of the blood in the animal used must be enormously increased, so that a small part of its blood serum would be able to neutralize or destroy all the poison produced in an ordinary case of the disease. Again, an animal must be used whose blood serum when introduced into the human circulation would produce little or no ill effects. Again, methods of preserving the serum must be discovered, so that it could be sent wherever needed. Methods for measuring its worth, poison-destroying or antitoxic power must be devised. These difficulties, Behring asserts, were one by one overcome. Various animals were experimented on—rabbits, sheep, goats, cattle, horses. It may be well to note that a satisfactory antitoxin was first worked out for tetanus, not diphtheria. But possibly on account of the infrequency of this disease, together with the fact that almost irreparable damage is done before it can be recognized clinically, and probably still more to the fact that the news was too good to believe, but little attention was given by the profession at large to these results. Not until after the reading of Roux's paper at the International Congress of Hygiene, held in Buda-Pesth, September last, was any very general interest aroused in the subject. Since then the medical journals and even the daily press have been filled with the subject.

I am appointed to-day to summarize for you, if I can, the results of the serum treatment of diphtheria.

The young science bacteriology, has claimed so much, demanded so much of our attention, asked to remake so much of our belief and practice, that when she puts forward a new claim for recognition, a claim

that in all the history of curative medicine has no parallel, many hesitate and say: "Once I was young, but now I am old; never have I known or seen such things. I do not believe."

Let us see. This, now, is a question of facts. It has ceased to be a question of opinion. It is no longer what you or I believe. It is, what are the facts?

With over ten thousand cases treated with this remedy—used by careful, critical, often fault-finding men—probably 80 per cent. of these cases being reported from hospitals, often the diagnosis made by one man, the treatment given by another, and the report made by still another, the larger part of the diagnosis being confirmed by disinterested bacteriologists; with these conditions, I repeat, it is not a question of opinion whether this remedy is, or is not, a success.

Now the question, what are the results? I do not believe it necessary, or appropriate to burden you with the reading of long columns of statistics. I may say that my work has been such as to require me to keep watch of these reports. I have looked with some care over the reports in the leading medical journals in this country, England, Germany and France. It is well within bounds to say that an average of all the reports made, shows a reduction in mortality of over one-half.

The comparative estimates, treatment with serum and treatment by other means come largely from the hospitals. For the most part the death rate with the serum treatment is compared with that immediately preceding its use. But it is noteworthy, that in several cases when the serum was not to be had, or from some cause there was an interruption in its use, *i. e.*, up to a certain date the ordinary treatment, then serum, then the usual treatment, and then again the serum; in every such case that I have noticed, where the serum treatment was interrupted, the death rate rose to the old figures. Virchow reports such an instance, and although his remarks have been widely quoted, I shall repeat them. He says: "Treatment by diphtheria antitoxin was begun last March in the Kaiser and Kaiserin Friedrichs Hospital. In June and July nearly all diphtheria cases were treated with the serum. The results were as follows: in eight weeks sixty-three cases were treated, with a mortality of less than 13 per cent. Suddenly the supply of serum ceased, as, unfortunately, the very horses from which the serum was taken died. The old methods of diphtheria treatment had again to be resorted to, and the results were, in the next seven weeks 109 cases treated with 55 deaths, a mortality of over 50 per cent. This sad increase in the mortality induced the hospital to return to the serum. Immediately there was a change. In the next six weeks eighty-four cases were treated with a mortality of less than 15 per cent." The total figures he gives are as follows: five hundred and thirty-three cases were treated; 303 with the serum, with a death rate of 13.2 per cent.; 230 without serum with a death rate of 47.8 per cent. Virchow continued, that in view of the results, he held it to be the duty of every doctor to use the serum. "All theoretical considerations," he added, "must give way to the brute force of these figures." Further, he says that even if disagreeable by-effects were proved to occur here and there, they were not sufficient to dissuade him from continuing the treatment.

Roux reports that in one Paris hospital the mortality for four years was 51.71 per cent. In the six months since antitoxin was used, 448 cases gave 24 per cent. mortality, and during the same six months, in another hospital in the same city where serum was not used, 60 per cent. died.

I could, if needed, cite a number of reports fully as favorable as these. I wish you to note that these reports effectually answer the statement that has been made, that diphtheria has been a very mild disease the past year, since the advent of serum-therapy, and yet in Virchow's report the mortality with the old treatment was 47.8 per cent. In the Trousseau Hospital in Paris, 60 per cent.

	Cases.	Albuminuria. Per cent.	Nephritis. (Clinical) Per Cent.	Nephritis. (P. M.) Per cent.	Deaths. Per cent.
Without serum..	993	42.00	25.78	16.31	43.2
With serum . . .	525	40.95	12.57	15.80	15.8

I want to call your attention to the above table. This is taken from a very recent report or book of 336 pages on the serum treatment of diphtheria, by Dr. Baginsky, Professor of Diseases of Children in the University of Berlin, and Director of the Royal Hospital for Children, in Berlin. This is one of the largest and best equipped children's hospitals in the world. Baginsky discusses at length the influence of the serum treatment on the complications and sequelæ of diphtheria. In his opinion the injection of serum does not increase the frequency of nephritis. Cardiac collapse occurred in 10.9 per cent. of those treated without serum, and in 5.69 per cent. of those treated with it. He finds little difference in regard to the frequency of diphtherial paralysis, but such difference as there was is in favor of the serum treatment, the percentages being 6.8 without and 5.14 with the serum.

One more set of figures and I am through with statistics. Dr. Foster, of Washington, in February last tabulated the reports of 7,185 cases, collected from all sources. Of these, 4,445 were treated without antitoxin, with a mortality of 45.56 per cent.; 2,740 cases were treated with serum, with a mortality of 18.54 per cent. Of the cases treated with antitoxin, there was not a single death when the treatment was given in the first day of the disease. When it was begun on the second day, the mortality was 2.83 per cent.; begun on the third day, the death rate was 9.99 per cent.; on the fourth, 20 per cent.; on the fifth, 33.33; after the fifth day, 41.38.

These figures seem to establish Behring's prediction that the mortality will not exceed 5 per cent. if the treatment is begun within forty-eight hours after the attack.

It would not be fair to you, gentlemen, if I did not remind you that there have been a few men who have questioned the efficacy of the serum treatment. It was in reply to an attack made by his own assistant, who denied the efficacy of the serum, that Virchow made the statement I have already quoted. This attitude of Virchow is the more noteworthy, since as you are doubtless aware, he has been for years the severest critic, the most persistent fault finder and "doubting Thomas" that the bacteriologists have had to face. But even Virchow was disarmed, and forced to champion the therapy, as he says, "by the brute force of these figures." In this country there have been two adverse reports made in regard to this treatment. One of these was by Dr. Winters, of New

York. He made a sweeping challenge of every claim made for serum-therapy, attacked the statistics and alleged a number of serious after-effects due to the antitoxin. Dr. Winters' opinions were the outcome of his observations in the Willard Parker Hospital. At this distance we can only judge of the facts from the statements made. This report of Dr. Winters was made to the New York Academy of Medicine. In the reports of the meeting, it does not appear that Dr. Winters had a single supporter; on the other hand, Dr. Somerset, who had been connected with the hospital for the past sixteen months, virtually contradicted every conclusion drawn by Dr. Winters. Dr. Biggs showed that over and above every question of opinion, was the fact that since the introduction of antitoxin in Willard Parker Hospital, the mortality had decreased over 10 per cent. He concluded by saying that, "Dr. Winters had shown from the beginning of the antitoxin treatment in the hospital, profound distrust of the method," and then declared that, so far as he knew, there was not a single distinguished clinician, pathologist or bacteriologist in Europe who had not accepted the new treatment of diphtheria as the most important advance in therapeutics in modern times.

The other adverse report comes from Assistant-Surgeon Cordeiro, of the United States Navy.

If there were need and time for such, for every such adverse report I could show you an hundred, from men of as wide experience and with broader training, the finding being, as stated before, a reduction of at least 50 per cent. in the death rate, with no increase in the after-effects of the disease.

In judging of these statistics, I want to ask your attention to one point that has not yet received the consideration it deserves. In the statistics of the treatment of diphtheria under the old methods, it is to be remembered that in nearly all cases the diagnosis was made from the clinical symptoms; while in the larger part of those reported with serum treatment, the diagnosis has been confirmed by bacteriologic examination, and those cases which did not show the germs of diphtheria were not included in the reports—that is to say, speaking generally—the statistics for serum treatment refer to diphtheria, while those for the older methods refer to diphtheria and those diphtheroid conditions which are so often indistinguishable, clinically, from the true disease. That such cases often pass for diphtheria is well shown in the results of the examinations made in the Willard Parker Hospital in New York. These cases were first diagnosed by the health officers, they were then sent to the hospital, and the diagnosis confirmed by the physicians in charge; and yet subsequent bacteriologic examination in these cases showed that from 30 to 50 per cent. were not diphtheria, but maladies of non-infectious character. During the last six months I have made a bacteriologic study of a number of cases that were called diphtheria; a part of these cases were in private practice, a part from Harper Hospital, Detroit. In less than half of all the cases examined was I able to find the germs of diphtheria. Now, if these diphtheroid cases, cases in which the mortality is much lower than in the true disease, could be excluded from the statistics given for the old methods, as they have very largely been from those given for the serum treatment, we would find a far greater difference in the figures.

The after-effects of antitoxin—urticaria and erythema, in the neighborhood of the locality of the injection—are rather frequent. Widespread urticaria occasionally occurs. Aronson says that these rashes only occur when a new serum is used; that if the serum is kept for some time, none of these effects are to be found. These rashes have occurred much oftener when large doses of a weak serum have been used. Occasionally neuralgic pains have been noticed, particularly in the legs. This may go further, and we have swollen painful joints, and occasionally paralysis.

Dr. Paquin, of St. Louis, who has used the serum of immunized horses for the treatment of tuberculosis, tells me that he has occasionally had these symptoms in some of his patients. A New York observer who used the serum from an untreated healthy mule reported symptoms practically as above. These symptoms, it seems to me, are justly referred to the serum. For the most part the rashes are transitory and, save for the itching, are of no importance. The graver ill-effects are fortunately rare.

A number of workers are endeavoring to isolate the active principle from the serum and it is a reasonable hope that this will soon be accomplished. It is to be remembered that antitoxin has no restorative power. It is only what the name indicates, a poison neutralizing or destroying agent. If this poison has been at work long enough to damage the cells of the kidney, or paralyze the nerves of the leg, antitoxin will not repair them or restore their functions.

If we give an experimental animal 1 milligram of antitoxin and then give it ten times the fatal dose of diphtheria poison or toxin, this will more surely protect it from the effects of the poison than if we give it a thousand times as much antitoxin twenty-four hours after giving the poison.

In tetanus, the dose of antitoxin necessary to save an animal when given some time after the poison, is more than a million times as large as that which will protect it when given before the poison. So in treatment, the clinical evidence goes to show that one drop of the serum given the first day of the disease is of as much value as hundreds of times this amount given on the fifth day.

It is not to be forgotten that for the most part antitoxin has been made and used by unskilled hands, and yet see the results.

In conclusion, it is possible that these figures and these men are all wrong, but if they are right, curative medicine has never before seen such results.

SKIN GRAFT—INCISION TO PREVENT SCARS.

BY CARL BECK, M.D.

CHICAGO.

In operations on the face and neck, we are often confronted with the difficult problem, "how to prevent ugly scars." The rules of surgery require extensive incisions, while cosmetic reasons call for the opposite, and even the most exact coaptation will not prevent cicatrices.

It is evident that if we found a method which would enable us to make an ample incision, and leave little or no trace of it, this method would be of great advantage.

After having studied this question theoretically and by experiments I have, in a few instances, made use of a special method. The results, though few as yet,

and not conclusive, are so much encouraging that I venture to publish it.

The method is simple. Contrary to the accepted rule of our technique, the incision is made obliquely to the surface with a razor or a scalpel, one border of the wound forming a broad strip like a Thiersch's graft, then the incision is carried down as deeply as needed. In uniting the wound, the graft is exactly spread out and adapted to the surface from which it was taken.

Small incisions are sealed without suture with colodion, or treated in the usual way of skin grafting.

In large incisions, deep catgut sutures may be employed to close the wound, the graft spread over the same and treated as before stated.

Drainage may be used, but this complicates and endangers the healing.

The same method may be of value in some cases to remove existing cicatrices.

The theoretical consideration, experiments and details will be the subject of a paper in connection with the exhibition of cases.

CRANIECTOMY—AN IMPROVED TECHNIQUE.

Read at the Meeting of the Tri-State Medical Society, held in St. Louis, April 2, 3 and 4, 1895.

BY A. H. MEISENBACH, M.D.

PROFESSOR OF SURGERY IN THE MARION SIMS COLLEGE OF MEDICINE.
ST. LOUIS.

In this paper I do not wish to discuss the rationale of, or the indications for, craniectomy; but wish to limit myself to the description of an operation which differs in its technique from those heretofore described.

Craniectomy may be either linear, circular or irregular in form; may be confined to one or both sides of the cranium, and may be anterior or posterior. The method of performing craniectomy (one-sided linear) employed by most surgeons, is as follows: a large scalp flap is cut so as to expose the entire field of operation on the bone beneath it. The flap has its base at the base of the skull and extends in a curved line along the sagittal suture, beginning at the hair line of the forehead anteriorly to the coronal suture, and extending posteriorly across the lambdoid suture onto the occipital bone. Its upper border runs parallel with the superior longitudinal sinus, and may extend as high on the vault of the cranium as the sagittal suture. The flap includes all the tissues of the scalp and the pericranium. It is important that the incision be firmly made and carried directly down to the skull, making a smooth, clean incision through the pericranium. With a flat periosteal elevator the pericranium is lifted off of the skull and with it the tissues of the scalp. In this manner the bone is bared as far as the base of the scalp flap, which is on a level with the tip of the ear.

With a small-sized trephine an opening is now made on the frontal bone, anterior to the coronal suture and at a safe distance from the superior longitudinal sinus. The trephine opening is the starting point for the next step in the operation, viz., the cutting of a longitudinal strip of bone out of the cranium, three-eighths to one-half inches wide, including both

tables, and extending backward from the trephine opening in the frontal bone, across the parietal and on to the occipital, as near to the lateral sinus as is safe. This part of the operation is done with especially devised bone-cutting forceps (Keen's, Lannelongue's, etc.), or the chisel.¹ The bony parts divided are parts of the frontal, the parietal and part of the occipital bone. In skulls in which the tables are soft, or not very thick and moderately ossified, the cutting out of this strip of bone by Keen's or other forceps, may be readily accomplished in a moderate space of time, say one-half hour. In skulls, however, that are thick and hard, the cutting out of the bony strip is not an easy or rapid task.

It is in cases in which the skulls are thick and hard that I have devised the operation which I shall now describe. The instruments required are a scalpel, artery forceps, periosteal elevator, double-bladed saw (see cut), a chisel with a beak (see cut), an ordinary chisel three-eighths inches wide, a mallet and dural elevators (see cut).

Fig. 1, double-bladed saw (author's.) Fig. 2, beaked chisel (author's)
Fig. 3, dural elevators (author's).¹

I make the scalp flap as already described. When the bone is cleared and the flap retracted, a button of bone is taken out of the frontal bone (or elsewhere, according to the operation to be done) with a small-sized trephine. It is in the removal of the bony strip that the improvement in the operation consists. Beginning at the trephine opening with the double-bladed saw, I cut a strip of bone the width of the saw (three-eighths to one-half inch) as far back as indicated. The saw cut is carried through the outer tables, the diploic structure, and onto or into the inner table. The outer table is now cut out by means of the ordinary narrow surgical chisel. The next step in the operation is to cut out the inner table by means of the beaked chisel; with a dural elevator (see cut) the dura is separated from the inner table; separating it step by step, as piece after piece of the inner table is cut out. The beaked chisel is of much service; for, on account of the dull projecting beak, the dura is not injured, as the beak glides over it readily. I hardly need mention that with the ordinary chisel this part of the operation is not free from danger to the dura.

¹ There is no doubt but that the quickest way of opening the skull is with a properly constructed electrical or dental engine, with properly constructed saws. Those devised by Cryor, of Philadelphia, are the best, but they are very expensive and not available outside of large well-equipped hospitals.

¹ The above instruments were made for me by Hokekamp-Moore Instrument Company, St. Louis.

REMARKS.

The double-bladed saw that I use was devised by me some years ago, to cut off plaster-of-Paris casts. It cuts a strip three-eighths of an inch wide. It very much facilitates the operation of craniectomy, as described.

I have found the beaked chisel (my own device) very useful in operations on the skull, especially where the inner table is to be cut through. On account of the blunt beak the dura is not liable to be injured. I have found it very useful also, in cases of depressed fractures where it was necessary to smooth off the sharp projecting edges of the inner table. The chisel is about eight to ten inches long and made of three-eighths to one-half inch octagonal steel; the blunt beak projects one-eighth to one-quarter of an inch beyond the perpendicular edge. The cutting edge is at right angles to the shaft of the chisel, and is one-half to three-quarters of an inch long. The chisel has a curve so that the contour of the cranium can be easily followed.

I am well aware that many surgeons deprecate the use of the chisel in operations on the cranium, for fear of the resulting concussion of the brain. This seems to me to depend, in a measure, on the skill of the operator, and also on the character of the chisel used. It is a noticeable fact that most chisels made by instrument makers are improper

The above cut shows the skull exposed, flap of scalp turned down, and the different stages of the operation on the cranium.

tools, being too short and also too light for proper manipulation. In my estimation, the best chisel for surgical purposes generally is the carpenter's or joiner's socket-framing or firming chisel, into the socket of which a metal knob has been fitted to receive the mallet blows. It seems to me that with a chisel of this form (or any other long heavy chisel) the concussion of the brain is much less than where a short light chisel is used. Surgery is mechanical in part, and the surgeon can learn many important technical lessons from the skilled craftsman in the workshop. A skilled sculptor or mechanic would not think of using a tool so short that he would continually run the risk of pounding his fingers; for, certainly, the fear of hitting the fingers would detract materially from the delicacy in execution of the work to be done. How often do we see improper instruments used in surgery, and, if bad results follow, the blame laid to other causes than to the execution of the operation? The old saw is

true, "a good mechanic needs but few tools;" and I would add that they must be of "proper construction and properly used."

I should be loth to present for your consideration a procedure that I had not tested, both on the cadaver and on the living. On the cadaver, I have cut out the bone, as described, within twelve to fifteen minutes.

Within the last year I had the opportunity to execute the operation on two cases.² The first, a modified linear craniectomy in a child 7 years old, for ossification of the cranium and defective development of the brain; the second, a metastatic tumor of the cranium (carcinoma), in a woman, age 56, in which I removed the tumor with the same instruments, double-bladed saw, trephine and beaked chisel. In this case the bone (and tumor) excised was rectangular, measuring about two inches square. In both cases there were no untoward symptoms, as far as the operation was concerned, viz., concussion from the use of the chisel. I refrain from reporting these cases *in extenso* at this time, as I shall incorporate them in a future paper.

2229 South Broadway.

SOCIETY PROCEEDINGS.

The Ohio State Medical Society.

Annual Meeting held at Columbus, May 15, 16 and 17, 1895.

(Concluded from page 328.)

DR. W. J. MEANS, of Columbus, Ohio, presented a paper on INFLAMMATORY DISEASES OF THE CERVICAL LYMPHATIC GLANDS.

After outlining the topographical anatomy of the neck, and calling attention to the important and intimate relations of the various structures, Dr. Means continued:

The inflammatory diseases of the cervical lymphatic glands in their general features are so well understood that I will not devote much space to a description. Since the management of the different forms is in many instances so radically different, I am compelled, however, to give a classification and a short clinical history of each.

The most practical grand divisions are simple and specific. The simple variety is met with in children perhaps oftener than most any other disease. In severity, simple adenitis exists from the evanescent swelling of the glands that passes off in a few days, to that of suppuration or chronic enlargement that continues for weeks, causes the patient much trouble and is liable to become specific from secondary infection. The etiologic factors are numerous. Inflammatory processes about the mouth, face, head and ears, such as ulceration of a tooth, stomatitis, tonsillitis or any of the diseases of mucous membranes, eczema of the face or scalp, dermatitis, otitis media, pediculosis capitis and other diseases too numerous to mention are frequent causes. The eruption of the teeth, exposure to cold and sprains are all common causes in producing swelling of the cervical glands.

The pathologic changes that take place are first found in the cortex of the gland. It becomes more vascular, soft and swollen; the reticulum loses its distinctiveness, the lymph passages become packed with lymph. The capillaries become enlarged and the gland becomes a deep purple in color. The termination may be by resolution, chronic enlargement or suppuration. Owing to the inherent power of the glands to throw off foreign bodies and to resist the attacks of invading microbes, a large proportion of them undergo resolution and disappear. When the inflammation becomes chronic there is a failure to absorb the exudates and they become organized. This thickens the capsule and it becomes hard and adherent to the surrounding tissues. In some cases the lymphatic vessels are compressed and there follows dilatation of them and edema of the parts. If the termination is by suppuration, the gland itself will be the seat of necrosis,

² Since the writing of this paper I have performed two additional craniectomies after the method herein described. In both cases the results were perfect, as far as the operation is concerned. No shock; *unio per primam intentionem*.

or the tissues surrounding it. If the latter, the gland is often found partially intact in the abscess.

There is always danger of a simple adenitis becoming tubercular. A healthy gland has a resisting power to the growth of tubercle bacilli, but when diseased it very readily becomes a nidus for their cultivation. I do not believe the profession is fully alive to the danger of this source of tubercular infection. Enlarged glands are so frequent and terminate favorably in so many cases that the physician becomes indifferent to the gravity of them.

Under the specific inflammatory enlargements we have tubercular, syphilitic and glandular and a few others. It is now a well established fact that the lymphatic glands all over the body are frequently affected by tuberculosis. The cervical glands are especially prone to be affected, probably owing to the numerous sources of infection about the mouth, face and head. It is claimed that 95 per cent. of all the cases of tubercular adenitis occur in the cervical lymphatic glands. The source of infection is much the same as in the simple variety. There is some abrasion or disintegration of the skin or mucous membrane through which the bacilli gain entrance to the lymphatic vessels and are carried to the gland. The bacillus tuberculosis is non-motile, so this is the only explanation we can give of its entrance and progress. Another clinical fact goes to prove this, in that when a gland becomes infected, belonging to the superficial set, others in the same chain become affected. It is so with the deep set. This is the most conclusive evidence that the bacilli are carried by the lymph current. In the active stage of the inflammatory process the lymph vessels are sometimes occluded and thus prevent the extension of tubercular infection for the time being. There are some exceptions to this rule of invasion in the direction of the lymph current. These exceptions may be accounted for by the wandering leucocytes, to which the bacilli may become attached.

We may note another clinical feature that bears upon the above theory, that as long as the bacilli are confined to the lymphatic glands there is no danger of general infection, but when they pass these filters and the germ gets into the general circulation there follows general tuberculosis, generally pulmonary. For an extended description of the pathologic anatomy I will refer the reader to the works on that subject. Suffice it to say that cell necrosis is followed by caseation, and the bacilli within these nodules die or become inert and remain frequently for months or years without any signs of activity. During this time the gland is not tender and remains quiescent and gives the patient no particular trouble. The cheesy material may dry and become inclosed in the capsule or connective tissue and remain in calcification, or it may undergo liquefaction.

Secondary infection may take place from pus microbes when an acute inflammatory process will set up, involving the surrounding tissues, followed by suppuration. When a group of glands are diseased the first infected may have undergone the degenerative process above mentioned while the last ones are simply pinkish and only show the primary stage of the disease. I recently removed eighteen axillary glands from a patient where they ranged in size from a walnut to that of a small almond. They were knotted together by connective tissue and the larger ones had undergone the cheesy degeneration. Liquefaction had not taken place in any of them. Several of them had a few foci of necrotic degeneration, and the smaller ones did not present any changes further than the hyperemic enlargement.

In simple adenitis there is difficulty oftentimes to differentiate the true condition. Suppurative adenitis is an acute inflammatory process that terminates in a few days in pus. Adenitis developing from a sore about the lips, that has the characteristic of a sore, can be easily differentiated from the simple or tubercular varieties.

In tertiary syphilis, the whole glandular system, especially the superficial set, is affected. The affected glands are painless, indurated and loose in the tissues. Carcinoma never occurs as a primary affection of the lymphatic glands. When enlargement of glands occurs close to a suspicious tumor, there is not much doubt as to its character. Lymphoma always affects but one and the cause is benign.

Lympho-sarcoma gives rise to regional and general infections. In this respect it is like tubercular adenitis, but it is not inflammatory and therefore does not produce degeneration of the tissues. A prognosis of inflammation of the cervical glands depends largely upon the variety and the management. If left to themselves or treated in an improper manner, they become a frequent cause of death. Simple adenitis *per se*, is not dangerous, but when we consider the danger of secondary infection from tuberculosis, it becomes

a grave disease. Local tuberculosis is a constant menace to the life of the patient, and therefore the gravity of tubercular adenitis in the cervical glands especially should be recognized. General infection may not occur, but the disease remains there with the wand of death, ready to beckon its victim.

The treatment of cervical adenitis after a careful diagnosis has been made is important. In the simple variety much can be done to avoid suppuration and secondary infection. One of the cardinal principles in treating adenitis, of whatever kind, is to remove the cause or source of the trouble. When called to see a patient with enlarged cervical glands, it is the imperative duty on the part of the physician to carefully examine the mouth, throat, nose, ears and scalp to find the cause of the trouble; and if found, it should be removed. Rest and the application of cold to the swollen glands is about the only treatment necessary following the removal of the cause. I wish here to protest against the almost universal custom of applying local irritants over swollen glands. I also protest against the indiscriminate use of fomentations. The ancient theory that iodine applied externally causes absorption of exudates or will reduce enlarged glands, seems to be prevalent among physicians of the present day. The external use of tincture of iodine is unsightly, painful, and may be injurious. Local irritants stimulate the peri-cellular tissues to a vascular hyperemia and thus may convert a quiescent enlarged gland into an acute inflammatory section and possible suppuration.

Another source of danger may arise from abrasion of the skin so that microbes may find their way into the lymph currents and diseased gland. These restrictions on the use of irritants apply both to the simple and specific varieties. When suppuration has taken place, fomentations may take the place of the cold applications. As soon as fluctuation can be detected, a free incision should be made into the pus cavity. The patient should be anesthetized, and then the abscess can be opened carefully and thoroughly cleaned out. By "cleaning out" I mean cretting and washing with antiseptic solution and then packing with iodoform gauze. If this plan can be followed there will be a speedy recovery with the least possible drain upon the system and resulting scar. Constitutional treatment is necessary to support the system. I depend upon the lime salts, arsenic and iron. If the suppuration is found to be in the peri-glandular tissues and the gland not fully broken down, which is often the case, it should be removed and the cavity treated in the above manner. The treatment of the tubercular variety is one of the most interesting and important subjects pertaining to the management of the lymphatic glands. The treatment very naturally resolves itself into two forms—constitutional and local or surgical. Under the constitutional treatment there lurks much danger to the patient. The old idea of the effect of the alterative treatment in scrofula is still abroad in the profession. No one knows what it means, but through ignorance of the action of drugs and the pathology of tubercular adenitis, the physician goes on prescribing nauseating medicines, hoping thereby to cure these local swellings, but his patient goes on toward the grave, or a return to health, after months or years of running sores and resulting hideous scars. The true purpose of constitutional treatment is, or should be, to build up the system. This can best be accomplished with cod-liver oil (pure); (emulsions should be discarded), arsenic, iron, nutritious diet and proper hygienic surroundings.

The curative treatment is surgical and should be resorted to at the earliest possible time. On general principles there are no good reasons for delay. Early extirpation of tubercular glands affords as great immunity from subsequent infection as it does in carcinoma. In the face of modern statistics, no one would advise delay in removing a malignant tumor before the surrounding tissues and glands become infected. So it is with tubercular lymphatic glands; if left alone, additional glands become infected; there is constant danger of general infection and there will be more or less peri-cellulitis, thus complicating operative interference, and other complications will arise that will make what primarily would have been a simple surgical operation, one of the most formidable known to surgery, thus jeopardizing the life of the patient.

The surgeon must be thoroughly familiar with the topographical arrangement of the tissues and organs of the neck before he ventures to operate, and he must be prepared to meet emergencies of the gravest character. Exercising all the skill and care possible, he will meet with difficulties that will require mature judgment to overcome. I have found it necessary to ligate the jugular vein in two cases, and the

external artery in one. These cases presented no unusual features, except that the enlarged glands were closely adhered to the vessels by adhesions caused from peri-cellulitis, and could not be diagnosed before the incision was made. In the posterior triangle of the neck, if a tumor is large and with a tendency to grow downward, there is a considerable danger from direct infection through the apex of the lung. In one case, operated about three years ago, the gland had become quite large and pressed upon the lung in such a way as to produce a severe cough. The tumor was found to be attached to the pleura and subclavian artery and the several cords of the brachial plexus. A subsidence of the cough followed the removal of the tumor, what seemed to be an incipient tuberculosis was fully arrested, and the patient now enjoys perfect health.

There are some important points in the technique of these operations, that should be closely observed:

1. The incision through the integument should be large enough to expose the glands to be removed. By adhering to this rule, many of the accidents referred to will be obviated.

2. Never use a cutting instrument if it is possible to avoid it. One of the best instruments for the purpose is the plain curved scissors; the concavity fits nicely over the surface of the tumor and reduces the danger of injury to either the cyst or blood vessels to a minimum. The finger is also an efficient and intelligent dissector, to be used in preference to any other instrument, if space will admit of it.

3. If suppuration has taken place, the sac should be thoroughly curetted, removing if possible all the diseased tissues, and have the exposed surfaces wiped out with pure carbolic acid and then packed with iodoform gauze. There should be no effort to close the incision by sutures. Tubercle bacilli do not flourish in a dry place; therefore, the wound should be kept as free from secretions as possible. The dressings should be changed every second or third day.

4. If suppuration has not taken place and the glands can be removed without bursting the sac, the incision can be closed up without drainage.

5. It is highly necessary to remove all the glands that can be found in the region infected. The operator will often be surprised at the number affected, when he comes to make an examination directly through the wound. One small gland left, if infected, will defeat the result of the operation.

CONCLUSIONS.

1. Inflammatory diseases of the cervical lymphatic glands are frequent, and a common source of grave complications.

2. Simple adenitis should receive careful and prompt attention from the physician.

3. Constitutional treatment has no direct influence on these enlarged glands.

4. Irritating local applications are unsightly, painful and a frequent source of secondary infection from pathogenic microbes.

5. The tubercular form frequently leads to general tuberculosis and death, or chronic suppurating sinuses, that continue for years and eventually leave disfiguring scars.

6. The early removal of chronically enlarged glands or tubercular glands is followed by a greater immunity from a return than is the early removal of carcinoma.

7. The operation should be thorough, removing all the glands in the plexus that can be found.

SELECTIONS.

Significance of the Löffler Bacillus in Apparently Healthy Individuals.—Dr. P. Aaser, Christiania, relates in the *Deutsche Medicinische Wochenschrift* of May 30, 1895, that in the middle of June, 1894, a severe case of diphtheria occurred in certain cavalry barracks. The patient was removed to a hospital, the room was disinfected with soap and water and a 5 per cent. carbolic solution, and his clothing subjected to steam at 110 degrees C. June 20 and July 2, two other cases were found. They were isolated and the room again disinfected. Yet August 1 a fresh case appeared. All the men were then quartered in another room, fresh clothing furnished, then all the rooms were painted. The infected clothing was steamed each time. In spite of this, September 21 a case was discovered. At this point the suggestion was made to immunize all by antitoxin; lack of material prevented. But all in the barracks were then subjected to bacteriologic examination, and

out of eighty-nine persons, cultures of Löffler bacilli were obtained from the throats of seventeen. Here was a possible source for the spread of the disease. The seventeen suspects were at once isolated. On the next day one severe case of diphtheria developed and later two cases of tonsillitis. The health of the remainder was undisturbed apparently, but in each the mucous membrane of the throat was reddened and this persisted until it was no longer possible to demonstrate diphtheria bacilli, some three or four weeks.

Dr. Aasen has made investigations of this sort several times. In another instance a case of diphtheria developed in a scarlet fever pavilion. Examination showed bacilli of diphtheria in 20 per cent. of the children. Antitoxin was used in all. Nearly a month later one of these children, in whom the latest examination developed only very few bacilli, was allowed to go home. A few days only elapsed before two younger sisters were brought to the hospital with diphtheria. All other chances for this infection were eliminated.

An Unusual Source of Lead-Poisoning.—During my term of residence in the Manchester Royal Infirmary as house physician, a man (P. N.), 27 years of age, was brought to the accident room one day, as a case of acute intestinal obstruction, for immediate operation. As no very urgent symptoms were apparent, he was admitted to the medical wards, under Dr. Steell, to be under observation. The following morning the discovery of a very well-marked blue line on the gums cleared up the case, the diagnosis being lead-poisoning, with colic and constipation. The patient was pale, anemic and rather nervous in manner; he complained of severe pain in the abdomen, chiefly referred to the umbilical region, relieved somewhat on pressure. There was a history of constipation for some days, but the bowels were moved on the day following admission.

The patient rapidly improved under the administration of potassium iodid; colic and constipation disappeared, and he left the infirmary in nine days, feeling perfectly well. There were no signs of neuritis, except occasionally feeling of pins and needles in the feet, and numbness and coldness of the hands on washing with cold water. Knee jerks and plantar reflex, wrist jerks and triceps reaction were all readily obtained.

At first, no clue could be perceived as to the source of the lead in this case. The patient stated that he was a worker in a rubber factory, and questioning ultimately brought out the fact that he had been for some time in the habit of chewing portions of the soft unfinished rubber. He believed white lead and red lead were used in the process of manufacture of the rubber, but had not to handle these himself. He was asked to bring a specimen of the material he had been in the habit of chewing, and it turned out to be in the form of thin sheets of brownish-red rubber, about one-sixteenth of an inch thick.

On incinerating the rubber, much residue remained, which, dissolved in nitric acid, gave very abundantly the characteristic reactions for lead. When opportunity offered I made a more systematic examination, with the following results: the specific gravity of the rubber was 1.647, while, according to "Thorpe's Dictionary of Applied Chemistry," the specific gravity of pure caoutchouc is 0.925. A piece of the rubber 1 inch long and a half inch wide weighed about 13 grains, and on ignition and incineration left 51.55 per cent. of residue, consisting chiefly of sulphate and carbonate of lead, with iron, etc. Quantitative analysis revealed the presence of 23.57 per cent. of lead, calculated as metallic lead (Pb), which would correspond to 29.44 per cent. of white lead, calculated as $2\text{PbCO}_3 + \text{PbH}_2\text{O}_2$, or 27.62 per cent. red lead, calculated as Pb_3O_4 . This comparatively enormous quantity of lead would easily account for the symptoms of poisoning following the chewing of the rubber material. The patient was seen about twelve months after he had left the infirmary, and was then enjoying good health, but he still complained of weakness and cramps in his fingers after they had been in cold water.

I have to thank Dr. Steell for kind permission to report this case, which may be of some interest as pointing out a possible source of lead poisoning which I believe has not been hitherto suspected.—By FRANCIS J. H. COURTS, M.B., F. C.S., in *The Druggists Circular*, July, 1895.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 86 Fifth Avenue, Chicago.

SATURDAY, AUGUST 31, 1895.

THE VENOM OF SERPENTS.

From the childhood of the world, serpents have been objects of great interest to mankind, regarded with awe and worshiped. Indeed snake worship is to be found even at the present time and in our own country, as witness the "snake dance" of the Moqui Indians of Arizona. The fact that these animals can progress rapidly over the ground, climb trees and swim through the water without limbs probably accounts for some of the interest manifested in them; but it is as agencies of terrible death that they exert a peculiar fascination. Animals, the bites of whose insignificant fangs will cause the death of even "My Lord, the Elephant" in two hours, are surely of more than ordinary interest. It is their poisonous qualities, then, that most concern the medical man, since about one-third the known species of snakes are poisonous, and the mortality from snake bites amounts to several thousand a year—20,000 per annum in India alone—FAYRER. Even in France and Switzerland, of 433 persons bitten in twenty years by the European viper, 61 died, and in Germany the mortality of those bitten is 25 per cent.

A serpent's mouth is provided with three groups of glands; one, the inferior labial, is under the lower lip; another, the sublingual, under the tongue; the third the superior labial, in the cul-de-sac of the upper lip. From this last, in the venomous serpents alone is found a prolongation backward on each side, the glandula venenata, which secretes the poison and is of a whitish-yellow, contrasting with the rosy color of the ordinary glands. The venom glands differ in size in different species, but all agree in

having a reservoir, in which the venom may be stored for use, and a duct leading to the base of each fang. In the group of serpents containing the cobra da capello the fangs are permanently erect and fastened to the maxilla; in another, represented by our rattlesnakes, the fangs are depressed and can be raised by muscular contraction which turns the maxillæ and elevates the quadrate bones thus carrying the mandible away from the upper jaw and preventing the snake from biting itself. Rattlesnakes shed their fangs periodically and the small imperfect teeth in the back of the mouth move forward to be developed into the fangs, somewhat as in the sharks.

The chemic composition and physiologic action of snake venom seem to vary but little in different species and is practically identical, save for the intensity of its toxic effects. Fresh venom is a viscid, nearly tasteless fluid, ranging from light yellow to amber or even greenish-yellow in color and occasionally colorless; the specific gravity is from 1030 to 1046 and the reaction is acid. It sometimes happens that the alkanin secretion of the ordinary salivary glands is mixed with it, when it becomes neutral. When dried, venom presents itself as small, brilliant, yellowish-brown scales. Fresh or dried, it dissolves easily in hot or cold water, glycerin and dilute alcohol; it is insoluble and immediately precipitated in absolute alcohol, ether, ammonia, oils, etc.¹ In the dried state or in solution it seems to keep indefinitely. DR. WEIR MITCHELL kept a glycerin solution unchanged for twenty years.

As the venom gland is the homologue of a salivary gland, it is interesting to note that the earlier writers looked upon the venom as the saliva of serpents. In 1881 GAUTHIER announced that "the venom of serpents appears to me to differ from our saliva only in the intensity of its effects." This author and STERNBERG have been able to cause death in rabbits and pigeons by injecting human saliva. The chemic construction of ptyalin is very similar to that of venom, as may be seen from the following analysis:

	C.	H.	N.	Ash.
Ptyalin (Hüfner)	43.1	7.75	11.86	6.1
Cobra venom (Armstrong)	43.4	7.	12.45	traces.

The chemic composition of serpent venom seems to have been investigated for the first time in 1845 by PRINCE LUCIEN BONAPARTE. In 1886 WEIR MITCHELL and REICHERT² succeeded in extracting from cobra and rattlesnake venom, three substances with which they experimented on pigeons. These were: (a) peptone venom, but feebly active; (b) globulin venom, very active; (c) albumin venom, inactive. In the same year WOLFENDEN, in communicating the results of his studies of cobra venom, stated that he found four toxalbumins, to which he gave the names of globulin, serin, acid albumin and peptone. The

¹ Roux; Province Médicale, No. 13, 1895.

² Researches upon the Venoms of Poisonous Serpents.

last one is inactive and inconstant; the globulin is the most abundant and most active; and is an asphyxiant and paralyzant; the acid albumin has similar properties and the serin kills by ascending medullary paralysis. Lately PHISALIX and BERTRAND,³ investigating the venom of vipers, have separated a phlogogenous substance analogous to some diastases, and to which they give the name of *echidnose*; and a substance which they call *echidnotoxin*, having a systemic action capable of causing death by itself, acting violently on the nervous system—vasomotor disturbances. These authors brought venom to the boiling point for 20 to 25 seconds; it was then quickly cooled, when it was found that the local effects—caused by their *echidnose*—did not appear, while the general effects, due to their *echidnotoxin*, persisted and caused death, thus confirming KAUFMANN's opinion, 1890: "Venom probably contains two sorts of active principles, one producing local, the other general effects; the former is surely destroyed by permanganate of potash or chromic acid, while the toxicity of the other is only attenuated."

The amount of venom furnished by serpents varies with the species; *e. g.*, the European viper furnishes about .15 ctgm., the rattlesnake 1 gr. .50, the cobra 1 gr. .20 and even as much as 3 gms. in a very large specimen. CALMETTE has investigated the question of relative toxicity by experiments with the venom of serpents from different parts of the globe. Fresh venom was used from the cobra da capello, the rattlesnake, the fer-de-lance, the asp and the horned viper, and dried venom from five other species. All these venoms naturally present very different degrees of toxicity, but a more interesting fact is that the secretion of the same serpent varies in considerable proportions, according to the length of time it has fasted and, perhaps, other conditions at present unknown. M. CALMETTE kept an Egyptian asp for eight months during which period it refused all nourishment. When it first arrived, venom collected in a watch glass and dried in vacuo killed a rabbit weighing 1700 gr. in four hours in the dose of 0 mg. 7; at the end of eight months and before the animal's death, a rabbit of nearly 2 kilos weight was killed by 0 mg. 1. The same experiments were made on a cobra with similar results. A cobra which has not bitten anything for at least two months may furnish 220 milligrams of venom.⁴

Warm-blooded animals are more easily affected by snake venom—birds, especially, dying very rapidly; the bite of a large cobra is fatal to a fowl in one minute. Cold-blooded animals succumb less rapidly. It is interesting to note that in sea snakes, which are very poisonous and which live on fish, the venom has such a paralyzing effect that the fish die with the spiny fins depressed, thus allowing them to be

swallowed. The size of an animal seems to bear some relation to the fatal dose; for example, the bite of *Ophiophagus Elaps* of India and Burmah, the most poisonous serpent known, is fatal to man in three minutes, to an elephant in two hours. On the other hand, cats can resist a given quantity of the venom as long as dogs several times their size. CALMETTE⁵ has made some interesting studies in this direction, which he sums up as follows:

Serpent experiments.	Fatal dose in 45 minutes for a rabbit of 1 k. 600 to 2 k.	Fatal dose in 40 minutes for a guinea pig of 450 to 500 gms.
Cobra No. 1	0.5 milligr.	0.05 milligr.
Cobra No. 2	0.6 "	" "
Cobra No. 3	0.3 "	" "
Horned viper No. 4	0.7 "	0.07 "
Horned viper No. 5	0.3 "	" "
Horned viper No. 6	0.6 "	" "
Asp No. 7	1.5 "	0.1 "
Asp No. 8	2 "	" "
Rattlesnake No. 9	3.5 "	0.3 "
Banana snake No. 10	2.15 "	0.2 "
Broad-headed snake No. 11	2.5 "	" "
Death adder No. 12	1. "	0.08 "

"We see from this table," says CALMETTE, "that the respective resistances of the rabbit and guinea pig are in nowise proportioned to the animal's weight; thus, to kill 500 grams of rabbit, it took nearly twice as much venom as to kill 500 grams of guinea pig. The same held true of dogs; it took 6 mgs. of cobra venom No. 1 to kill a dog of 7 kilos in twelve hours, while the same quantity would kill twelve rabbits in three hours."

The principal cause of death after snake bite is paralysis of the heart or respiratory centers; cobra venom first irritates, then depresses, the respiratory center. Changes in the blood, though profound are not the cause, for, as BRENNING points out,⁶ frogs whose blood has been replaced by a 0.07 per cent. solution of sodium chlorid, have the same symptoms.

Therapeutic efforts for the relief of snake bite have been almost as numerous as the sands of the sea for number; they vary from the savage's invocation of his fetich, through amputation of the part and other heroic measures, to the resources of our modern materia medica.

The temperature limit at which the toxic power of venom is annihilated is from 80 to 100 degrees Centigrade. Heating to 38 degrees Centigrade for fifteen hours has no effect on the virulence. Carbolic acid, bichlorid of mercury (1 to 1000), sulphate of copper, nitrate of silver, iodine, alcohol have no action, either *in vitro* or in the organism, even if injected at the same time as the poison. Permanganate of potash, introduced by LACERDI of Rio de Janeiro in 1881, seems to neutralize the poison when mixed with ten parts of a 1 per cent. solution to one part of the venom. Chromic acid was recommended in 1888 by KAUFMANN. In 1891 CALMETTE endeavored to ascertain the real value of the permanganate and demonstrated that it is an excellent antidote—provided

³ Soc. de Biologie, Feb. 10, 1894.

⁴ Gaz. Med. de l'Algerie, No. 10, 1895.

⁵ Loc. cit.

⁶ Die Vergiftung bei Schlangen, 1895.

that it is exhibited immediately after the bite or experimental punctures and through the same openings. These conditions preclude it having much practical value. From theoretical considerations he was led to use chlorid of gold, and announced that this agent, "in sufficient quantities—ten drops of a 1 per cent. solution to one drop of the venom— injected into the tissues of an animal inoculated with a mortal dose of cobra venom, even away from the point of inoculation, prevents intoxication when done before symptoms of bulbar asphyxia are manifested."

This author, who is Director of the Bacteriological Laboratory at Saigon, Cochin China, also undertook experiments in order to produce artificial immunity. Three different methods were used: 1, successive inoculations of heated venom, then of virulent venom; 2, injection of mixtures of virulent venom with permanganate of potash or chlorid of gold; 3, ingestion of increasing doses of virulent venom. These results were absolutely negative at first, but during the course of his researches covering a period of some two years, he discovered that chlorid of calcium is the best chemic agent to use. For the immediate treatment of the wound a one-twelfth solution of the salt is preferable, diluted at the moment of use to one thirty-sixth; 20 to 30 c. c. of this dilute solution are injected into the wound direct and for a considerable distance around it. This substance, like the other alkalin hypochlorites, seems to owe its efficiency, without injurious action on the tissues, to the liberation of hydrochlorous acid. Two cases have been recently reported of successful results from this treatment following bites by the brown-banded snake of Australia, the most dangerous reptile of that country.

In 1888 F. A. PERROUX, of Calcutta, addressed a "confidential memorandum" to the Department of State in which it was asserted, with much circumstantiality of detail, that "Asiatic cholera is certainly cured by the inoculation of cobra venom," and that this inoculation is practiced only in India where it is "jealously guarded as a precious secret" by the few who are familiar with it. This memorandum was referred through the Secretary of the Treasury to DR. JOHN B. HAMILTON, then Surgeon-General of the U. S. Marine-Hospital Service, who, while pointing out the inherent improbability of the claim, agreed to submit the cobra poison, if a specimen could be obtained, to an investigation as to its germicidal property by application to the different bacteria and especially to the comma bacillus. Two collections of the venom—one from four and the other from fourteen live cobras—being received from MR. PERROUX, they were exhaustively experimented upon by Assistant Surgeon J. J. KINYOUN at the U. S. Marine-Hospital Laboratory in New York harbor. The conclusions drawn from DR. KINYOUN'S elaborate

report to Surgeon-General HAMILTON, and indorsed by the latter, are: 1, cobra venom is germicidal to the cholera spirillum in a three-fourths per cent. solution; 2, there is no antagonism between the cobra venom and the poison (toxin) of the spirillum of cholera; 3, the venom does not prevent the coagulation of blood; 4, when the two poisons are administered together, or the cholera poison followed by the cobra venom, the toxic effects of cholera are intensified.⁷

In the latter part of 1893 MM. PHISALIX and BERTRAND created a new epoch in the history of serpent venoms by their announcement to the Paris Biological Society that their researches show that there exist in viper's blood, principles similar to venom, with great physiologic activity—2 c.c. of its serum being capable of killing a guinea pig of 480 grams, and that this is to be considered as the reason for the immunity of the viper to its own venom. In February, 1894, they announced that by heating viper venom with certain precautions, they gave it certain vaccinal properties and transformed it into *echidno-vaccin*. This does not confer immediate immunity—it takes a certain length of time, during which the *echidno-vaccin* leads to the formation of an antitoxic substance in the blood, capable of attenuating or even completely neutralizing the toxic properties of the venom. Thus, while 0 mgm. .3 of venom, diluted with 3 c.c. of serum from an animal previously inoculated, injected into a guinea pig of 380 gms. only caused some insignificant symptoms which rapidly disappeared, 0 mgm. .15 of normal venom kills a guinea pig of 500 gms. in less than twelve hours.

At the same meeting of the Biological Society CALMETTE also announced a means of securing immunity against snake-bite which, according to this author, may be accomplished in four ways: 1, by the use of increasing doses of diluted venom—not recommended; 2, by the use of large doses of the venom followed by chlorid of calcium or the alkalin hypochlorites; 3, by repeated injections of mixtures of mortal doses of venom with decreasing doses of gold chlorid or, better of hypochlorite of calcium or soda; 4, by injections of 6 to 8 c.c. of hypochlorite of calcium to one-sixtieth, repeated four or five days in succession—rabbits are thus rendered insusceptible to twice the fatal dose,

FRASER⁸ has confirmed these ideas of immunity very recently, and it seems that fresh triumphs are in store for serotherapy. It is probable as ROUX⁹ suggests, that the serum of animals which seem to be naturally immune, such as the hog and the hedgehog, will be productive of even better results.

MEDICAL SUPERINTENDENTS FOR PUBLIC INSTITUTIONS.

A daily Chicago paper, editorially commenting upon a proposed reform of the medical institutions of the county, gives utterance to the following: "The medical profession ought to be debarred from the business management of every public institution and every public department, but it should be made suprême in the medical portion of each public institution and every public department requiring its coöperation."

The first part of this quotation is the expression of a delusion that has apparently a strong hold of the professional politician, whose business capacities are not, to judge by the usual results of his administration of public affairs, the most brilliant; and the second part is theoretically and practically an absolute negation of the first.

How is the medical profession to be debarred from all part in the business management of an institution or department and yet be made suprême in the medical portion of every department requiring its coöperation? Experience has not demonstrated the success of divided authority in medical establishments and hospitals, and their exclusive lay management has everywhere and at all times made a record of maladministration and abuse. Medical supremacy, it must be understood, implies necessarily more than the mere doling out of drugs, and the nursing and medical care of the patients; it includes the general sanitation, the inspection of supplies, the direction of construction and repairs, the regulation of the lighting, heating, and water supply, and a host of other details that can not be safely intrusted to any one not fully acquainted with, and fully in accord with, the direct and ultimate objects of the institution. It would be as correct to say that the paymaster of a man-of-war should be suprême over the captain and the admiral, as to claim preëminence for a "business" man without professional qualifications in a hospital, or, more especially, an asylum. As long as the administrative department is in full accord with the medical, and recognizes its right to dictate on all matters even remotely pertaining to the proper functions of the establishment, there may be no gross mismanagement, but human nature seldom furnishes all the requirements for this state of affairs, and it is easy to see how, without this, lay supremacy in purely medical institutions can only lead to mismanagement and abuses.

This is the plain, common sense view in the case, and it ought to require no illustrations of its truth to the average citizen who gives it any consideration whatever. If illustrations are wanted, however, they can be had in abundance, and opposing facts are absolutely wanting. Every medical establishment in the world that is worthy of being cited as a model is such, only so far as it is under absolute medical

authority. In successful general hospitals the word of the clinical staff is law to the administration, and the only asylums in the country that are worthy of the name, or that are not a reproach to the communities that support them, are under exclusive medical control.

Even the most sacred obligations of religion are no security against abuses, as was shown in the recent *exposé* of the Mariaburg Asylum in Prussia, which, it is to be hoped, will have some effect in counteracting the agitation that is being made in Germany in favor of placing asylums under lay (clerical) control. Ecclesiastics and business men are alike unfitted to have chief charge of institutions for the care of the invalid and the insane; the medical authority should be suprême. Any other arrangement is abnormal, and while it may be accepted for want of a better one, and while in some rare instances, by reason of the good judgment of the layman in charge and his practical recognition of the superior authority of the physician in all matters of medical importance, it may possibly not work actual disaster, this must be taken only as a happy accident which experience shows to be of rare occurrence.

The State of Illinois tried for years in its medical charities the system of a divided responsibility, but was forced to abandon it, and the reasons why the chief control of such institutions should be medical are logically stated in the following quotation from a special report of the State Board of Charities on one of the Cook County institutions in 1886:

"The reason why a medical man should be at the head of this hospital, rather than a business man, is that, in a medical institution every question to be decided has a medical bearing, which a non-medical man may not perceive, and the final word on every subject should be spoken by the physician from which there should be no appeal."

The fiction that physicians are not good business men has certainly no such excuse as could be afforded by the experience of Cook County with lay heads of its medical institutions.

Another point is, that the alleged "business" men are seldom anything more than mere politicians who have failed in every private business, and many times have failed even in politics to command a sufficient following to cause their return to elective positions.

OMPHALOPSYCHISM, OR FAITH HEALING, MODERN AND ANCIENT.

The *Lancet* is interested in some mild cases of mind-cure that has obtained a tentative foothold on the shores of Albion. We quote below a portion of a well-written annotation, in the issue of that journal for August 10, in the course of which the editorial writer demands that a law be passed, in England,

which will prevent the experiments of faith-healers being tried upon the persons of helpless children. This is a practical view that may properly be taken, even in this land of free-and-easy habits of thought, in the handling of quackery and superstitions. The American mind tolerates too easily the various phases of crankism; and no doubt lives are lost in that manner, especially in the cases of children and other feeble dependents. The *Lancet* says: "An inquest was recently held upon the body of a girl aged 17, who died in Brixton of acute tuberculosis and peritonitis from a perforating gastric ulcer, having been very ill since last Easter. She had no medical advice because, according to the evidence of the woman in whose house she stayed, 'she trusted in the Lord to heal her without medical aid.' It is useless to point out to people of this cast of mind the falsity of their theological reasoning, but we do think that the Legislature, which takes care to prevent people jumping off the monument or going on ice too thin to bear their weight, might step in and prevent peculiar people and faith-healers from murdering their children by neglect. We should be the last to deny the power of faith, but, as a recognized authority says, 'faith without works is dead,' and it is a canon of theology that the Almighty works by means, and those means humanity is bound to use. The *New Science Review* for July contains an article entitled 'Has Mental Healing any Scientific Basis?' The teaching of this article appears to be that there is a broad field for 'auto-suggestion and systematic concentration with happy results.' The way and means to become properly auto-suggestive is as follows: You say mentally to yourself—even mechanically at first—until the habit is formed, 'I [the real ego] am well. I am strong. I am pure. I am perfect. I am one with the Divine Spirit of Wholeness.' The next step is, 'To insure progress, special times and seasons should be set apart for the focalized thought and affirmation. . . . At times when the objective world, with all its cares and anxieties, may conveniently be barred out, the full glare of the consciousness is turned upon the Divine ideal within, which thereby gradually becomes graphic and ruling.' It is evidently quite easy to become a mental healer, but we seem to remember that this process is not new. There was once a sect in the Eastern Church called the Omphalopsuchoi, who by steadily gazing at their navels were at length rewarded by a sight of the light (created or uncreated) which shone at the Transfiguration. This method, we suppose, is what Mr. Henry Wood, the writer of the article in question, calls 'keeping company with his inner ideal.' However, he does not seem to have much faith in the process he recommends, for he concludes: 'As related to illness, prevention is the end to be sought, so that in time cures may be unnecessary.' If any one

by 'keeping company with his inner ideal' can cure a gastric ulcer he would be a most valuable addition to our present therapeutic agents."

THE BENEFICENT MICROBE.

In his presidential address before the British Medical Association, DR. RUSSELL REYNOLDS calls attention to the "gradually increasing appreciation of the fact" that the lower forms of life that we include under the general head of microbes, and to which it is the popular fashion nowadays to refer all manner of disease, are not altogether mischievous in the influences they exert on the human economy, but are, on the contrary, often beneficial. Though this is no new medical view, its statement under such circumstances by so high an authority at this time has a certain significance. It is a recognition of a truth that is becoming more and more evident, that we only know as yet a small part of the beneficent functions of these bodies, and that even the maleficent ones may have their uses to mankind. DR. REYNOLDS goes at some length into the subject of immunization as indicating this utility and alludes to the long-known facts that bacteria are useful and probably essential in many of the healthy processes taking place in the human body. It has been taken for granted as a fact in physiology that they have their part in digestion, and it seems to be established that they are under certain conditions essential in the life of some higher vegetable types, and in other instances, as in the case of the normal vaginal bacillus, they seem to exercise a directly protective influence. These facts are known to medical men, but in these days of popular "microbe killers," and with the general tendency of the public to absorb a little medical knowledge to its own hurt, a little reiteration and consideration of them may not be altogether a bad thing.

Even the pathogenic bacteria may have their uses in causing a constant and general immunizing process in human populations. Probably, with less frequency of these occurrences and a less general distribution they would be far more virulent when they did attack the system—the fatality of measles and other comparatively harmless infections of civilization among savages, the extra virulence of new epidemics and the occasionally observed proportional mildness of the same disease after it has become common, quite apart from the selective process that might be assumed were the disorders always self-protective or fatal, all point in this direction. While, therefore, there are many of these organisms which mankind could well dispense with, were that possible in any absolute sense, it may be that we are gradually getting better off as regards their influence by their very frequency. Pathologic familiarity may breed a physiologic contempt.

These are only suggestions, and may not be necessarily accepted, but they are permissible ones in the present state of our knowledge, which is still largely in the suggestive phase.

NOTICE TO OUR READERS.

We have been informed that some person to the JOURNAL unknown, is traveling in New York pretending to represent this publication. We have no traveling agents, and no credence should be given any such party—and we *once more* advise that no money be paid to any person on account of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION. Payments of whatever character should be made to the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION and to no other person whatsoever. Checks or drafts in payment of annual subscription to the ASSOCIATION (membership dues) should be made payable to HENRY P. NEWMAN, M.D., Treasurer.

Canvassers for subscribers to the JOURNAL are not authorized to receive money, and all canvassers are furnished with written authority to solicit subscriptions.

CORRESPONDENCE.

Is After the Reviewer.

3910 WALNUT ST., PHILADELPHIA, Aug. 26, 1895.

To the Editor:—In our JOURNAL for the 17th inst., appears a notice of the third volume of the "Twentieth Century Practice of Medicine," in which I am charged with "looseness in the manner of quotation" in my section on the Diseases of Occupations. The charge is based, so well as I can understand it, upon the alleged fact that in quoting a passage from Patissier I did not give credit to the real author and that I ascribed sentiments to Patissier which he did not express.

The exact facts are as follows:

Patissier, a French author, in his *Traité des Maladies des Artisans* (Paris, 1822) page 196, writing of pastry-cooks, says that Cadet-Gassicourt said that these workmen are less debauched than bakers and more gentle and more sociable. Patissier does not include this statement from Cadet-Gassicourt in quotation marks, nor give the reference to the original. He evidently adopts the opinion as his own, else he would not take the care to incorporate it without quotation marks in his own text.

In my article, page 312 (not 512 as your reviewer erroneously has it) I wrote as follows: "As an example of Patissier's method and acumen the following may serve: 'Pastry-cooks,' he quotes, 'are less debauched than bakers, and more gentle and more sociable.' He thinks he sees in pie-dough a mysterious influence that renders a man more sweet and companionable than his fellow who makes bread."

It is to be observed here that I do not say that Patissier *said* so-and-so, but that he *quotes* it. As he does not give the reference to the original, but adopts the statement as his own without noting its rank absurdity, I do not see how I have misrepresented him in concluding that he thinks he sees some mysterious influence in pie-dough. On the contrary, I think that I had a perfect right to nail this on Patissier, and to point out that "this extravagant induction" (not deduction, as your reviewer misquotes me) "is on a par with much that has been and is still being written" (not *still is being*, as

your reviewer misquotes me again) "on the influence of occupation on health."

I submit that your reviewer has made a rather serious charge against me on a rather slight foundation, and that he himself is careless in his quotations. Kindly publish this and oblige,

Yours very truly,

JAS. HENDRIE LLOYD.

ANSWER:—The statement made in the review is not invalidated by calling the reviewer "another." It was Cadet-Gassicourt, and not Patissier, who made the statement mentioned, and as he made no comment upon it, there is no evidence that he approved or disapproved it.

Treatment of Typhoid Fever.

GRAND RAPIDS, MICH., Aug. 10, 1895.

To the Editor:—I have just been reading Dr. Woodbridge's article, read at Baltimore, giving quotations from my letters. I notice one mistake. In one of the aborted cases the types read that *four* grains of quinin were given in twelve hours. It should have read *forty* grains. The object I had in mentioning the quinin at all was to show that a large dose had no effect in the fever, and that the medicine did, after the quinin failed to abort the disease.

I have had no typhoid cases this year but have had the druggist put in a stock of Parke, Davis & Co.'s "Woodbridge" treatments and will try the new formula upon the first suspicious case that presents. Sincerely yours,

W. T. DODGE.

What the Code Is.

ORAN, MO., Aug. 26, 1895.

To the Editor:—If allowed space I will make a brief reply to Amicus Veritatis.

To *believers* in the Code, medicine is a *profession*; to non-believers it is used as a *trade*. The Code was written for the benefit of believers and in condemnation of unbelievers and their practices. Any argument on the question should be addressed to believers. To them the Code is effective and has penalties for its violation—but to the unbeliever it is a dead letter. Very respectfully submitted,

W. P. HOWLE, M.D.

A Poser.

SAN JOSE, CAL., Aug. 19, 1895.

To the Editor:—If you have the information at command will you be kind enough to publish, for the information of the readers of the JOURNAL, a list of all countries on the globe in which the medical profession of same are governed by a written code of ethics? Yours truly,

A. C. SIMONTON, M.D.

SOCIETY NEWS.

The Tri-State Medical Society.—The autumnal meeting of this society will be held in Des Moines, Iowa, October 1 to 3. Dr. Howard A. Kelly, of Baltimore, Md., will deliver the Address on Gynecology and hold a clinic; Dr. Sanger Brown, of Chicago, will deliver the Address on Medicine; Dr. Nicholas Senn, of Chicago, will endeavor to be present and will conduct a clinic. Papers have been promised from leading physicians of Illinois, Iowa and Missouri. The meeting promises to be a great success. If there are other physicians who wish to contribute to the program, kindly notify the secretary,
FRANK P. NORNURY, M. D.,
1006 Olive Street, St. Louis, Mo.

Steuben Co. (Ind.) Medical Society.—The thirty-fourth annual meeting of the Steuben County (Ind.) Medical Society was held at the Court House, Angola, Ind., Aug. 23, 1895. The following papers were read: The Medical Man, F. B.

Humphreys, Fremont, Ind.; Rheumatism, D. W. Fenton, Reading, Mich.; Modern Therapeutics, T. J. Creel, Angola, Ind.; Some of the Diseases Incident to the Summer Months, T. F. Wood, Angola, Ind.; Hernia, W. H. Myer, Fort Wayne, Ind.; Dislocation of the Shoulder Joint Complicated with Fracture of the Upper Third of the Humerus, C. B. Stemen, Fort Wayne, Ind.; The Treatment of Retro-deviations of the Uterus, C. N. Smith, Toledo, Ohio; Etiology and Treatment of Granular Conjunctivitis, A. E. Bulson, Fort Wayne, Ind.; A Few Thoughts on Strychnia, G. W. McCaskey, Fort Wayne, Ind. A forenoon, afternoon and evening session was held, together with a banquet at Hotel Hendry in the evening. T. J. CREEL, Secretary.

American Dermatological Association.—Program of the nineteenth annual meeting to be held at the Windsor Hotel, Montreal, Canada, Sept. 17, 18 and 19, 1895:

Scientific Session (open meeting) at 10:30 A. M.: Address by the President, S. Sherwell; Angiokeratoma of the Scrotum, Raynaud's Disease of the Ears. Report of Cases, by J. A. Fordyce; Two Cases of Hydroa Vacciniforme, by J. E. Graham; Two Cases of Bromide Eruption, by G. T. Jackson.

Scientific Session at 3 P. M.: The Value and Limits of Usefulness of Electrolysis in Dermatology. General Discussion: Dermatologic Notes, by W. A. Hardaway; The Epithelial Layer of the Epidermis and Its Relationship to Ichthyosis Congenita, by J. T. Bowen.

Second Day, Scientific Session at 10:30 A. M.: Remarkable Drug Eruption, by F. J. Shepherd; A Hitherto Undescribed Sequel of Non-Parasitic Syphilis, by J. A. Cantrell and J. F. Schamberg; The Infected Scratch and its Relations to Impetigo and Ecthyma, by H. G. Klotz; A Contribution to the Study of Mycetozoa, by J. N. Hyde.

Afternoon Session at 3 P. M.: Unusual Papulo-Pustular and Fungating Bromid of Potash Eruption in a Baby (illustrated), by G. T. Elliot; An Etiologic Puzzle, by J. C. White; Studies on some Dermatologic Subjects, by A. R. Robinson.

Third Day, Thursday, Sept. 19, Morning Session at 9:30 A. M.: A Unique Case of Agminate Folliculitis of Parasitic Origin, by M. B. Hartzell; Note on Antiparasitic Treatment of Eczema, by J. Zeisler; The Treatment of Erysipelas based upon a Second Series of Fifty Cases, by C. W. Allen; Notes on Drug Eruptions, by J. A. Fordyce; A Further Study of Alopecia Prematura and its most frequent Cause, by G. T. Elliot.

Afternoon Session at 3 P. M.: The Prevalence of Germ Dermatoses, by J. C. White; Symbiosis of Cutaneous Eruptions, by J. Zeisler; Sleep in Its Relation to Diseases of the Skin, by L. D. Bulkley; Exhibition of Photographs of Unusual Cases, by H. W. Stelwagon; Urticaria Pigmentosa—Case Twenty Years Under Observation, by P. A. Morrow; Note on the Elastic Circular Bandage, by G. H. Fox.

Officers for 1895: S. Sherwell, President, Brooklyn; J. A. Fordyce, Vice-President, New York; C. W. Allen, Secretary and Treasurer, New York.

BOOK NOTICES.

Jahrbuch der Practischen Medicin, edited by Dr. J. SCHWALBE. Pp. 666. Stuttgart: Ferdinand Enke. 1895.

With the large amount of literature which appears annually in each department of medicine, it is impossible for the average reader to keep posted upon the whole field by means of the current periodicals. By the publication of annual volumes which briefly cover the whole ground, it becomes comparatively easy for the student in special departments of medicine as well as the general practitioner to become intelligently acquainted with the progress which is being made throughout the whole domain of medicine, without excessive effort or waste of time. Of books of this character the one under consideration is an excellent example. The contents are arranged under thirteen chapters, which are given the following headings: General Pathology and Pathologic Anatomy; Internal Medicine; Surgery; Obstetrics and Gynecology; Diseases of the Eye and Ear; Diseases of the Nose, Throat, Mouth and Larynx; Skin and Venereal Diseases; Pediatrics; Climatology and Balneology; Materia Medica and Toxicology; Legal Medicine and

Public Health. Each of these general topics is dealt with by a sub-editor who is particularly fitted to review the literature of his own department. The contents of each chapter are arranged under systematic subdivisions so that one may readily refer to any part desired. In each instance the most important papers of the year are briefly reviewed and only the valuable facts to be gained from them are stated and in a concise manner. The reference to the original articles is given in the text, avoiding any necessity of referring to foot notes or a system of numbers.

The references to German literature are quite complete, and fairly full references are given to the French. It is noticed that there is no mention of some valuable articles by American writers which have appeared during the year. At the end of each chapter is a list of text-books bearing on the subject, which have been issued during the year.

PUBLIC HEALTH.

Hygiene of the Teeth.—In a communication to the Berlin Medical Society, Dr. Ritter reported that after having examined the teeth of 637 persons, more than half of whom were under 15 years of age, he found only 4 with sound teeth. On this basis the number of individuals with their teeth in good condition is only about 6.2 per 1000, which shows how necessary is a scrupulous hygiene of the mouth and teeth.¹

Wrapping Paper for Articles of Food.—The city of Montpellier is said to be the first in France to adopt regulations concerning the kind of paper to be used for wrapping up articles of food. By a municipal decree, in force for some months, the use of colored paper is absolutely forbidden. Printed paper and old manuscript may only be used for dried vegetables, roots and tubers. For other articles of food, new paper either white or straw-colored, must be used.²

Three New Cases of Actinomycosis.—Professor Poncet, of Lyons, has pointed out that actinomycosis is somewhat frequent in the region around that city. Dr. Meunier, of Tours, shows that it is not rare in Touraine, for he reports three cases all of which were at first diagnosed as alveolar abscesses. The microscope corrected this diagnosis and iodid of potash effected a speedy cure of the local lesions, which in one case at least had assumed a very grave appearance.³

Variola in Marseilles.—According to statistics furnished by Professor Proust there were during the first six months of 1895, 175 deaths from smallpox in the city of Marseilles. The city has 406,000 inhabitants, hence there were 4 deaths to each 10,000 of population. During the same period, Paris, with a population of 2,424,000, had only 10 deaths, or 0.04 per 10,000, according to N. Martin. In Paris, vaccination and re-vaccination are regularly and seriously carried out; in Marseilles, however, it seems either that the system of vaccination is defective or that the cosmopolitan population refuses to take advantage of the means of protection offered by the authorities against a disease which should claim only exceptional victims. The mayor of Marseilles is a medical man, Dr. Flaissieres, and as our contemporary⁴ remarks, it is to be hoped he will be able to overcome this state of affairs.

Epidemic Spread of Cholera in Japan.—Much anxiety is felt in Japan lest the cholera scourge extend throughout that country, notwithstanding the efforts made by the sanitary officials. The *Japan Gazette*, August 1, published in Yokohama, has the following paragraph compiled from facts given by native authorities:

"Fears are entertained in some quarters that this year may

¹ Jour. d. Hygiene, July 25, 1895.

² Jour. de Med. de Bordeaux.

³ Le Progres Medical, 1895, No. 29.

⁴ Le Progres Medical, 1895, No. 29.

prove one of the most calamitous Japan has witnessed for many years past. To begin with, cholera broke out in the country early in the year, slowly but steadily working its way even to the remote corners of the Empire. Though stringent precautionary measures are taken by the authorities, and the exceptionally cool weather has been prevailing, and the malady has so far been prevented from general spread in a city like Tokyo, we are still in the middle of summer, and the worst may yet be brought about. In Osaka, Hiroshima, and other western cities, the disease shows no signs of abatement. The official report to hand puts the total fatalities from cholera up to the 28th, noon, at 6,592. This is by no means a small figure, though it is small compared with that in 1883 and the year following."

Tubercle Bacilli in Butter.—Roth of Geneva, after demonstrating the frequency of the bacillus of tuberculosis in milk, relates¹ his experiments with cooking such infected milk—from which it appears that a simple ebullition destroys the virulence of milk drawn from cows with sore udders and shown to be very infectious by inoculations on other animals. So far as butter is concerned, cooking changes its taste too much to be used as a means of prevention. Nevertheless, as Rang had already demonstrated, Roth proves that the cream and butter of milk from cows with tuberculous udders will infect guinea pigs; with some samples of butter sold in the market he infected two out of twenty and Broferro has infected one in nine. Unfortunately, there is no method of promptly recognizing the bacillus in butter. Cream may be sterilized by successive boilings, but butter so treated has a somewhat strong taste which, however, disappears after keeping for some time. Butter which is very carefully and thoroughly washed is less liable to be infected and, moreover, it keeps better and for a longer time. Infected milk may also be sterilized by cooking and the butter made from it will be good, though the quantity will be smaller. The most effectual means of preventing the tubercle bacilli in butter is an early diagnosis of infected cattle and their prompt destruction.

Disinfection of the Rooms of Tuberculous Patients.—At a recent séance of the Paris Academy of Medicine,² M. Landouzy presented the results of some important experimental researches into the infectiousness of the dust of rooms of tuberculous patients after disinfection, undertaken by Dr. Lalesque, of Arcachon, and M. Rivière, of the Bordeaux Faculty of Medicine. The conclusions of the authors, which confirm those of Cornet and Kirchner, are founded on results obtained by inoculating 70 guinea pigs in the cellular tissue of the thigh with dust taken from rooms inhabited by consumptives with purulent expectoration and after the rooms had been disinfected. The disinfection consisted in placing all hangings, carpets, etc., in a Geneste-Herscher stove, wiping walls and furniture repeatedly with cloths soaked in 1 to 1000 sublimate solution, washing the woodwork with boiling water and then with sublimate solution. The dust for the inoculations was collected from places cleaned with difficulty, such as tables, around the bed and chimney, in corners, cracks in the floor, joints between hearth-tiles, etc. Of the 70 animals inoculated, 57 lived and 13 succumbed to septicemia or tetanus within a few days. When the 57 were killed in from 40 to 45 days, none of the organs showed a trace of any tuberculous lesions whatsoever. MM. Lalesque and Rivière conclude from their experiments, which were made on a much larger scale than those of Cornet and Kirchner, that the measures for cleansing and disinfection, as practiced at Arcachon in localities occupied by tuberculous patients, are perfectly efficacious and suffice to prevent contagion of tuberculosis from the air of such disinfected localities.

Medical Climatology of Chili.—Chili, which is one of the most thickly populated countries of South America for its size—751,216 sq. kilom.—has the shape of a long, narrow strip, 3,000 miles long, washed by the Pacific and bounded by the Argentine Republic, Peru and Bolivia. On the east are very

high peaks, among them Aconcaqua, with numerous spurs; on the west the Coast Range. Between these mountain chains is the central valley. A great part of the country is rainless and arid, especially in the north. The guano industry is highly developed here. In other regions, rains are abundant and heavy and agriculture is successful. The climate, on the whole, may be said to be agreeable and the mean temperature varies between 10 and 18 degrees C. The temperature record of the four principal cities is as follows:

	Santiago	Copiapo	Talca	Puerto Mont
Winter	7.80°	18.0°	7.88°	8.44°
Spring	13.06°	17.78°	14.42°	11.72°
Summer	18.47°	22.69°	11.43°	11.43°
Autumn	12.68°	17.18°	14.01°	11.95°

The population, including 50,000 nomad Indians in the south, is estimated at 2,958,418, of which 42 per cent. is urban. The annual increment is about 45,000. The annual mortality shows the following oscillations: 1849-1875, 26.3 deaths per 1,000, or 1 for each 1,000 inhabitants; 1876-1885, 21.7 deaths per 1,000, or 1 for each 40 inhabitants; 1886-1889 30.3 deaths per 1,000, or 1 for each 34 inhabitants. The Chilian hygienists attribute this large mortality to a number of causes—absence of good drinking water; want of proper means of disposing of the filth, which impregnates the soil; the action of the marshes, which are produced by the inundations of the Biobio; the damp, cold atmosphere; the dampness of the houses, which are built in earth, etc. It is interesting to note that some departments which are close to the Biobio River have a high mortality—Talcahuano, 1 in 23—while others at a distance from that stream are among the healthiest in the country—Coelemu, 1 in 63. The morbidity is chiefly caused by tuberculosis, variola—in 1892 the deaths from variola were 6,012; while tuberculosis represents 25 per cent. of the general mortality—scarlatina, syphilis, erysipelas, influenza, enteric fever, cardiac lesions, alcoholism, and the *tepidias* of summer, cholera. Goitre is observed among the inhabitants of the Coast Range at the sources of the streams, but it is not frequent. Among endemic diseases may be mentioned measles, dysentery and hepatic disorders. Santiago, the capital, 1,755 feet above the level of the sea, has a population of about 240,000. The climate is said to be one of the most agreeable in the world and its skies the most beautiful. The system of sewers is still incomplete and leaves much to be desired from a hygienic standpoint. The inhabitants of the province of Santiago suffer from intense variations of electric tension. The electrometer in the same day changes many times, passing from positive to negative, which is exceedingly rare in any climate so far known. Immigration to Chili is small. According to a late census, there are 5,625 foreigners in the province of Santiago, 5,000 of whom live in the city. Valparaiso, with a population of 130,000, is the most important seaport. Part of the town is built on a long strip of land between the Coast Range and the sea, and another part climbs up between the mountains, which gives the town a very singular appearance, especially at night. The hygiene is bad, by reason of a considerable part of the population being crowded together along the shore, with the consequent pollution of the soil due to want of means for disposing of the filth and also by reason of insufficient drinking water. Alcoholism is the curse of the town. In 1894 the police arrested 23,000 persons for drunkenness.¹

Health Reports.—The following health reports have been received in the office of the Supervising Surgeon-General Marine-Hospital Service:

SMALLPOX—UNITED STATES.

Arizona: Arivaca, August 15, 5 cases; Nogales, August 15, 2 cases.

Illinois: Chicago, July 1 to 31, 3 deaths.

Louisiana: New Orleans, August 10 to 17, 8 cases, 1 death.

Tennessee: Cow Island, July 15 to August 14, 16 cases; Memphis, July 15 to August 14, 8 cases.

Texas: Eagle Pass, August 21 to 23, 8 cases, 5 deaths.

SMALLPOX—FOREIGN.

Dublin: August 3 to 10, 5 cases.

¹ Jour. d' Hygiene, July 25, 1895.

¹ Les Nouveaux Remedes, July 24, 1895.

² Bulletin Acad. de Med., July 23, 1895.

Buda Pesth: July 29 to August 5, 1 case.
 Calcutta: July 6 to 13, 4 deaths.
 Glasgow: August 3 to 10, 3 cases.
 Guayaquil: July 26 to August 7, 3 deaths.
 London: August 3 to 10, 3 deaths.
 Madrid: July 28 to August 5, 5 deaths.
 Montevideo: July 13 to 20, 2 cases.
 Rio de Janeiro: June 22 to 29, 25 deaths.
 St. Petersburg: July 27 to August 3, 1 case.
 Warsaw: July 27 to August 3, 1 death.

CHOLERA—FOREIGN.

India: Calcutta, July 6 to 13, 29 deaths.
 Japan: Nagasaki, July 16 to 23, 19 cases 15 deaths; Yokohama, July 12 to 26, 13 cases, 11 deaths.

YELLOW FEVER—FOREIGN.

Cuba: Havana, August 8 to 15, 75 cases, 27 deaths; Santiago, August 10 to 17, 34 deaths.
 Brazil: Rio de Janeiro, June 22 to 29, 21 deaths.
 Mexico: Vera Cruz, August 8 to 15, 9 deaths.

NECROLOGY.

GEORGE KEATING DYAS, M.D., of Chicago, August 24. He had been afflicted with tuberculosis since last March and during the last two months was confined to his home. Dr. Dyas was a son of the late Dr. William Godfrey Dyas, who was killed by a railroad accident at Park Manor last February, and was 59 years old. He was born at Rathangan, County Kildare, Ireland. At the age of 17 he came to this country. At the breaking out of the civil war he entered the Southern army as a private and rose to the rank of lieutenant. Soon after the close of the war he studied medicine at the Chicago Medical College and was admitted to his profession in this city.

MISCELLANY.

Quintuple Birth in the Dominion.—The Associated Press has received a dispatch from Charlotte, P. E. I., which says Mrs. Alexander Campbell, of Montague, gave birth to five daughters on July 28. Her husband is a tailor and is in his eighty-fourth year.

To Abort Erysipelas.—Bar-iodo-potassic-arsenite.—A medical student in the University of the South, Mr. W. E. DeLong, sends the JOURNAL a letter in which he says that by the hypodermic use of this agent, he is able to abort erysipelas, by destroying the streptococcus. The same result is claimed by him, when the medicine is administered internally.

Burial of a "Weighty" Man.—A butcher named Brissollier, who died recently at Mondeville, near Caen, in Normandy, had reached the extraordinary weight of 251 kilograms. It was necessary to use great precautions in order to prevent accident with the bier, which weighed about 300 kilos. The coffin was 2 meters long, 1 m. .05 high and 85 centimeters wide, and had to be lowered into the grave by the aid of very strong pulleys. All the persons at the funeral were heavily impressed, says our exchange.¹

Change in the Wisconsin Pharmacy Law.—The Wisconsin pharmacy law was almost entirely rewritten, and considerably changed, in a statute passed by the Legislature at its session, relating to the practice of pharmacy, the licensing of persons to carry on such practice, and the sale of poisons in the State, the changes made showing an intention to improve the State law on these subjects and make same more efficient in many respects.

Liability of Volunteer in Providing Surgical Services.—Where one, as a volunteer, undertakes to provide necessary surgical services for another, he can not be held liable in damages for the negligence or malpractice of such surgeon as he

summons, the Supreme Court of Nebraska holds (Chicago, B. & Q. R. Co., v. Howard, decided June 21, 1895,) provided such surgeon possesses the knowledge and skill ordinarily possessed by other surgeons, and the employer had no reason to suspect that such surgeon would neglect or fail to use his knowledge and skill to the advantage of his patient.

How Doctors' Fees are Collected in France.—Dr. C. had attended a "young person" who was recommended to him by a Mr. D. Failing to receive his fee from either the "young person" or Mr. D., he wrote to the wife of the latter, stating the circumstance and advising that she see the bill paid to avoid scandal. Receiving no reply, Dr. C. sued for the amount of his bill, 420 francs, and Mr. D. sued the Doctor for 5,000 francs for betraying a professional secret. The court decided that the Doctor was entitled to 300 francs instead of 420, and decreed that it be paid by Mr. D. On the other hand, the judge ordered the Doctor to pay 300 francs to Mr. D. for violation of professional secrecy and grave inattention to his duties as a physician. The costs were divided equally.¹

Large Bequests to Massachusetts Institutions.—Under the will of the late Thomas O. H. P. Burnham, who was for many years a dealer in second-hand books, nearly two-thirds of an estate of \$602,562 will go to charitable and educational organizations. The Massachusetts General Hospital was made the residuary legatee, and has been paid \$263,048. The Home for Aged Men, and Tuft's College will receive \$10,000 each; Children's Home, Children's Hospital, Boston Asylum and Farm School, Washington Home, Massachusetts School for Feeble Minded Children, Perkins' Institute for the Blind and Boston Lying-in Hospital, \$5,000, each; Boston Dispensary, Asylum for Aged Females, New England Hospital for Women and Children and Consumptives' Home, \$2,000.

Castration as a Sectarian Rite.—The *Lancet* has recently referred to a book, by a French writer, regarding a sect in Russia, known as "The Skoptzies." The *Lancet* paragraph states that "there is a very singular religious sect in Russia, whose chief tenet consists in castration. These ridiculous fanatics are said to be convinced that mankind can only obtain admission to Paradise in a mutilated condition, and consequently all males who join their ranks must submit to be deprived of their testicles, but whether the females have to undergo spaying or any analogous operation is not clear. According to M. E. Teinturier, who has written a book entitled 'Les Skoptzy,' these blind enthusiasts are tolerably numerous; but, happily, there is one good point connected with their particular form of madness—it can not be transmitted hereditarily."

Confidential Communications.—Confidential communications in the Iowa Code, which provides that no practicing physician shall be allowed in giving testimony to disclose any confidential communication properly intrusted to him in his professional capacity, and necessary and proper to enable him to discharge the functions of his office according to the usual course of practice, the Supreme Court of Iowa, holds, in the case of Prader v. National Masonic Accident Association, decided May 28, 1895, covers, not merely verbal communications, but the prohibition of the statute refers to those of any kind by which information of the character of that specified in a statute is imparted. Information of the actual condition of the patient, the court says, may be more readily communicated to or acquired by a physician through a personal examination than by statements of the patient. In many cases, exact knowledge can only be obtained by means of such examination, and it is clear that it is in the interest of the patient to have the information so obtained treated as confidential, as it would be had he known and communicated it verbally. Consequently, it is concluded that the prohibition of such a statute as the above extends to facts which are learned by a physician in the dis-

¹ Le Progres Medical, 1895, No. 29.

¹ Gaz. Med. de Paris, 1895, No. 29.

charge of his duties, from his own observation and examination of the patient. If the facts thus learned are of a confidential character, and are necessary and proper to enable the physician to discharge his professional duty to his client they are protected.

Term of Office for Kansas Insane Asylums.—Under section 3, chapter 113 of Kansas Session Laws for 1879, (paragraph 6188, General Statutes of 1889), which provides that "each insane asylum shall have a superintendent, an assistant superintendent, steward and matron, who shall be chosen by the board of trustees, and shall hold their office for the term of three years," no vacant unexpired or fractional terms are recognized, says the Supreme Court of that State, in the case of *State v. Wentworth*, decided June 8, 1895, and such officers, whenever appointed, are entitled to hold their respective offices for the period of three years from the date that the appointment of each takes effect.

Annual Report of the New York City Hospital.—This year's report of the above named institution is an elaborately illustrated book. Interior and exterior views of the hospital and its annexes are given, to the number of about twenty that will excite the envy of many a younger, struggling board of managers. The total number of patients receiving care and treatment in all departments of the service, for the year 1894 was 39,012, and the grand total since the beginning of hospital work, Jan. 3, 1891, 656,017. The proportion of patients in the wards of the several institutions receiving absolutely free treatment during 1894 was 64 per cent., and a large proportion of the remainder paid less than the actual cost of treatment. At the New York Hospital in West Fifteenth Street, the number of patients receiving medical or surgical treatment in its wards was 4,878, and the highest census of the hospital was 201, and the lowest 151, the average number of patients being 174. The average number of days of treatment per patient was 13, and the per capita cost was \$1.88 plus. Of the total days of treatment of ward patients, namely, 68,183, 84 per cent. were absolutely free. In the Out-Patient Department connected with the hospital, 8,700 patients were treated in its several classes, and the total number of visits of such patients amounted for the year to 40,792, and the number of prescriptions compounded, 35,957. The Ambulance Department at the New York Hospital responded to 1,441 calls, and at the House of Relief to 2,812 calls, the daily average ambulance calls at the New York Hospital numbering 4, and at the House of Relief, 7.

To Prevent Life-Loss from Fires on Shipboard.—The veteran chemist, Dr. R. Ogden Doremus, of New York city, has recently published a plea for the more general furnishing of liquified carbonic acid by ship owners as a life-saving and property-saving expedient, especially on all passenger steamships. Liquified carbonic acid has been quoted abroad as low as 12½ cents per two and one-half pounds, in iron bottles. The published remarks of Professor Doremus contain the following statements favorable to a wider employment of this substance: "About thirty years ago, the United States government appointed a commission to examine and report on methods for saving life on shipboard. I repeatedly exhibited to this commission the efficacy of liquid carbonic acid in extinguishing fires, and suggested that wrought-iron cylinders filled with this liquid should be placed on the decks of vessels and connected with iron tubes passing by the sides of the stanchions into various compartments. Should spontaneous combustion of cotton, jute, coal, etc., occur, the fire would be instantly extinguished by releasing the gas and driving it by its enormous pressure into the hold or compartment of the ship where the fire exists. The commission reported unanimously in favor of this method, and advised the passage of a law by the United States government requiring all our vessels to be provided with such means for extinguishing fires and saving life. Similar experiments were also shown to a committee appointed by the New York Board of Marine Underwriters. The committee commended this mode of putting out fires in the highest terms. With carbonic acid gas released into said compartment from wrought-iron cylinders filled with the liquified gas, the fire could have been extinguished in-

stantly and without injury to the 'high class freight.' Liquified carbonic acid is now a commercial article. It is prepared in this city, at Saratoga Springs, and is even exported from Germany."

Treatment of Inebriates at County Expense.—The Wisconsin Legislature enacted, at its recent session, that when any citizen of the State becomes a habitual drunkard and is peculiarly unable to procure and pay for treatment for such disease, any citizen of the State, the next friend, the attending physician, or any public officer may petition the county court or judge thereof, within and for the county where such habitual drunkard resides, for an order of said court or judge thereof, permitting said habitual drunkard to take treatment at some institution for the cure of drunkenness and drug addictions, established within the State, at the expense of the county, as the judge may select. But no such court or judge thereof shall entertain a petition or make any order to send any person for treatment, as set forth, a second time. Persons treated, who desire to do so, may reimburse the county. The term "habitual drunkard," under this act, it is said, shall include all persons addicted to the use of spirituous, malt or fermented liquors, morphin, opium, cocain, or other drugs or narcotics to such a degree as to deprive him of the power of reasonable self-control.

Intravenous Injections of Mercury.—Intravenous injections of sublimate, introduced by Bacelli and principally employed in the treatment of syphilis, has had different results in the hands of various observers. The general opinion is that they are efficacious, but opinions differ as to their inconvenience and the indications for their use. Görl, in a recent article¹ gives a resumé of the advantages and disadvantages of this method. The injections are painless, provided they are made in the lumen of the vessel. Pain at the moment of injection shows that the point of the needle is not free in the cavity of the vein. These injections enable us to incorporate precise and very small quantities of mercury, which will reassure timid patients and avoid intoxicating those with an idiosyncrasy. A third advantage is the rapidity of action, a fact of the greatest importance in certain cases of cerebral or ocular syphilis. Lastly, Bacelli's method is not dangerous, at least no fatal cases have been reported yet; does not frighten the patients and does not cause any incapacity for work. On the other hand, they are impossible or very difficult in individuals in whom the subcutaneous veins are not visible, obese persons, for example. The principal objection is that their effects are of short duration. It is true that after warding off the most menacing symptoms of syphilis by these injections we may prolong the effect either by subcutaneous or intramuscular injections of insoluble mercurial salts, or by administering the metal in the form of inunctions or pills.

Diabetes Mellitus in a Child.—This disease is rare in children and very fatal; death generally occurs quickly, as a new case reported by Cnopf shows.² It occurred in the person of a child aged 2½ years who had always been healthy. During a stay in the country it was noticed that while the child was apparently in perfect health it did not increase in weight as it should from drinking two or three liters of milk daily. This lasted for some weeks, after which the author was consulted. The child was much emaciated, the skin was pale, there was no fever; the nervous system, heart and lungs were negative; the liver, spleen and stomach appeared healthy; there was no diarrhea, but the child vomited the milk from time to time. The author advised that the quantity of milk be diminished and that it be drunk cold. Hydrochloric acid and wet packs were prescribed, but this treatment was of no avail. The child wished to drink constantly, day and night, and continued to vomit without signs of any digestive disturbance. Fearing a beginning meningitis, the eyes were examined with negative results. Urinalysis finally revealed the presence of a great quantity of sugar and a little albumin. This was hardly determined when the child was seized with diabetic coma, with the characteristic respiratory symptoms, and died in a few hours. A

¹ Münch. Med. Woch., 1895, No. 20.

² Münch. Med. Woch., 1895, No. 18.

necropsy was refused. We are unable to determine exactly the duration of the glycosuria in this case; it may be that therapeutics might have been of some avail if the child had been treated more than four days. Statistics show that in at least nine out of ten cases, diabetes in children is a rapidly fatal disease. In the case detailed neither heredity, cranial or abdominal lesion, traumatism, convalescence from a grave pyrexia nor any other of the usual causes of the disease in children was discovered. The case emphasizes the importance of a complete and early examination of the urine even in children.

A Neuropathic Family.—Max Nordau relates the pathologic history of a neuropathic family which he observed in Berillon's clinic. The mother is emotional and with exaggerated affectivity. Her sister died paralytic. There are no other exact details regarding other relations, but vague indications of various neuro- and psychopathies. Her husband, who in life was a man of vigorous health, had been dead for many years, and she had borne five children, three of whom were girls. Her daughter, A., born in 1873, did not walk until 5, nor talk until 8. She learned to read and write and served as an apprentice to a dressmaker, but without gaining sufficient expertness to obtain a situation as a workwoman. When 20 years and 3 months old she had an attack of epilepsy for the first time, which has been repeated every two or three months since. Each attack is followed by stupor, then by delirium lasting many hours or days. For the last year she has had paralysis of the tongue and all the limbs, which is constantly progressing. Her mental state is also constantly deteriorating and rapidly tends toward dementia. Her sister C., born in 1874, was always sickly and feeble. Otitis media caused a slight deafness; character diffident and undisciplined. She witnessed the attacks of her sister which impressed her profoundly. In March, 1895, at exactly the same age, 20 years and 3 months, she had an epileptiform attack, which has been repeated several times since; and always with phenomena which enable us to exclude true epilepsy. A brother, born in 1871, having witnessed one of the epileptiform attacks of C. in his turn had precisely similar attacks. One daughter and a son present no anomalies. This is a case of family contagion. A. alone is a true epileptic; C. had a "suggestion" that she was bound to have the same sickness as her sister and at the same time; and M. by unconscious mimicry, reproduced the accesses of C.¹

The Physics of the Bicycle.—When a wheelman is moving forward on a bicycle, what keeps him up? is a question often asked, as the rider passes swiftly along on a wheel base practically without width. Sitting on a still wheel is an almost impracticable feat; but it is simple enough to maintain an upright position when moving at a very slow speed. It is a physical fact that a body in motion persists in maintaining its plane of motion, and unless some additional force acts on the body at an angle to the original line of motion, it will continue to move in its original plane until stopped by friction or arrested by an obstruction. A body set in motion tends to move in a straight line, and will do so unless affected by a force acting on it in a different direction from that of the first movement. A wheelman is propelled through space at a velocity sufficient to cause him to maintain his plane of movement. Should he desire to change this plane of motion, as in describing a curve, he can do it only by calling in the aid of gravity, *i. e.*, he must lean to the concave side of the circle, more or less, according to the radius of the curve he is following. And further, in describing a curve, he is impelled outwardly by centrifugal force, which is more or less, according to his velocity, and he must oppose this force by a centripetal force, which in this case is gravity. This he does also by inclining his body toward the center of curvature of the path he is describing. In this case the wheel sometimes forms a considerable angle with the ground, so that under some conditions it slips from under the rider. The ability of a bicycle and rider in rapid motion to do serious damage in a collision with another machine or with a pedestrian is fully appreciated by few wheelmen. A man weighing 150 pounds and moving at the rate of ten feet per second (which is only about seven miles per hour) has a

momentum of 1,500 pounds, leaving out of the account the weight of the wheel. This is sufficient to upset any pedestrian with terrific force. A collision between two wheels, each with a 150 pound rider, spinning at the moderate speed of seven miles per hour, would result in a smashup with a force of 3,000 pounds. In view of these facts, it is no wonder that bicycle accidents are often very serious. The tractive force required to propel a bicycle over a smooth level surface is estimated at 0.01 of the load; calling the load 150 pounds, a force of one and one-half pounds would be required to move the wheel forward, and this calls for a pressure on the pedals of six and three-fourths pounds on a wheel geared in the usual manner. When, however, the road is rough or on an up grade, the case is different. On a grade of 1 in 10, for example, the rider, in addition to the tractive force, actually lifts one-tenth of his weight and that of the machine. With a rigid or semi-rigid tire the rider is obliged to exert sufficient force to lift himself over every obstruction encountered by the wheel; the descent from the obstruction gives back a portion of the power expended in surmounting it, but not all of it. In the case of the pneumatic tire, however, the small obstructions are not an opposing element of any consequence, as the tire yields in lieu of the wheel being raised, and the result is the wheel travels as upon a smooth track.—*Scientific American.*

A Brilliant Scheme.—A physician recently answered an advertisement for a partner and received the following circular. The person is not a member of the ASSOCIATION as he claims, and is not on the JOURNAL list, either as member or subscriber. His advertisement was presented to the clerk, who referring to the medical directory, noted that Dr. Henderson was alleged to be a member of the ASSOCIATION and therefore presumably in good standing—in this the directory was wrong. As the JOURNAL has no desire to further the interests of any scheme of this stripe, we turn on the light by printing the document.

This is the advertisement:

PARTNER WANTED.

Thoroughly competent physician, honest, honorable, to take charge of my city office practice and correspondence. A rare chance to right physician, and a fortune to one who perseveres. Address,

Dr. H., 84 Adams St., Suite 81, Chicago.

This is the reply sent to a physician who answered the advertisement:

Illinois State Institute of Physicians and Surgeons; devoted to the treatment of Chronic Diseases, Deformities and Surgical Operations. Conducted by a full staff of specialists. Ample facilities for room and board. Office and laboratory, 82 and 84 Adams Street.

CHICAGO, August 13, 1895.

"Dr. _____.

"Dear Doctor:—Your letter of recent date has been received in reply to my advertisement for a partner. I am desirous of obtaining a partner to take charge of my city practice, which is almost entirely office work, and of my country correspondence. It is difficult to give you a correct idea in the short space of a letter of all the advantages which are to be had with taking charge of my office. You will observe in the above heading that I am doing institute work which is all outside of the city and is very remunerative, the gross receipts therefrom being about \$12,000 last year. The office work is of course from influence within the city and which I can bring to any one who takes the office here. Owing to sickness and three deaths in our immediate family, I have been unable to get out of the city to do any advertising since January of this year, but the receipts from that part have kept up remarkably well. The receipts in city practice are excellent, considering the time of year when there is so little sickness and so many patrons out of town, the receipts of the past month (July) being \$65. My object in taking a partner is that I may devote all my time to the road work. I will expect the partner to pay \$500 in cash, and in return he will own all the fixtures and stock of medicines that the office contains, and will be entitled to all the receipts of the office that come from within the city. I will then travel and give him half the receipts of the country work for putting up the medicines and doing the correspondence. The actual value of the office is about \$800, so you see I do not ask any bonus or pay for goodwill or even full pay for the actual value of the outfit. To do the work in the office requires just such an outfit as I have here and

¹ Le Bulletin Medical, July 24, 1895.

were we to begin new it would require more capital than this to start. The office expenses, including the telephone, are \$27.50 a month. Each box of medicine sent to a patient for one month's treatment averages about forty cents and I get from four to fifteen dollars for it, so you can see the profit. This is the best part of the year for the country work, from September 1 to January 1, and I am satisfied we can clear \$800 per month each. The amount you get out of the office work will more than pay your expenses of living, etc., so you will have all the receipts of the road work clear. I have been doing this country work about half of my time the past five years and am a member of the AMERICAN MEDICAL ASSOCIATION, so you see it is all right and legitimate. As an act of justice to my large patronage in the city, and to the large list of patients I am now treating in the country, I am anxious to get a competent man in here. Hoping to hear from you at your earliest convenience, and with best wishes, I am

Fraternally yours,
J. P. HENDERSON, M.D."

Hospital Notes.

THE addition to St. Mary's Hospital at St. Louis, Mo., is nearing completion and a portion of the rooms are now in use. The addition is three stories high with a frontage of 100 feet, and will be devoted mainly to wards, operating rooms and a laboratory. It is expected that the entire structure will be ready for occupancy on September 15.—Plans and specifications for the addition to St. Joseph's Hospital at St. Paul, Minn., have been filed with the building inspector of that city. The building will be 135x54 feet in dimensions, four stories high, with basement and attic. It will be constructed of brick with stone trimmings, with steel roof and fire-proof walls.—Articles of incorporation of the St. Alexis Hospital Association of Cleveland, Ohio, were filed August 21. The institution is incorporated to furnish hospital care to all persons, regardless of race, color, creed, or other condition.—The monthly report of the Cleveland State Hospital shows that there were in the hospital on July 15, 996 inmates; that 25 were admitted during the month, and 29 discharged, leaving 992 persons remaining.—The convict prison hospital of the Tennessee Coal, Iron & Railway Company at Pratt Mines, Ala., where State convicts are worked in the coal mines, was burned to the ground August 28. The fire originated from a defective flue and the flames spread so rapidly that the twenty-five inmates were rescued with difficulty. The laboratory and surgical instruments were a total loss.—The new hospital for contagious diseases at Boston, Mass., will be ready for occupancy September 1. The cost of the building was nearly \$500,000.

Louisville Notes.

G. A. R.—Elaborate preparations are being made by the local profession for the care of the sick during the encampment. The following are the officers: Medical Director, W. P. White; Secretary, Henry E. Tuley; Assistant Secretaries, T. S. Bullock and C. T. Pope; Chief Surgeon, T. P. Satterwhite; Chief of Ambulance Corps, Samuel H. Garvin; Assistant, L. D. Kastenbine; Chairman of Ladies' Medical Department, Dr. Julia Ingram; Secretary, Anna Lawrence. The following are the chiefs of the ambulance corps divisions: Drs. Peter Gunterman, J. M. Krim, I. N. Bloom, J. M. Mathews, Ewing Marshall, George Simpson, W. B. Doherty, H. H. Grant. Dr. Charles P. Cook will be in charge of the ambulance corps from New Albany, and Dr. T. A. Graham from Jeffersonville, Ind. The members of each ambulance corps will be uniformed and mounted. An ambulance fully equipped will follow each division in the parade; in it will be a driver and surgeon, and two stretcher bearers, with two stretchers. Each chief of ambulance will have ten mounted physicians in his corps, who will notify the ambulance when needed. There will be 120 cots at the City Hospital, 20 cots at the Louisville Medical College, 20 cots at the Kentucky School of Medicine Hospital and 15 at the "Homeopathic" Medical College, if needed, and 15 at St. Joseph's Infirmary. These hospitals will be under the charge of Dr. T. P. Satterwhite and a corps of physicians, who will be arranged in relief corps, two on duty at each hospital at all hours during the day of the parade. These hospitals are located at conven-

ient points along the route of the procession, so little time will be consumed in making a trip with sick or injured. On the day of the great barbecue, when it is expected 200,000 will be fed, there will be two hospital tents with physicians in attendance, on the grounds. The admirable arrangements for taking care of the sick during the G. A. R. encampment are due to the Medical Director, Dr. W. P. White.

Washington Notes.

HEALTH OF THE DISTRICT.—The report of the Health Officer for the week ended August 17, is as follows: number of deaths (still-births not included): white, 79; colored, 56; total, 135. Death rate per 1,000 per annum, white, 22.38; colored, 33.47; total, 25.95.

INSPECTOR OF CONTAGIOUS DISEASES RESIGNS.—Dr. Austin O'Malley, who has had charge of the department of contagious diseases in the health office has resigned and intends discontinuing the practice of medicine. He has accepted a position as professor of English literature in Notre Dame College, Indiana. The duties of Dr. O'Malley in the past will be divided. One physician will have charge of the inspection of cases of contagious disease, while another will be appointed bacteriologist. An excellent laboratory will be provided in the health office.

MRS. ANNA WOLCOTT'S CHARITY.—The will of the late Mrs. Anna Wolcott, which was filed for probate on the 21st inst., directs that her entire estate be turned over to Benjamin P. Snyder and Mahlon Ashford in trust. They are to invest \$41,000, and from the income shall use \$25 per annum in keeping in order the burial lot of the deceased at Oak Hill Cemetery, and with the balance establish and maintain in the Washington Home for Incurables, in memory of the daughter of Mrs. Wolcott, a ward, to be called the "Lillie Wolcott Ward," for the treatment in the best manner and free of charge of children afflicted with curvature of the spine and kindred diseases. Should the Home for Incurables decline the bequest for the purpose specifically designated, it is provided that the trustees shall select some other hospital in Washington, Baltimore or New York city for the purpose described.

THE PUBLIC SERVICES.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending August 24, 1895.

August 17, Surgeon S. H. DICKSON, detached from the Medical Examining Board to temporary duty in Bureau of Medicine and Surgery. P. A. Surgeon H. T. PERCY, detached from the Washington Navy Yard to duty as member of Medical Examining Board, Washington. Assistant Surgeon C. P. BAGG, detached from the "Monterey" and granted two months' leave. Assistant Surgeon H. D. WILSON, on arrival of "Monongahela" at Annapolis, detached from that vessel and ordered to temporary duty at the Washington Navy Yard.

The Journal of the American Medical Association

VOL. XXV.

CHICAGO, SEPTEMBER 7, 1895.

No. 10.

ADDRESS.

OUR PRESENT KNOWLEDGE OF TUMORS AND CANCERS.

Read before the Mississippi Valley Medical Association, Sept. 3, 1895.

BY THEODORE A. MCGRAW, M.D.

DETROIT, MICH.

It is natural in selecting a subject for an address on an occasion like this to choose those achievements in surgery which have made the glory of this generation. The rehearsal of triumphs is a most pleasant theme for both orator and hearers, and I have been tempted to indulge in that mutual congratulation which is not out of place when a great profession is called together to debate matters of common interest. It has been with a good deal of self-denial and some misgivings that I have turned from these pleasanter matters to ask you to join me in an attempt to review the darkest and most difficult field of surgery, in order, if possible, to gain some clear ideas as to the present state of our knowledge of the pathology of tumors and cancers. In this department of medicine, we may indeed claim some advances in exact knowledge made during the last three decades, but we can not pretend to any such triumphs as have in the same period revolutionized the methods of operative surgery.

If we compare the ideas that prevailed relative to these diseases, thirty years ago, with those which the profession hold to-day, we find a change which is marked rather by a clearer view of the nature of the problem than by any actual gain in its solution. Before Virchow, the subject of tumors and cancers was wrapped in the greatest confusion. It was not only that pathologists had not learned to distinguish accurately between neoplasms and the many false tumors which stimulate them, a kind of diagnosis indeed which is still very defective, but chiefly because at that time there were no clear conceptions of those cellular relations which to-day are regarded as fundamental in all pathology. Tumors were divided and classified in that era according to their clinical histories. They were divided into the innocent, which were looked upon as purely local, and the malignant, which were regarded as due to dyscrasia, the seat of which was in the blood. The latter were looked upon by many as parasitic, and surgeons who dabbled with the microscope were sure that they recognized peculiar cells which differed from all others, and indicated the cancerous nature of the disorder.

Under the influence of the new cellular pathology the faith in so-called dyscrasia was abandoned and supplanted by a new doctrine, which taught that tumors and cancers resulted ever and always from aberrations in cellular nutrition, development and growth. For three decades pathologists have sought

the explanation of the mystery of morbid growth in histologic studies. It may be truly said that during this time the energies of the profession, as far as tumors are concerned, have been confined almost solely to this channel. Clinical observation and chemic analysis had failed alike in throwing light upon this most vexed problem, and the profession turned with enthusiastic hope to the study of the morphology of the cellular elements of the body, as a new field in which they could work without despair. There can be no doubt of the gain which has accrued from these labors; clearer ideas have been acquired of cellular relations and even incidentally, of cellular pathology. Systems of classification have been founded for the study of tumors which if not altogether satisfactory have, nevertheless, some warrant in science. The important rôle played by the embryonic processes of development in the causation of certain morbid growths has been established, and the educated physician of to-day could not possibly fall into some of the gross errors which were common thirty years ago, but after all, our progress, great as it has been in some respects, has been thus far disappointing, that it has not brought us to our goal. We have been like those early wanderers in Florida, who sought for the magic fountains; they found innumerable tribes of Indians, they crossed many great rivers, they learned more of the new world, than they had ever dreamed of, but the magic waters continually eluded them. So we have learned much of cell life and have wondered more and more at the living tissue, but know hardly more of the causes which underlie the growth of a neoplasm than the surgeon who lived a hundred years ago. It is interesting as well as wonderful to note how after thirty years of cellular study, many in the profession are reverting to the old theory of parasitism, by which since the world began, men have tried to account for malignant diseases. In fact, notwithstanding the ingenious systems of classification now in vogue, it is to-day as difficult to define exactly the word tumor, as it was when Virchow wrote his great book. All sorts of enlargements at that time were huddled together in the same category. Hematoceles, dropsies, inflammations, aneurysms and varicoceles, retention cysts, the distended bladder and even the pregnant uterus were all spoken of in the same chapter with the neoplasm, as tumors. Now, while to-day, more judgment is used in this respect, we nevertheless find even in our newest text-books the true tumors discussed in connection with purely accidental swellings. It does not help us much, to recognize the fact that the difficulties in classification are inherent and insurmountable with our present knowledge of pathologic processes.

In the term, cancers and tumors, we group together certain diseases in common that distinguish them from all other maladies, but when we come to

ask ourselves what these common traits are, and try to define them, we become at once perplexed. The reason of this is that, in studying the subject closely, we find a multitude of growths which occupy that doubtful zone which lies between the neoplasm on the one hand, and the accidental and inflammatory enlargements on the other. We find swellings which seem in part accidental, and yet which belong clinically to the new growths. I became first fully aware of this when I tried for purposes of classification to divide all morbid enlargements into two classes: 1, the neoplasms proper, or true tumors; and 2, those swellings which imitate them, but are purely accidental or inflammatory, the false tumors. I had wished in this way to simplify the subject, but when I began to classify tumors and to determine which properly belonged to the neoplasms and which to the false tumors, I became involved in difficulties. There are, in the first place, many growths of inflammatory origin which eventually develop into undoubted neoplasms, and it is impossible to draw a line and say, Now, this is an inflammation and this is a tumor. A wound will heal badly and there will be left a large, thick, ungainly scar which in its structure resembles closely the keloid growths which spring from scars and are regarded as true tumors. Are we to look upon every permanent thickening of a scar as a neoplasm?

The retention cysts are usually regarded as accidental formations, due either to closure of a duct or to a thickening of secretion. They sometimes result directly from injury, and yet there are retention cysts or cysts which can not be distinguished from them, which occur under circumstances which make us conclude that they are true neoplasms. It is, however, especially with those tumors which spring from irregularities in embryonic development that we are puzzled in classification. There are cysts under the tongue which are due to an imperfect closure of the thyro-glossal duct. The duct becomes obliterated at both ends, but leaves a cavity in the middle lined with secreting cells, and as a result there is a cyst. Here, then, is no new growth whatever, only a defect in coalescence, and if the defect is still greater and the duct remains open at the outer end, there is no tumor at all, but only a fistula.

A dermoid cyst is caused by the infolding of the epiblast, which become displaced and shut in among the connective tissues. The cells thus sequestered continue to develop and there results an epidermal cyst, universally reckoned among the neoplasms, but a post anal dimple is formed in precisely the same way, except that the burial is not quite so complete and yet no one thinks of calling such a recess a tumor.

If we are to class those growths which arise from superfluous and aberrant embryonic germs with the neoplasms, how can we leave out of the category those extra fingers and toes which often hang from the side of the hand or foot by a mere thread of tissue. We may say of an extra toe, when it is in its proper place on the foot and endowed with tendons, nerves and all of the apparatus for motion, that although unusual it is nevertheless not abnormal. But the extra toe that grows from the skin on the side of the foot is, in its origin and growth, just as much of a tumor as the sequestered piece of epidermis that we call a dermoid and yet no one thinks of calling it a neoplasm.

It is practically impossible to sharply define pro-

cesses which are in their nature transitional, and the utmost which can be done as yet in the way of classification is to establish certain broad distinctions which may act as landmarks by which we mark the passage of nutritive operations from the normal to those essentially abnormal conditions such as we find most pronounced in the typical neoplasm. It is a gain, nevertheless, to know that the transition is gradual and that the healthy structure is not sharply defined from that which is morbid.

There is no theory which has yet been framed which satisfactorily accounts for the phenomena exhibited by morbid growths. Virchow's doctrine of the proliferation of the cellular elements under prolonged irritations is too vague to be of practical value. What we need to know and what we have not been able to find out, is the nature of the conditions under which irritation will produce that effect, for we know very well that, as a rule, in healthy individuals, prolonged irritations cause chronic inflammation but not tumors. It may be that there are specific irritations which generate neoplasms or that common irritations acting upon peculiar local or constitutional conditions may produce such results. But of these things we have as yet no exact knowledge whatever.

The most successful attempt to account for the origin of tumors and cancers was that of Cohenheim. Like Virchow, he sought for the causes of their being in local conditions, but referred their origin to anomalies in embryonic development. He supposed that in the differentiation of the ovum and the cells of the embryo there was in many individuals an excess of material over and above the needs of the organism for the formation of the various tissues, and that the superfluous cells remained as living germs undeveloped among the unfolding structures. He further supposed that while they drew their nutriment from the organism, they were not able on account of their lack of development to establish physiologic relations with it, and came to occupy the position of parasites. Living thus in a condition of latency, they were liable to be stimulated into sudden activity by any chance irritation, and would then begin to grow and multiply, but coming belated into active life would not be able to form normal relations with the body and would develop into tumors.

He accounted for the varieties of tumors on the hypothesis that the malignant kinds dated from the very earliest periods of embryonic existence, when the cells had an enormous power of multiplication, and the more innocent, from a later period after the tissues had become more differentiated. The original chapters in which Cohenheim dilated upon his theory are among the most entertaining in all medical literature, and when we consider that his was the first and, even now, the only intelligent theory in explanation of the origin of these peculiar diseases, we can understand the enthusiasm with which it was received by very many physicians. The immediate result of its publication was to stimulate pathologists to investigate their cases with the view of testing its correctness. Evidences were therefore sought for in all tumors, of an embryonic origin, and the search was rewarded in many cases by finding traces of anomalous development.

The dermoid cysts, the enchondromata of the parotid, certain tumors of the kidneys, the adenomata of the axilla, the rhabdomyomata, and many other

neoplasms were connected with the aberration and sequestration of embryonic tissues. It was, however, quite another thing to establish this as a general law for all tumors and, thus far, research in this direction has only established the fact that certain tumors date from intra-uterine life, while others apparently originate in more or less adult structures. In cancers, and sarcomas especially, the proof of an embryonic origin is lacking. The growth of these tumors differs widely in kind from the growth of embryonic cells. The latter are marked by a vigorous multiplication and growth, in which there occurs a constant succession of new forms. The malignant tumor repeats indefinitely the one form of cell with which it started. The cells of the embryonic increase in numbers vigorously at first, then more slowly, and finally cease to multiply. Those of a sarcoma or cancer become more fruitful as the malady continues, until finally they destroy all the tissues around them. The type of embryonic development then is a rapid propagation of new cells, each new brood of which differs from the mother cells, with a continuous loss of generative momentum. The characteristics of malignant growth are a repetition of one cell form with a continuous gain in generative momentum. It is wrong to regard the embryonic faults where they occur as mere accidents. The peculiarities of the phenomena do not admit of so easy an explanation. Behind the fault in development there is some defect in energy or in the mode of its expression, which causes the fault. This theory of Cohenheim's has been variously modified. Grawitz's theory of "*schlummerzellen*" and Bibbert's of cells which have lost their organic connections would never have seen the light had not their authors read Cohenheim. Among the most fanciful of conceptions must be regarded that of Schleich who conceived the idea that tumors arose by a process of morbid cellular conception. He fancied that under the influence of certain irritations a cell became diseased, and that joining with neighboring cellular elements in a sexual union, produced a morbid progeny. The repetition of these processes led to the formation of those great aggregations which we call tumors. Such speculations, founded on no other basis than the imagination of the author, contribute little to our actual knowledge. The revival of the old theory of parasites, in explanation of the malignant growths, is an index of the insufficiency of the theories which have for thirty years past formed the stimulus to research. The belief that cancers owe their being to a parasitic infection is almost as old as human experience. It is a kind of blind faith to which the mind constantly recurs when all other explanations fail. The existence of many false tumors which are caused by parasitic infection, and the evidently infectious course of malignant tumors gives support to the theory that they too owe their origin to the introduction of living cells from without. One can not study the history of actinomycosis, or that of the coccidia of rabbits without feeling struck with the similarity of the phenomena which they present to those of sarcoma and cancer. So, too, the formation of granulation cells under the stimulus of bacteria suggests possibilities, as regards the origin of those forms of sarcoma, which can not be distinguished from granulation tissue. While we have as yet no positive evidence that the enormous cellular proliferation of sarcoma or cancer is due either to bacteria

or to protozoa, there is, nevertheless, nothing in such an hypothesis inherently impossible. The burden of proof, however, must rest on the advocates of the doctrine, and as yet they have not been able to establish their case. The objects observed in the cells of cancer are of such doubtful nature that they have been variously described by different experts as bacilli, protozoa, invaginated epithelium, products of degeneration, leucocytes, etc. No one has as yet succeeded in cultivating the parasite in artificial media, and even the efforts to inoculate it into the healthy animals have been rarely successful. As long as the histologic evidence is so doubtful that every observer feels at liberty to interpret it according to his own prejudices we shall be obliged to defer judgment, or to pronounce it on other grounds. The arguments offered in defense of the parasitic theory of cancer are: 1, the microscopic evidences, the uncertain character of which has just been remarked; 2, the frequent occurrence of auto-inoculation, and the evidently infectious course of the disease in the organism; 3, the endemic occurrence of cancer in certain localities, and in rare instances in the same houses; and, 4, an occasional success in inoculating the disease in healthy animals.

The arguments against it are: 1, the many instances of hereditary tendency; 2, the general failure of experiments of inoculation; 3, the fact that metastases occur, not through the transfer from one point to another of parasitic germs, as is usual in parasitic diseases, but by the transmigration of cells bearing the same characters as the cells of the original tumor, and the subsequent proliferation of the migrating cells; 4, the fact that not only cancers but tumors of all kinds have a more or less tendency to produce metastases; and, 5, the tendency exhibited by embryonic remains and histoid tumors to develop into malignant disease.

It is difficult to understand why, if cancers and sarcoma are parasitic, surgeons who operate often with cut fingers, and nurses who take charge of cancerous sores, never become infected unless, indeed, as has been suggested, the cancer germs have to undergo some transformations out of the body before they can reproduce the disease.

It is very possible that among the sarcomata some may be found arising from this cause, but even though this may be so, we would be as much as ever in the dark as to the causality of those other remaining tumors which could not be explained on that basis. The understanding of actinomycosis has not advanced our knowledge of true tumors, neither would the discovery of other false tumors now reckoned among the neoplasms. Among the influences which predispose to or against the growth of cancers and tumors, race must be considered the most efficient. Detroit has a pretty large colored population, and there is a thick settlement of negroes on the opposite shore in Canada. Detroit physicians, therefore, see a variety of morbid conditions in that race. I think it is the common belief among them that malignant tumors in negroes are very rare. I have seen a great many fibroids and fatty tumors, but never yet a cancer or sarcoma in a pure negro. I believe that the experience of Southern physicians will corroborate my own in this particular. Dr. R. Williams states, on what authority I do not know, that while in 100,000 whites there 27.96 cases of cancer, there are in the same number of blacks only

12.17. I have reason also to believe that tumors of any kind are rare among the Indians. Some years ago I sent a printed circular to the medical men employed at the various Indian agencies in the West, asking for information on that point. The answers that I received were not sufficiently exact and trustworthy to warrant publication, but I gathered from them the information which I have stated. It would be an exceedingly valuable addition to our knowledge if we could secure exact data as to the prevalence of these diseases in various races all over the world. It would be a proper undertaking for the government, but much could be done in that way by international medical associations. As far as appears from the meager evidence on this point, the white and yellow races seem to be most afflicted with malignant disorders, and the black and red races most exempt.

After race, locality would seem to be most important. Certain districts in England and some in this country yield an extraordinary number of cases of cancer, while other places are comparatively immune. Whether this indicates a possible infectious influence in certain soils, or an hereditary tendency to the disease in certain families, is an important question. The facts in regard to the relative frequency of malignant disease in various places are as yet too meager to afford data for argument. The question of heredity, too, has never as yet received that intelligent investigation which can be accomplished only by large numbers of physicians acting in concert. It must be remembered in estimating hereditary influences that every human being represents an immense number of ancestors, and that few of us can go back two or three generations without finding in the direct or collateral lines examples of almost every variety of disease, common to the country and climate.

Let us suppose that a man who died of cancer had thirty grandchildren, and that one of these became cancerous while the other twenty-nine remained immune, how should we reckon the hereditary influence? There are cases undoubtedly in which the cancerous tendency is so marked in certain families as to be unmistakable. There is a form of heredity in cancers and tumors which has been too little studied, and which has an even more important bearing on the question of the essential nature of cancer than the heredity of cancer itself, and that is an heredity marked by an alternation of histoid or other comparatively innocent tumors with cancer or sarcoma.

We might explain the heredity of cancer as we do that of tuberculosis, as merely an hereditary weakness which made the organism liable to parasitic invasion, but if we can establish the fact that the hereditary influence in a given family is not limited to the growth of malignant tumors alone, but exhibits itself in the production of a variety of dissimilar growths, we shall have done much to disprove the whole theory of parasitism. There occurred in my own practice once, some cases illustrating forcibly this tendency. Mr. X. had numerous atheromatous cysts on the scalp which, however, gave him little trouble. He died from other causes. He had two daughters. His oldest died of cancer of the breast. His youngest daughter had numerous cystic tumors on the body. In 1863 she had a large cyst removed from the shoulder, and one shortly after from the thigh, in 1871 one from the head, in 1873 one from the abdomen, and one from under the chin, and in

1875 came to me on account of an ulcerated cyst in the small of the back. I removed this and examined it closely. It had every characteristic of an atheromatous cyst and nothing more. During her convalescence she had an attack of erysipelas, during which I discovered on one shoulder a small sebaceous cyst which had been overlooked. The result of the erysipelas was to cause suppuration in this cyst and the discharge of the usual contents of such formations. She recovered and has been since then, as far as I know, well.

The daughter of the first child of Mr. X. had atheromatous cysts of the scalp. The second child had four children of whom the oldest, a son, had cysts on the head and shoulder.

Her second child was exempt. The third child, a daughter, had cysts on the scalp. The fourth child, a daughter, the wife of a physician, was attacked by a sarcoma of the breast while nursing her only child. I amputated the breast, but she had an immediate and general recurrence and died. Here then were seven persons in three generations affected with tumors. In five, the tumors had the characteristics of ordinary atheromatous and sebaceous cysts. In two, there were malignant tumors causing death. It is impossible to explain such a history on the theory of parasitism. The influence of age and sex, the greater tendency of these diseases to certain parts of the body, and the effect of injuries as predisposing causes, are all too well understood to warrant me in detaining you for their discussion.

In considering the forces which further or retard the growth of neoplasms, we have to take in those dark and hidden influences which our ancestors used to call constitutional. With the advent of cellular pathology, this word has become "taboo" with the pathologists of to-day who boast of their efforts, sometimes crowned with success, to trace all morbid action to local forces. To ascribe maladies to constitutional causes is, in their estimation a confession of ignorance, best to be avoided. In order, however, to explain the immunity of some people to these disorders, as well as the long periods of latency which often exist even with malignant tumors before they manifest their full capacity for growth and infection, it has been necessary to assume the existence of some protective force residing somewhere within the organism. In conformity with the prevailing tendencies, this force has been imagined as inherent in the various tissues of the body, rather than in the body as a whole. Thiersch's theory, adopted and amplified by Cohenheim, assigns to every structure a certain capacity of self-preservation by virtue of which it is enabled to hold its proper place among the tissues and to resist any encroachment of other cells or membranes upon its territory. By virtue of this local force, granulations which fill an open wound to the surface are then inhibited from further growth by the epidermis, which begins, so to speak, to assert its rights and grow over the granulations, as a covering. This local influence, too, holds the adherent embryonic germs in check, and prevents their development until some chance inflammation or injury deprives the tissues of their self-preserving power. Two coinciding conditions are, therefore, held by Cohenheim to be necessary to the development of any tumor, the first of which is the existence among the normal structures of some belated germs, and the second of which is the loss of resisting power on the

part of the surrounding structures. The effect of an injury in producing a neoplasm is supposed to be twofold. It at the same time weakens the normal membranes and stimulates into activity the parasitic cells. All the influences which concern the formation of tumors, whether to favor or hinder their growth, are imagined to be purely local in character. It is a great question whether the facts of pathology justify the total abandonment of the conception of a constitutional something by which the power of an organism to resist injury is determined. The old doctrines of primary humoral dyscrasia are untenable, and we have no plausible hypothesis, as yet, on which we may satisfactorily explain all the phenomena, but we may recognize the existence of things which we can not explain. The constitutional tendencies of individuals to certain maladies, and the immunity enjoyed by other individuals are facts which have to be acknowledged.

A person suffering from cancer is exceedingly liable to auto-inoculation by cancerous material which can not be inoculated into another individual. Surgeons are continually working in that material, often with cut fingers, and yet never infected, although it is a prevailing belief among practical surgeons that recurrence in the patient often takes place from an auto-inoculation during the operation. As such patients may be inoculated on any part of the body, and as all tissues become alike infected, it is impossible to avoid the conclusion that the cancer is after all only the local expression of a general tendency. It is not difficult to imagine that an organism developing from a common center, should in all parts exhibit traits peculiar to itself. All of its component cells, descended from a common matrix, would have nearly the same tendencies and would on occasion tend to show the same strength and the same weakness. While it is not possible for us in any given case to demonstrate in what the constitutional peculiarities of such an organism consist, we must, nevertheless, admit that they exist and make the individual what he is, different from all other individuals, even of his own family. The doctrine that the resisting power inherent in a healthy organism is simply a local force resident in the tissue has never seemed to me to be tenable. When we consider the human body composed as it is of an infinite multitude of cellular elements, each of which may on occasion live an independent life, when we note the perfect coördination with which they perform their functions and with which they multiply and grow with sole reference to the good of the organism, we are struck with wonder and admiration at the perfection of the mechanism. It is inconceivable that such complicated processes are carried on without regulation by some governing center. To insure the perfect nutrition of the body, control must be constantly exercised not only over cell functions, but also over cell generation and multiplication, and though we may conceive this control to be rendered easy by the automatic reactions of the cells to stimulus, we may hardly imagine it as a merely local function. There is no fact more positively certain than that this power of control is exercised in the healthy body with an iron consequence. We see evidence of it in all the processes of nutrition and growth. We see it in the repair of injuries, in which the growth of granulation tissue is permitted to reach the proper level, and then inhibited from further increase, and in which the epidermal cells

remain in quiescence until the granulations are prepared for their protective covering, and then grow like a mantle over them. It may be noted in the destruction of all useless tissues. It is a law of the healthy body that all structures which have become worthless for its purpose shall be made to degenerate and disappear. The alveolar process when deprived of its teeth, the synovial membrane, when the joint is kept too long at rest, the muscles of the amputated limb, the generative organs after the change of life, all tend to atrophy or to undergo fatty degeneration. The law which makes existence in the organism depend upon the constant exercise of function is so rigid that a man can not stop the working of any organ without injuring it. If he ceases to think vigorously, his brain grows less, and if he ceases to exercise his muscles they grow weak.

On the other hand, in response to the demands of the organism, organs will increase in size and vigor, just as the one kidney becomes hypertrophied if its neighbor becomes incapacitated.

While the fact of the control on the part of the healthy organism of its component parts is then beyond question, while indeed its very existence as an organism depends upon that control, we are as yet in the dark as to where the controlling force resides and as to how it is exercised. There are some facts which indicate that it may be located in the central nervous system. We may infer this from the disorganization which is apt to follow upon disease of the spinal cord. No one who has seen the diseased joints of locomotor ataxia, the muscular wasting of poliomyelitis, or progressive muscular atrophy, or the sloughing bed-sores which follow upon injuries of the spine, can refuse to recognize the effect of the disorganization of the spinal center upon the nutrition of the body. It is, however, not only in the disorganization which ensues upon the destruction of the spinal cord that we may note this influence, but in an actual growth of tissue which follows upon certain disorders of the nervous centers. Of late, some observations have been made in that peculiar condition called acromegaly which indicates that it is caused by disease of the pituitary body. Acromegaly manifests itself in an abnormal growth of one side of the face, or jaw, or of the hands, or feet, or other parts of the body, and may occur in connection with gigantism. Now, in several cases of this disorder, the pituitary body has been found to be enlarged and apparently diseased.

In pseudo-hypertrophic paralysis and in Graves' disease, there is reason to believe that the abnormal growth of connective tissue in the one malady, and of thyro-glandular tissue in the other are directly due to nervous disturbance. The theory that tumors originated from some trouble of the nervous system is not new.

Virchow quotes Schroeder Vanderkalk, as advocating the doctrine that neoplasms owed their origin to a disease or injury of the central nervous system and the loss thereby of that governing force which regulates cell growth and reproduction, but himself rejects the theory on the ground that paralyzed animals are not especially given to the production of tumors.

This conclusion does not seem to be altogether justified, for while paralytic conditions are more or less apt to lead to disorganization and atrophy rather than growth of tissue, it is not impossible that cell

nutrition and reproduction may be, like some functions of the body, regulated by centers of two ganglia, one of which would stimulate and the other inhibit all proliferation. In that case it may be easily possible that an injury which would totally destroy the spinal cord or cut off all communication with it, would result in disintegration, while one confined to the inhibiting centers might become manifest by a growth of new tissue.

The disorderly growth in acromegaly, marked in many instances by an enlargement of the pituitary body is supposed to depend, not upon the paralysis, but on the over-stimulation of a nervous center. Whatever weight may be eventually accorded to Vanderkalk's theory, it would seem to be a lead worth following. For that which distinguishes the neoplasm from all other morbid enlargements is the fact that the cells which compose it have, in some way, succeeded in escaping control, and in proliferating without regard to the necessities of the organism. This characteristic of a persistent growth of useless tissue and reckless, uncontrollable reproduction is our only criterion of a true tumor. Lücke's definition of a neoplasm "that it is a mass of growing tissue which has no physiologic connection with the organism," does not seem to me to express the whole truth. I should define it rather as a mass of growing cells over whose nutrition and growth the organism had lost control. For this seems to me to be the one essential factor in the growth of any neoplasm.

When one considers the absolute necessity imposed upon a complicated organism, made up of a multitude of semi-independent cells, of holding these, so to speak, in discipline, and obliging them to conform in all their activities to organic law, it becomes apparent that the power of control is that which is most essential to its healthy existence. The loss of that power over any of its parts means something more than a merely local defect or local disease. The commonest fatty tumor has, therefore, in its very existence something portentous. It does not mean merely that a few fat cells have been stimulated to needlessly multiply, but it signifies also that in that organism there is some defect in the mechanism of control. It may mean too that there exists a liability to the development sooner or later of more formidable growths.

For these reasons, I can not but dissent from the prevailing doctrines which ignore all other causes in the production of tumors than those of local significance. There is a tendency in modern pathology to exaggerate the significance of local conditions and operations, and, in the study of cancer, this may be remarked in the undue importance attributed in its causation to local irritations. If we examine, for example, the list for alleged causes of cancer of the lower lip, and for the immunity of the upper we shall find that they will not bear criticism. Tillmann lays great stress on the use of tobacco and brandy, but Bardelsen tells us that the inhabitants of the coast of Pomerania who do not smoke, but who chew tobacco, have frequently cancers of the lip but few of the mouth or fauces. Surely if tobacco causes the disease the reverse ought to be true. All the world uses tobacco and brandy and no persons more so than certain inhabitants of the tropics and yet cancer is said to be rare in the tropics. Thiersch ascribes its prevalence among the peasants to the injuries inflicted on the lower lip by the weekly use of a dull razor but

it is frequent, as I can testify, among a class of American farmers who never shave and some of whom use neither brandy nor tobacco.

It is difficult, too, to understand why exposure to the weather, another alleged cause of labial cancer, should not affect the upper as well as the lower lip.

So, too, as regards the occurrence of cancer at the cardiac and pyloric orifices of the stomach and the comparative immunity of the rest of the organ, we read that the greater liability of the cardia and pylorus to insults and injuries is the cause of their greater susceptibility to the disorder—but here arises the question of fact. Are those places more subject to repeated irritations than the mucous membranes of the interior of the stomach? When food passes through those orifices there may be a momentary friction, but is that more irritating than the long presence of great masses of undigestible food, or acid fluids, some of which are absorbed directly through its walls?

It is a notorious fact that the mucous membrane of the stomach is especially exposed to the greatest variety of chemical and mechanical insults and that inflammation is a frequently recurring result of such injuries.

I do not think that any unprejudiced man, examining the facts impartially, would affirm that the extremities of the organ suffered more in this respect than its interior. If repeated cellular irritations cause cancer, how is it that the liver is so rarely affected with the primary disease? It is peculiarly exposed to injury by the frequent passage through its vessels of alcoholic and other irritants, which frequently cause destructive chronic inflammations. As the liver is especially prone to the secondary manifestations of the disease, it can not be said that its comparative immunity from the primary is due to any peculiar power of local resistance. If we wish to get at the truth of the etiology of cancer and tumors it will not do to accept statements with so little criticism.

We have not yet collected the data on which we can found a rational judgment as to the origin of cancer. We do not know, for instance, the relative frequency of the disease among the people who do not use tobacco, or who do and do not shave. That local irritations may excite the growth of neoplasms in some subjects and in some tissues is beyond all question, but this irritation can be but one factor in what is a complicated chain of morbid activities. Whether we can consider the beginning of trouble, with Schroeder Vanderkalk, to lie in a morbid change in some nervous center, or whether we rest content in our present ignorance, to ascribe it to some vague constitutional defect, we must, nevertheless, recognize behind the neoplasm, an impairment of that controlling mechanism, without which no complicated organism can exist. It does not militate against its existence that we are unable to define and locate it. Now if we apply this principle to those tumors which result from anomalies in embryonic development, we shall interpret the phenomena far otherwise than was done by Cohenheim.

To Cohenheim, the occurrence of useless aberrant germs was something merely accidental. While the excess of germinal matter itself was regarded as something fortuitous, its persistence was considered as a matter of course. It did not seem to occur to that investigator there might be in every embryo a

larger supply of germinal matter than is actually needed for the development of the various organs and tissues, and yet there are reasons which I shall not discuss here for believing that that is the case.

Nature is a spendthrift in all that concerns the proliferation of organic bodies. In the development of the embryo there must be a large surplussage of embryonal cells, which have to be disposed of. Whenever embryonal junctions take place, there must be a liability to the infolding and dislocation of germs. When such superfluous and aberrant cells remain undeveloped among the tissues, that which is morbid is not their primary existence, nor their displacement, but their persistence. In the healthy embryo they would be treated like the *débris* of a new building, they would be destroyed and expelled. This disposal of useless material must be a constantly occurring process in every organism which passes through the stages of development in a normal manner. Occasionally an exuberance of growth will be corrected after birth. This may be seen in the frequent disappearance in the early months of life of the milder forms of congenital *nævi*. A child will be born with numerous stains on the skin, caused by a growth of the minute capillaries, and in a few months they will be no longer perceptible. Sometimes even larger *nævi* will thus spontaneously lessen in size, and finally vanish, as if the organism were finally perfecting itself and acquiring a late control over its members.

In some cases, indeed, in which the effort to get rid of useless material has been only partially successful, we may see, nevertheless, that the effort has been made. If a supernumerary finger or toe is so located among the digits as to be a useful member, nature is content to leave it undisturbed, but when it grows from the side of the hand or foot, where it is only an inconvenience, she will apparently try to cut it off. Such growths are often formed to hang by a mere thread of tissue, although otherwise quite well developed. We may believe that in many cases the amputation thus begun may have succeeded, and the useless member thus disposed of. The survival then of embryonal remains must indicate something more than an accidental excess of tissue. It means that there exists a congenital defect in the mechanism of control, which if not corrected may lead to danger. Experience shows, indeed, that such imperfect structures are exceedingly liable to malignant degenerations.

In speaking of the loss of control as a defect, it must not be understood that it is always congenital, or always permanent or progressive. We may believe that while certain individuals are born defective in this particular, others become so by the wear and tear of time, and even that, in some cases, the power may be regained by a return of the individual to a state of health. We can imagine that in some cases the loss of power might result from organic change, while in others it would be a mere functional disturbance. We may also suppose that even though the controlling power is weak, it would suffice to maintain order until the occurrence of prolonged local irritations would excite a cellular rebellion, and that a neoplasm once formed would tend to increase the disorder. The extirpation of the tumor and of the disturbed area would in many cases cure the malady, temporarily, at least, by removing an element of contagion, as well as of irritation.

The knowledge that behind the local growth there was a constitutional defect should cause no relaxation in our efforts to get rid of a presence, which, either by scattering seed, or possibly by some catalytic influence, would tend to spread the disorder over new areas. The established fact that cancer may be easily inoculated on the individual who has it, though with great difficulty on healthy persons, shows the influence of constitutional conditions on such growths, but the equally established fact that thorough extirpation will often act curatively for many years, proves no less the influence of local conditions and of the contagion exercised by the disease.

The test, then, of a true tumor is that it is a cellular rebellion. All other morbid enlargements are either established in the interests of the organism, to protect it from harm or to repair injuries, like the inflammatory exudate, or are accidental products of disease, or are tumefactions caused by parasites. The inflammation becomes a cancer when the cellular proliferation takes place, no more in the interests of the organism, but as a wild and purposeless growth. It marks the loss of control, which is one of the worst forms of degeneration.

As regards the treatment of these maladies, whatever success has been obtained has been by complete and thorough extirpation. Whatever the character of a tumor, whether fatty, or fibrous, or cancerous, or embryonic, it always has the tendency to an aggressive growth. While extirpation does not cure the underlying defect, it may and often does prevent it from becoming operative. All that we have gained in treatment has been in the way of earlier and more thorough operative procedures. If we compare the practice of to-day relative to cancer of the breast with that of thirty years ago, we may see best the change which has taken place in this respect. The surgeons of the earlier day rarely operated in the early stages of the disease. Only when the infection had become pronounced was the patient brought to the knife. Care was taken in operating to leave sufficient integument to cover the wound, and the axilla was only opened when the glandular infection had become very apparent.

Now, notwithstanding the many sins still committed in this respect, physicians send many cases to the surgeon as soon as their attention is called to the trouble. In all cases the competent surgeon removes the entire breast, following it up in its many ramifications over and between the pectorals, and everywhere far under the integument. He invariably removes all of the axillary glands, all of the infected skin, the pectoral fascia, and often both pectoral muscles. He explores the sub- and supraclavicular spaces, and extirpates any perceptibly swollen glands, and following the practice of Tiffany, when the inner edge of the breast is involved, he resects a couple of ribs, in order to get the infected glands out from under the sternum, and, finally, if the blood vessels and nerves have become so infiltrated as to preclude recovery by any method of lesser gravity, he may proceed to amputate the arm at the shoulder in order to extirpate the affected tissues.

If we seek from the literature to learn the success of these radical operations, we find ourselves at fault on account of the insufficiency of the statistics. It is impossible to judge from the published statements what proportion of cases were operated on in the early and what in the late stages of the disorder, and

yet, this is the most important point of all to be considered. There is little value in figures which say simply that during a given time at a given place so many cases were operated on and so many recovered, for it is evident that such operations as were undertaken after general infection had been accomplished would entirely vitiate the statistics of those cases subjected to operation in the beginning of the disorder. All that we may safely say, as regards this question, is that a considerable minority of the cases operated on early, possibly 20 per cent., have been radically cured.

The important thing for the profession now to consider is the direction in which we may push our investigations to the best advantage. The hopes which were entertained on the first introduction of the cellular pathology of the speedy solution of the problem of morbid growth have not been realized. We have learned to trace certain tumors to embryonic anomalies, we have been treated to a great number of improved theories. We have added an element to our diagnosis of somewhat uncertain value, but the study of histology has not enabled us to know why certain cells rebel against the organism and grow into it as foes and parasites. Neither may we hope ever to gain that insight by purely histologic studies, for the explanation of physiologic and pathologic processes does not inhere in anatomic knowledge. It is a long way from the knowledge of form to that of function. We can not tell why one cell will secrete gastric juice and another mucus, nor can we tell by examining a cell what it will secrete. For this reason, the exclusive devotion to histologic investigations of the last thirty years has failed to bring the required understanding. Even the efforts to classify tumors according to their cellular genesis have been only partially successful. If, however, we could learn to trace every cell in every tumor back to its early progenitors and follow every step in the acts of the genesis, we should indeed know much that we do not now know, but should nevertheless be as much as ever in the dark regarding the causes and essential nature of the pathologic change. It would be as it is now with a superfluous finger. We know that the finger has originated in superfluous aberrant embryonic cells, but why the unnecessary tissues was formed, and why it was not cut off and destroyed, we do not know. We can not too highly estimate the gain to the world from the line of thought initiated by Rudolph Virchow, and from the painstaking work which has been accomplished in the field of minute anatomy during the last three decades, but we should make a great mistake if we neglected those other sources of knowledge which no less require patience and laborious study. The relations of the cell to the organism can never be understood if we confine our attention to the cell alone. We must study also that complex mechanism which out of a multitude of cells makes an organism. The secret of the neoplasm is hidden in the laws of organic control. This most evasive of physiologic laws may never be fully understood, but it at least, calls for an effort at investigation. We need a much more complete knowledge of the functions of nervous centers. The post-mortem examinations of patients dying of tumors or cancers should not be confined to cellular changes exhibited by the growths, but should be extended to the sympathetic ganglia and the central nervous system. Perchance in the spinal cord, pituitary body or some

large mass of ganglionic cells, we may be able to locate the original seat of trouble. If the results of such examinations should prove to be altogether negative, they would still have been of service.

There are many relations of tumors to the organism and to each other which have never yet been ascertained. We have never yet learned in any exact way the relations of the more innocent to the more malignant growths. Whether a man who has a fatty tumor is more liable than another to cancer, whether the persistence of useless embryonic remains indicate a constitutional or local defect, whether the benign tumors occur in a community in the same relative proportion as the malignant growths, and whether they are alternate with one another in cases of proved heredity, these, and a multitude of others are questions to which, with our present knowledge, we can give no satisfactory answer. One difficulty in eliciting satisfactory information is the length of time over which the history of a cancer stretches. One must know the medical records of several generations to be able to correctly judge of a given case.

It is exceedingly important to determine, if possible, the real truth regarding the alleged parasitism of cancer and sarcoma. This ought not to be the most difficult of the difficult problems to be solved in this study. If we ask what the profession can do, that it has not done to make these researches more intelligently and efficiently, the answer would perhaps be this, that while individuals in the profession have made most laborious researches in special directions, there has never yet been that systematic well-directed coöperative investigation of these diseases which promises the best returns.

The men who have chiefly studied these maladies, have been the school men in their hospitals and laboratories. But there is a vast amount of information needed which can never be acquired from such sources. What can the hospital surgeon or the pathologist in his laboratory learn, except at second hand, of the racial peculiarities of these diseases or of the family tendencies, or of the endemic relations of soil and water, or of similar troubles of the lower animals, or of the modes of life of the persons affected. While the hospital and laboratory work will probably always occupy the first place in these researches, there are other lines of investigation which we can not afford to neglect.

The French have recently formed a society called the League against Cancer, whose object is to institute a crusade against the malignant diseases. I am inclined to think that some of the more stolid Anglo-Saxons regard the movement as fantastic, and yet the work which could be accomplished by such an association of enthusiastic observers might be invaluable. Instead of the limited investigations of specialists in narrow fields, there could be instituted a comprehensive scheme of inquiry, by which every possible source of knowledge could be probed to its depths. The etiology of all true tumors and cancers, in their relations to the numerous animal species as well as human races, and as influenced by civilization, habits of life, hereditary, climate, water supplies, and all endemic conditions, could be studied in a way that would give us exact scientific data instead of the no knowledge which we possess to-day. The influence of hereditary syphilis to which the elder Gross and after him Esmarch have ascribed the origin of

certain so-called sarcomata, could be made the subject of special study.

The practicing physicians who more than any one else have access to the facts upon which our doctrines of hereditary transmission rest, could be interested in keeping exact records on blanks furnished them by the association. Boards of health could be stimulated to use the material at hand for scientific research.

In every large city, competent pathologists and histologists could be appointed and paid, for carefully examining and reporting on all tumors sent to them by physicians living within a certain radius, and printed instructions, directing in detail the methods of investigating cases, making post-mortems, and preserving the morbid specimens, could be sent to all applying for them. Veterinary surgeons could be enlisted in the work for the purpose of bringing to our aid the knowledge to be gained from the study of comparative pathology, and the experiments which we are forbidden to make on the human subject could be instituted on the lower animals. Medical colleges could be invited to add to their clinics for the treatment of human maladies, clinics for the domestic animals which would then provide the material for study. The various governments of the world could be asked to collect careful statistics as to the prevalence of these diseases among the many peoples.

Physicians could be better instructed in the means of diagnosis and in the necessity of early operative treatment. And last, but not least, the laity, admitted to the association could be induced to assist, not only with liberal contributions of means, but also by that intelligent coöperation which would lessen our difficulties in collecting evidence and making post-mortems and keep the sufferers out of the hands of the quacks.

It seems to me that there can be no question of the utility of a project which would put the direction of the investigations in the hands of the best men in the profession, and which could enlist even its humblest in the work of supplying the necessary knowledge. The movement of the French society deserves our applause and sympathy, and we should manifest our approval by taking measures for effective coöperation.

It is fitting that this society, composed of the flower of the profession of the great Mississippi Valley should assume the initiative in this country in effecting an organization for this purpose.

SANITATION IN STREET PAVEMENT.

Read in the Section on State Medicine at the Forty-sixth Annual Meeting of the American Medical Association, held at Baltimore, Md., May 7-10, 1895.

BY HENRY O. MARCY, M.D.

BOSTON, MASS.

One of the most interesting problems of modern sanitation is found in the making and maintaining of the roadbed in the streets of all our larger cities. The dangers therefrom consist chiefly in the atmospheric contamination induced by the great variety of material which necessarily collects upon the roadway and is usually denominated as dust. This, when it is wet, is generally considered as mud, but is better stigmatized by the use of the English acceptance of the word "nasty." When dry, as dust, the atmospheric currents disseminate it in all directions. This the passers-by must often inhale

and, by any means yet known, it can not be excluded from the neighboring houses. In great measure, dust is the bane of the housekeeper in urban surroundings. In character it is composite, consisting chiefly of the pulverized material from the surface of the roadbed, mixed with animal excreta, incident to ordinary travel. Under favorable conditions of heat, moisture, etc., these furnish the media for the development and dissemination of disease germs. Infective bacteria are almost never absent from street dust, and they often find an easy entrance into the human economy by means of respiration. So long ago as 1883, I cultivated various forms of bacteria taken from excavations at different depths beneath the best streets in the city of Boston, a noteworthy illustration of which, published at the time, was taken from Beacon Street, opposite the Public Garden, a considerable distance beneath the surface.

Dr. Sternberg, the present Surgeon-General of the United States Army, was one of the first scientists to call attention to these dangers, and after reporting the results of his investigations upon the filth of cities, as dangerous in large degree, because of septic organisms, wrote: "It must be remembered that the gutter mud of to-day, with its deadly septic organisms, is the dust of to-morrow, which, in respiration, is deposited upon the mucous membrane of the respiratory passages of those who breathe the air loaded with it."

In a circular just issued by the State Board of Health of Massachusetts, indorsed and circulated by the Boston Board of Health, emphasis is made upon the danger arising from the dissemination of the bacilli of tuberculosis. I quote briefly: "Consumption is the most destructive disease of New England; the number of persons dying annually from this cause in Massachusetts alone, amounting to nearly six thousand. The disease is infectious. The chief danger exists in the expectoration of the sick; and if this expectoration is destroyed, little danger is to be feared. Consumptives should be instructed not to spit in open places, "nor in the streets." Remember, the sputa must never be allowed to dry. One of the most common forms of the dissemination of consumption is by the respiration of street dust, never free from infectious material."

Dr. George Baird, discussing the subject of "Sanitation in Street Paving," writes as follows: "Should sanitarians be consulted by municipal authorities in reference to the material used for street paving, and the manner of laying it so as best to protect the lives and health of the citizens?" To this question there should be only an affirmative answer. The macadam road, the cobble pavement, the wood pavement in its various forms, and the granite pavement have all been found more or less objectionable from a sanitary standpoint. The macadam, with its rapidly worn surface and its clouds of dust, carrying disease germs in them; the cobble pavement, with its noise and innumerable pockets, furnishing lodging places for decaying animal and vegetable matter; the wooden pavement, decaying in a few years, and absorbing urine of horses and foul liquids of all kinds which are poured out upon its surface; and the granite, with its noise far exceeding the cobble, its slippery surface when worn, and its open crevices between the blocks, permitting liquids of all kinds to pass down and pollute the street surface beneath, are

each and all of them subject to adverse criticism."

The least unsanitary of all pavement must be impenetrable, present a surface easily cleaned and be kept as free as possible from dust and dirt. The important questions of expense, durability and economy of repair, are the determining factors in the selection of pavement material. In streets subject to the heaviest of teaming, where the weight of the constantly passing load, the minimum resistance offered to traction are important desiderata, it is necessary not alone to have a firm foundation, but also of the first importance to have a surface highly resistant to wear. For this purpose, granite blocks are in much favor. But they should be put down by the pouring of hot asphalt or some of the tarry products, filling the interstices. In this way we have an unyielding, comparatively even-wearing surface, giving a good foothold for the horses' feet, and at the same time easily cleaned and impenetrable to fluids. Although noisy and expensive, it is perhaps the best adapted for service in this class of streets.

In the residence portions of a city, such pavement is undesirable, and at present some form of macadam is more commonly used. In the form of macadam, with or without the Telford foundation of large stones, crushed rock has been used as a road covering in Europe and America for nearly a century. Macadamized surfaces become more or less rapidly worn; the wearing is produced by the pulverization of its surface, which, when dry, is a dust more or less mingled with vegetable and animal matter. When wet, it is mud. This surface is costly to keep in repair and is cleaned with much difficulty. In fact, it can never be freed entirely from objectionable material.

Asphalt, on the contrary, forms an impenetrable surface, is easily cleaned and can be kept clean at small cost. It is comparatively noiseless, is durable and can be easily repaired. Its first cost is greater than macadam.

From a paper published the present year by the Rensselaer Society of Engineers of Troy, N. Y., for the use of professors and students of the Institute, by J. M. Howard, upon "Natural Asphalt and Its Compounds," I quote: "The civilization of cities can be gauged by the condition of their streets. The suppression of noise and dirt, made possible by asphalt pavements, in a great measure determines the character and progress of a city. . . . Jan. 1, 1894, the total asphalt street pavements of European cities are as follows: London, twenty-four miles; Paris, twenty-six miles; Berlin, eighty-three miles.

"In the United States and Canada, Trinidad asphalt, 911 miles; asphaltic limestone and other asphaltic materials, 51 miles. The volume of this industry is measured by the fact that the one branch, asphaltic paving, is found in more than ninety-one American and fifty-five European cities. This means an investment of at least fifty-five millions of municipal funds and a working capital, if combined, of \$15,000,000."

A publication upon asphaltum in 1893, from the United States Department of the Interior, by Richardson and Parker, under the head of the durability of asphalt pavements, gives the following: "With the best materials, combined and laid with the greatest skill, where traffic is of the ordinary character, and the street not too narrow, so as to confine the wheels to ruts, the life of the pavement should

be fifteen years. There are surfaces in existence to-day which are of that age, which have had scarcely any repairs and seem to be good for many years to come. Such a pavement can be seen in front of the Arlington Hotel on Vermont Avenue, Washington."

Washington is to-day known as the best paved city in America. Its seventy miles of smooth, durable asphalt afford roads which for comfort, convenience and economy of transit are unequalled.

Asphalt offers a smooth and uniform surface, which reduces the force of the traction and thereby effects an economy in transportation, and at the same time adds to the comfort of every person who rides in a carriage; in its cleanliness, containing no joints to collect street filth and give it off in dust, and no vegetable matter to decay and poison the air with noxious germs; in its noiselessness, which relieves the racket and roar of great cities, so trying to the nerves.

These excellent qualities are not denied by any one. Two defects have been alleged against it: 1, that it is slippery; 2, that it is not durable. Neither allegation is founded in fact. Careful observations by competent engineers have established the fact that under ordinary conditions of weather the number of accidents to horses from falling is greater on stone than on asphalt pavements.

The great cause of horses slipping on asphalt pavement is the foreign material which may be allowed to remain on it. For example, the slipping of the pedestrian who inadvertently steps upon a banana peel left upon the sidewalk.

When in Paris in 1890, I examined carefully a piece of roadbed on one of the public thoroughfares, laid in 1812, probably the oldest asphalt pavement in existence. The surface was even, without cracks. When put down, it was eight inches thick, and the constant service of nearly eighty years was said to have reduced its thickness less than one inch.

In Hamburg, I was shown an excellent piece of asphalt pavement, which was put down in 1840. I might refer to our own experiences in Boston, but they have not been as satisfactory. The asphalt first laid here was defective, improper material being used. The trouble is in the asphalt sheet being quite too thin. The more recent paving with the asphalt has been much better constructed.

The repairs to such a pavement are really quite difficult to make. "If the day is cold when they are undertaken, the old surface is in a contracted condition, while the new material put in, being in a heated condition is considerably expanded. If the patch is left perfectly level with the surrounding pavement when finished, it soon settles and forms a little depression. In hot summer weather the expansion of the surrounding pavement has a tendency to push this patch on every side and make it rise above the surface surrounding it, causing a ridge. In making these patches it is customary to cut through the asphalt coating with heavy chisels, so that the part to be repaired can be removed. Then the hot mixture of asphalt and other materials is rammed into the place and tamped and rubbed with hot iron implements until it is apparently united with the old coating around it and the foundation below. It requires considerable skill and experience to do this well, and even the best men fail at times. Recently a special machine has been designed to facilitate and improve such repairs, which has been highly recom-

mended in several cities where it is used. It consists of a sheet metal tank containing gasoline and mounted on a pair of wheels so that it can be easily moved from place to place. Behind the tank is a collection of burners so arranged that when the vaporized gasoline is forced through them by means of a small air-pump attached to the tank, the several jets of flame warm up the surface of the asphalt below them. The material becomes as soft as when first laid, and while in this condition enough of it is taken off from the injured portions by a hoe to secure a clean fresh surface. On this, fresh asphalt is rammed and rolled to the desired surface, and as the old and new material is at about the same temperature when the tamping begins, it has been found possible to weld the whole together into a homogeneous mass. Another advantage of this method of repairs is that asphalt is removed from half an inch to an inch in thickness so that not only is less new material used, but the thin coating is more easily rolled and tamped and less likely to contract and leave a depression."

The present month Hon. E. P. North, in charge of the street paving of New York city, presented his report for the paving to be accomplished the ensuing year. It includes 109,025 square yards, at an estimated cost of \$780,100. Coming from such an authority and as the result of long study and observation, I have thought it advisable to quote from the report quite freely:

"This proposal is in conformity with your general instructions to expend the public money for the greatest public good by providing asphalt pavements in the poorer and more densely populated portions of the city and on streets that are likely to become great thoroughfares. The larger sum is expended for asphalt pavements, instead of granite and trap pavements, and the money is expended either in the service of the poorer portion of the community, or in the service of all by increasing the facilities for communication between all parts of the city.

"Somewhat over 63 per cent. of the pavements re-laid since and including 1889 have been granite or trap pavements, and rather less than 37 per cent. asphalt. Of the 1,196,079 square yards of asphalt pavement now laid in this city, between 60 and 70 per cent. has been laid in the area bounded by Fourth Street on the south, Third Avenue on the east, on the west by Seventh Avenue to Fifty-ninth Street, and thence north along the Hudson River. These boundaries, somewhat roughly, include the habitations of the wealthier portions of our population.

"Most of the asphalt in this region has been laid in short lengths, which do not average, in the cross streets, a block and a half long, there being over sixty separate pieces a full block or less in length. Some of these are without connection with other asphalted streets, so that much of the work done in this area has been a matter of luxury and convenience to those living on such streets, and is not calculated to appreciably affect either the death rate or the general health of the city, and its utility where it can not be incorporated in a general scheme is practically confined to the immediate vicinity in which it is laid.

"In the project now submitted, the only region favored is that occupied by our wage earning population, and aside from this, nothing has been incorporated that does not serve large areas and all classes of people. The principle has been to continue the

very necessary work, in a sanitary point of view, commenced under our predecessor, mainly through the efforts of your consulting engineer, Mr. Towle, of asphaltting the streets in the overcrowded districts east of the Bowery, to which is added the populous regions about the Five Points. In addition to this, streets have been selected for asphalt pavement that will extend the present lines of transportation and open routes across the city which will cheapen the delivery of goods and give comfortable access to some of the more important ferries.

"Two and four-tenths per cent. of the proposed work is south of Chambers Street, in the business part of the city; 40.6 per cent. is in regions east of Centre Street and south of First Street, and 57 per cent. is devoted to routes of distribution. Of this only 22.3 per cent. is in that division of the city which contains between 60 and 70 per cent. of the asphalt now laid. So that in fact 77.7 per cent. of the proposed new work will be where most needed for sanitary purposes, in the lower parts of the city.

"It seems that as a financial measure there is sound economy in replacing our wornout pavements with asphalt. It is, however, as a sanitary appliance that an asphalt pavement presents the greatest value. It is nearly a non-absorbent, is free from cracks that offer lurking places for disease germs, and can be thoroughly washed whenever it is thought advisable.

"Leaving the streets that swarm with the children of our poorest population paved with rough stones, the interstices between which are filled with disease-breeding filth, while the streets bordering on Fifth Avenue are paved with asphalt, does not make for the greatest good to the greatest number, and in case of a serious epidemic the practice imperils the health of the entire city."

The attention of the public is being drawn more at present to the proper construction of roadbeds than perhaps ever before. Previous to the development of the railroad system in the United States, however, it is interesting to note the engrossing attention which former generations gave to the improvement of internal intercommunication throughout the older States. It was well understood by them that good roads are desirable on the highest economic grounds, not to speak of their value when judged from the esthetic point of view. The revival of this spirit has been especially noteworthy in Massachusetts during the last few years, largely brought about by one of her indefatigable public-spirited citizens, Col. Albert A. Pope, seconded by his cohorts of bicyclists.

Massachusetts has a State Highway Commission, appointed for the supervision of the construction of new, and rebuilding of old roads. Her appropriation of last year was expended in making short pieces of thoroughly good country roads, in selected parts of the State, in large measure as object lessons for instruction. This year her Legislature appropriates \$300,000 for the further prosecution of this popular work.

The attention of scientists all over the world has been directed anew to the development of improved methods of road building, and Congress has recently made an appropriation for the investigation of this subject, in order that information upon the best methods of road making may be widely discussed and disseminated.

Laboratory work is being carried on at Harvard

University upon the value of the different kinds of stones best adapted to road building.

In Massachusetts, the towns are taking up the subject and the dissemination of the good work in this important branch of internal improvements is thus permeating the entire State. This work is not limited to Massachusetts, since a number of the States have already passed new road laws, and the subject is being popularly discussed throughout the entire country. Especially in urban life is the sanitation of the street of the greatest importance, and it seems to me most fitting that the scientific men of the country should exercise a molding influence upon the development of this great public improvement. I have therefore deemed it fitting to ask the attention of the members of the Section in State Medicine of the AMERICAN MEDICAL ASSOCIATION to this subject and to give it due discussion and deliberation.

The subjoined letters are of interest and value. They represent purposely, several of our larger cities in widely varying latitudes with marked variations of climate:

CHIEF SANITARY INSPECTOR'S OFFICE,
ATLANTA, GA., July 23, 1894.

HENRY O. MARCY, M.D.—*Dear Sir:*—Your letter of July 20 to hand, and in reply will state that I consider the "asphalt paving" the prettiest paving for your avenues in Boston; it is easily kept clean, is noiseless, and would give entire satisfaction. Any further information I will gladly furnish.

Very respectfully, THOS. E. VEAL, Chief Inspector.

CITY SURVEYOR'S OFFICE,
MONTREAL, CAN., July 23, 1894.

HENRY O. MARCY, M.D.—*Dear Sir:*—I am in receipt of your letter of July 20, asking me for my opinion as to the best pavement to be used for a residential street with light traffic thereon. I would certainly recommend Trinidad asphalt. We have had Trinidad asphalt laid by the Warren Scharff Co., of New York, and it has stood this climate for seven years with heavy traffic.

Yours truly,
P. W. ST. GEORGE, City Surveyor.

OFFICE OF CITY ENGINEER,
SAVANNAH, GA., July 23, 1894.

HENRY O. MARCY, M.D.—*Dear Sir:*—Your note of July 20 came to hand and contents noted. The city of Savannah has a great many streets paved with asphalt, and it gives entire satisfaction. The Warren Scharff Paving Co. has done most of our work. It stands heavy traffic as well as light.

I am yours respectfully,
JOHN FITZGERALD, Sup't Streets.

DEPARTMENT OF PUBLIC WORKS,
CHICAGO, July 23, 1894.

HENRY O. MARCY, M.D.—*Dear Sir:*—Your favor of July 20, relative to asphalt pavement received. We have 16.65 miles of sheet asphalt streets in this city. This class of improvement when well laid has given general satisfaction on residential streets in this city. Dearborn Avenue, which was improved with asphalt eleven years ago, has just been repaired at an expense to the city of \$570. It is now in as perfect condition as it was when originally completed.

Yours very truly,
JOHN MCCARTHY,
Superintendent of Streets.

DEPARTMENT OF PUBLIC WORKS, COMMISSIONER'S OFFICE,
No. 31 CHAMBERS STREET, NEW YORK, July 24, 1894.

HENRY O. MARCY, M.D.—*Dear Sir:*—In answer to your inquiry of July 20, regarding experience in this city with asphalt pavements, I beg to say that the experience of the last six years has shown good asphalt to be the very best pavement for residential streets and on streets used for pleasure driving, provided the grades are not too steep; that is, not to exceed 4 in 100. It has many advantages over macadam or stone, in being noiseless, impervious to liquid filth, easy to keep clean, and about one-fourth less expensive to maintain. We have now in this city fifty-five miles of asphalt pavement, nearly all in private residential and tenement-house districts.

Very respectfully,
MICHAEL T. DALY,
Commissioner of Public Works.

STREET DEPARTMENT, STREET COMMISSIONER'S OFFICE,
St. Louis, Mo., July 24, 1894.

HENRY O. MARCY, M.D.—*Dear Sir:*—Answering your favor of July 20, would say that we have a little over nine miles of asphalt streets in St. Louis, and they are giving entire satisfaction to the tax-payers. We have not confined the use of asphaltum streets to light traffic alone, as we have roadways here paved with that material over which from 5,000 to 7,000 vehicles pass daily with loads of from 1,000 to 10,000 pounds. Personally and officially I am in favor of asphalt for paving all classes of streets.

Very respectfully,
M. J. MURPHY,
Street Commissioner.

PHYSICAL EDUCATION IN CHILDHOOD AND YOUTH A MEANS OF PREVENTING DISEASE.

Read in the Section on State Medicine, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY C. F. ULRICH, A.M., M.D.
WHEELING, W. VA.

The time is rapidly approaching when the prevention of disease will be regarded as of infinitely more importance than its cure. The medical profession, although not absolutely pure, is *par excellence*, a benevolent and unselfish body. Where will you find a set of men who do so much for the general welfare, although their efforts tend continually to diminish their own profits and curtail their own income, as the medical brotherhood? Herculean labors have been performed by the fraternity to improve the water supply of our cities for the purpose of preventing disease and diminishing the death rate. Jenner's discovery, aided by a highly improved system of quarantine, has so diminished the ravages of variola that it is no longer a terror to any community, and its approach is not dreaded as in times past. Cholera has not the same terrors for us now that it had in days of yore. Although Professor Koch's discovery of tuberculin was prematurely launched into the world and has consequently disappointed the expectations of its friends, it is only a question of time, and not a very long time, until this discovery is supplemented by others that will enable us to come as near stamping out that fatal scourge as we have the smallpox. Diphtheria has hitherto baffled our efforts, and continued to slay its thousands. But the discovery of antitoxin bids fair to remand that much dreaded disease to the list of those which we have under our control. The unselfish physician is persevering in his unflinching efforts to prevent disease; or at least to soften its asperity and shorten its duration; notwithstanding this work seems to go directly against his private interest, in removing to a great extent the source of his income.

There is, however, one prolific source of disease, or at least tendency to disease, of which I have heard very little mention made in medical societies, nor have I read anything about it in medical journals. I refer to the neglect of physical training in childhood and youth. In the earlier ages of the world, when war and the chase formed the principal occupations of the human race, there was not so much need of admonition on this subject. The male child, in its tenderest years, was taken in hand and instructed in running, leaping, hurling the javelin and bending the bow, to prepare it for the life it was destined to lead when it reached the period of manhood. The barbaric tribes knew the necessity of health and strength in the mother to enable her to bear healthy

children. They accordingly trained their female infants in the exercises that were necessary to prepare them for the duties devolving upon them in womanhood. In our modern exotic civilization, the idea of the necessity for such early training seems to have been lost sight of. Intellectual culture, money-making and general business habits seem to occupy the entire attention of our people at the present time.

A child inheriting a weak constitution from its parents, whose physical development has been neglected by parents who devoted themselves exclusively to intellectual or financial pursuits, or to fashionable follies, is sent to school to be crammed with evanescent knowledge, instead of having its physical organization developed and trained to endure the hardships of life, and its intellectual faculties drawn out to enable it to think for itself and acquire the necessary education after its school days are over. This child is required to sit at the school desk from four to six hours every day, trying to absorb knowledge, perhaps to be forgotten in a few months after leaving school. There is not even any supervision exercised over the position of the child's body, and frequently the naturally weak child comes out of school with stooped shoulders or lateral curvature of the spine. The general circulation not being promoted by judicious and methodical training, the child is pale and flabby, drags itself along like an invalid of long standing, loses even its ambition to excel in the intellectual pursuits that first inspired it, and sometimes becomes a burden to itself and its friends.

If the child is of an active disposition, fond of physical exercise, it will sit during school hours fidgeting about, anxious for the recess or intermission to be announced. Then it will rush out, leap, run and bound like some wild animal escaped from the cage, perhaps doing itself an injury. There will be no system about the exercise, some organs being worked too much and others not enough. The body will be overheated and the muscles tired out. The body is not refreshed and the mind not rested. The blood that has been overheated will cool off too rapidly and a revulsion will set in. The muscles that have been overworked will be tired out and sore, being relaxed and unfit for duty the next day. The heart, that great machine that keeps the body alive, as well as the mind, by supplying the necessary nutriment, being overexcited, gradually loses its strength, becomes flabby; dilatations and valvular insufficiency are established. The buoyant health and strength that this child started with, which was perhaps the only heritage it received, is lost by mismanagement; the foundations of life sapped, and its future prospects destroyed.

Take, now, another class; those who, although not robust but rather of a delicate physique, are not suffering from any constitutional debility. We will suppose these children to be of a studious nature, possessing a large and active brain, with no particular desire for physical exercise. Such children go to school, sit in their confined seats, devoted to their studies. When recess is called they feel a bodily languor that makes them feel indisposed to move about and exercise their limbs. They prefer to remain in the schoolroom and study their lessons. When school is dismissed they drag themselves languidly along the street to their homes. They do not engage in the sports of their companions for they are

always tired. They are pale and thin; their flesh is flabby; the heart beats feebly; the brain is always in a state of excitement, and frequently a hectic flush is seen on their cheeks.

Let us now look at the child that has been systematically trained in all those physical exercises that develop the muscles without breaking them down; that strengthen and regulate the nerves without unduly exciting them; that cause a regular and healthy circulation of the blood without overheating it or allowing it to stagnate. If such a child has inherited a good constitution this course of training will still further improve it. The child of weak constitution, by such a course, will be strengthened and improved until its cachectic condition has almost disappeared; although, of course, it is not as robust as the one that began life with an inheritance of good health.

Now let us compare two children that are stricken down by disease; one whose physical training has been neglected, whose condition is as I have described above, and one whose physical forces have been well developed by a judicious course of training. Let us suppose that pneumonia is the disease that has attacked these two children. Which one will have the better prospect for recovery? The strong child has, by skillful training, developed all its organs, especially the lungs, which, by continual exercise under the supervision of a competent instructor, have been well developed and are consequently able to throw off the products of the disease, or even resist the attacks altogether, while the child whose physical education has been entirely neglected, who has been allowed to sit bent up in the schoolroom, having little or no play of the lungs; either not going out on the playground at all, or endeavoring to play with the stronger, more robust and more active children; overdoing itself and leaving its lungs in a worse condition than before, has to succumb to the terrible disease.

Take a case of typhoid fever and see how the two will fare. In this, as in other fevers, the heart has to double, treble, or even quadruple the work that is required of it in health. Now which heart will be able to accomplish it without coming to grief? You all know it will be the heart of the strong child, the one that has enjoyed good physical training and has been strengthened by a judicious and well regulated course of exercise; while the weak and flabby heart, with its imperfect valves, its thin walls, its dilated ventricles, which is scarcely able to perform its work when no disease is present, is sure to fail when double even quadruple the labor is required of it. In typhoid fever we have a diseased condition of the intestines near the ileocecal valve. Frequently, the coats of the intestines in this region are very much thinned. During the period of convalescence, when the patient begins to eat, owing to the slow digestion gases accumulate in the bowels, rupture of the intestinal coats takes place and death ensues. In which patient is this more likely to occur? In the one whose organs and tissues, owing to a good physical development, are all in a sound and healthy condition, able to endure a strain, to throw off the products of the disease, to resist the encroachment of the destroying malady; or in the one who is weak, the muscular coat of whose intestines has lost its peristaltic power, rendering it unable to carry off the products of the disease, which are thus permitted to remain stationary, preying still

farther on the tissues until they become thin, unelastic and friable.

Consider another class of diseases, a product of our modern civilization, of which the ancients knew nothing; nervous affections. I presume no one will hesitate to decide which class is most liable to these affections. The man or woman who has been properly trained, the intellectual and physical powers having been developed *pari passu*, whose organization is well balanced; the brain with its dependencies; the nervous system; the muscular system, with its locomotive powers; the alimentary tract; the assimilative apparatus, as well as all the emunctories, in good condition as a result of a sensible course of physical training in childhood and youth, will surely be less affected by nervous disorders and their concomitant pain and misery than the pale, weak, flabby being that is in every respect the reverse of the one I have just described.

It is hardly necessary to say anything as to the causes that render such persons amenable to all kinds of nervous diseases, for I am sure every one of you can see it at a glance. When one of these nervous, excitable creatures is attacked by fever, no matter what may be its character, it is easy to foresee the result. There is no power of resistance and the patient must succumb. Should this person, nevertheless, survive the attack, he or she would remain a wreck and life would be a burden. It is unnecessary to multiply instances as the matter is self-evident, and every physician, yes, every intelligent layman will see it as soon as it is suggested to him.

I remember when I was a boy, the men in my native land, Germany, were not very robust, because they devoted themselves to intellectual pursuits without giving proper care to the condition of their bodily functions and powers. About forty-five or fifty years ago, Father Jahn, as he was popularly called, organized gymnastic societies, known as the Turnerbund. The young men, with great enthusiasm, affiliated with this association. Teachers were appointed; regular systematic instructions were imparted and the youth of the period became more and more athletic. When Prussia assumed the lead in the German confederation, thorough military drill was superadded to the gymnastic training, and the German people became a nation of athletes, recovering the reputation for strength and size of limb they enjoyed in the days of Tacitus, the ancient Roman historian. When, after an absence of half a century, I revisited my native land I was astonished to find so large a proportion of the population large, strong and athletic. Nor had they suffered in intellect by this physical growth, as was very plainly shown by their artistic, scientific, literary and educational display at the World's Fair in 1893.

Having now shown, I hope, to your satisfaction, the importance, yes, the absolute necessity of early physical training, and its remarkable influence on the health of, not only the present, but also future generations, and its great bearing on the physical and intellectual welfare of the human race, I will close these remarks by expressing the hope that our sanitarians will take the subject into consideration and see if something can not be done to promote a wise system of physical training, in connection with our intellectual education, which would certainly be an excellent safeguard against deterioration, both physical and intellectual, and would surely do more to

advance our people to the highest degree of culture than the present system of cramming the brain with evanescent knowledge, and allowing the physical powers to dwindle away, a prey to the ravages of disease and death. According to the laws of heredity and the survival of the fittest, the time would not be very far distant when the earth would be peopled with a healthy, strong and intellectual race, among whom sickness, suffering and premature death would be the exception and not the rule.

THE HYGIENIC AND SCIENTIFIC VALUE OF EXAMINATIONS OF THE EYES AND EARS OF SCHOOL CHILDREN.

Read in the Section on State Medicine at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY B. ALEX. RANDALL, M.A., M.D.

PHILADELPHIA, PA.

Much work has been done in the last half century for the improvement of the hygiene of the school, with the result of formulating with much precision the best arrangement of the school building as regards site, plan, ventilation and illumination, and much of this is continually being put into practice with ever-growing advance in these matters of the school surroundings. The parallel and equally important field of educational methods has also been well worked by the pedagogues and others in response to the protest as to overburdened pupils; and while the standards of requirement have advanced and educational forcing has continued unabated, it is probable that the resulting damage has been materially lessened. More sweeping application of the rules generally accepted as requisite, is alone needful to place this aspect of the matter in fairly satisfactory shape.

Forced into rather wholesale dealing with their scholars by large classes and the pressure of changing methods of instruction, the teachers as a class are yet sedulously careful of the health of their pupils and often nobly self-sacrificing in their efforts to save them from any injury in the educational process. Were they enabled to make more discriminating application of preventive care to the cases requiring it, much more might be accomplished through the agencies already more or less practically in existence. The conditions surrounding the scholar have greatly improved; yet near-sight and many more certain evils have been little if at all decreased.

The difficulty is not so much with the machine methods as with the material submitted to them. The hygiene of the school may be perfect; yet that of the scholar very poor. Collective methods have their value—often great; but the application to individual cases may not only fail of good, but even be productive of much injury. Perfectly hygienic school surroundings with moderate demands upon the eyes may save the majority of pupils from trouble, palliate the defective relations of others, and yet spread disaster among a notable minority. Very injurious home surroundings undermine the advantages of the most perfect sanitation in the school, and can be met only by personal examination of the scholars and the exclusion of the unfit from school tasks. Preventive measures can be only partially applied to the whole school population; while their application to the individuals most in need, will generally come only after some damage has become irretrievable, if

we wait for the conditions to force themselves into notice.

To the oculist it is needless to specify what are the evils to be thus combated; for his practice daily exemplifies them most sadly. To the general practitioner it may be well to explain that the "myopia in the schools" of which he may have heard much, is but one element and not the most important. Would-be evolutionists may claim that the near-sight is an adaptation of the eye to the tasks of its civilized environment. On the other hand, the inflammatory intra-ocular conditions such as cause myopia may wreak their ill-effects in other ways and gain serious headway before the vision is affected or unmistakable evidence of injury appears to any one except the ophthalmoscopist. To his methods, alone, will appear the optical defects of the eye which frequently are the cause of trouble and demand correction by glasses. Any medical man or an intelligent layman can quickly learn to make the rest of the tests, just as Dr. Thomson has arranged for examination of the railroad employes by non-medical clerks. These tests are as really outside of the habitual work of the general practitioner as of the school teacher; and it is merely a question of the individual, as to how perfect or how worthless may be the results obtained. The skillful use of the ophthalmoscope constitutes the acme of the difficulty of the work, while it is also its most valuable part, and occasions the most crying need for the ophthalmic expert.

It will naturally be objected that no reasonable amount of labor will suffice for such examinations as I advocate—they cost too much time of both scholar and examiner. I have elsewhere shown that such an investigation of the eyes and ears as seems to me requisite, if not indeed adequate, to inform us of the condition of these organs of our school children, costs an average of five minutes apiece, since from twelve to twenty per hour can be studied and recorded by an expert examiner, unaided—while efficient help can double the number. A dozen hours a week devoted to this work instead of to the dispensary or hospital service to which most oculists devote that much time, would suffice for examining with a thoroughness as great as many men use in their private practice, from one hundred and fifty to two hundred pupils; so that in the months before and after opening of the schools, 1,000 would be readily studied. As the conveniences for the examination can generally be arranged at the school, the loss of time to the scholars ought to be unimportant. The entire study can be made by artificial light, as I have preferred to do, except for the color tests; and it may suit all concerned to work outside of the school hours.

There are men in most communities, capable and willing to make such investigations even without compensation, if invited to do so; while most school boards are able and should be willing to pay an honorarium of, say, \$100 for each thousand examinations thus made. The main difficulty really lies in the probability of professional jealousy; for there are many men whose sordid motives seem to compel them to attribute the same to any others who might in any such way come prominently before the public. Let those of us who earnestly desire genuine advance in these matters strive to place and keep this in its proper light; or we may find that no self-respecting men will be willing to undertake such labors, much

less to inaugurate them. Absolutely disinterested investigators can often be found, who will undertake the work from their sense of duty to the community; and when these are lacking, there will be found men who will consider the time thus employed fairly repaid by the absolutely legitimate recompense offered. If the report on each case is made only officially to the school authorities, and through them impersonally conveyed to the parents, the opportunity for self-aggrandizement will be largely taken away from any so inclined.

Finally, yet fundamentally, as to the method and aims of the examination. The perfection and safety of the visual function depends upon the acuity of vision, the accommodative power, the muscle relations and the health of the retina and choroid. Defects of refraction come in as causes of disturbance of each and all of these, just as do questions of school and home tasks, prints, illumination, seating, ventilation, etc. Perfect function is compatible with marked refraction errors, if the physique be good and the eyes not greatly abused, as witness the proportion of eyes reported comfortable when defect of refraction is almost universal. Given a notable error of refraction, and the margin of safety is surely lessened, if not overstepped; and functional disturbance, if not positive damage is likely to result even under conditions more ideal than are likely to surround our school children. Hence the importance of detecting the defects of refraction present, as well as the mere sharpness of vision for far and near; since good vision and comfort can hardly be maintained under the handicap of ametropia. How small a defect is noteworthy, depends largely on the general vigor of the individual and the health of the interior of the eye. This last can be decided only by the ophthalmoscope, which in expert hands can at the same time give us the surest ready estimate of the refraction and its errors. Minute record should be made and preserved of all these details for future comparison; but it is better to simplify the report made to the school authorities for transmission to the parents, merely stating the vision, any notable error of refraction and any need of prompt medical attention. The fuller technical record, however, should state the date, school and class; the name, age and sex; the general and ocular health; the visual sharpness, muscle relations and choice of astigmatic lines at a distance for each eye separately; the nearest point of distinct vision, the muscle balance and color sense of each near by; the refraction as measured by ophthalmoscope, retinoscopy and, perhaps, the test lenses, with the condition of the eye grounds. To this I have added the record of the inspection of the drumheads, the anterior nares and the pharynx, and of the tests of hearing for whisper and conversational voice and for the tuning-forks by air- and bone-conduction in Weber's and Rinne's tests. An examiner who has practiced independence of tongue depressors and aural and nasal specula, can usually dispense with them in these studies; and while posterior rhinoscopy would be a most valuable aid, it has been omitted, since such introduction of instruments as it necessitates is often alarming to the ignorant or nervous, and might easily awaken serious opposition.

These determinations and records can be satisfactorily made by an expert examiner in from four to six minutes for each pupil, and with good assistance in about three. Each detail can be fairly reliable in

itself and also serve as a check upon the rest; and the results, while not unimpeachable, ought to give us a true estimate of the present condition and future prospects of each eye and ear in the school, such as has all too rarely been even attempted in school investigations. Couple with this a record of the needed anthropometric data of height, body and limb girth, leg and thigh length, elbow height when seated and the condition of the spine; and we may be said to know the physical condition of each scholar, so far as is needful for the safeguarding of the organs of sight and hearing. With these data in the hands of the school authorities and the parents, perversity alone should prevent the application of preventive medicine to those individuals most in need of it.

THE PROPER RELATIONS BETWEEN NATIONAL, STATE AND MUNICI- PAL QUARANTINES.

Read in the Section on State Medicine at the Forty-sixth Annual Meeting of the American Medical Association, held at Baltimore, Md., May 7-10, 1895.

BY JEROME COCHRAN, M.D.
MONTGOMERY, ALA.

I think it must be evident that the machinery of quarantine administration best adapted to the needs of any particular country has to be determined by the political organization and commercial institutions of such country. It is hence easy to understand that a system of quarantine that might be best for England or France, or for China or Hindoostan, might not be best for the United States or for the State of Alabama.

Our system of government is very complex. We have the federal government for the management of foreign affairs and the commerce between the States. We have the State government, with large powers, for the regulation of internal and domestic affairs and the conservation of the lives, the liberties and the property of the people. Within the State, and deriving their powers from the State, we have the counties and the municipalities invested with important jurisdictions and extending the principles of home rule to the utmost practicable limits. In view of these statements it would seem to be a plausible contention that all these concurrent and coöperative governmental bodies should concur and coöperate in the management of quarantines for the protection of the people against the introduction and dissemination of migrating pestilences, just as they might all concur and coöperate to oppose the invasion and subsequent progress of an army with banners.

Here it becomes necessary to inquire what is meant by the word quarantine, in the phraseology of the question under discussion, because there are practically several different kinds of quarantine.

1. There is maritime quarantine, or quarantine to oppose the importation of epidemic diseases by way of the sea from foreign countries.

2. There is inter-State quarantine to oppose the spread of epidemic diseases from one State into another State, by way of rivers and railroads, and other means of communication between the States.

3. There is intra-State quarantine, or quarantine to oppose the spread of epidemic diseases from one part of a State to another part of the same State, by the ordinary avenues of traffic and travel.

4. There is municipal or local quarantine, or quarantine involving the management of epidemic dis-

eases in a city or a country community, so as to limit the local spread of such diseases and lessen their disastrous consequences.

These statements open the way for the examination of the question of national quarantine jurisdiction, both in its legal and in its practical relations. Has Congress the right to establish and conduct quarantines? And if so, what sort of quarantines? Maritime quarantine? Inter-State quarantine? Intra-State quarantine? Municipal quarantine? No power to legislate in regard to any sort of quarantine is expressly given in the Constitution, and if such power exists it must be involved in the power to regulate commerce with foreign nations and between the States; and under this section of the Constitution, Congress would have to confine its legislative action to the regulation of maritime and inter-State quarantine. It manifestly could not legislate for the regulation of intra-State and municipal quarantine.

The Supreme Court of the United States has never had occasion to decide any case in which this question of the quarantine power of the general government was directly at issue, and consequently the ultimate issue in regard to it is unsettled and uncertain, and we are left without other guidance than the opinion of legal experts, and among these there is a wide difference of opinion. But not even the most thorough-going advocate of the supremacy of the federal power would go further than I have gone in the statement just made, to the effect that the quarantine powers of Congress can not go beyond the regulation of foreign and inter-State quarantine.

In the meantime, without waiting for the judicial settlement of these constitutional questions, Congress has, from time to time enacted quarantine and health laws which have played a large part in the recent sanitary history of the country.

In 1879, the National Board of Health was established, with no power to inaugurate or to control quarantines, but with power to act in coöperation with State and local health boards and to afford them financial assistance. To this end the National Board was intrusted with the administration of a large epidemic fund.

A few years later this board fell into bad repute and the distribution of the epidemic fund was placed in the hands of the Marine-Hospital Service, and it was provided that it should still be used in coöperation with the health authorities of the States.

In 1890 Congress passed a very important act for the regulation of inter-State quarantine under the supervision of the Marine-Hospital Service. This act provides that whenever it shall be made to appear to the satisfaction of the President, that cholera, yellow fever, smallpox or plague exists in any State or territory, and that there is danger of the spread of such disease into any other State or territory, he is authorized to cause the Secretary of the Treasury to promulgate such regulations as may, in his judgment, be considered necessary to prevent such spread—such rules to be prepared by the Supervising Surgeon-General of the Marine-Hospital Service.

Again, in 1893, under the stimulus of the big panic caused by the widespread prevalence of cholera in Europe, Congress passed another act giving very large additional quarantine powers to the Marine-Hospital Service. Of this act, the following is the most significant section:

SEC. 3.—That the Supervising Surgeon-General of the

Marine-Hospital Service shall, immediately after this act takes effect, examine the quarantine regulations of all State and municipal boards of health, and shall, under the direction of the Secretary of the Treasury, cooperate with and aid State and municipal boards of health in the execution and enforcement of the rules and regulations of such boards and in the execution and enforcement of the rules and regulations made by the Secretary of the Treasury to prevent the introduction of contagious or infectious diseases into the United States from foreign countries, and into one State or Territory or the District of Columbia from another State or Territory or the District of Columbia; and all rules and regulations made by the Secretary of the Treasury shall operate uniformly and in no manner discriminate against any port or place; and at such ports and places within the United States as have no quarantine regulations under State or municipal authority, where such regulations are, in the opinion of the Secretary of the Treasury, necessary to prevent the introduction of contagious or infectious diseases into the United States from foreign countries, or into one State or Territory or the District of Columbia from another State or Territory or the District of Columbia, and at such ports and places within the United States where quarantine regulations exist under the authority of the State or municipality which, in the opinion of the Secretary of the Treasury, are not sufficient to prevent the introduction of such diseases in the United States, or into one State or Territory or the District of Columbia from another State or Territory or the District of Columbia, the Secretary of the Treasury shall, if in his judgment it is necessary and proper, make such additional rules and regulations as are necessary to prevent the introduction of such diseases into the United States from foreign countries, or into one State or Territory or the District of Columbia from another State or Territory or the District of Columbia, and when said rules and regulations have been made they shall be promulgated by the Secretary of the Treasury and enforced by the sanitary authorities of the States and municipalities, where the State or municipal health authorities will undertake to execute and enforce them; but if the State or municipal authorities shall fail or refuse to enforce said rules and regulations the President shall execute and enforce the same and adopt such measures as in his judgment shall be necessary to prevent the introduction or spread of such diseases, and may detail or appoint officers for that purpose. The Secretary of the Treasury shall make such rules and regulations as are necessary to be observed by vessels at the port of departure and on the voyage, where such vessels sail from any foreign port or place in the United States, to secure the best sanitary condition of such vessel, her cargo, passengers and crew; which shall be published and communicated to and enforced by the consular officers of the United States. None of the penalties herein imposed shall attach to any vessel or owner or officer thereof until a copy of this act, with the rules and regulations made in pursuance thereof, has been posted up in the office of the consul or other consular officer of the United States for ten days, in the port from which said vessel sailed; and the certificate of such consul or consular officer over his official signature shall be competent evidence of such posting in any court of the United States."

It will be observed that the first of these two recent acts relates to inter-State quarantine exclusively, while the second act provides for both inter-State and maritime quarantine. In both, provision is made for the recognition of local quarantines; provided said local quarantines are conducted under regulations satisfactory to the Secretary of the Treasury, or to the Supervising Surgeon-General of the Marine-Hospital Service which is practically the same thing. Of course, with that power, the Surgeon-General will have it all his own way.

But does this high officer know any more than the rest of us how quarantines ought to be conducted? If so, where did he get his expert knowledge? There is only one way for anybody to get expert knowledge of quarantine, and that is by practical quarantine experience. Some of the medical officers of this Service have seen some yellow fever, and a few of them have seen a good deal of yellow fever; while a few of them have had some experience in quarantine work.

But if any of them have acquired any large amount of expert knowledge either of yellow fever or of quarantine no proof of it has been vouchsafed to the outside world.

It seems to be taken for granted, by a great many persons, that a quarantine conducted under federal authority will be safer and more to be depended upon than quarantine conducted by local health authorities. But to my mind this is a very questionable proposition, and it certainly finds no warrant in our recent quarantine history. They always have plenty of money to spend—these national quarantine officers—and they know how to spend it admirably well. A rapid historical sketch of what they have done in the way of quarantine work up to this time is not without a certain measure of interest.

In 1879 the National Board of Health appropriated \$50,000 to the Tennessee State Board of Health to prevent the extension of yellow fever from the city of Memphis, where it was then prevalent to the rest of the State. They appropriated, also, at the same time \$12,000 to the Mississippi State Board of Health, and \$8,000 to the Alabama State Board of Health for the protection of their respective States. The fever did not spread in Tennessee or in Mississippi, both of which took the money. Neither did it spread in Alabama which did not take the money; and I undertake to say, as a quarantine expert, that so far as the prevention of the spread of the fever was concerned the \$62,000 so expended was very nearly thrown away.

A few years later, the Marine-Hospital Service and the State of Texas together expended the monstrous sum of \$100,000 to fence up yellow fever in the town of Brownsville on the Rio Grande, opposite the Mexican town of Matamoros. This, in my judgment, was a wanton waste of money. There might have been good reason for spending \$5,000, but hardly for more.

In 1883, the Marine-Hospital Service had charge of the Pensacola quarantine, or at any rate it was in charge of a medical officer of that Service. That year yellow fever got through the quarantine into Pensacola and into the Navy Yard near Pensacola. The Marine-Hospital Service proceeded to put a cordon around the Navy Yard for the protection of the rest of the country, but left Pensacola to scatter the disease over the adjacent portions of Florida and Alabama, as, for example, to Millview, Oakfield, Brewton and Daphne.

In 1887-88, yellow fever spread widely over the State of Florida, and the Marine-Hospital Service was appealed to for help, and responded in its usual energetic and lavish fashion. So far as the State of Florida was concerned, the effort to prevent the dissemination of the fever does not seem to have borne much fruit. Some protection was probably afforded to the State of Georgia. What the cost of this enterprise was to the government I was never able to find out; but it must have been very great. One item I remember—the expenditure of \$60,000 in the absurd and utterly useless work of the post-epidemic disinfection of the city of Jacksonville.

In 1893, at Brunswick, Ga., a case of yellow fever got through the quarantine and died at a logging camp somewhere near that city. Whereupon the Marine-Hospital Service declared the Brunswick quarantine to be inefficient and pushed the local authorities aside, and took charge themselves. The experiment was an unfortunate one. In a short time thereafter, yellow fever broke out in the city, the first

case so far as known occurring in the person of Surgeon Brannan, whom they had made quarantine officer. The next thing the Marine-Hospital Service did was to invade the territory of the sovereign State of Georgia and take possession of Brunswick under the plea of inter-State quarantine, and with the cordon and the camp of detention undertook to confine the epidemic to the stricken city. Yellow fever spread to Jessup before the cordon was drawn around Brunswick. But why was not Jessup also subjected to the potent coercion of the cordon? If the cordon prevented the spread of yellow fever from Brunswick, what prevented its spread from Jessup?

I have given this brief sketch of the history of the quarantine achievements of the general government, with the object in view of calling special attention to what I regard as a very serious menace to the authority and usefulness of our State health authorities—to the danger, namely, that all the quarantine functions which naturally belong to the State health authorities may be absorbed and monopolized by the Marine-Hospital Service, or by some other agency of the federal government. A few of the large cities like New York, or New Orleans, or Boston, will resist the innovation for a long time, but there is danger that smaller ports will yield speedily, and that the large ones will finally also give way.

Some plausible reasons may be urged in favor of national sea quarantine. Quarantine is an incident of commerce, and it would seem to be the natural solution of the problem that the power which regulates commerce should also regulate quarantine. The great objection to this solution of the problem of sea quarantine is that it involves a central bureaucratic administration that is necessarily expensive, necessarily arbitrary, and necessarily based on insufficient knowledge of local circumstances and conditions. It would not be difficult to frame a quarantine system in which, by the thorough-going coöperation of national and State authorities, most of these objections could be obviated.

There are just three places in which to oppose the dissemination of migrating pestilences in connection with the transportation of passengers, immigrants, and merchandise. The first of these is at the port of departure in the foreign country. The second is at the port of arrival in this country. The third is at the place of destination in the interior of the country, at the end of the journey. The quarantine of the foreign port, including the inspection and disinfection of ships, passengers, immigrants, and merchandise, and a general system of bills of health and cable notification when anything is wrong—all these things should be in charge of officers of the national government. And there should be at suitable places along our sea coast, refuge stations for dealing with infected ships, crews, passengers and cargoes; and these refuge stations should also be under national control.

Inside of the refuge stations, there should be an inner line of defenses in the shape of local inspection stations at our various seaports; and these should be in the hands of the local or State officers.

Then, from time to time, when in spite of all these defenses some epidemic pestilence gets into the country, we will need to institute land quarantines, railroad quarantines, local quarantines according to circumstances; and these should be under the control of the State and local authorities. If the pesti-

lence swells beyond the power of control at the command of the State and local authorities, then the national government should come to their assistance, not to push them aside as was done in Brunswick, but in the way of supplement and coöperation.

This is in outline the theory of our present quarantine system—the system that has been developed during the last twenty years. I can imagine no better system if it is carried out in its real spirit and purpose. But it now stands in danger of being marred and outraged by the encroachments of the Marine-Hospital Service under the acts of 1890 and 1893—said Service not being satisfied with the control at foreign ports and on the high seas and at the refuge stations, but seeking also the control of the inspection stations and of internal quarantines.

TUBERCULOSIS AND ITS PREVENTION.

Read in the Section on State Medicine, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY CHARLES E. WINSLOW, M.D.

LOS ANGELES, CAL.

Living, as I have, for the past few years, in a region of the Rockies, where hundreds of consumptives annually come to breathe the pure invigorating atmosphere, hoping to regain lost health and wasted strength, my mind has constantly turned toward the peril to our inhabitants of contagion from these invalids. Although in our high altitude the risk is greatly diminished, still "how to prevent the danger" has been an ever recurring question, and when your chairman kindly invited me to prepare a paper on "Preventive Medicine," my thoughts naturally turned to this subject.

With no space for argument in favor of statistics and cases brought forth by advanced thinkers in their researches, I simply accept their conclusions based on their proofs of facts. My ideas may be crude and my theories familiar, still if they stimulate action along the line of duty that is before us, as earnest and intelligent workers for humanity, I shall accomplish my purpose.

For thousands of years, it may be from the time Adam and Eve bade adieu to fair Eden, to battle with sorrow and death, consumption has been the great enemy of mankind. Men of thought and action have for the sake of their fellowmen, stood up and fought, with the best weapons at their command, and failed to conquer this great destroyer. Here and there down the ages have been seen the beacon fires of progress, until in 1892, Koch kindled a blaze that illumined the whole world. Then the clouds of ignorance lifted, giving us a vision of the boundless realms of preventive medicine. While the advance in curative medicine has been wonderful, the strides made in preventive medicine have been miraculous, and yet we are only on the border line of the Land of Promise, and there is still room for discoveries in preventive medicine. An earnest seeker of dauntless courage may achieve brilliant results in this line of work that will add new luster to our glory as physicians, and longer life to humanity. To-day, men are beginning to judge a physician's success by his ability to prevent as well as to cure disease.

The field is broadening. As we gain knowledge we increase in strength. We need men of strong character and keen intellect to fight the battle of life

against disease. Ours is a peculiar warfare, for not only the enemy, but those of our own household must be overcome. I take for granted that most of the men in this Section believe that tuberculosis is transmissible and that it comes from living bacilli. There are some honest doubters to all great truths and this is no exception.

Tuberculosis is by far the most destructive disease of the human race, outnumbering in its death rate, war and pestilence. In the United States every twenty-four hours, 440 human beings die of tubercular disease. While this great Association is in session, over two thousand five hundred men, women and children, through the agency of this king of terrors, will fill consumptives' graves, and homes all over this land will be in mourning for dear ones whose lives have been cut short by a disease that could have been prevented.

To-day, pulmonary tuberculosis is more widely diffused by infection from sputum than by any other means. The sputum, becoming dry and in the form of dust being carried far and wide, is inhaled into the lungs. Wherever it finds good feeding ground it makes a home. Scientific investigation has shown that a patient in advanced pulmonary tuberculosis may give off millions of bacilli in twenty-four hours. Koch found the dust taken from the rooms occupied by consumptives produced infection in two-thirds of his experiments; others have shown that the sputum retained its virulence as long as seven months. If this be true, and the sputum of tubercular patients, teeming with bacilli, is allowed to become dust, to be carried here and there, inhaled by hundreds of people, settling upon fruit and upon water, to be eaten and to be drunk by hundreds more, is it any wonder that phthisis pulmonalis is no respecter of persons but spreads to the high and the low, the rich and the poor, the young and the old, infecting whole communities once healthy? A common way of infection is through the alimentary canal, by the use of milk from tubercular cows, and meat tainted with tubercular germs; while candies, fruits and vegetables exposed for sale, becoming infected by bacilli-laden dust settling upon them, may spread the disease. With examples too numerous to mention, of the spread of the contamination from husband to wife, brother to brother and friend to friend, knowing the consumptive taints the very air we breathe, the food we eat and the water we drink, how can we, members of this great human family, keepers of our brothers, sit idly by and make no effort to save them?

Among intelligent reasoners the belief that it is an inherited disease is fast passing away, until now we rarely hear the statement. Though one does not inherit tubercular disease, he may inherit the predisposition to consumption, and his lungs form good soil in which the seed will thrive. With these facts before us, proved by a great cloud of witnesses, we are enabled to fight the disease on an intelligent basis, first by destroying the vitality of the seed, then by strengthening the soil till the germs find no nutriment. We have no hidden foe to fight, but one whose methods are known. We may have a knowledge of the best way to prevent infection, still, unaided, we can do nothing. We must have an intelligent people roused, until city, State and nation are compelled to adopt stringent measures for the protection of its inhabitants from this direful disease. When public opinion is educated to the full realization of the

danger, and awakened government enforces the laws, we can stamp out this greatest enemy of mankind, or, at least, so control it that it will cease to be a scourge to humanity.

Sanitation and disinfection have given preventive medicine a prominent place among the sciences. To-day it comes nearer giving specific treatment for this class of diseases than does curative medicine. It not only prevents disease in the present generation but it affects posterity. In this age of enlightenment, disease is no longer considered a visitation of Providence but a punishment for neglected laws of health. The people should be made to understand this, and the physician's duty is to instill into their minds the rules of good health, enabling them to save millions of lives. He must show them that although this plague of plagues causes more deaths than all other epidemic diseases combined, still it can be controlled. He should instruct them in their daily intercourse, and teach them through the great molders of public opinion, the press. He should encourage the forming of societies of hygiene, until every hamlet and city in our great nation has an organization for the promotion of life and health. Rouse the women of the land to organize another crusade, for the protection of the homes from sickness and death. One that will sweep across our beloved land, leaving peace and long life to the inhabitants. Seize every opportunity to spread the doctrines of good health. Make the way so plain that the simple can understand. We may be called alarmists, so was Paul Revere. Among our own number will be those who have no faith in things new; even Christ had his doubting Thomas. Others will ignorantly scoff at our danger signals; so did the ancient people at Noah's warning of the flood. A few medical men, with hearts like Nero, will overlook any danger to others, so long as they reap a harvest. As conscientious physicians, champions in the cause of public health, let us do our whole duty, heeding neither indifference, ridicule nor censure. To-day's work will add to the public health, wealth and happiness, and will directly influence the shaping of the course of preventive medicine in coming ages.

A reasonable limitation should be placed upon all tubercular patients. Isolation would be an added burden to the invalid, but strict sanitation is necessary. Cannot proved beyond a doubt that when his patients strictly followed orders in disinfecting their sputum, the dust from their rooms was free from contagion. A thorough system of disinfection should be used in our hotels, theaters, school houses and other public buildings. All receptacles of sputum should contain solutions that will destroy the life of the germs, or keep them moist until life can be destroyed. All cars, steamships and other public conveyances, should be provided with the means for destroying the bacilli, and should be thoroughly disinfected at the end of each trip. Owners of factories and workshops should be compelled to surround their employes with such safeguards as disinfectants and pure air. Rented houses should be fumigated and a certificate from the proper health officer furnished the new tenants. Rooms, bedding and furniture known to have been occupied by a consumptive should be disinfected as soon as vacated. Make the sale of milk and meat from tubercular cattle a crime, and the punishment so severe that men in the business will scan well what leaves the dairy or shop.

Instruct the tubercular mother not to nurse her child. Enforce laws that will restrict immigration, excluding those who suffer with the dread disease. This should be under the supervision of medical experts.

To get at the root of the whole matter—educate the children. Place books in the schools that teach true sanitation, making it the most important study, instead of the least. Develop our youths by physical training so that their constitutions will throw off the seeds of disease instead of retaining them. Teach them that inherited defective organisms must be remedied, that a depleted system will be in condition to receive the germs of phthisis pulmonalis. If principles of sanitation are thoroughly instilled into the minds of our youth, the coming generation will be better able to overcome the dread disease than has been the present one.

Reading material on this subject should be furnished by our boards of health for free distribution. There should be special hospitals for consumptives. All this can not be carried out unless aided by the State and nation. A few of the States have taken a step in the right direction. There should be experimental stations with scientific men in charge, aided by the Government. No such encouragement as Pasteur and Koch received from France and Germany, in the way of funds and laboratories, has been given to the men of our country by the government. Must America in shame always follow, instead of taking her place in the front ranks of medical progress? If there are doubts in regard to advanced theories of health, it is the duty of our government to remove these doubts, or prove the theories false by experiment and research. She can not longer shift the responsibility. If, through mismanagement of railways and factories, a man is accidentally injured or killed, large damages are awarded and the utterance of public opinion is long and loud on account of criminal carelessness. Shall our nation be held guiltless for sickness and death, which she can, but will not prevent? The cost may be great, but, compared with the number of lives saved, the expense will be trifling. Money is freely spent in almost every other line of research, but there seems to be a prejudice against the passage and enforcement of sanitary laws. Our last Congress refused to pass Representative Barthold's bill to appoint a committee to investigate the cause of the pollution of water supplies, but \$40,000 was voted to be used in exterminating the gypsy moth, \$15,000 for experiments in irrigation and \$885,000 was granted to the Weather Bureau.

We do not criticise the expenditure of these immense sums for the benefit of our country. But is it not outrageous that the lives of our people are considered of so little value? Is the financial condition of our country more important than the health of our nation? Are the agricultural interests to take precedence of the lives of our citizens? With the President's recommendation to Congress of a Public Health Department, we passed another mile stone in the march of preventive medicine. That we may keep abreast of advancing civilization, let us agitate this question before the people, until there sits in the cabinet council one whose watchful eye is ever on the foes of mankind, and his finger on the pulse of the nation, seeking for signs of disease, in order that he may ward off threatened danger. Then, and not until then, shall we see the full realization of our hope; our land freed from tubercular disease.

ISOLATION HOSPITALS FOR CONTAGIOUS DISEASES OTHER THAN SMALLPOX.

Read in the Section on State Medicine at the Forty-sixth Annual Meeting of the American Medical Association at Baltimore, Md., May 7-10, 1895.

BY BENJAMIN LEE, M.D.

SECRETARY OF STATE BOARD OF HEALTH OF PENNSYLVANIA.
PHILADELPHIA.

It is well known to many members of this Section that the various State boards of health throughout the United States and Canada have been in the habit for many years of meeting annually in conference, each board sending one or more delegates. The object of this conference has been to compare notes with regard to sanitary administration, to render the experience of all the boards available for the information and instruction of each, and to discuss such questions with regard to inter-State and seaboard quarantine, and the mutual relations of the several boards, as have a wider scope than the interests of the individual commonwealths.

At the meeting of this conference, held in Cincinnati in 1888, the question of isolation hospitals was presented in an admirable paper by Dr. P. H. Bryce, Secretary of the Board of Health of the Province of Ontario. The title of his paper was, "The Duty of the Conference in urging the Erection of Isolation Hospitals for the treatment of Infectious Diseases (as scarlatina, diphtheria, etc., as well as smallpox) as a more economical and effective method than placarding and quarantining the houses where these diseases are present." This title appears to me to bring the subject before us in a very practical way. It is, in point of fact, essential that we should have isolation hospitals if we are to protect our communities from the ravages of the two affections mentioned, scarlatina and diphtheria, and to save the thousands of lives of little children which are sacrificed to them every year.

The only question is as to the form in which such hospitals shall be provided. Shall each house in which a case of one of these diseases occurs be made, for the time being, an isolation hospital, its inmates debarred from communication with the outer world, and subjected themselves to the risk of acquiring the disease for the entire period during which the patient is ill, with the added period of necessary quarantine after the patient has ceased to be an object of danger and the house has undergone disinfection? No one whose house has not thus been temporarily converted into an isolation hospital can appreciate the excessive annoyance, discomfort and loss which are thus entailed. Especially is this true with regard to those in moderate circumstances, such as mechanics or small tradesmen, to whom every day of loss of wages, or of business, is a matter of the most serious import. Experience in England, in New York and to a certain extent, in Philadelphia has amply demonstrated that the spread of these diseases in families is very much greater when the home is converted into an isolation hospital than when the member of the family first attacked is removed to a properly arranged and fully equipped isolation hospital. It need scarcely be said that no general hospital is now willing to receive infectious diseases, so that this first plan of converting homes into isolation hospitals must be continued, or other isolation hospitals must be provided.

The alternative plan is, therefore, to establish, not only in every city but also throughout the rural districts, hospitals to which those suffering from con-

tagious diseases, of whatever kind, may be properly removed as soon as the diagnosis is made. In a city of the large population and immense area of Philadelphia, for instance, one such hospital is not sufficient. There should be at least four, so arranged as to be comparatively easy of access from the different quarters of the city. These hospitals should not be magnificent structures several stories in height with elaborate architectural adornment, but should be constructed of wood, on what is known as the pavilion plan, and but one story in height. All of the expenditure should be devoted to the internal arrangement and equipment. In consequence of the horror which is inspired by smallpox, it would unquestionably be better that that disease should be treated in an entirely distinct hospital, and at a different location from the others. The other two should be treated in separate pavilions, but might be under a common administration. Separate ambulances should also be provided for the different diseases.

The advantage to the family in which such disease occurs can not be overestimated. At the time of the removal of the patient, the house can be inspected and disinfected, and the family, while not quarantined, can be kept under observation till the period of incubation is passed, and the wage earners, after a thorough first disinfection, be allowed to attend to their daily duties. In this way the interference with attendance of children on school will be very greatly diminished. The plan is in the highest sense both humanitarian and economical. As remarked by Dr. Bryce: "It is, in many instances, absolutely impossible for the mother of a large family to nurse, for instance, a case of diphtheria, and attend to the many other household duties. It is indeed cruel to permit a poor family to be, with an almost certainty, afflicted in all its susceptible members with a disease so fatal, and it is unjust and absurd to expect a wage earner to be prevented from earning the necessities of life, while, with almost absolute certainty, house quarantine will extend the area and period of sickness, inflicting as well as an unnecessarily large doctor's bill, a tolerably certain undertaker's bill in addition."

The paper by Dr. Bryce was generally discussed and his suggestions met with universal approval, so far as the desirability of the step proposed was concerned, the only question being with regard to its practicability in small towns and sparsely settled districts. The subject was referred to a committee which reported as follows:

"1. That the principle of the establishment of isolation hospitals, as a preferable method to placarding houses and quarantining families, has been fully confirmed, both by general experience and the experience of members of the conference.

"2. That the practical difficulties: 1, of expense of establishment; 2, of the removal of persons suffering from dangerous infectious diseases thereto are not so serious in practice as at first sight would appear, since the simple character of the isolated building required in many cases for handling first cases, and the discrimination which ought to be exercised by medical health officers in the removal of persons, will be found to largely remove what in many cases appeared insuperable difficulties.

"3. That it is most desirable that the position which all our State and provincial boards should take, is that of urging from the standpoints of duty and economy, their local boards to establish places of isolation for those cases of diphtheria, etc., which in their opinion will be dangerous to the household and to the community.

"4. That contemporaneously with education along the above lines, State and provincial boards ought to press for

such legislation as will place them and their local boards in a position to enforce such isolation as the circumstances may demand."

There is no question in my own mind that the existence of such hospitals, provided with every means which modern science can suggest for the proper treatment of such cases, not only comfortably but tastefully furnished, would be at once appreciated by the community, and that families in good circumstances would be anxious to avail themselves of such opportunities, and to pay well for the privilege, so that such establishments would not only pay for themselves but might be a profitable investment. The mother of the family or the elder sister could go with the patient, so that a little child would not be compelled to suffer the pangs of bereavement, and the home would thus cease to be an isolation hospital, with a placard on the front door stating the fact. As soon as proper disinfection had been performed, the father of the family could go out to business as usual, and the social life of the house could proceed without interruption.

All the discomforts, anxieties, vexation and perplexities accompanying the presence of a case of infectious disease in the house would thus be avoided. Not only would it be a means of protection to the other members of the family, but the chances for the patient himself would be greatly improved. I say this advisedly, and desire to give my reason for this belief. During the past year smallpox has prevailed in Harrisburg, the capital of Pennsylvania. At the earnest solicitation of the Secretary of the State Board of Health, the city council of Harrisburg erected a small isolation hospital, and after that building was in readiness to receive occupants every case was at once removed to it. Extreme care had been taken in the ventilation of the wards of the building. All the used-up and infected air of the building was drawn out by means of artificial exhaustion, and passed through a furnace designed for the destruction of the excreta and garbage of the institution. Warm fresh air was constantly introduced. The amount of fresh air thus furnished was greatly in excess of that with which the patients were provided in their own homes. The consequence was, as I have been assured by the chairman of the sanitary committee, who had the general charge and management of the epidemic, that soon after admission the temperature of the patients fell, the nervous irritability diminished, and as a rule they soon fell into a quiet sleep; in cases in which wild delirium had been present on entering, they awoke from this slumber refreshed and calm. The experience of Harrisburg in this matter is valuable as regards the necessary expense of such a building. Their hospital will accommodate with ease forty patients; it is one story high, seventy-six feet in length and thirty-six in width. Its ventilation, as I have said, is very perfect, and its cremation furnace is so effective that not a particle, either of infected material or of infected air can possibly escape from the building. I believe that it could with safety be placed in a populous neighborhood. The entire cost was only \$3,000.

Whether pay patients should be received in separate wards, separate pavilions or in entirely distinct establishments from charity cases is a mere question of detail. It might be quite possible to have distinct wards or distinct pavilions in the

same inclosure for such cases, as is now the custom in general hospitals. But, as one great object would be to make such refuges so attractive that compulsory removal would be unnecessary, it might be well to have entirely separate institutions. If this latter plan were adopted, however, it should be a *sine qua non* that the hospital should be under the direct supervision of the local health authorities, and that every detail of administration should be in accordance with their regulations. In this way alone could safety to the community be insured. This need not interfere, however, with the attendance of the family physician on his own case in the hospital. This would be essential to making the movement a popular one, and would go very far toward recommending it to the patient and his family. The relief to the physician himself from the anxiety which he always feels with regard to other members of the family would be very great. At the same time the facilities which would be provided him for the protection and disinfection of his own clothing and person would be such that he would be much less apprehensive of carrying the infection to other families. The methods of personal precaution insisted on in such a hospital, under the immediate supervision of the health authorities, would also be of very considerable educational value to the profession.

1532 Pine Street.

ADVANTAGES TO A COMMUNITY OF A HOSPITAL FOR CONTAGIOUS DISEASES.

Read in the Section on State Medicine, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY J. L. LEAL, A.M., M.D.

PATERSON, N. J.

Having had occasion recently to secure some information upon the subject of contagious disease hospitals, I communicated with the authorities of a large number of cities in this country, inquiring what facilities they possessed for the care and isolation of their cases of communicable disease. These inquiries were addressed to cities of the largest size as well as to those of not more than 25,000 inhabitants. The result, considering the advanced state of sanitary science, as well as the general interest regarding the public health which is now aroused, was most astonishing. I found very few cities making any claim to proper equipment for the handling of these diseases. The majority of them possess some sort of a pest house in which a stray case of smallpox, typhus or yellow fever, or cholera could be thrust and hidden away; but do not make the slightest provision for the care of those suffering from the ordinary endemic diseases of this class, or for the protection of the public from such sufferers. A certain small proportion of these cities possess, or contain, general hospitals which have wards or detached pavilions for the care of these cases, but in all of them the facilities are not adequate for the purpose; said wards or pavilions being used mostly for those unfortunates literally thrown upon the care of the city, or of the hospital, and for whom some provision had to be made. Charity and humanity are the ends in view and not the protection of the public health.

Now, in considering the condition of affairs here shown we must conclude, either that the advantages

of contagious disease hospitals are not thoroughly appreciated by the health authorities of the majority of these cities, or else that public opinion is not yet educated to the point of granting their demands for this most necessary sanitary equipment. The fault lies probably with the public, and the remedy will prove to be its further education in its needs in this direction. This education and enlightenment will come through the influence of such bodies as this, and the individual efforts of the men who compose them. It is comparatively a few years ago when general hospitals were rare outside of large cities. Now, a town of from five thousand to ten thousand inhabitants without its hospital is a rarity. The public appreciates their necessity and prides itself on their maintenance. They are local monuments to charity and humanity. The contagious disease hospital, on the other hand, is a bulwark against disease, a protection to every citizen, his family and his home. So, as selfishness is ingrained in mankind, and self-preservation is the first law of nature, it but needs the necessary intelligence and knowledge on the part of the citizen to place the contagious disease hospital upon a level of importance at least equal to the police station or the fire engine house.

Now, as to the character of such an institution. It should be a hospital in every sense of the word, and not a pest house. The pest house has outlived its usefulness and should be relegated to the past. Its location should be carefully selected both with reference to the safety of the community from contagion and with reference to the moral effect upon the patients and the community. It should be constructed and managed upon the most modern and scientific principles. The various buildings and departments should be so located and constructed as to secure the safety of patients suffering from one disease, from all danger of infection by another. Furniture should be simple, and floor walls and ceilings should be of such a character as to permit of thorough flushing and disinfection. Medical attendance, nursing and general management of the institution should receive at least as much attention as in the ordinary first-class general hospital. The advantages to a community of such an institution will easily far more than counterbalance the labor and expense involved. In the first place, it will provide proper care for homeless persons, those taken ill in hotels, boarding-houses and institutions, and such care can be given without danger to the public health. In the second place, with an institution of the above character, it would not be long before public sentiment would be educated to the point that the majority of patients suffering with communicable disease would be willing to go, and their friends to send them, to the hospital. Not only on account of the better care which they would there receive, but also on account of the danger to others due to their proximity, as well as to the pecuniary loss due to the public apprehension and the restrictive measures now in use by most health authorities. It would be then but a step further and the public would demand that these cases be removed, whether willing or not, for the sake of the public good. When that point is reached it seems to me that we will be a long way on the road toward the control and almost practical suppression of this class of diseases.

It has been proved that by prompt removal and isolation of persons suffering with smallpox, typhus,

yellow fever and cholera, communities have been saved from what would certainly have proved epidemics of those diseases. Then why would we not secure practically a like result by similar action in the cases of other diseases of this class? Scarlet fever and diphtheria are far more dangerous to the people of this country than any one of the diseases enumerated above. Why, then, so much excitement and so much exertion over the suppression of smallpox, cholera and typhus, while scarlet fever and diphtheria are always with us, and their presence and their ravages taken as a matter of course? Simply because our familiarity with these diseases has bred contempt. It is well known that the Mexican regards smallpox and the Hindoo cholera, in about the same light that we do scarlet fever and diphtheria. I believe that there is more danger to one of our communities from a case of scarlet fever or diphtheria than there is from a case of smallpox, typhus or cholera, and that at least as active measures should be taken for their suppression. Now almost the first thing done is to remove a case of typhus, cholera or smallpox to a place of some kind to get it away from the community, so that its presence may not be a menace to it. Owing largely to this method of procedure, these diseases have become a comparative rarity in well ordered communities. Certainly, this is strong presumptive evidence that we could secure practically similar results by the same procedure in the case of those more common diseases of the same class. To be sure, these diseases are now endemic with us and there exists such general infection that it would be difficult to overcome it. Still I firmly believe that with a proper institution for the purpose, and the prompt removal thither and proper isolation of the cases, together with the sanitary measures now in common use, that this general infection could be overcome and these diseases controlled practically as well as are the others mentioned. In the third place, from an economic point of view such a hospital would be an advantage to any community. An outbreak of communicable disease in the family of an ordinary working man is usually a very serious matter even in a financial way. There will be the usual extraordinary expenses attending illness of any kind, and beside there is usually loss of work for those members of the family through whom the income is received, due either to the restrictive measures employed by the authorities, or through the fear of employer and fellow-employees. Should the disease spread from one to another of the family, a great deal of time and its rewards will be thus lost, and in many cases the family never recovers from the effects. From being a self-supporting, spending member of the community, the working man is often obliged to call for public aid in his trouble. His community therefore loses not only the aid given him, but also what he should have earned and spent during that time. If, now, there were proper hospital facilities, the first case being at once removed from the premises, the chances are that the disease would not spread to other members of the family, and proper precautions having been taken, there would be no fear on the part of employer and public, and therefore no cessation of revenue and consequent financial difficulties. I am confident that a careful investigation on these lines in any community of size, will show a loss far beyond the expense of maintaining a hospital. We are certainly

justified, then, in claiming that a proper hospital, properly used, will furnish patients with better care, will tend to protect the general public from infection, and will save the community financially far more than its cost.

SIMPLE CATARACT EXTRACTION AND SOME THOUGHTS ON PROLAPSUS OF THE IRIS.

Read at the meeting of the Chicago Medical Society, June 5, 1895.

BY BOERNE BETTMAN, M.D.

Professor of Ophthalmology in the Chicago Post-Graduate Medical School; Oculist and Aurist to the Michael Reese and German Hospitals; Attending Surgeon to the Illinois Charity Eye and Ear Infirmary; Professor of Ophthalmology and Otolaryngology in the College of Physicians and Surgeons, Chicago.

Since the introduction of Daviel's flap operation for cataract in 1748, numerous methods for the extraction of opaque lenses have been introduced, modified and abandoned. The innovation of anti-sepsis was followed by the rejection of Graefe's modified linear extraction and the re-introduction of the corneal flap. Most of the leading oculists the world over, now make the corneal incision either within the corneo-scleral margin or at the limbus. The important question which has interested oculists with reference to cataract extraction since 1888 is whether to do the simple extraction or the combined operation. The war has been waged fierce and hot. The literature on the subject is extensive. The annuals devote separate chapters to the discussion of the two methods. After these years of probation some authorities who first advocated simple extraction have returned to that first love and do an iridectomy. Foremost among these stands Stellwag von Carion. Such reliable and skilled observers as Knapp, De Wecker, Schweiger, Hirschberg, Noyes, Gruening, Galezowski, Panas, Gayet and others affirm that simple extraction without iridectomy is the ideal cataract operation. Fuchs, Argyl-Robertson, Swanzy and Von Hippel have always advocated the combined method. In order to appreciate what gave rise to these diverse opinions it may be well to learn that the *causis belli* was the danger arising from prolapsus of the iris. The advocates of iridectomy rightly claim that the above mentioned mishap can not occur when a piece of the iris is removed. The upholders of simple extraction, on the other hand, assert that prolapsus of the iris does not frequently follow, and when it does, it is not a serious complication and can be readily overcome in many cases by snipping it off. Again, they maintain that iridectomy exposes the eye to many dangers which simple extraction obviates.

The advantages and disadvantages have been summarized by many writers. I will quote the opinion of a few only. Knapp¹ enumerates the advantages of the simple extraction as follows:

1. It preserves the natural appearance of the eye.
2. The acuteness of the vision, other things being equal, is greater.
3. Eccentric vision and "orientation" (correct localization of objects in the visual field) are much better, adding a great deal to the comfort and safety of the patient.
4. Parts in direct connection with the ciliary body, such as shreds of the capsule and iris, are not so liable to be locked up in the wound, and thus transmit morbid conditions to the most vulnerable part of the eye—the ciliary body.

¹ Annual of Medical Science, Sajous, vol. III., B. p. 51, 1888.

5. It may not necessitate so many after-operations. As disadvantages, may be mentioned:

1. The technique of the operation is more difficult in all its parts. (a), the section must be larger to let the lens pass through an aperture, the size of which is diminished by the iris lying in it; it must be more accurate to secure coaptation, and it must be more rapidly performed in order to prevent the iris from falling before the knife. (b), the opening of the capsule requires a deeper introduction of the cystotome into the anterior chamber. (c), the expulsion of the lens is more difficult; and (d), the cleansing of the pupillary area is much more troublesome than in the combined extraction.

2. Prolapsus of iris and posterior synechiæ are more numerous.

3. It requires a quieter and more manageable patient during and after the operation than is needed in the combined extraction.

4. It is not applicable to all patients; whereas, combined extraction can be used as a general method.

Bull's² conclusions and those of Schweigger³ are very similar to those already referred to. Further observations and experience have demonstrated that they are tenable at the present day. It is not my intention to discuss this subject at all, being fully satisfied that simple extraction in selected cases is, to use the words of Dr. Knapp, "an operation of the highest order." During the last four years I have done the simple extraction exclusively in all cases where no contra-indication existed. In the early part of my experience, I placed the upper part of my corneal section between 1 and 2 mm. within the corneo-scleral margin, completing the incision by turning the knife at right angles to the corneal surface and cutting out vertically. In every case I instilled eserine up to six months ago, to contract the pupil and forestall prolapsus of the iris. In some, adhesions formed between the iris and edge of the corneal wound which, as far as I know, did not cause any subsequent worse results than elongating the pupil. In only four of the cases operated upon up to the present date did a prolapsus of the iris occur. In two only was I obliged to snip it off. The two others disappeared after two or three weeks, leaving a clear corneal scar with adhesion of the iris to the posterior surface of the cornea.

After reading De Wecker's⁴ article on "*La Suppression Partielle De l'emploi Des Collyres*," in which he calls attention to the uselessness of eserine in preventing prolapsus of the iris, and to the dangers of sepsis resulting from the employment of eye drops which rarely are germ proof, I abandoned its use. The results became correspondingly better, synechiæ became rare, the great majority of eyes showing perfectly round, regular pupils. I also placed the corneal incision nearer the periphery within the corneo-scleral boundary. These changes in the technique of the operation improved my results. Thus the two imaginary safeguards in avoiding prolapse of the iris were found to be without foundation. I had supposed that the upper corneal flap, if I may so call it, acted as a support to the iris and prevented its incarceration in the corneal wound. During my recent sojourn in New York, I noticed that neither Gruening, Knapp, nor Noyes evidenced any fear of

prolapsus of the iris, the former dilating the pupil before and after extraction with a 10 per cent. solution of cocain, the others with atropin. Gruening affirms that the cocain reduces the intra-ocular tension. Accacio da Gama⁵ recommended the employment of atropin in simple extraction in 1890. I desire to report tonight my last cataract operations in which the incision was made in the extreme periphery of the cornea and atropin was employed to dilate the pupil before and after the extraction. The results obtained, with one exception, may be regarded as ideal.

Case 1.—John Mueller, aged 57. Mature senile cataract of right eye. Perception and projection good. March 2, atropin instilled into right eye two hours before operation. Incision made in limbus. Lens easily removed. Instillation of atropin; both eyes bandaged. Patient allowed to walk to his room. Bandage removed on third day. Wound healed, pupil round. Bandage removed on each succeeding day and atropin instilled. Left eye remained free after fourth day; right eye after sixth day. Patient out of bed on fourth day. Eyes protected by shade after tenth day.

Case 2.—Mike Walsh, age unknown. Diagnosis: mature senile cataract of right eye. Perception and projection good. Simple extraction March 4. Pupil dilated by atropin. Corneal incision in limbus. Lens readily removed. Atropin instilled, eyes bandaged, patient walked to his room. Two days later bandage taken off and eye found in excellent condition. Pupil round and dilated. Patient out of bed next day, without bandage on sixth day, given liberty of house, protected by shade.

Case 3.—John Sapp, aged 64. Diagnosis: mature senile cataract of left eye. Immature right eye. Perception and projection good. March 9, simple extraction done with left hand. Pupil did not react well to cocain mydriatic. My assistant had forgotten to employ atropin instead. Lens extracted with difficulty through contracted pupil. Edge of iris was slightly nicked by the voluminous lens being forced through pupil. Atropin instilled, eyes bandaged. Recovery uneventful. Pupil round, regular and free. After-treatment the same as in above cases.

Case 4.—John Hobert, age 42. Mature senile cataract left eye. Perception and projection good. Opacities of cornea due to chronic trachoma. March 26, simple extraction with left hand, atropin mydriasis. Bandage changed daily after third day; atropin instilled. Recovery normal. Result perfect.

Case 5.—A. G. Thomas, age 62. Mature senile cataract right eye. Perception and projection good. April 6, pupil under influence of atropin, simple extraction. After-treatment routine one. Result perfect. Patient kept quiet in bed two days; allowed to leave room on seventh day with shade.

Case 6.—Peter McNamee. Mature senile cataract left eye. Perception and projection good. Operation April 19, atropin mydriasis. Simple extraction with left hand. Uneventful recovery. No unpleasant reaction. Routine after-treatment. Perfect result. Pupil round and clear.

Case 7.—A. G. Thomas. Mature senile cataract left eye. May 2, simple extraction; atropin employed before and after operation. After-treatment as in above cases. Result perfect. In lower pupillary field, opaque capsule.

Case 8.—Lydia D., aged 52. Insane epileptic brought from Elgin Insane Asylum. Mature senile cataract left eye. Right eye had been operated one year ago, combined operation with good results. May 11 atropin instilled forty-eight hours before operation. Simple extraction done with left hand. On the second day patient pulled the bandage from the eye. It was re-bandaged by a patient. On dressing the eye May 13, I found a small prolapsus of the iris. The eye was otherwise normal in appearance. The right was exposed, the left re-bandaged every day and atropin instilled. The prolapsus fully disappeared after ten days' bandaging. On June 1 she was discharged. The pupil is oval, the upper part of the iris being incarcerated in the perfectly smooth cicatrix. Her vision is good.

Cases 9 and 10.—John W. F. Mueller, aged 50. Mature cataract both eyes. Lower one-third of left cornea covered by a dense scar. Right pupil dilated by atropin and lens extracted early in March. Simple extraction. Bandage removed two days later. Wound healed, pupil dilated and round. Left eye remained free after third day. Perfect

⁵ Accacio da Gama, Nov. 16, 1890.

recovery; allowed to walk about house at expiration of one week. Left eye operated with left hand May 16. Simple extraction. Result perfect.

Case 11.—Mrs. K., aged 62. Right eye, combined operation four years ago. Left eye, senile mature cataract. May 27, after instilling atropin four times during the day, I did a simple extraction with left hand. Bandage removed two days later. Eye slightly injected; wound healed; pupil dilated and regular; small quantity of opaque lens substance in pupillary field. This absorbed in time. Right eye left unbandaged after third day; left eye after seventh. Recovery rapid; result excellent.

In every one of the above cases, a wrinkling of the lens capsule ensued which impaired the vision. In some, I made a secondary capsulotomy which materially improved the vision. The others will be subjected to the same operative procedure within the next few weeks. My experience with atropin in simple cataract extraction is limited to the above cases, and being meager will not permit of any very general deductions. I can not refrain, however, from giving vent to some views regarding the occurrence of prolapsus of the iris and how best to avoid it. It is a well-known fact that this complication is due directly to opening of the corneal wound and indirectly to the escape of the aqueous humor which flushes the iris between the lips of the gaping wound. The pressure exerted by the aqueous in the anterior chamber upon the cornea is naturally the same over its entire posterior surface, but the upper part of this membrane, owing to its severed condition, naturally offers less resistance than its remaining part. If the pupil is contracted by eserine, the appearance of the iris must necessarily be forced out of position by the aqueous humor in the posterior chamber. If the iris were a rigid membrane, the contents of the posterior chamber would flow through the pupil into the anterior chamber and then through the re-opened corneal wound. But as the rainbow membrane is a delicate relaxed tissue, we can readily comprehend that the aqueous humor back of it in flowing out from the eye carries the iris before it, forcing it out of the eye, thus producing a hernia of the iris. Another factor which favors prolapsus is the contractile power of the sclerotic. In the normal eye this tunic is kept comparatively tense by the pressure exerted from within by the aqueous and vitreous humors. When the eye is opened the place formerly occupied by the drained off aqueous, is filled by the other ocular contents, which are propelled forward through a partial collapse or contraction of the sclerotic. If the sclerotic were composed of some firm and unyielding material, as bone, the anterior and posterior chambers might be evacuated without endangering to a great extent the position of the iris, especially if the pupil were dilated. The above mode of reasoning has been fully elucidated by Fuchs in his classical treatise on "Ophthalmology." If this line of argument is conceded to rest on fully established truths, several logical sequences result. Narrowing of the pupil by eserine increases the danger of large prolapsus of the iris, this tissue offering in its contracted state a larger surface for the aqueous back of it to force outward, than if it were widely dilated. In the latter case, a larger quantity of aqueous would find direct outlet through the pupil, and less iris surface act as resisting medium. The only valid reason for employing eserine at all would hold good if its use were based upon its property of reducing intra-ocular tension.

The first thought to present itself to an operator,

in trying to avoid prolapsus and still preserve the iris intact, is to make the corneal incision near the pupillary margin. The pressure from behind on the cornea is now more equally divided, or rather the resistance offered the aqueous humor is more uniform, the upper flaps being almost as firm as the lower ones. Such an operation was actually devised by Liebreich. The interference to vision by the subsequent corneal scar, the production of astigmatism, due to irregular curvature of the cornea, and the frequent occurrence of anterior synechia make this method undesirable. Therefore several operators favored a more peripheral incision, one within 1 and 2 mm. of the limbus. This is the cut I have heretofore practiced, as stated before. I still regard it as a desirable procedure. The upper corneal flap is from $1\frac{1}{2}$ to 2 mm. high. It offers a support to the iris and when a prolapsus does occur it can not be as large as when the incision is made in the corneo-scleral margin. Another method of decreasing the chances of prolapsus is that advocated by Galezowski and Fuchs—sphincterotomy. It consists in cutting out a small piece of the pupillary margin of the iris. It is asserted that an easier delivery of the lens is thus permitted and less resistance offered the aqueous in the posterior chamber. The importance given to iris hernia in this paper might lead one to suppose that it is of frequent occurrence. This is not so, as reference to statistics will verify.

Esson reported eight cases of incarceration of the iris in sixty operations.

Albrandt, in a series of 232 operations, done by Scholler, noted prolapsus twenty times.

Knapp,⁶ in 509 simple extractions, 42 cases of prolapsus (8.2 per cent.). In the majority of cases it was slight and either disappeared spontaneously or cicatrized without danger to the eye.

E. Greiff⁷ reports 450 cases operated by Schweigger, of Berlin, prolapsus thirty-five times (7.9 per cent.); nine were small and required no further attention; twenty-seven (6 per cent.) were amputated. One hundred and thirty cases (corneal incision above), prolapsus twenty-three times = 8.5 per cent.

Knapp⁸ in 300 simple extractions met with prolapsus and incarceration of iris eight times. The latest statistics by the same author, presented at the Eighth International Congress, held at Edinburg, August 7 to 11, 1894, show 35 cases (10.3 per cent. of prolapsus, incarceration, or adhesions of the iris in 548 operations.

To what, however, must we attribute the hernia iridis? The location of the corneal section does not appear to have a great bearing, the percentage of prolapse not being materially influenced by either method. During the last four years I have encountered but four cases of prolapsus. One occurred in an excessively nervous patient, who retched and vomited frequently during the twenty-four hours subsequent to the extraction. Two took place in patients who left their bed contrary to orders twelve hours after the operation. The fourth, the one reported above, must be attributed to the violence and unruliness of the insane woman. Two were snipped off, and two disappeared after a week's bandaging. In my opinion, the subsequent treatment and behavior of the patient is largely responsible for it. Bearing in mind that the intra-ocular tension after the extrac-

⁸ Archiv f. Augenhellkunde, XXII, p. 335.

tion is relatively greater than it was before the cornea was incised, we must endeavor by counter-pressure and immobility of the eye to hasten the re-adhesion and firmness of the corneal wound; in one word, to restore as rapidly as possible the equilibrium between external and internal pressure. Great differences of opinion exist regarding the after-treatment. Chisholm stands at the head of a faction who oppose bandages and restraint of all kinds. He simply fastens the lids of the operated eye by gold-beater's skin or a piece of adhesive plaster, leaves the other eye open and gives the patient, protected only by dark glasses, the freedom of the ward. Others, again, permit the bandaged patient to walk from the operating room to his bed and there remain quietly for two days. Some operators do not remove the first dressing until forty-eight hours elapse; others operate on the patient in bed so as to avoid any possible strain attributed to locomotion and undressing. I heartily agree with the innovators of the idea that patients should be free from the restraint which was formerly placed upon them, but it appears to me some go to the opposite extreme. When I was Professor Becker's assistant in Heidelberg, fifteen years ago, our cataract cases were indeed subjected to a most trying ordeal. During the first four or five days they were expected to lie prone on the back. Notwithstanding the impossibility of the occurrence of prolapsus, owing to the iridectomy done in every case, on the third or fourth day they were allowed to assume a half upright position, being supported by a back rest. At the end of a week one eye was unbandaged and the patient allowed to sit in a chair in a dark room. It required another week to accustom the operated eye to the light, which entered through a partially drawn Venetian blind. During the third week the patient was given the freedom of the hospital, the eye protected by smoked glasses. The middle course, not too much freedom and not too much restraint, I regard more in keeping with the demands of circumstances we are called upon to meet. The upper half of the cornea has been severed. This must re-unite. Any untoward movement of the eye or of the body which will tend to disturb the close adaptation of the flap, either on account of mechanical insult or increase of intra-ocular pressure, must be carefully avoided. This can best be accomplished by guarding the patient from such mishaps.

I do not intend to take up more of your time by entering into a detailed discussion of the various methods of after-treatment, but will, in conclusion, mention the method I invariably enforce. I always operate in the operating room, the patient reclining either in a chair or on an operating table. After extracting the cataract, both eyes are covered by pieces of clean linen dipped in boric acid. Over this are placed two thicknesses of thin cotton discs. The whole is kept in position either by a two inch broad gauze bandage, or more often by one made of starched mosquito bar netting. This latter material must not be starched too much, otherwise it will after drying, exert too much pressure on the eyes. The fine netting in commercial use will answer the purpose. After being sterilized it is dipped in boric acid and applied. The patient is led to his room, and such clothes as have not been previously removed are now taken off. The parting instructions are, "Remain quietly on your back, or on the non-operated side for

twelve hours." An aperient having been given the night before, the desire to evacuate the bowels will not arise until the third day. The bandage and wet cloths dry after a few hours and conform to the shape of the head and other parts they cover, thus exercising a uniform and gentle counter-pressure and rendering the eyes immobile. When the bandage is cut away it retains the form of the parts like a plaster-of-Paris dressing. Only fluid diet is allowed the first forty-eight hours. After twelve hours the patient is supported in a partially upright position by a back-rest. The eye is dressed for the first time on the third day unless subjective symptoms require an earlier inspection. After removal of the bandage (cut with scissors), the edges of the lids are washed with boric acid and the eye inspected. Boric acid and atropin are dropped between the lids and the eye re-bandaged. This method of dressing the eye is repeated daily until the fifth day, when the eye is left open, the non-operated eye having been freed already on the third day after the operation. On the third day the patient leaves the bed and sits in a comfortable chair. On the seventh he leaves his room. This is my routine practice in the general run of cases. Strict adherence to the above method, which contemplates rapid union of the corneal wound, by moderate quiet of the patient and immobility of the eyes, appears to me to be responsible for the few cases (four) of prolapsus which have occurred in my practice. The presence of a well trained nurse helps greatly in reaching the desired end.

Permit me, in conclusion, briefly to review the main features of this paper. My object in reporting the eleven cases operated under atropin and with a periphery incision and in referring to other methods in vogue, is to demonstrate that good results are obtained, no matter where the corneal incision is placed; neither does the employment or disuse of eserine, atropin and cocain affect the occurrence of prolapsed iris. The most important factor in an ideal outcome is the after-treatment, the observance of methods which will counteract intra-ocular tension and thus rapidly lead to reunion and firmness of the cornea.

CLINICAL MICROSCOPY.

Read by title before the Tri-State Medical Society at St. Louis, April 2 1895.

BY W. B. LA FORCE, Ph.B., M.D.

LECTURER ON PATHOLOGY AND DIRECTOR OF THE MICROSCOPIC AND BACTERIOLOGIC LABORATORY OF THE KEOKUK (IOWA) MEDICAL COLLEGE.

In presenting a paper on the subject of scientific medicine and the microscope, I have no discoveries to reveal, nor shall I attempt to review the progress in the science of medicine brought about through the revelations of the microscope; but rather will I direct your attention to its clinical value. With this in view, we will omit detailed reference to the important facts revealed by studying the minute anatomy of the different organs in both their normal and diseased conditions. It is axiomatic that the more we know of the structure, both macroscopic and microscopic, of organs healthy or diseased, the more capable are we to understand the physiologic and pathologic processes which occur in those organs or tissues; and so we will not dwell on those points. Moreover a large part of such knowledge has been acquired through study of the post-mortem specimen.

But to-day I desire to emphasize the growing im-

portance of the microscope in the clinic, or at the bedside, as an aid and sometimes as the all-essential factor in establishing an early and positive diagnosis and prognosis.

With the recent discoveries in chemistry, microscopy, and bacteriology, scientific medicine has probably advanced as much in the last few decades as in all previous time. The art of medicine is being replaced by the science of medicine. Not more than a generation ago, the successful practitioner must needs have had very extended observation of disease in order to weigh one symptom with another, and judge between them properly. Distinctive pathognomonic symptoms were not known so well as now. Diagnoses were more a matter of judgment, and naturally, other things being equal, the one who guessed the longest was the best guesser.

But at present, with a great many diseases, conditions have changed. Thorough laboratory courses may answer for several years of practice. Instead of looking for a combination of symptoms, we look for one distinctive symptom; and whereas the old practitioner, in many cases, after much observing and deliberation, could give only a probable diagnosis, to-day, the young physician well drilled in chemistry, microscopy and bacteriology is able in many of the same cases to give an immediate and positive diagnosis and a more correct prognosis. The artist is giving way to the scientist, conjecture and judgment to confidence and knowledge.

The diseases which often can be positively diagnosed by a microscopic examination of the blood, and sometimes only by such an examination are: leukemia, pseudo-leukemia, oligo-cythemia, pernicious anemia, simple leucocytosis, chlorosis, anthrax, miliary tuberculosis, glanders, typhoid fever, tetanus, relapsing fever and malaria, with its different tertian, quartan and atypical types; and those diseases caused by the animal parasites: distoma hematobium, and filaria sanguinis hominis.

To review a little, we find that oligo-cythemia is characterized by a decreased number of the red blood corpuscles without change in the number of the white. In health 1 cu. mm. of blood contains according to Vierordt, four to five million red blood corpuscles. In oligo-cythemia, the number has been known to be decreased to 360,000 for the same volume. Probably the best means of determining the number for clinical use in diagnosis and in estimating the effect of therapeutic measures is the microscope, together with the Thoma-Zeiss counting apparatus. The amount of contained hemoglobin can be most accurately determined with Fleischl's hemometer.

The condition oligo-cythemia is present in simple anemia, chlorosis and pernicious anemia. In the simple anemia there is merely a decrease in the number of the red corpuscles with a normal amount of hemoglobin for each corpuscle. In chlorosis there is, beside the decrease in the number of the red corpuscles, also a decreased amount of hemoglobin in each corpuscle. While in pernicious anemia, a disease which is always fatal, there is, beside the lessened number of red blood corpuscles and of their contained hemoglobin, the additional factor of poikilocytosis, *i. e.*, a marked irregularity in their size and shape, with relative increase of the amount of hemoglobin.

Leucocytosis, on the other hand, is a condition characterized by an increase in the number of the

blood's white corpuscles, which in health range from four thousand to ten thousand per cu. mm.

A much more serious condition, which is generally fatal, and the diagnosis of which is therefore valuable, mainly for the prognosis, is leukemia, or leucocythemia, characterized by a great increase of the number of the white corpuscles, a decrease of the number of the red and of their relative hemoglobin contents, associated with a marked increase of lymphoid tissue in the body. But pseudo-leukemia or Hodgkin's disease shows the increase of lymphoid tissue but not of the leucocytes.

Of the infectious diseases whose germs are sometimes found in the blood, those of anthrax, relapsing fever, and malaria may be recognized by microscopic examination of fresh blood; but in glanders, typhoid, tetanus and general miliary tuberculosis, cover-glass preparations of the blood must be made and stained before examined.

Given a suspected case of anthrax, anthrax edema, anthrax carbuncle, malignant pustule or woolsorter's disease, as the affection is variously called, an early diagnosis from acute phlegmonous inflammation and malignant edema is important, especially when the seat of origin is in the skin, for an early, and therefore thorough excision of the part may prevent general infection which latter when it occurs is generally fatal.

The diseases likely to be confounded with relapsing fever or its synonyms, bilious typhoid, famine fever, mild yellow fever, seven days fever, bilious relapsing fever, are atypical cases of malaria, sepsis, miliary tuberculosis, etc. But probably in none of the infectious diseases is the exciting cause more readily demonstrated in the blood than is the spirillum Obermeier in the blood of those suffering from relapsing fever. In acute general miliary tuberculosis, always a fatal disease, the diagnosis not infrequently is difficult in the extreme. Typhoid fever, septicemia, pyemia, chronic local tuberculosis of the kidneys, complicated by uremia, non-tubercular meningitis, capillary bronchitis, and general carcinomatous or sarcomatous metastases are all similar in many points. The finding of bacillus tuberculosis in the blood, cover-glass preparations of which are made and stained in the same way as from sputum settles the question, both as to diagnosis and the inevitable prognosis.

The blood of typhoid patients is but rarely found to contain Eberth's bacillus, especially in the early stages of the disease, being found much earlier in the fecal evacuations. However, its demonstration in the blood would speak positively for the diagnosis and indicate a very serious condition of the patient.

Glanders seldom attacks the human species, but when it does the demonstration of the Rotz bacillus or bacillus Mallei is best done by staining the cover-glass preparation according to Löffler's method. When the disease is purely local it may be confounded with syphilis or tuberculosis, but diagnosed and treated properly may be cured; however, when the germs have entered the circulation, a fatal ending is only a question of time.

Tetanus, although not a frequent disease in this climate, yet occasionally appearing as a wound disease, the discovery of the bacillus in the blood bids fair to assume considerable practical importance by reason of the discovery by Tizzoni and Cattani in the blood serum of an immune animal, of the tetanus antitoxin, analogous to Behring's diphtheria antitoxin.

In malarial affections we distinguish three distinct types of the disease: tertian, quartan, and irregular, and each is known to be accompanied by different forms of the plasmodium malarie.

In the tertian type, which is the most common, the plasmodium or hemamœba malarie requires two days for the growth of a generation, each attack of chill and fever marking the advent of a new generation and the parent is seen divided into fifteen to twenty segments.

In the quartan type, the parasite requires three days for its complete development and its progeny is six to twelve.

The atypical cases where the paroxysm is quite irregular, or even approaches the type of a remittent or continuous fever, or takes the form designated as chronic malarial poisoning, or malarial cachexia, is characterized most frequently by the half moon or sickle-shaped plasmodium of Laveran.

The pure intermittent quotidian is caused by three generations of the quartan type, each maturing on separate days.

Ordinarily, the pure tertian type, with the attack every other day, offers no great difficulty in diagnosis; but in the atypical forms already mentioned, a positive diagnosis is often long delayed and not infrequently impossible without the aid of the microscope.

From sputum and secretions and excretions of the oral cavity we recognize: parasitic stomatitis, tuberculosis pulmonalis, diphtheria or membranous croup, actinomycosis and croupous pneumonia.

In the examination of sputum for pulmonary tuberculosis, and of tonsillar or faucial exudates for the Klebs-Löffler bacillus of diphtheria, the microscope scores two of its greatest triumphs, the practical value of which is so well known that I shall not here dwell on them.

By examination of fecal discharge we may diagnose: cholera, typhoid fever, intestinal tuberculosis, and various animal parasites causing more or less of acute enteritis and the varieties under the sub-kingdom vermes as tœnia, trichinæ, etc.

In microscopic examination of urine, much positive knowledge is obtained with reference to disease of genito-urinary organs, especially in differential diagnosis between simple hematuria, acute nephritis, chronic nephritis, contracted kidney and amyloid kidney, passive congestion of kidney and nephritic infarcts.

The form of predominating crystals in urinary sediment may reveal the nature of any existing calculi. Not infrequently, different tumors of the urinary tract, as papilloma, epithelioma and sarcoma shed small portions of their substance which are voided in the urine and whose nature can then be revealed best by the microscope.

Tuberculosis of the urinary tract can often be positively diagnosed only by cover-glass preparations of urinary sediments; and the seat of the ulcer, whether in the bladder, ureter or kidney, can often be determined by the predominance in the sediment of certain characteristic forms of epithelium desquamated by the ulcerous process.

Differentiation between a simple non-infective and gonorrhœal urethritis is possible in all cases by the proper microscopic and bacteriologic methods, and in some cases where all other methods would fail. Prostatorrhœa, spermatorrhœa and male sterility are also questions for the microscope to determine.

Finally, the finding in the urine of actinomycosis, ecchinococci, distoma hematobium, filarial sanguinis hominis and ascarides would explain otherwise very puzzling cases.

Of the cutaneous parasites, we recognize trichophyton tonsurans of ringworm, achorion Schoenlinii, of forms of ascoptes hominis of scabies, acarus folliculorum, beside the varieties of pediculi.

Then in different varieties of abscess, or purulent exudates, we can often appeal with advantage to the microscope to determine whether it is caused by the common pyogenic germs; or the bacillus tuberculosis or, less frequently, by anthrax, lepra or tetanus bacilli, or by echinococci or actinomycosis.

Another very important field for microscopy is in the recognition and differential diagnosis of benign and malignant tumors, especially in parts suitable for operation; and in many cases, as has so frequently been stated already in this paper, the microscope offers the only means of making a positive diagnosis early enough to allow of effective treatment.

Then in the domain of medical jurisprudence, where facts are demanded and conjecture is not allowed, the microscope plays an important rôle in the recognition of blood, hair, spermatozoa, etc.

In many of the conditions and diseases referred to, diagnosis can often be made with great probability, and even positively, by noting a combination of symptoms and observing the course of the disease, or by excluding the possibility of other diseases in the case. But such methods are always unsatisfactory and often dangerous in their delay. For some one or more of the combination of symptoms may remain absent or be slow in manifesting itself, the patient may die before the course of the disease is run, and diagnosis by simple exclusion is likewise a slow and unsatisfactory method. It is saying what the disease is not, rather than what it is.

But the progress of medicine, as a science, demands and is achieving early and positive diagnoses. The single and distinctive pathognomonic symptom is being sought and found. The essential and exciting cause (without which the disease would not exist, no matter how many predisposing factors were operating) is being recognized, and the way better paved for the train of therapeutic measures to follow.

The hospital, with its clinical and bedside teaching, has always been and always will be essential in proper medical training. Laboratories are becoming so, more and more every day. They are making the clinics more available and practical; and those colleges with limited clinical facilities can not establish themselves as thorough and practical institutions without equipping and maintaining good laboratories, and with such they can become eminently practical and scientific, for they can then, and not till then, use their clinical material to the best advantage.

CONCLUSIONS.

1. Medicine in many points is fast becoming a practical science.
2. Microscopy and other laboratory methods are doing a great deal toward establishing the science of medicine.
3. Thorough drill of the student in laboratory methods may answer for several years of general practice.
4. Positive diagnoses and more correct prognoses are possible in a goodly number of diseases only by

the microscope, and general practitioners not having had thorough training in this instrument of precision should, at least for the benefit of their patients, avail themselves of it, or call on the services of an expert in that line.

5. Medical colleges with limited clinical facilities may make their teaching eminently scientific and practical, by establishing and conducting good laboratories and thus get the best good from their clinics.

PERITONEAL SUPPORTS—(LIGAMENTUM PERITONEI).

BY BYRON ROBINSON.

PROFESSOR OF GYNECOLOGY POST-GRADUATE SCHOOL.
CHICAGO.

(Continued from page 326.)

In my opinion to Meckel belongs the chief credit of the coalescence theory (1817) and Müller in 1830 simply confirmed his views and enlightened the world as to the origin and development of the great omentum. Yet it is not necessary to believe that even such celebrated men as Meckel and Müller could

and duodenum. Hence one of Müller's errors is pointed out and corrected. Again, Müller noted that at first the mesogastrium arises in the mid-dorsal line, but with the change of the position of the stomach it becomes shifted toward the left. This is also an error of Müller, for the insertion of the mesogaster is always in the mid-dorsal line. Any one can prove that the mesogaster is always in the mid-dorsal line by opening up an adult cat, when it will be found that the mesogaster has never varied from the mid-dorsal line. In adult man, it appears that the mesogaster is not in the middle line, but that is owing to a displacement of the serous membrane toward the left or, as the coalescence theorists would have it, the left blade of the mesogaster has coalesced with the dorsal parietal peritoneum. Hence, it is plain to observe two errors of Müller. Again he asserts that the coalescence (*verklebung*) between the anterior blade of the great omentum and the upper blade of the transverse mesocolon can be easily divided in embryos of the third and fourth month. Whether this be an error or not, I will say that I never found this condition of re-dividing or re-sep-

Fig. 39 (after Henle, 1873) represents a horizontal section of the abdomen between the third and fourth lumbar vertebrae. The upper section, the small intestines, are spread out forward. 1, border and under surface of the liver; 2, section of the mesentery; 3, colon dextrum; 4, right kidney; 5, vena cava; 6, aorta; 7, the lower transverse portion of the duodenum shimmering through the mesentery; 8, left kidney; 9, colon sinistrum; 10, appendix epiploicus of same; 11, parietal layer of peritoneum; 12, under surface of the mesentery. Observe that Henle, the greatest of modern anatomists, draws in the sketch no mesocolon, right or left.

not make mistakes. I have read with care and pleasure Müller's article on the "Origin of the Great Omentum," written in German in 1830. I find that even Müller could labor under errors. For example, Müller states that the mesogaster ceases at the point where the duodenum begins. Any one can easily disprove this statement by opening a human embryo at six weeks or, still better, a dog or cat, whence in all three cases it will be plain and easy to see that the mesogaster extends all the way down the duodenum to the junction with the ileum. The mesogaster includes the mesentery of the stomach

and arating the coalesced membranes possible in any embryo of any age. Since we have found several palpable errors in Müller's noted essay of 1830, is it not possible that he was in error (and his followers) when he announced the confirmation of Meckel's theory of coalescence of the anterior blade of the great omentum with the upper blade of the transverse mesocolon? It must be admitted, however, that when a very accurate and keen investigator like Toldt of Vienna, lends his voice and pen to aid in supporting the theory of coalescence, it demands prudence and caution in opposing it. Respectful attention to

the arguments which make its "rock base" are called for.

In regard to the theory of displacement of the peritoneum in producing acquired mesenteries much may be said. I was led to the theory of displacement by my labors on the dog's peritoneum and viscera. It was by watching the beginning of the rotation of the intestinal loop as may be well observed in the dog, cat and human embryos which led me to the view of displacement of serous surfaces instead of their destruction in the formation of new or acquired supports. The convincing impression of displacement of serous membranes may be acquired to perfection, by observing how the left end of the great bowel moves up or pushes up the serous layer on the left surface of the duodenal mesentery. It leaves intact the membrana mesenterii propria, but raises its serous endothelial layer as this blind end of the bowel moves onward and downward in its travels. The process is beautifully observed in the slight rotation of the bowel found in early embryos or in the adult cat and dog. Yet it is not so easy of interpretation.

As supports to the theory of displacement we may say:

Fig. 40 (after Abey, 1871) represents a cross section of the abdominal cavity at the root of the colon transversum. Adult, one-fifth natural size. The upper surface. *a*, right, and *b*, left kidney; *a1* and *b1*, the ureters; *c*, cross section of ascending colon, and *c1*, of the descending colon; *d*, duodenum; *e*, transverse colon; *B*, vena cava and aorta. Notice in the figure how this Swiss anatomist sketches no mesocolon, right or left, in the drawing. *S*, quadratus muscle. The peritoneal line in the figure is drawn white.

1. Coalescence of any epithelial surface is an unusual matter and even rare (without inflammation).

2. The serous endothelial layer rests on a loose bed of soft, pliable connective tissue which endows the real peritoneal layer with an extensive gliding power. I have practiced in cadavers to see how far one could shove the endothelial layer on the subperitoneal tissue and was surprised to see how far the upper layer would shift on the lower. The endothelial layer will glide extensively on the subserous tissue. In the dead, it is easy in many parts to shove the serous layer over an inch on the subserous. Hence, by slow forcing, the serous endothelial layer can be easily and extensively displaced and the slow traveling of the cecum would give ample time to displace the right serous layer of the mesoduodenum, and sufficient time to displace and drag out the serous peritoneal pouch which exists between the anterior blade of the mesogaster and the upper blade of the transverse mesocolon. It appears more reasonable to suppose the above recesses peritonei becomes obliterated by coalescence and consequent destruction of the endothelium

3. As an actual fact in favor of the displacement theory, I can only find two distinct peritoneal blades in the ligamentum gastro-colicum and only two distinct blades in the transverse mesocolon. The four layer affair of the mesocolon is no doubt an interpolation made to help out and fit the coalescence theory of Meckel.

4. It does not appear to me to be reasonable to consider the serous endothelia as not genuine, as simply connective tissue cells, ready at any moment to "physiologic coalescence," and at a chance obliterate a man's peritoneal cavity. Wherein lies the intelligence of these non-genuine endothelial connective tissue cells to refrain from obliterating the serous abdominal cavity? Why do they simply act in the great omentum and sigmoid? Is it heredity or life's inscrutable method of progress?

Finally, I mention here two points which I have carefully examined. The first is a certain white line found most distinctly on the left side of the sigmoid flexure. This line is interpreted by Toldt to be the evidence of coalescence of the left blade of the left mesocolon with the layer of peritoneum on the dorsal wall. The facts in the case appear to me to be insufficient to establish the theory. However, the white line can be definitely observed, it is the inter-

Fig. 41 (after Abey, 1871) represents a cross section of the body in the region of the iliac crests, just high enough to strike a full section of the mesentery or the small intestine. A part of the iliac crests are cut among *c* as shown in the figure. Adults one-fifth natural size, lower surface. *c1*, descending colon of small intestine; *f1*, lower end of ascending colon; quadratus muscle. *A1* and *B1*, ureters; *a1*, *a2*, common iliac arteries. *B1* vena cava showing its septum of division preparing to divide into the two iliac veins. Observe no peritoneal coverings drawn on the posterior surfaces of its vertical colons. The peritoneal line in the figure is sketched white. The section occurs below it—both kidneys, so that only the ureters appear in the figure slightly differently located.

pretation of its existence which we await. It seems to me the line is evidence of displacement just as much as coalescence. I have often noted that when peritoneum turns from one surface to another, *e. g.*, at the duodenal flexure it may show a white line.

Again, I have frequently found in the dorsal peritoneum of both sides, but most frequently on the left side, small depression or pockets of peritoneum which would admit the point of a pencil or an object up to the size of the thumb. These pouches are lined with peritoneum, serous endothelium. Toldt again interprets these retroperitoneal pouches as evidence of progressive coalescence. I interpret them exactly opposite, as being simply the product of a local peritonitis. This local peritonitis may have originated by a gut lying on the place for some time and allowing its microbes or products to pass through the wall and infect the peritoneum locally. This is apt to occur as the dorsal peritoneum is immovable and could not get away from any infected bowel. The above two points are placed outside of the systematic argument as I consider the interpretation of them as not yet settled. No adequate explanation of the great length of the omentum has appeared.

THE LESSER OMENTAL CAVITY.

Lesser sac or bag of the peritoneum; cavity of the great omentum; cul-de-sac, or diverticle of the peritoneum; bursa omentalis; baccus peritonei; retroverticularis.

The lesser omentum is formed by elongation of the mesogaster toward the left side. The sac is at first situated behind the stomach, but later extends between the stomach and colon down in front of the small intestines, as far as the pelvis. At first the lesser omental sac is a mere depression in the right surface of the mesogaster, with development and elongation of the mesogaster, the depression in its wall deepens until the circumference of the depression contracts into a neck, the hiatus Winslowii. The atrophying liver drags the neck of the sac. Winslow's foramen to the right of the median line by means of the ligamentum hepato-duodenale. The posterior wall of the lesser omental cavity is the two-bladed mesogaster and the ascending double layered omentum and the upper layer of the transverse mesocolon. The anterior wall of the cavity is the posterior wall of the stomach above and below the two converged serous layers from the stomach descending to the pelvis, whence the layers return on themselves to the transverse colon, which by dividing, they embrace, and again converge to form the transverse mesocolon and then pass to the posterior abdominal wall. The left end is closed in by the blades of the mesogaster while the right end converges to a small neck, orificum epiploön. The lesser omental cavity is almost perfectly observed in a child of the first year or in a cat or dog of the first year. Even in early adult life the lateral edges begin to coalesce from local peritonitis.

To trace the exact lining of the adult lesser omental sac, begin at the transverse fissure of the liver and pass along the under surface of the lesser omental sac (see figure), to the small curvature of the stomach, thence along the posterior surface of the stomach to its greater curvature. Now, pass along the posterior surface of the posterior blade of the great omentum to where it turns upon itself in the pelvis and follow it upward to the transverse colon, thence to the dorsal wall along the upper blade of the transverse mesocolon. The single upper mesocolic blade now turns upward and ascends over the pancreas, thence along the dorsal wall as far as the coronary ligament of the liver, whence it returns to the transverse fissure of the liver where we started. To trace the left wall of the sac is very easy by beginning at the right side of the right blade of the mesogaster and passing to the left to the spleen and ligamentum gastro-lienale, thence back to the greater curvature of the stomach. The right end of the sac is constructed to a small neck, foramen primum bursa omentalis, omenti minoris, lessening the size of the sac. The shape of sac is that of a collapsed grain-bag with its neck constricted. With care it may be blown up, by forcing air through Winslow's foramen.

The size of the sac is perhaps one-quarter of the size of the skin surface of the body, as the peritoneal surface is probably equal to the skin surface. The walls of the lesser sac are composed of double blades of peritoneum, except where the posterior surface of the stomach and upper surface of the transverse colon intervenes, where only a single layer of peritoneum exists. A slight piece of spleen forms also

an exception. If one introduces the finger into the neck of this sac, Winslow's orifice, in young subjects, it will pass first into an ante-room which contains Spigel's lobe. This space is smooth, closed in front by the pars flaccida of the lesser omentum and is about the size of the fist in an adult. If now the finger be pushed further on it will pass through a second and larger foramen, foramen bursa omentalis majoris (Huschke's foramen) whence the finger enters into a wide space, a pendulous bag, smooth and moist on its surface. The bag extends to the left side and to the pelvis.

On opening the lesser omental bag at a point between the stomach and colon, we observe a sleek shining peritoneum lining the whole sac. The inside of the sac extends to the left costal wall in the ligamentum phrenico-colicum. It extends to the right as far as the flexura coli hepatis and also passes on down the ascending colon to a various extent. This right part of the great omentum is known as omentum Halleri.

Fig. 42 (after Deblierre 1890, modified) represents a cross section at the 1st lumbar vertebra to show the disposition of the peritoneum. The line of the peritoneum the artist has drawn in heavy black. r, kidney; R, spleen; e, stomach; ri, round ligament of liver; D, duodenum in association with the pancreas P; c, vena cava; a, aorta; 3, transversalis fascia; 4, parietal peritoneum; 5, falfiform ligament of liver; 6, hiatus of Winslow; 7, right border of gastro-hepatic omentum containing portal vein, hepatic duct and hepatic artery; 11, vena cava; 12, splenic artery; 13, splenic vein; 14, vena cava; 15, pillars of diaphragm; 16, psoas. The diaphragm does not show the spleen uncovered by peritoneum on the posterior border as my dissections induce me to think is a normal condition. It is also uncovered at the hilus to transmit sustaining structures.

In the lesser omental cavity, just to the left of the septum bursa omentalis, I have found varying folds and peritoneal projections due to muscular action of the left crus of the diaphragm inducing local peritonitis. These projections are so frequent in adults as to call for mention. The lesser omental cavity is divided into two compartments (in some I noted three compartments). The division is caused by a fold of peritoneum projected into the sac by the gastric artery and to some extent by the gastric vein. The fold is one to two inches high and distinct in every body which I have examined. The fold reaches to the upper border of the pancreas and is called the ligamentum gastro-pancreaticum (Huschke). As this fold divides the lesser omental cavity into departments it may be called the septum bursa omentalis. The fold or septum separates the visceral part (Spigel's lobe) of the lesser omental sac from the non-visceral or empty part. The right portion of the sac called the bursa omenti minoris contains Spigel's lobe of the liver and its anterior wall is mainly the pars flaccida or middle portion of the gastro-

hepatic omentum. The main portion of the lesser omental sac is the bursa omenti majoris. It lies on the left side behind the stomach. The bursa omenti minoris communicates with the bursa omenti majoris by means of the foramen omenti majoris or what I have termed Huschke's foramen. The foramen omenti minoris is Winslow's foramen. The aperture between the two sacs of the lesser omental cavity varies according to the size of the peritoneal duplicature thrown up by the gastric artery.

(To be continued.)

SELECTIONS.

Suppuration from the Use of Catgut.—Lauenstein, of Hamburg, has found very frequently in catgut, purchased as "sterile," bacteria capable of development and therefore advises circumspection. Kocher, years ago, showed the danger of infection from catgut, and refers to silk as alone capable of trustworthy disinfection. In his operations for goitre he has obtained first intention much oftener with silk than catgut.—*Weiner Klinische Rundschau*, July 14, 1895.

Contributions to the Histogeny of Carcinoma. (*Virchow's Archiv.*)—It is well recognized that at the start the connective tissue takes on an active increase of its cells, the so-called cell infiltration. The writer attributes a greater significance to this proliferative process. He maintains that absence of cell infiltration at the beginning prevents the formation of cancer. Observations were made on cancer of the skin, but the conclusions apply also to primary cancer of glandular organs and the cylindrical celled: 1, the development of carcinoma of the skin starts with active proliferation of the connective tissue, which produces a sub-epithelial stratum of cell infiltration of varying thickness. 2, at the same time the epithelium is thickened, but does not yet extend beyond its lower boundary; on the contrary the connective tissue penetrates the epithelial layer, causing the appearance of a tap-like process of epithelium entering the connective tissue. 3, by this means the individual cells of this epithelial process are being continually separated from one another, until at last one or several are entirely isolated. This gives the idea of metastasis of epithelium in the connective tissue. 4, from these isolated epithelial cells is started the real development of cancer, since the cells increase in numbers and penetrate deeper into the connective tissue, particularly in the direction of least resistance, that is, into the lymph spaces so that the elements of connective tissue, filaments and cells become inclosed.—*Centralblatt für Gynäkologie*, No. VI, Feb. 9, 1895.

Subcutaneous Use of Arsenic.—Dr. Kernig reports thirty-five cases from the Obuchow Woman's Hospital. The internal use of arsenic was inadmissible on account of the condition of the digestive tract (diarrhea, etc.). Some of these were severe cases of anemia, cancer, tubercle, joined with gastro-intestinal catarrh, in which a large number of injections, 20 to 150, were used. In another group there was temporary disturbance of digestion and only six to twelve injections were used, until the internal administration could be begun. In many cases a favorable effect was at once produced, and as other means had been generally tried without effect, Dr. Kernig felt warranted in attributing the result to the arsenic. At first he used 1 part of Fowler's solution with 2 of water, and a half of a Pravaz syringe full at a dose; later, after the example of Professor Sacharjin, of Moscow, Fowler's solution undiluted. The solution must be clear. Seldom did the injection cause pain, and only once an abscess. His

usual dose was 4 drops a day. No effect was produced on the intestines and no cutaneous eruption.—*St. Petersburger Medicinische Wochenschrift*, July 13, 1895.

Prophylaxis of Tuberculosis and Its Results.—After Cornet had proved that tubercle bacilli were not so ubiquitous as was before generally believed, but that they only existed when sputa were left to dry and so effect an entrance into the air passages of other individuals, prophylaxis against the bacilli seemed demanded. As early as 1886, he recommended united efforts to check the unrestricted expectoration. Cornet's efforts met with success in Prussia and later in Hamburg, but not in other German states or Austria. Although the time is yet too short for statistics, Cornet feels prompted to advance some figures, on account of the remissness of the people in carrying out prophylactic measures. In the Prussian penal institutions, the figures for tuberculosis since 1887 have fallen considerably, while in Bavaria they have remained about the same; the same holds true for the lunatic asylums. If one considers the whole population, there is in Prussia a greater decline in the mortality from tuberculosis, also in Hamburg, in the last five years since the introduction of prophylactic measures. It is manifest that in Prussia alone, from 1889 to 1893, the mortality list from tuberculosis was 70,000 less than was to be expected from the average of previous years. Virchow doubts if dependence can be placed upon these figures, owing to the shortness of the period.—*Wiener Klinische Rundschau*, July 14, 1895.

Operation for Abscess of Lung Following Rupture of Lung.—Maydl reports the case of a coachman, 29 years old, who fell under a carriage and sustained a fracture of the sixth rib in the right mid-axilla. He was found almost in collapse, the sputum was a bloody froth and there were blood and air in the thoracic cavity. Subcutaneous emphysema extended over the whole trunk and even the neck and face were greatly swollen. It was believed the fractured rib had penetrated the lung, so the ends were freely exposed and 12 cm. excised. Two liters of fluid blood were evacuated through the opening, but no point of rupture of the lung could be made out by the hand in the pleural cavity. Later, it was made clear that the rupture existed posteriorly at the angle of the scapula. Two drainage tubes were left in the opening, but the following day these were removed and the wound was closed. No infection resulted and there was not even a serous effusion. The wound healed by first intention in a few days. The small amount of air and blood in the pleural cavity was absorbed, and the patient improved rapidly. But after fourteen days a dullness appeared in the back at the angle of the scapula, and after two weeks more there were signs of a large cavity in the lung. The sputum was purulent, abundant, and contained numerous streptococci. The patient's strength rapidly diminished. Need of relief on account of the abscess was urgent, and a month after the first operation it was undertaken. Maydl resected a rib over the area of dullness and since the two layers of the pleura had become adherent, a Paquelin cautery was pressed through a layer of lung tissue, some centimeters thick, and opened a cavity, as large as a child's head, filled with fetid fluid. From the cavity masses of gangrenous lung tissue were drawn. The largest of these was over 1 dm. long, 4 cm. broad. Pulmonary edema followed on two occasions and a catarrhal pneumonia of the sound lung. At the time of publication the patient had been for some time without rise of temperature and was walking about. The wound was granulating rapidly, and the cavity was slowly diminishing. Maydl warns against irrigating such cavities with solutions of thymol and recommends the physiologic salt solution or boric acid.—*Wiener Klinische Rundschau*, June 23, 1895.

THE

Journal of the American Medical Association

PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

PER ANNUM, IN ADVANCE \$5.00

SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,

No. 86 FIFTH AVENUE, CHICAGO, ILLINOIS.

W. H. LOWDERMILK & CO., WASHINGTON AGENT.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 86 Fifth Avenue, Chicago.

SATURDAY, SEPTEMBER 7, 1895.

THE PATHOLOGY OF EXOPHTHALMIC GOITRE.

The pathology of BASEDOW-GRAVES' disease, or exophthalmic goitre is one of the questions that is just at present to the fore in neurologic medicine, and has been the subject of one or two rather noteworthy papers in recent periodical literature. Formerly the generally prevalent notion in regard to it, as far as there could be said to be any definite theory, was that it was a disorder of the sympathetic system and the vagus, probably connected with some lesion, functional or organic, of the centers in the medulla. This view, held in varying degrees of indefiniteness may be said to have predominated up to a comparatively recent date. Within a few years, however, the thyroidean theory of the affection has come into vogue and may be said to be perhaps the one that is most popular at the present time; it is that the disease is the result of an auto-intoxication from disordered action of the thyroid gland, manifesting itself by symptoms due to nervous affections, or infections, of the bulbar vasomotor centers.

It will be seen that the toxic theory carries the pathology a little farther back toward a primal cause, which fact alone is strongly in its favor with the majority, and is in accord with a tendency at the present time to refer many heretofore misty pathologies to auto-intoxications. Whether this toxic action is due to hyper- or hypo-functioning or to the derangement or alteration of the thyroid secretion, is still a question, though the weight of opinion among those who adopt the theory is probably in favor of a hyperthyroidization of the system.

That this is the last word, however, as regards the

etiologic pathology of GRAVES' disease, no one can positively claim with our present knowledge. The thyroidean theory is, moreover, not universally accepted in its entirety; for example, PUTNAM, of Boston, in a very able paper (*Boston Medical and Surgical Journal*, August 8), considers it a "degenerative neurosis" dependent on original weakness or disharmony of the nerve elements and holds that its symptoms form a coherent group, "characteristic of strong emotion of the nature of expectant fear . . . Although often excited by emotion, this segmented group of activities may be called out in various other ways. The prolonged existence, for example, of either one of the symptoms may after a time call out the rest." In this way, DR. PUTNAM explains how emotional excitement may give rise to the disorder, while he admits that thyroid hypersecretion may also have its part in augmenting the nervous erythism in a predisposed person.

DR. PUTNAM's theory has in its support the well known emotional origin of many cases of this affection, and also the other fact that its one constant symptom, the one that first appears and, as pointed out by BRISSAUD, the one around which may be ranged all the others, tachycardia, is also one that is directly and almost constantly connected with emotional disturbances. It is not difficult to suppose that the psychical disturbances of emotion may, in their action on the cell elements of the nerve centers, cause derangements of distant organs which in turn may react and render permanent in some degree the original morbid condition. The intimate connections of the higher nerve centers of which we really know so little, but conjecture so much, is here strongly suggested. We need not reject the thyroidean theory absolutely; the facts so far as known seem to point very strongly to the implication of the thyroid in many cases, and we may therefore attribute to it a certain rôle in the keeping up at least of the disease. But there are equally valid arguments in favor of a prior nervous influence in the etiology of the disorder. Whether after this, the pathology is to be considered as that of hyper- or hypothyroidization or of simple alteration of the thyroid secretion, or that in its normal quantity and quality, it fails in its necessary function of counteracting some other morbid process or secretion, is a question which, as DR. PUTNAM says, we must wait for more light before venturing to decide. The theory of the participation of the thyroid gland, however, is a marked advance in the pathology of the affection, even though the exact part it takes may be still in doubt, and the original *primum movens* in its etiology is yet to some extent an open question.

The effect of the theory on the therapeutics of the disease has been marked, but it also indicates the uncertainty as to the exact nature of the thyroid participation. Results are claimed both from extrir-

pation of the gland and from thyroid feeding, as well as from ingestion of thymus, considered as anti-thyroid in its action. It can not therefore be said to have developed as yet any absolutely scientific and unempirical method for all cases.

The alleviation of the disease by the cardiac tonics is still a constant experience of practitioners and indicates that we are not yet ready to altogether reject the other symptomatic treatment.

CHOLERA IN THE PACIFIC.

A ripple of excitement has been created in sanitary circles by the news of cholera in the Sandwich Islands, its spread in Russia, China, and Japan, and its invasion of Corea, to say nothing of the reported cases at Grimsby in England. As early as July 25 last, Passed Assistant Surgeon WILLIAM G. STIMPSON, U. S. M.-H. S., was led to treat the British steamship *Antwerp City*, as a cholera-infected vessel on her arrival at Port Townsend, Wash., from Hiogo, Japan; but the port authorities of San Francisco seem to have been "caught napping" by the steamer *Belgic* last week, which vessel obtained free pratique through gross misrepresentation of the events of her voyage. It remains to be seen what action will be taken with her officers should she again enter the Golden Gate.

There is, probably, no serious ground for apprehension in the present situation; but the JOURNAL can not refrain from warning against a too implicit reliance on quarantine restrictions to protect this country against an invasion of the disease. Both the Atlantic and the Pacific seaboard are now threatened, and the ease with which the passengers of the *Belgic* passed through the San Francisco quarantine, from a vessel which is now known to have had three cholera deaths on board during her voyage from China, shows again what an elaborate system of leakage the quarantine of the period may prove to be.

We must repeat our lesson of a few weeks since; we may not be able to shut out cholera from our shores by quarantine; but we can and should make our environment so wholesome and cleanly as that it shall be fatal to the cholera germ as well as to the germs of all other filth diseases. And in this connection it is well to remind sanitary and civic authorities that wherever typhoid fever exists and flourishes, there also may Asiatic cholera exist and flourish.

There is a warning in this for many of our American cities. Pittsburg, for example, where typhoid is again epidemic, and in a multitude of smaller places in which the disease is now prevailing with more than its usual autumnal increase. The aspiring western metropolis, Chicago, is by no means beyond the danger line in this respect; the almost constant presence of the disgustingly suggestive *coli communis* in its public water supply is pregnant with meaning

to the sanitarian, and the city is absolutely without any sort of hospital provision in case of any epidemic but one of smallpox. Even if the new isolation hospital were ready for use—which it will not be for many months—it would be wholly inadequate for the needs of nearly one hundred and ninety square miles of territory. There should be a supply of the small portable hospitals provided at once—hospitals capable of receiving eight patients each, complete in themselves and ready to be set up in any epidemic center in an hour's notice. When a thing of this sort is needed, it is needed at once. Epidemic diseases don't usually wait to give warning and allow time for preparation. Chicago's Health Department should take immediate action in this matter—not especially with reference to Asiatic cholera, but to the epidemic diseases in general.

THE INSANITY OF CONDUCT.

In the discussion of a paper read before the British Medical Association at its recent meeting, DR. CHARLES MERCIER laid down the following four propositions which have an important bearing as regards the medico-legal relations of mental disorder: 1, that there are cases in which insanity is evinced by conduct and can not be established from mental disorder alone; 2, that there are cases in which disorder of the mind exists without insanity; 3, that therefore insanity is not essentially a disorder of the mind nor ought insanity and unsoundness of mind to be used as convertible terms; 4, that our conception of insanity is not complete until it is understood to include as a necessary and integral element, disorder of conduct.

While the limitations of the term "mind," as here used may be questioned, it seems well to state these propositions as including a valuable truth that has not yet penetrated to any extent the intricacies of the legal intellect. Conduct is simply a concrete manifestation of mental action, and therefore when absolutely irrational, though assisted with apparently perfect and even brilliant intellection may be a very clear evidence of insanity, entirely apart from delusions or other common symptoms of mental disease. Purposed and elaborated actions are evidence of the functioning of the intellectual organs of the brain as much as motion is of that of the motor centers, and when they are disordered and irregular in their type, they mean mental disorder as truly as do incoherent or irrational speech; indeed far more than the latter, which is a possibility with the perfect retention of the judgment and control of conduct that are the essential elements of responsibility and sanity. These may be deficient or absolutely lacking with the most perfect and brilliant intellection, and the condition be only revealed by irrational acts. That which is self-evident to an

alienist and psychologist seems to be one of the most difficult of all truths in its practical application.

A man may make himself a public and private nuisance, a laughing stock to the rabble, and even very dangerous in his eccentricities to himself and others; provided he can talk rationally before the court all the evidence is swept aside as worthless, as compared with that which is under the eyes or perhaps we should say the ears, of the legal experts. Even if committed to an asylum, especially if he possess legal knowledge or have officious legal friends, it is impossible to hold him, notwithstanding the fact that his insanity is essentially one from which society most needs protection. DR. RAY gives a very striking account of a case of insanity of conduct of this kind; our knowledge of it is, therefore, not a recent acquisition; instances are indeed of not infrequent occurrence, but its legal status is as yet undefined and its settlement is one of the social needs of our day. This, however, can only be effected by a general psychologic enlightenment of the legal profession, not perhaps a result to be hoped for in the very near future.

THE "NEW AILMENT" (SCHNEIDERITIS) OF LONDONERS.

According to the *Sanitary Record* for July 26, the condition of the streets of London, brought about in part by the prolonged dry weather, and in part by the kind of materials used for street paving, have caused not a little irritative trouble which for convenience has been termed the "new ailment." The *Record* also, in this same connection, calls aloud for more water in cities, especially in London; the supply of water in that city has never yet been as lavish as it should be, and not at all in keeping with its many other civic improvements. London has not enough drinking fountains for the public, and no very definite legislation compulsory as to the laying down of water pipes for rented properties. In other words, London has shown itself backward in procuring a sanitarily lavish supply of sweet pure water.

The *Sanitary Record* says:

"The question of the best kind of material for the pavements of the London streets is not unlikely to be again agitated, if there be truth in the view that what is called the 'new ailment' is due to the deleterious action of the *débris* that accumulates on the wooden pavement now in general use. The mucous membrane of the nose, which is the part chiefly affected in the ailment, becomes inflamed and thickened, and the blood vessels that ramify through this membrane become turgid, with the consequence that bleeding is set up on very slight provocation.

"The immediate occasion of the outbreak has apparently been the prolonged dry weather, that has proved injurious to many things beside the mucous membrane of the nose; and it is believed that the affection is due to the innumerable minute particles of straw and other organic substances that naturally ac-

cumulate when there has been no sufficient flushing of the pavements by rain or otherwise. Now that the weather has changed, we may hope to hear no more of this trouble; but its presence is one more illustration, on the negative side, of *the extreme value of rain as a hygienic agent*. It may not always be pleasant, but it is health-bringing.

"Water is best." The truth of that old Greek adage is continually receiving fresh illustrations. But it has not yet taken a firm hold of all the members of the community—even of all sanitary authorities. For complaints have still from time to time to be made regarding the *inadequate supply* of water furnished for the wants of the people; for *drinking*—which is a kind of flushing of the human body—for *bathing*, for *washing*, and for the essential purposes of *drainage*. And the specific complaint is being made, we observe, that in the administration of the Public Health Acts, the clauses that refer to the matter of water supply are interpreted without due regard to the public welfare.

"Every owner shall provide a water supply at or near. There is a delightful elasticity, it will be observed, in this word 'near,' which enables it to lend itself very readily to various interpretations. And it is complained that in the interpretation of the word some sanitary authorities have been neglectful of their duty, in not insisting that a supply shall be furnished even when it is reasonably required. Cost must, of course, be considered. It is not to be expected that, whatever may be the expense, water is to be introduced wherever it may be thought needful. But individuals and communities alike can not easily learn any wholesomer lesson than that wise expenditure in such matters is the truest economy."

THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

The meeting of the Mississippi Valley Medical Association at Detroit was characterized by unusual harmony and the papers presented were above the average. PROFESSOR PEPPER'S Address in Medicine which we shall have the pleasure of presenting to our readers in full next week, was a masterly eulogium of DANIEL DRAKE, and a faithful portrayal of the marvelous changes that have taken place in the great Interior Valley since the time of DRAKE.

The popular author, the grandeur of the theme, the audience comprising the descendants of those hardy pioneers who have made the valley what it is to-day, and the historic city in which the meeting was held all conspired to make it an occasion long to be remembered in the civic annals of Detroit and the whole valley.

The other addresses were excellent, notably the address of PRESIDENT WISHARD and the address of PROFESSOR MCGRAW which we publish in this issue.

The Committee of Arrangements, under the admirable management of DR. H. O. WALKER, left nothing undone that could add to the international reputation of Detroit as the hospitality center of the communities living on the Great Lakes.

The election of DR. H. O. WALKER to the Presidency was a public testimony to his high standing in the

Association, and is an honor which he has worthily won.

The selection of Minneapolis as the next place of meeting was wise, and gives assurance in advance, if any were needed, of the prospective success of next year's meeting.

CORRESPONDENCE.

A Philological Problem from Philadelphia.

PHILADELPHIA, PA., Aug. 15, 1895.

To the Editor:—In one of the latest numbers of the JOURNAL is an extract from the *Deutsche Medicinische Wochenschrift* on "The New Anatomic Nomenclature," and the number also contains an editorial commendation of the idea. In reading the extract I note that, "it was resolved that the terms should be in one language, that is, Latin designations only. . . . The names shall be Latin, and etymologically correct."

That promises well, but when I look at the examples given by the JOURNAL, I find the first one given to be "osteologia," a pure Greek word, with nothing Latin about it! Liddell and Scott define *ὀστέολογια* as "the science which treats of bones." "Splanchnologia" and "angiologia" are also Greek, from *σπλαγχνον* viscera, and *ἄγγειον* a blood vessel, respectively, and these are not the only examples.

I do not wish to be considered a captious critic, but isn't it rather singular that a nomenclature which professes to contain only Latin terms, and those etymologically correct, should bristle with so many pure Greek words?

Very truly yours, D. W. NEAL, M.D.

ANSWER:—We do not dispute the Greek origin of the words mentioned, but they are transferred words, and used in Latin with entire propriety. Osteologia is given in Foster's Medical Dictionary as a Latin word. Leverett's Latin Lexicon gives osteologia as the Latin synonym for the English word, osteology. So also does Wm. Young in his Latin English Dictionary. Nearly all scientific words used by the Latin writers were transferred bodily.

A Question of Ethics.

ORAN, MO., Aug. 8, 1895.

To the Editor:—Will you kindly answer the following question in your next issue:

Is it unprofessional or not, to divide your fees with "Granny women?" I have a colleague who gives his assistant midwife \$1 while he takes \$9 for his obstetrical fee. I told him that it was the business of the patron to pay the fees of both physician and nurse, and that when a physician divided his fees with would-be midwives it looked very much like "drumming" for practice. Please answer and oblige.

Very respectfully yours, W. P. HOWLE, M.D.

ANSWER:—The dividing the fee in an obstetrical case with the nurse or other attendant is in the nature of drumming for practice, or the acceptance by the physician of a percentage from an apothecary. No self-respecting physician should indulge in such methods.

A Staunch Defender.

ATLANTA, GA.

To the Editor:—The sanious exudation from a gangrenous ulcer does not indicate more clearly its true character, than does the utter disregard of correct principle show the reviewership of the communication in your number of August 24, headed, "The Code, Once More," and signed "Amicus Veritatis."

It should have had for a caption, "No Code," and for signature, "Vox Asini." Respectfully, VIRTUS.

BOOK NOTICES.

The Cell, Outlines of General Anatomy and Physiology.—By DR. OSCAR HERTWIG, Professor Extraordinarius of Anatomy and Comparative Anatomy, Director of the II Anatomical Institute of the University of Berlin. Translated by M. CAMPBELL and edited by DR. HENRY JOHNSTONE CAMPBELL, of London. With 168 illustrations, 8 vo., cloth, pp. 368. Price, \$3. London: Swan, Sonnenschein & Co. New York: MacMillan & Co. 1895.

The author has in this book not only prepared a supplement to his work on embryology, but has endeavored to fix the scientific standpoint at present occupied by the doctrines of cell and tissue formation.

Much in the book is necessarily theoretical, and may yet be changed by the advance of science, for as the author well says: "The cell is a marvelously complicated organism, a small universe, into the construction of which we can only laboriously penetrate by means of microscopic, chemico-physical and experimental methods of inquiry."

"In many respects," says our author, "the cell theory is the center around which the biologic research of the present time revolves," and while he admits with Max Schultze that "the protoplasm of plants and animals and the sarcode of the lowest organisms are identical," and that the term "cell" is incorrect, he yet retains it under the definition that the "cell is a little mass of protoplasm, which contains in its interior a specially formed portion, the nucleus." The chemico-physical and morphologic properties of the cell are first described, and then the vital properties are treated of. These include: 1, Contractility; 2, Irritability; 3, Metabolism; 4, Reproduction. The work concludes with a chapter on "the cell as the elementary germ of an organism," and "theories of heredity." This book, then, is seen to deal with one of the most important of all the fundamental problems of biology, and we can commend it to the readers of the JOURNAL as embodying in entertaining and easily understood language, the most advanced theories concerning the anatomy and physiology of that mass of protoplasm which we term a cell, and of its nucleus, which in the present state of knowledge we must regard as the true elemental organ of life.

Parvin's Science and Art of Obstetrics; the Science and Art of Obstetrics. By THEOPHILUS PARVIN, M.D., LL.D., Professor of Obstetrics and Diseases of Women and Children in Jefferson Medical College, Philadelphia. New (3d) edition. In one very handsome octavo volume of 677 pages, with 267 engravings, and 2 colored plates. Cloth, \$4.25; leather, \$5.25. Philadelphia: Lea Brothers & Co., Publishers. 1895.

The publication of the new edition of Parvin's standard treatise emphasizes well the fact that it has for some years supplied the need for a new text-book from the great Philadelphia school. The University had Dewees and Hodge, and Jefferson had Meigs. The long sway held by Meigs at Jefferson and the great popularity of his text-book, based as it was on elegance of style, quaintness of expression, keen observation and natural eloquence, made it rather difficult for Professor Parvin, but it must be conceded that he well filled the vacancy. His scientific knowledge, his wide range of information and his vast acquaintance with general literature, enabled him to prepare a book that is not less entertaining from a literary standpoint than from a professional one. Much valuable historical matter finds a place in this volume.

Old members of the ASSOCIATION will recall with pleasure that Professor Parvin presided at the thirtieth annual meeting at Atlanta in 1879, and will rejoice to see that although more than a quarter of a century has elapsed, the venerable ex-President revises and largely re-writes a work which shows him still in the foreground in his chosen field of medical science.

Modern Medicine and Homeopathy. By JOHN B. ROBERTS, A.M., M.D. 16 mo., cloth, pp. 72. Price, 75 cents. Philadelphia: The Edwards & Docker Co. 1895.

It is with pleasure that we record the publication of the two essays of Professor Roberts in a form more convenient for preservation and reference than the Transactions of the Society in which they were read, or even our beloved JOURNAL in which one of them was previously printed. These essays, which are written in a spirit of friendliness to our erring brothers, have given rise to some controversy, on the ground that Dr. Roberts has to the homeopaths been

"To their virtues very kind,
To their faults a little blind."

but it is evidently in a purely philanthropic spirit that the essays were written, and they have very appropriately emanated from the City of Brotherly Love, and Dr. Roberts.

Those who wish to become acquainted with the peculiar tenets of the homeopathic sect, in their relations with modern medicine will do well to procure this little work—which, while giving the points in which "homeopathy" still adheres to the teachings of modern medicine, sets forth clearly and without abuse, the fallacies and distorted views held by some of the sectarians under consideration.

The Pocket Materia Medica and Therapeutics.—A Resumé of the Action and Doses of all Official and non-Official Drugs now in common use. By C. HENRI LEONARD, A.M., M.D., Professor of the Medical and Surgical Diseases of Women and Clinical Gynecology in the Detroit College of Medicine; member of the AMERICAN MEDICAL ASSOCIATION, etc. Second edition, revised and enlarged. Cloth, large 16 mo., 367 pages, price, postpaid, \$1. Detroit: The Illustrated Medical Journal Co., Publishers. 1895.

The second edition of this popular therapeutic work has had sixty-seven pages added to it, beside typographical errors corrected, etc. A new and complete cross-index has been prepared, which renders the quick finding of a non-familiar drug possible. This is an important feature lacking in many ready-reference books. The metric doses have been given throughout and the book has been brought up to date. Its alphabetical arrangement makes it very convenient for reference.

PUBLIC HEALTH.

How to Prevent the Sale of Hurtful Cosmetics.—Notwithstanding all that has been published regarding the poisonous nature and injurious effects of the nostrums advertised to improve the complexion, still their sale goes bravely on. It is everywhere a difficult traffic to control, but the police of Berlin have hit upon an ingenious way of putting a stop to their sale, without invoking the law against the advertisers. They insert in all the papers of the city a notice stating that they have caused an analysis to be made of this or that preparation, and that its ingredients are so-and-so; and they also add the intrinsic value of the ingredients. In one celebrated preparation, they showed that a compound that cost 1 cent was sold for \$2.50 a bottle. They do not concern themselves with non-poisonous nostrums.

Seaboard Precautions as to Cholera.—The August issue of *Public Health* (London) quotes from the Annual Report of Dr. D. S. Davis, Health Officer of Bristol, England, his observations regarding the theory of maritime precautions for exposed cities against cholera. Dr. Davis' report for 1894 offers the following points germane to conditions existing in England:

"The aim of medical inspection, which has supplanted quarantine in England as a means of dealing with imported cholera, is briefly as follows:

"1. By medical inspection of persons arriving, to detect actual cases of cholera, and to secure proper isolation of patients in hospital, and disinfection of their belongings, and of the berths or places they may have infected.

"2. By the same medical inspection, to detect cases apparently sickening, and so to isolate and watch them.

"3. To notify forward to the sanitary authorities of the districts whither they are bound, the names and addresses of the rest of the crew and passengers, who are apparently well, but who may possibly have the disease in an undeveloped form. The responsibility of watching and caring for any cases which may develop after arrival at their destination devolves upon the respective sanitary authorities having charge of such districts.

"In short, medical inspection deals with actual and probable cases but can only notify forward possible cases. Herein it differs from quarantine, in that no cases except actual or threatened cases are detained at the port of arrival, nor is the vessel detained when a hospital is available, except a reasonable time for purposes of disinfection; and in that the responsibility of dealing with any cholera that may arise is shared not only by port districts, but by inland districts, to which some one of the cases allowed to go forward may take the disease. But such inland districts have the advantage of being forewarned, and any spread of the disease must be a measure of their own neglect.

"Fortunately, the incubation period of cholera is generally short (a few days only), so that a long distance ship with no recent cases on board involves, as a rule, little danger." This is in effect the American practice, and it has taken the British all these years to learn that although we still use the word "quarantine," we long ceased the practice of detention *per se*.

Heredity of Tuberculosis.—At a recent meeting of the *Societe de Biologie*, of Paris, MM. Bar and Renon presented a communication concerning the results of their efforts to elucidate the question of direct transmissibility by the placenta of the bacillus of Koch from the mother to the fetus in the human species. M. Bar had, in five instances, obtained at the moment of birth a certain quantity of blood as it flowed out of the placental end of the umbilical vein, and injected it at once under the skin of the abdomen of guinea pigs. In three cases the results were negative—that is, the animals did not become tuberculous—but of the remaining two, one was that of a woman in the third stage of consumption, and whose expectoration contained the tubercle bacilli of Koch. She was delivered of a fetus that had died the day previous; the placenta did not present any apparent lesions. The blood flowing from the umbilical vein was injected into a guinea pig, which succumbed two months later from tuberculosis of the liver and spleen. No signs of tuberculosis were discovered in the organs of the fetus on necropsy. However, the pulp of the liver and lungs was injected into two more guinea pigs, both of which succumbed with all the signs of tuberculous infection, ulcer at the seat of inoculation, granulation of the liver and spleen, etc. In the second case, the mother had large pulmonary vomicae, but the expectoration had not been tested. The child died on the fortieth day from broncho-pneumonia. At the moment of birth the blood of the umbilical vein was injected into two guinea pigs. One of the animals lived, while the other succumbed, with a chancre of inoculation and a generalized visceral tuberculosis.

We note that some of our foreign exchanges profess to regard these results as conclusive of the heredity of tuberculosis—the Paris correspondent of the *Medical Press* of the 21st ult., for example, asserting that the authors have "discovered the bacillus in the blood of the fetal cord;" that the discovery "is, consequently, of the highest interest, confirming as it does clinical observations, and settling the question once and for all." At this distance from France it does not appear that MM. Bar and Renon have set up any such claim; on the contrary, there is no mention in the correspondent's account of the detection of the tubercle bacillus in anything but the sputum of one of the two women, and it is not definitely asserted that the other had tuberculosis at all—"pulmonary vomicae" are not always and necessarily tuberculous, although, of course, the majority are. The question of the heredity of tuberculosis may not be "settled once and for all" in this out-of-hand fashion. As thus far made known, the experiments cited are by no means conclusive, and they add absolutely nothing confirmatory of the observations of such students as Baumgarten, Birch-Hirschfeld, Hericourt and Richey, Whittredge Williams and others in this field, who have demonstrated the direct transmission of the bacilli from the mother to the fetus.

Churning the Milkmen.—The usual periodical agitation of the milk question is on in great force and vigor this season and it really seems as though some good results might accrue. The most comprehensive and thorough work has been that of the Special Analytical and Biological Commission of the *British Medical Journal* on the milk supply of London. The preliminary report of this Commission was published July 6, and the editorial review is given in the issue of August 24. The closing paragraph is as follows: "The moral of the whole matter is that producers and vendors must be compelled, within reasonable limits, accurately and fully to describe the articles which they supply to the public, and that the standard of composition for a natural product such as milk shall not be that of an abnormal fluid yielded by a diseased or improperly fed animal, but shall be the normal composition which, within certain well-ascertained limits, the mixed milk of healthy and properly fed cows is known to possess. 'Milk' does not mean 'thinned milk,' nor does it mean 'separated milk.' These, which are, of course, articles of commerce, should be described by their distinctive titles. Condensed milk means condensed whole milk, and if a preparation which has been obtained by condensing separated milk is called condensed milk, a distinct fraud is perpetrated upon the public. If sophistication, adulteration and the production of milk under insanitary conditions are to be suppressed or appreciably minimized, an awakened and vigorous public feeling on the matter is essential. It rests mainly with the medical profession to bring this about." Thus far Mr. Ernest Hart, and it pretty fully indicates the principal evils which beset the milk supply of most large cities—London as well as New York, Chicago equally with Philadelphia. But Dr. Gould, in the *Medical News*,¹ is not so sanguine that cow's milk, howsoever pure, will materially reduce the waste of infant life and asserts that, notwithstanding all the improvement that has been effected in the milk supply of cities, "hand-fed babes die in summer now as they did twenty years ago." He thinks that it would be well for medical men to direct their energies toward "bettering or rather increasing the number of human milkers instead of looking for substitutes." "If," he says, "the time and talent now expended in endeavoring to obtain a pure supply of cow's milk were directed to this other question, and the subject freely discussed in the lay press as well as in the medical journals, we would have a lessened infant death rate and the problem 'how and what to feed the baby' would not excite so much attention as it now does." Meanwhile, what the newspapers call the "crusade" against the milkmen is being vigorously pushed both in New York and Chicago and the lower courts of both cities are congested with the multitude of "milk cases." To show that there is need of some such action it is only necessary to cite one statement made by Dr. Gehrman of the Chicago Municipal Laboratory. He says he has made no bacteriologic examination of Chicago milk without producing numerous colonies of the unspeakable bacillus coli. Mr. Sidney Rowland of the English Commission testifies to the same effect. This is damning proof of filth of the most disgusting sort in the dairies, the vessels and the water used and on the hands and persons of the milkers and handlers. But a municipality can not deal with these horribly insanitary conditions except in an indirect way. Six-sevenths of the London milk supply, as large a proportion of that of Chicago and a still greater proportion of the New York supply is furnished from territory beyond the jurisdiction of the several cities. Only the State can correct this basic evil and that by a rigid sanitary inspection of dairies and milk-producing plants through State Boards of Health and kindred agencies. Until this is done and the remedy is applied at the source and beginning of the evil the efforts of municipalities will continue to be ineffectual.

Reduction of Diphtheria Mortality.—At the recent meeting of the British Medical Association, during the discussion on the antitoxin treatment of diphtheria, statistics were presented from the hospitals of England, Scotland, Munich, Berlin and New York, showing a striking reduction of the mortality from diphtheria under the use of the antitoxin.

¹ The Milk Question, Aug. 31, 1895.

Dr. E. W. Goodall, Medical Superintendent of the Eastern Hospital, Homerton, presented the following results of 241 cases under his own care or observation between January 1 and June 30 of this year:

Treated with antitoxin:

Under 5	57 cases, of whom 17 died	29.8 per cent.
5 to 10	36 cases, of whom 6 died	16.6 per cent.
10 to 15	32 cases, of whom 1 died	8.8 per cent.
	105	24
		22.8

Treated without antitoxin:

Under 5	67 cases, of whom 30 died	44.7 per cent.
5 to 10	46 cases, of whom 14 died	30.4 per cent.
10 to 15	23 cases, of whom 1 died	4.3 per cent.
	136	45
		33.6

Prof. Dr. Von Ranke, of the University of Munich, between Sept. 24, 1895, and July 1, 1895, had 163 cases of primary diphtheria, with a mortality of 29=17.7 per cent. Of these there were 154 cases bacterially diagnosed as undoubted diphtheria, with a mortality of 18.8 per cent. The necessity of a prompt resort to the serum is shown in the following figures:

Of 19 cases treated on the first day	1 died	5.2 per cent.
Of 47 cases treated on the second day	4 died	8.5 per cent.
Of 39 cases treated on the third day	7 died	17.9 per cent.
Of 19 cases treated on the fourth day	3 died	15.8 per cent.
Of 9 cases treated on the fifth day	1 died	11.1 per cent.
Of 10 cases treated on the sixth day	4 died	40.0 per cent.
Of 15 cases treated on the seventh and later 7 died		46.6 per cent.

Mortality of patients according to age:

Under 12 months	5, all of whom died	100.0 per cent.
Under 2 years	24, of whom 9 died	37.5 per cent.
Under 3 years	25, of whom 3 died	12.0 per cent.
Under 4 years	32, of whom 4 died	12.5 per cent.
Under 5 years	17, of whom 2 died	11.8 per cent.
Under 6 years	20, of whom 2 died	10.0 per cent.
7 and over	39, of whom 3 died	7.7 per cent.

Mortality of primary diphtheria in former years:

1887	42.2 per cent.	1891	46.0 per cent.
1888	48.9 per cent.	1892	56.2 per cent.
1889	46.5 per cent.	1893	46.0 per cent.
1890	47.9 per cent.	1894	57.0 per cent.

Since beginning serum treatment 17.7 per cent.

The mortality has, therefore, been reduced considerably more than one-half from that of the best ante-serum year, and more than two-thirds from that of the worst. Prof. Dr. A. Baginsky, of the University of Berlin, reported that during the past year he had treated 525 cases of diphtheria with serum. Previous to the introduction of this form of treatment the mortality had, during four years, averaged 41 per cent. When the cases come to be examined in detail the improvement is even more striking.

Of cases	Previous Mortality.	Present Mortality.
	Per cent.	Per cent.
Under 2	63.30	25.20
2 to 4	52.85	17.12
4 to 6	37.90	17.24
6 to 8	27.41	11.39
8 to 10	19.35	5.11
10 to 12	15.07	10.00
12 to 13	13.00	0.13

As to the general condition of the patients, Dr. Baginsky considered that the serum treatment not only reduced the mortality, but that the general condition of the children was improved; that there was very much less danger from heart disease; that there were fewer cases of nephritis; that there was less danger of laryngeal stenosis—no case in his experience ever having had laryngeal obstruction unless this condition had already begun, and that intubation was always possible, whereas under the older treatment tracheotomy was very often necessary. Finally, Dr. Herman Biggs, Bacteriologist to the New York City Board of Health, stated that he had had under his charge between 400 and 500 cases of diphtheria which had been treated with antitoxin in their own homes. These had all been severe cases and the mortality had been slightly over 16 per cent. The mortality for the whole of New York, he added, had been reduced over 40 per cent. Dr. Biggs then dwelt upon the importance of the antitoxin in preventing the spread of the disease by rendering those who were exposed to the infection immune. In one hospital there had been 107 cases of diphtheria in 108 days; immunizing injections of the serum

were then resorted to with all the inmates—200 units of Behring's preparation being used in each case. During the next thirty days only one very mild case occurred; in the following thirty days another mild case occurred and then five more. Injections of 225 units were then used and there were no more cases. The same result was obtained in three other institutions and the value of the immunizing power of the antitoxin was conclusively demonstrated. The speaker concluded by saying that in over eight hundred subjects treated for the purpose of rendering them immune he had in no case observed any unfavorable symptom; in a few cases rashes, apparently urticarial in nature, had occurred on the eighth day, and in some there had been a temporary rise in temperature which, however, had in no case resisted treatment more than twelve hours.

Smallpox Epidemic in London.—The belief which was expressed about the middle of August that the epidemic manifestation of smallpox in London had reached its highest point, with 327 cases under treatment on the 10th of that month—proves to have been not well founded. A cable dispatch of the 3d inst. announces that the disease has been officially declared epidemic in the east districts, in which there were 482 cases under treatment on the 2d inst. This rapid increase of the disease during the summer season excites grave apprehension as to its possible extent during the approaching cold weather, and the Local Government Board is putting forth every effort for its suppression before winter. So far as can be ascertained the disease first manifested itself in Whitechapel, and the *British Medical Journal* of August 24, significantly adds, in this connection: "For some time past the Board of Guardians have not enforced the [vaccination] act, there being a majority of anti-vaccinationists on the Board."

SOCIETY NEWS.

Medico-Legal Congress.—Dr. Forbes Winslow, of London, sailed on August 24 from Southampton and will preside as chairman over the Department of Insanity and Mental Medicine at the Medico-Legal Congress, held at the United States Court Room, Post Office Building, New York, on September 4, 5 and 6. He will also read a paper at the same congress on "Suicide as an Epidemic." Dr. Winslow will make an extended visit in the United States.

American Association of Obstetricians and Gynecologists.—The eighth annual meeting of this flourishing society will be held in Chicago Sept. 24, 25 and 26, 1895. The following is the preliminary program:

- President's annual address, J. Henry Carstens, Detroit.
- Relation of pelvic suppuration to structural changes that may occur in the Fallopian tubes, A. P. Clarke, Cambridge.
- Nephrorrhaphies, George Ben Johnston, Richmond.
- Detached fibroids, George H. Rohé, Catonsville.
- A clinical contribution to lateral displacements of the uterus, Edward J. Ill, Newark.
- Appendicitis, A. Vander Veer, Albany.
- Intermediate treatment of puerperal sepsis, A. B. Miller, Syracuse.
- Kraurosis vulvæ, a contribution to its pathology and therapeutics, H. W. Longyear, Detroit.
- Report of three recent cases in gall-bladder surgery, Edwin Ricketts, Cincinnati.
- Subject to be announced, H. E. Hayd, Buffalo.
- Intestinal obstruction following peritoneal operations, A. H. Cordier, Kansas City.
- Subject to be announced, S. Y. Howell, Buffalo.
- Cure of tubal distension without laparotomy, F. A. Glasgow, St. Louis.
- Subject to be announced, W. B. Dorsett, St. Louis.
- Subject to be announced, C. C. Frederick, Buffalo.
- Hysterectomy in bilateral diseases of the appendages, giving remote results, Florian Krug, New York.

Discussion: Vaginal hysterectomy *versus* Abdominal section for pus tubes. (a), title unannounced, (affirmative) X. O. Werder, Pittsburg; (b), when shall hysterectomy accompany bilateral removal of the appendages? Reuben Peterson, Grand Rapids; (c), pathologic and surgical contraindications of the vaginal route in dealing with puriform diseases of tubes and ovaries, Joseph Price, Philadelphia; (d), title unannounced, (affirmative) George H. Rohé, Catonsville.

Discussion: Eclampsia gravidarum. (a), Etiology, Frederick Blume, Allegheny; (b), Pathology, George F. Hulbert, St. Louis; (c), title to be announced, W. H. Taylor, Cincinnati; (d), Prophylaxis, H. W. Longyear, Detroit; (e), Puerperal convulsions *versus* Insanity, W. P. Manton, Detroit; (f), Treatment, J. M. Duff, Pittsburg; A. H. Wright, Toronto; Thomas Lothrop, Buffalo.

Exhibition of various types of rectal papillæ, R. T. Morris, New York.

Subject to be announced, E. Arnold Praeger, Los Angeles, Cal.

Ruptured interstitial pregnancy, L. H. Dunning, Indianapolis.

Has gynecology received just recognition as a specialty? M. B. Ward, Topeka.

Indications for operation in puerperal sepsis, L. S. McMurry, Louisville.

Pneumo-peritoneum, James F. W. Ross, Toronto.

Subject to be announced, J. B. Murphy, Chicago.

Subject to be announced, Charles A. L. Reed, Cincinnati.

Subject to be announced, M. Rosenwasser, Cleveland.

The regular program will be issued September 1.

J. HENRY CARSTENS, President.

WILLIAM WARREN POTTER, Secretary.

Section on State Medicine.—Minutes of the proceedings of the forty-sixth annual meeting of this Section of the AMERICAN MEDICAL ASSOCIATION held at Baltimore, Md., May 7 to 10, 1895. The first session convened in the north side stage room of the new Music Hall at 3 o'clock P.M., Tuesday, May 7, the chairman, Dr. L. H. Montgomery of Chicago, presiding and Dr. Charles H. Shepard of Brooklyn, N. Y., Secretary.

After registration: The next order of business Dr. James F. Hibberd was requested to occupy the chair pro tem, while the chairman read the Annual Address which was upon motion referred for publication.

The first paper was by Dr. Henry O. Marcy, entitled "Sanitation in Street Pavement." Discussed by Drs. A. L. Gihon, Jerome Cochran, G. P. Conn, C. F. Ulrich, B. A. Randall, J. A. Stewart, D. W. Cathell, R. Beverly Cole, W. C. Woodward and the author, and referred for publication.

The next paper read was by Dr. C. F. Ulrich, on "Physical Training in Childhood and Youth as a Preventive of Disease," which was upon motion of Dr. I. N. Quimby referred for publication.

Dr. B. Alexander Randall read the next paper on "Hygiene of the Eyes and Ears in Schools," referred for publication in the JOURNAL.

The following gentlemen were appointed members of the Business Committee to represent the Section during the meeting of the ASSOCIATION: Drs. George W. Stoner, J. J. Kinyoun and Dr. J. A. Stewart of Baltimore.

The paper "Anticipative Treatment of Disease, Organically, Functionally and Specifically," by Dr. W. G. A. Bonwill, read by title, which was followed by the reading of a paper entitled, "The Proper Relations of National, State, and Municipal Quarantine," by Dr. Jerome Cochran. Discussed by Drs. A. G. Field, Woodward, Ulrich, Rogers and the chairman and referred for publication in the JOURNAL.

Upon motion of Dr. Charles H. Shepard, seconded by a number of the members, the following suggestion embodied in the address of the chairman was unanimously adopted, and referred to the general session of the ASSOCIATION with the request that it be read there and similar action taken regarding the appropriation. As it is in reference to the proposed Department of Public Health, the suggestion is herewith transmitted in its entirety:

"That we advise and recommend to the ASSOCIATION in general session, ere its final adjournment, that the perpetuity of the special committee appointed by the ASSOCIATION in 1891 be continued. To memorialize Congress to establish another branch of the Federal Government, known as the Department of Public Health, with a medical secretary of same. That this committee be clothed with additional substantial authority, and with the request also from this Section that sufficient financial aid from the Treasury of the ASSOCIATION be appropriated, which should not be less than

\$1,000 for the ensuing two years to defray the necessary expenses of the committee."

After the appointment of the nominating committee, which consisted of Drs. G. P. Conn, C. F. Ulrich and A. G. Field, the Section adjourned until 9 o'clock A.M., Wednesday.

SECOND DAY—WEDNESDAY, MAY 8.

The first paper "Lighting the School Room" with illustrations, was read by Dr. Archelaus G. Field, and upon motion Dr. Field was permitted to re-read his paper before the Section in Ophthalmology if agreeable for him to do so. Otherwise the same was referred for publication.

"Depopulation of Civilized Nations" was the next paper announced to be read by Dr. James W. Cokenower. As the author was not present it was read by title.

The following papers were also read by title, in the absence of the authors: "Tuberculosis and its Prevention," by Dr. Charles E. Winslow, Los Angeles, Cal.; "Prevention of Tuberculosis by Feeding," by Dr. E. Cutter, New York, N. Y.; "Importance to a Municipality of a Contagious Disease Hospital," by Dr. J. T. Leal, Paterson, N. J.

The Secretary then read a paper by Dr. Benjamin Lee of Philadelphia, on the subject of "The Necessity for Increased Hospital Accommodations for the Treatment of Contagious Diseases in Large Cities." The Section then adjourned until 3 o'clock P.M.

Afternoon Session. Second day continued. The first business was the report of the Nominating Committee of officers of the Section for the ensuing year: Chairman, Charles H. Shepard, Brooklyn, N. Y.; Secretary, Albert L. Gihon, U.S.N., Washington, D. C.

Executive Committee: one year, Charles A. Lindsley, New Haven, Conn.; two years, George W. Stoner, Baltimore, Md.; three years, Liston H. Montgomery, Chicago, Ill. Upon motion, duly seconded, the report of the committee was unanimously adopted.

Reading and discussion of papers was then proceeded with. "The Bath in Modern Medicine," was the first topic considered, which paper was read by Dr. Charles H. Shepard and upon motion was referred for publication.

"A Practical Demonstration of the Natural Facilities for Water Contamination," by Dr. R. Harvey Reed, Columbus, Ohio, was read by title.

"Why Baltimore is a Healthy City," was read by Dr. D. W. Cathell. Discussed by Dr. James A. Stewart, ex-Commissioner of Health of Baltimore, and Secretary of the Maryland State Board of Health, Dr. Jerome Cochran, the chairman, and the author. This paper was referred for publication.

The next paper read was entitled, "The Use of Vaccine Serum in Variola," by Dr. Llewellyn Eliot, and was discussed by George M. Kober, Jos. J. Kinyoun and the writer. Upon motion, duly seconded, the paper was referred for publication in the JOURNAL.

The next paper announced on the program was read by title, namely, "Importance of State Government Control of Artificial Agencies that may be Productive of Noises," by Augustus P. Clarke, Cambridge, Mass.

"Reform in Medical Expert Testimony," was the title of an essay contributed by Dr. S. S. Herrick, of San Francisco, Cal., which was read by the Chairman, and upon motion, the same was referred for publication.

This was followed by Dr. Elmer Lee, who read a paper entitled "Prevention of Cholera," which was upon motion referred.

The succeeding paper, "The Gold in Garbage," by Dr. Douglas H. Stewart, of New York, N. Y., was, upon motion, passed, as neither the author nor the paper had been seen.

The same course was pursued regarding the paper that was next announced on the program "with no title," by Dr. Cressy A. Wilbur, of Lansing, Mich.

The subjoined list of papers were read by title and referred for publication, as the papers were on hand and the authors had been present during previous sessions:

"The Proprietary System," by Dr. F. E. Stewart, Detroit, Mich.

"How to make Practical Life Insurance Examinations," by Dr. John L. Davis, Cincinnati, Ohio.

"Observations on Hydrophobia and the Pasteur Treatment," by Dr. Antonio Lagorio, Chicago, Ill.

Dr. Granville P. Conn read a paper on "State Medicine v. Fads."

The Section then adjourned until 3 o'clock Thursday afternoon.

THIRD DAY—THURSDAY, MAY 9.

The Section convened at 3 o'clock. Increased interest was

manifest as it was known that a series of essays and papers were to be read by members of the American Medical Temperance Association, constituting what the chairman termed a Symposium on Alcohol.

This is the first time that the members of the A. M. T. A., as a body, had ever been invited to participate with any of the sections of the Association proper.

At 3:05 o'clock, Dr. N. S. Davis, President of the A. M. T. A., read an address, "Does Alcohol ever Act as Food, or as a Generator of any Natural Force in the Living Body?"

The discussion that ensued was participated in by Drs. I. N. Quimby and J. H. Kellogg. The address was, upon motion and seconded, referred for publication, as were all the other papers of the series that were read.

At 3:35 o'clock, Dr. Henry D. Didama read a paper with nearly the same title.

Dr. J. H. Kellogg read a paper on "The Influence of Alcohol upon Urinary Toxicity," discussed by Drs. I. N. Quimby and Elmer Lee.

Dr. I. N. Quimby's paper on the "Fatality of Surgical Operations," was announced, but Dr. Quimby was obliged to retire to keep an appointment elsewhere. The paper was read by title and referred for publication.

Drs. David Paulson and Howard F. Rand, of Battle Creek, Mich., were announced to read "A Report of a Series of Physiologic Tests, Showing the Effects of Alcohol in Moderate Doses upon the Nervous System." As neither author was present the report was passed.

Dr. W. H. Riley's paper "On the Treatment of Typhoid Fever without Alcohol," was read by title, as were also the succeeding papers, entitled "Six Cases of Typhoid Fever Successfully Treated without Alcohol," by Dr. Kate Lindsay, of Battle Creek, and "Alcohol in La Grippe," by Dr. Charles H. Shepard.

The paper announced to be read by Dr. George W. Burleigh, of California, having for its title "Influence of Alcohol on the Blood," was, upon motion, passed, as neither the author nor his paper were present.

Dr. F. W. Grosvenor, of Buffalo, N. Y., read a paper upon "Some of the Factors in the Solution of the Alcoholic Problem."

The succeeding three papers were read by title, namely: "Alcoholic Intolerance and Predispositions," by Dr. T. D. Crothers, Hartford, Conn.

"Alcoholic Anesthesia," by Dr. L. D. Mason, Brooklyn, N. Y.

"Acute Alcoholic Insanity, as Distinguished from Delirium Tremens," by Dr. John Morris, Baltimore, Md.

An instructive and interesting discussion ensued which was participated in by Drs. N. S. Davis, C. G. Comegys, A. P. Clarke and J. H. Kellogg.

The chairman, Dr. Montgomery, in conclusion, renewed his thanks to the members of the Section for what they have done toward contributing the unprecedented number of valuable essays and papers that have been presented at this meeting, and for personal courtesies extended to himself.

Dr. Jerome Cochran and G. P. Conn were appointed a committee to conduct Chairman-Elect Dr. Charles H. Shepard to the chair, who briefly responded for the new honor that had been conferred upon him, and inquired if there was any miscellaneous or unfinished business to be transacted. Dr. Montgomery announced that he had been informed by the Chairman of the Nominating Committee, that Dr. Gihon could not serve as Secretary of the Section, and as Dr. Gihon had informed the speaker personally of such fact, he moved that Dr. Elmer Lee, of Chicago, be elected Secretary of the Section for the coming year. Carried.

The Chairman then declared the Section adjourned *sine die*.

Since adjournment, Dr. Charles E. Winslow's paper, "Tuberculosis and its Prevention," has come into possession of the JOURNAL, and will appear in due time in the published Transactions.

NECROLOGY.

CHARLES F. J. LEHLBACH, M.D., of Newark, N. J., died August 14. He was 60 years old; was born in Baden-Baden, Germany, and came to America when 14 years old, settling in Newark. He received a classical education from his father, the Rev. Frederick Augustus Lehlbach, who had gained eminence in Germany by his writings. He was graduated from the College of Physicians and Surgeons, New York. In 1861 he enlisted as a private in the District of Columbia Volunteers, and afterward joined Battery B,

1st Pennsylvania Light Infantry. In 1863 he became assistant surgeon, serving till the close of the war, when he resumed practice in Newark. In 1867 he was made county physician. He leaves a wife and several adult children. One son is health officer of Newark.

JAMES W. MARTIN, M.D., of Lebanon, Ind., August 26.—Alfred G. Lebault, M.D., of Norfolk, Va., August 27, aged 84 years.—W. W. Cable, M.D., of Pittsburg, Pa., August 25, aged 71 years.—S. B. Finch, M.D., of Washington, D. C., August 26.—H. S. Costikyan, M.D., of Chicago, August 31, aged 53.—Fayette Montrose Weller, of Chicago, September 2, aged 40 years.—J. S. Clark, M.D., of Chicago, August 31, aged 74 years.—Asa Morgan, M.D., of Cedar Bayou, Tex., August 24, aged 67 years.—Frank Drake Stannard, M.D., of Chicago, September 1, aged 33 years.—O. W. Searing, M.D., of East Oakland, Cal., August 22, aged 65 years.—S. K. Towle, M. D., of Haverhill, Mass., August 16, aged 66 years.—N. P. Howard Sr., M.D., of Greenfield, Ind., August 25, aged 73.—R. L. Vaughn, M.D., of Chattanooga, Tenn., August 28.—R. P. Eckert, M.D., of Chicago, August 28.—Wiley Gordon, M.D., of Jacksonville, Ill., August 22.—D. P. Nuzeum, M.D., of Elwood, Ind., August 23.—Frank Honnecker, M.D., of St. Louis, Mo., August 23, aged 25 years.

MISCELLANY.

Ten Thousand Unfit Dwellings.—It is stated that in Birmingham, England, there are not less than ten thousand houses that are unfit for human habitation, and yet are allowed to be occupied and even overcrowded.

Important Charitable Bequests.—The will of the late Sarah Gay, of Newburg, N. Y., gives, under certain conditions, the sum of \$10,000 to the St. Luke's Hospital of New York city, and a like amount to the Home for the Friendless.

Ovaries, Tubes and Uterus in a Hernial Sac.—In operating for the relief of a right inguinal hernia in a female infant, Mr. Leopold Hudson, surgeon to the Middlesex Hospital, London, found both ovaries, both Fallopian tubes and the uterus in the sac. The tubes were much congested from constriction at the neck; a director was passed in, the constriction divided, and the organs were replaced—the left ovary and tube being first returned, then the uterus, and lastly the right appendages. Many abnormal contents of hernial sacs have been recorded—a bladder, an ovary, etc., and once an ovary in a femoral hernia with the Fallopian tube constricted at the neck; but Mr. Hudson's case is probably unique.

More Bacteriology and Sanitation Should be Taught at West Point.—The *Independent* predicts that bacteriology must in the near future, be given a place in the curriculum of our national schools of warfare. It is stated that the superintendent at West Point has subjected himself to severe animadversion from opposing the introduction of a short course of instruction in hygiene and first aid to the injured. The reason for his opposition seems to be that no time for such a course can be spared from the courses of study already marked out and followed. The Board of Visitors for 1894 had, among others, the celebrated anatomist and surgeon, Dr. W. W. Keen, who was surprised to find that the entire instruction in hygiene and physiology consisted in six advance and five review lessons, with an occasional incidental allusion to such subjects as ventilation, choice of site for camps. The visitors thought that a little of the time now given to mineralogy and geology might be profitably devoted to a study of the structure and physiologic needs of the human frame; and certainly the military leader of the future will need to know much that belongs to bacteriology and sanitation, or he will fall out of step with his age.

Important Section of Kansas Crimes Act Invalid.—Section 15 of the Kansas Crimes Act, which provides that "every person

who shall administer to any woman, pregnant with a quick child, any medicine, drug or substance whatsoever, or shall use or employ any instrument or other means, with intent thereby to destroy such child, unless the same shall have been necessary to preserve the life of such mother, or shall have been advised by a physician to be necessary for that purpose, shall be guilty of manslaughter in the second degree," the Supreme Court of that State holds (*State v. Young*, decided June 8, 1895,) is inoperative and invalid, as it undertakes to establish a degree of felonious homicide where neither the death of the child nor the mother results from the acts committed, and where there may be no killing or homicide.

A New Title.—The *Kansas City World*, of August 27, contains the following amusing slip of the compositor:

"NEW MEDICAL SCHOOL.

"Proposes to put finishing touches upon medical educations. The *Kansas City Pyrotechnic Post-Graduate Medical School* to-day filed articles of incorporation in the office of the county recorder. The incorporators are: Homer C. Crowell, five shares; George M. Gray, five shares; Jacob Block, five shares; George W. Grove, five shares; George Halley, one share, and Homer C. Crowell, as trustee, seventy-nine shares. The board of directors comprises Homer C. Crowell, Jacob Block and George Halley. The capital stock is \$2,000."

"Pyrotechnic" would be an appropriate designation for some schools, but probably not for this one.

A Hospital Broken Up by a Chinese Mob.—On August 6, the Mission Hospital at Fat-Shan was destroyed by Chinese rioters. The hospital, with other destroyed property, was owned by the English Wesleyan Church. The city where it was located is a large manufacturing center, fifteen miles west of the city of Canton. It has a population of 500,000, and is frequently spoken of as the "Birmingham" of China. Missionary work in its various forms has been carried on there for about thirty-five years. The London Mission has a flourishing work there, which is sustained by the Chinese church in Hongkong. The English Wesleyan Mission has chapels, school, hospital and residence for several missionary families there, a very prosperous mission. Their hospital, which has developed under the efficient management of Dr. Wenyon and his colleague, Dr. Macdonald, is one of the notable institutions in South China. Not only has the medical and surgical work done been of a very high character, but the hospital has, by judicious management, become practically self-supporting. It has been patronized by many of the wealthier people. Their pecuniary acknowledgments of benefits received, and the fees received by the physicians in charge for service rendered in answer to special calls, have sufficed to cover the current expenses of the hospital. It has demonstrated the fact that even Chinamen can appreciate superior talent and not only respect it, but desire it the more when they have to pay for it. The high standing of this hospital among the respectable residents of Fat-Shan has not saved it from the mob.

Another Prevaricator.—One Dr. R. B. Miller, who claims his residence at 170 Oakwood Boulevard, Chicago, and his reference, the Globe Savings Bank, Chicago, has published a four-page blanket sheet in which, with much bad spelling and bombast, he sets forth his utter contempt for the old hide-bound fogies who stick to the Code and prefer to grope in the dark rather than encourage such bright and shining lights as Miller, who to use his own language, "is pushing to the front, determined to conquer disease by any and all remedies known, or that they may discover." Miller's sheet says that "we are proud of our past achievements, having treated and cured thousands of cases in Illinois during the past five years, many of whom had been given up as hopeless and left to their fate to die in despair."

According to the register of the Illinois State Board of Health, Russell B. Miller registered as a physician and his license was issued Oct. 16, 1891. He has not yet completed

his five years, but at the rate he is "pushing to the front" he may complete the remainder of it in a summary fashion. This person announces himself as the "President of the AMERICAN MEDICAL ASSOCIATION of Chicago," which announcement evidently meant to catch the unwary, is one of the basest subterfuges. The State Board of Health should revoke the man's license without delay.

Wisconsin Has Provided a Cholera Contingent Fund.—The Wisconsin Legislature, at its last session, appropriated to the State Board of Health a sum not exceeding \$50,000 for the two years ending Feb. 1, 1897, which shall be a fund, which, by and with the advice and consent of the Governor, may be drawn upon by said board, and used by it in such manner as may seem to it necessary to prevent the introduction or spread of Asiatic cholera or other dangerous contagious disease in the State. Any member of the State Board of Health, except the Secretary, who is engaged in work for the prevention of cholera outside of the city in which such member resides, shall be allowed and paid for the time in which he is actually so engaged, such sum as the Governor may approve, not exceeding \$15 per day in addition to traveling and other necessary expenses.

Louisville Notes.

HEALTH OFFICER'S REPORT.—During the month there were 265 deaths, of which 143 were male, 200 white, 79 married and 138 natives of Louisville. The total is 42 less than August of last year. Consumption heads the list with 28; typhoid fever and organic heart disease, each 13; inanition, 14; meningitis, cerebral, 12. Eight of those dying were over 100 years of age. The annual death rate per 1,000, 15; white (164,261), 14; colored (35,739), 23.

G. A. R.—There was a well attended meeting held in the City Hall, of those doctors who are to serve in the coming Encampment. Dr. Geo. W. Griffiths, Vice-President of the Executive Committee, addressed those present, emphasizing the necessity of prompt organization.

BLOOM.—Dr. I. N. Bloom has been elected to the Chair of Genito-Urinary and Skin Diseases in the University of Louisville, Medical Department. Dr. John L. Howard will direct the workings of the bacteriologic laboratory in the same school.

Washington Notes.

HEALTH OF THE DISTRICT.—The report of the Health Officer for the week ended August 24, is as follows: death rate per 1,000 per annum, white, 20.40; colored, 28.69; total, 23.06. There was an improvement in the health of the city last week. According to the reports received at the Health Department, the deaths fell off 11 per cent. as compared with the last report. The death rate accordingly fell from 25.95 to 23.06. The improvement was mainly owing to the decrease in mortality among children under 5 years old. There was a notable absence of deaths from the dangerous contagious maladies, with the exception of those from diphtheria, from which there were three deaths while no new cases were reported.

SECRETARY MORTON'S HYGIENIC ORDER.—An important order, giving full protection to foreign consumers of American meat products, was issued last week by Secretary Morton. It will prevent the exportation of any beef that is not inspected, and will cause the exporters of horse meat so to mark the packages that the nature of the contents shall be apparent. The action is authorized by an act of March 3, 1891, amended March 2, last. The order follows:

"It is ordered that from and after Sept. 16, 1895, all beef offered for exportation, whether fresh, salted, canned, corned or packed, shall be accompanied by a certificate showing that the cattle from which it was produced were found free from disease, and the meat sound and wholesome, by an inspector of this department. And in order that it may be determined whether all beef exported has been so inspected and found to be sound and wholesome, it is further ordered that the meat of all other species of animals, which for any reason does not bear the inspection tags and stamps of this department, shall be packed in barrels, cases or other packages which are legibly marked in such manner as to clearly indicate the

species of animal from which the meat was produced. Meat which is not so marked, and which is not accompanied by a certificate of inspection will be classed as uninspected beef, and will not be allowed exportation.

"Notice is hereby given to exporters of meat, whether said meat is fresh, salted, corned, packed or otherwise prepared, and to owners and agents of vessels upon which said meat is exported, that no clearance can be given to any vessel having on board said meat until the provisions of this order are complied with. J. STERLING MORTON, Secretary."

PHYSICIANS APPOINTED TO OFFICE.—The Commissioners have made an appointment to fill the vacancy caused by Dr. Austin O'Malley, medical sanitary inspector of the Health Department, whose resignation was formally accepted. Dr. John E. Walsh is appointed sanitary inspector, with a salary of \$1,200 per annum and an indefinite leave of absence without pay, pending his return to Washington. Dr. Walsh is at present in the Arctic regions with the Peary relief expedition. Dr. R. D. Boss has been appointed acting medical inspector, to serve until Dr. Walsh is ready to take charge of his new office. Dr. Edward M. Parker was appointed bacteriologist at a salary of \$400 per annum, vice O'Malley, appointment to take effect September 1. Dr. G. C. Clark has been appointed physician to the poor at \$30 per month, to fill the vacancy caused by the promotion of Dr. Boss. The appointment of Dr. Parker is a particularly fitting one. He is the assistant pathologist, and is in charge of the Bacteriologic Laboratory in the Central Dispensary and Emergency Hospital here, and has been assistant to Dr. Welch at the Johns Hopkins Hospital. The District Health Office is to be congratulated upon securing the services of Dr. Parker; the salary is, however, entirely too small to begin to compensate the Doctor for his valuable services.

GARBAGE LAW TO BE ENFORCED.—About fifty cases of violations of the garbage law by citizens were tried in the police court during the past week. The Health Department is not demanding the payment of fines, but simply requires compliance with the laws on the subject.

THE PUBLIC SERVICES.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from August 24, 1895, to August 30, 1895.

1st Lieut. William W. Quinton, Assistant Surgeon, is relieved from duty at Fort Riley, Kansas, and ordered to Fort Logan, Colorado, for temporary duty at Fort Logan, Colorado, relieving Captain Louis A. La Garde, Asst. Surgeon. Captain La Garde, on being thus relieved, will proceed to Boston, Mass., and report for duty as Attending Surgeon and Examiner of Recruits. Leave of absence, to date from August 21, and to include September 30, 1895, is granted Lieut.-Col. John S. Billings, Deputy Surgeon General, U. S. Army.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending August 31, 1895.

August 29. Surgeon J. E. Gardner, and P. A. Surgeon F. J. B. Cordelro, to temporary duty as members of the medical board at the Naval Academy, September 5.

CHICAGO, SEPTEMBER 14, 1895.

No. 11.

ADDRESS.

DANIEL DRAKE: OR THEN AND NOW.

The Address in Medicine delivered before the Mississippi Valley Medical Association, Detroit, Mich., Sept. 4, 1895.

BY WILLIAM PEPPER, M.D., (UNIV. OF PENNSYLVANIA.)
PHILADELPHIA.

Mr. President and Gentlemen, Members of the Mississippi Valley Medical Association:—As I left Jersey City and traveled in twenty-four hours to this beautiful city, the place of your meeting this year, it was impossible that my thoughts should not have turned to the strangely different journey, taken in his infancy over this same route, more than one hundred years ago, by one who was destined to play so prominent and so honorable a part in the life of the Mississippi Valley during the ensuing sixty-five years.

Dr. Daniel Drake, to whose life work I beg to invite your attention this evening, was born in New Jersey, of humble parentage, on Oct. 20, 1785; and in the latter part of the spring of 1788 his parents removed to Kentucky. Taking Daniel and his baby sister Elizabeth, and an unmarried sister of Mrs. Drake, with all their worldly goods, in one Jersey wagon, the journey was made over the Alleghenies to Fort Pitt; and then in a boat crowded with other families, and accompanied by similar boats for fear of Indians, to Maysville. More than sixty years afterward, Dr. Drake gave (in a series of reminiscent letters addressed to his children) an account of the toils and hardships and dangers endured by that pioneer family for the ensuing twelve years, until as a lad of 15 years of age, he was sent himself to study medicine under Dr. Goforth at Cincinnati. I can point to no work in which a more vivid and life-like picture is given of a primitive condition of society, and in which, at the same time, the author reveals with such frankness and fullness his own character and individuality. It is not surprising that all who knew Dr. Drake, at every stage of his life, should have concurred in unanimous testimony to the lofty and at the same time attractive qualities of his nature. It is a long time since I first began to study his works, and I think I may safely say I have read all that he ever wrote for publication, and nearly all of the many publications concerning him which appeared after his death. Whence it is that some gifted persons acquire their rare charm of literary style, it were idle to inquire. To Drake, it was the gift of nature, the power of expressing in pure and flowing and brilliant language the lofty ideals, the clear thoughts, the graceful fancies of his ardent nature and his powerful mind. His childhood was spent in the ceaseless labor of the farm; but through it all, Nature spoke to him as to a favorite son and opened his eyes to her infinite charms and inspired him with a love for herself which never lost its ardor. It was

this which sustained him through a long life, into which were crowded far more than an usual number of severe trials and disappointments, and kept his spirit to the end as fresh and buoyant and enthusiastic as a boy's. There came readily with this true love of nature those precious things of life—the power to appreciate purity and nobility in humanity; the power to form and to sustain lofty ideals; and the power to scorn petty groveling ways and to pursue the chosen higher path. This was eminently true of Drake. His character is known to us with a rare fullness, and yet there does not appear in it a single vice. He was ambitious; but his aims were never selfish or personal. His proper self-respect was untainted with vanity. His desire for office was to secure larger opportunities for public service. Money had no attraction for him, save to promote scientific investigation and to discharge his obligations. He was familiar with the pinching grip of poverty; he longed for the larger opportunities of study and action which wealth would give; at one time he entered almost recklessly into commercial operations which involved him in financial disaster; he accepted the load of debt with cheerful courage, and eventually paid every creditor in full. And yet he never allowed himself to pursue his profession as a mere money-making calling, but resolutely devoted a large part of his talents, time and strength to the advancement of education and science.

It may seem to you that it were more fitting, had an address upon the character and work of Daniel Drake been delivered in Cincinnati, with whose institutions his memory is most intimately associated. But when we consider that this is distinctly a gathering of the medical men of the Mississippi Valley, and when we reflect upon the colossal work which Drake achieved for the entire valley, and upon the splendid conception which he formed in the early days as to its future development and destiny, there can be no doubt that wherever this Association may meet, there should the memory of Drake be cherished.

The census of 1790, two years after his family came to Kentucky, gave the population of the United States as 3,929,214. Of the many States which now must be included in the great Central Valley, only Kentucky and Tennessee are there mentioned, with an aggregate population of 109,368, or 2.7 per cent. of the whole, and the center of population was twenty-three miles east of Baltimore; in 1800, the year in which he began to study medicine at the age of 15 in the town of Cincinnati, which did not then contain more than 500 inhabitants, the census gives the total population of the country as 5,308,483, and that of the Central Valley (comprising Tennessee, Ohio, Indiana and Mississippi) as 386,413, or 7.2 per cent. of the whole, and the center of population was eighteen miles west of Baltimore; while in 1895 the estimated population¹ of the coun-

try is 69,212,057, and the population of the great Central Valley, including eighteen States, is 29,614,304, or about 43 per cent., and the center of population is about Columbus, Ind., a westward movement of 525 miles in one hundred years. From an early age the tremendous magnitude of the physical and sociological features of the interior valley of North America, including the Canadian portion, impressed the imagination of Drake with overwhelming force. This vast stretch of territory beginning within the tropics and terminating within the Polar circle, and bounded laterally by the Appalachian Mountains on the East and on the West by the Rocky Mountains, embraces over 5,000,000 of miles—the northern part alone being rendered unavailable by the state of its surface and climate. Even that part belonging to the United States and which may be strictly called the Mississippi Valley amounts to 1,244,000 miles. To the clear vision of Drake, this valley presented itself as the last crucible into which living materials in great and diversified streams could be poured for amalgamation. The commingling of races upon a scale such as the world has never elsewhere witnessed could not fail in the end to give a new physiologic and psychologic development. No man could have less than Drake of the exuberant national spirit which made Elijah Pogram so great a terror to the effete civilizations of Europe. When Drake expressed his conviction that the vast homogeneous population which would eventually fill the interior valley of North America would present the last and greatest development of society, the opinion was based, not on the surpassing natural advantages of the territory, but upon his faith in the physical and social perfectibility of the race when it should attain its growth under conditions of civil and religious liberty. The contemplation of this great vision filled him with a passionate desire as a philanthropist and social reformer, that at the earliest day the foundations of education and of charity should be laid deep and strong there, so that the mighty tide of promiscuous immigration which was rising rapidly should have a saving element infused at once. Again he foresaw, as a natural philosopher, the immense importance of securing in the early days of the settlement of the valley, an accurate account of its topography, and of the climate, the flora and the fauna; and parallel with this, an account of the physical condition and habits of life of the pioneers. Lastly, as a medical philosopher, he recognized early the absolute necessity of a wide-spread enforcement of public and private hygiene; and of radical measures for the elevation of medical education.

When we consider the achievements of Drake in each of these three difficult fields of labor, we marvel at the courage, the ability and the unsparing ceaseless activity displayed.

Throughout his life he was intensely interested in public affairs. Intimately associated with many of the most eminent men of the country, he threw himself with ardor into the great political questions of the day, and in his speeches and writings evinced a pure and lofty patriotism. His repeated journeys up and down the Mississippi Valley had resulted in an equal love and respect for the North and the South. Later, in 1851, this expressed itself in a series of remarkable letters to Dr. John C. Warren of Boston, on the slavery ques-

tion, in which he insisted that a marked amelioration in the condition of the slaves had occurred under his own observation, and advocated the restriction of slavery to the States then holding slaves, and that emancipation should be coupled with colonization in Africa.

When only 30 years of age, he published a notable work, entitled, "A Picture of Cincinnati," which attracted wide-spread attention both in America and abroad; and in this he began to urge extensive internal improvements, and then made the first public suggestion of almost all the canals which have since been constructed in this region. In 1833 he advocated warmly, and acted as chairman of a special commission of three, to promote the construction of a railway which should connect the Ohio River at Cincinnati with the Atlantic at Charleston. It was not on commercial grounds he urged it, but because he believed it would tend to efface sectional hostility if the North and South should thus pledge themselves to common national interests. He was largely instrumental in founding the Free Library in Cincinnati. He organized the Cincinnati College, which according to his design was to embrace the features of a fully developed university, while its medical school and hospital in an especial sense owe their existence to him. The Museum of Science and Art was another of his creations. He labored hard for these institutions; he secured legislative grants in their favor; he personally solicited funds for their endowment and support. It is probably unnecessary to state that he was treated with injustice and ingratitude, for such is the almost inevitable reward of true benefactors. Such treatment never discouraged him. His ambition was for the cause and not for himself; and he never lost, until the very end, his enthusiasm for humanity and his zeal in the service of the community. Truly did the great and wise Gross speak of him as equally eminent as a patriot, a philanthropist and a medical author. The eloquent Charles D. Meigs, in delivering the biographical address on Drake at the College of Physicians of Philadelphia, spoke of him as "a man of great and merited reputation, which extended even to the outer boundaries of the republic of medical letters, while as a citizen he reflected honor on his country, so that his name is destined to be reverently pronounced wherever the medical biography and history of America shall hereafter become known."

But I must hasten to speak of the colossal work to which Drake devoted the greater part of his life. I have told you that from his earliest years the future importance of the great Central Valley of North America impressed itself indelibly upon him. He became a geologist and an archæologist in his study of the formations through which the Mississippi forced its way to the Gulf. His early familiarity with the forest and the fields led naturally to a profound study of botany, in which branch of science he became a high authority. He mastered the science of meteorology and enriched it by numerous accurate and original observations. He collected the materials upon which his descriptions and conclusions are based, by personal exploration of the entire valley from the Gulf to Lake Superior and from the Alleghenies to the Rockies, in the course of which he traveled over 30,000 miles. He visited hundreds of medical men along the valley, and actually instituted the earliest collective investigation with which I am acquainted,

¹ According to an estimate made for the World Almanac of 1895, by the Governors of the States and Territories.

by issuing series of circulars to all the physicians of that region, soliciting their coöperation in securing the data desired. It was over thirty years after the first announcement of the work that the first volume was published; the second volume did not appear until nearly two years after the death of the author in 1852.² Drake dedicated his work to the physicians of the Interior Valley of North America, and, with habitual modesty, styled it "An imperfect attempt to lay an extended foundation for a history of its diseases." A careful and critical perusal of the 1,700 pages of this monumental work will convince you that Drake was true to the principle announced in the preface, "that he who would observe correctly must have no theories either to maintain or destroy." As stated by him, the theory that the geological, hydrographical, topographical, climatic, social and physiologic conditions of communities must affect their medical histories; and that where different communities differ widely in one or several of these conditions, a corresponding diversity must appear in the respective histories of all the diseases which admit of modification from causes referable to those heads will not be disputed. It may readily be pushed to extremes; but the task which Drake assumed was to portray these conditions as they existed in the early part of the nineteenth century in this great valley, and then to furnish an accurate account of the diseases therein prevalent. Faithful to this duty, he ascended the streams to their mountain sources, or descended them to the sea at points exceedingly distant from each other. His masterly statement of the contrast between the medical relations of the Mississippi, the river of latitudes, and the St. Lawrence, the river of longitudes, may be referred to as an excellent example of his method.

The accumulation of facts is simply prodigious; the style is clear and admirably adapted; while the obvious sincerity of purpose and the philosophical breadth of view impress you with a sense of the permanent value of the work.³ It is easy in the light of our more accurate diagnosis and pathology to point to serious mistakes. The most important of these is the failure to admit the distinct individuality of typhoid fever, which had then recently been demonstrated by Gerhard and Pennock. Nevertheless the existence of severe outbreaks of typhoid at many points of the valley, and in different years, is clearly established by the excellent account furnished of the symptoms and course of the disease, and of the lesions found in fatal cases. These accounts should be referred to with care by those who are now meeting with typhoid fever in the same localities, but under widely different local conditions. How far there may

² I may call attention to the fact that the first 186 pages of the second volume are a reprint of the last 164 of the first volume. This was in all probability intentional on the part of the able editors, since it enabled the second volume to open at the beginning of the discussion of Febrile Diseases.

³ In regard to Drake's great work, the Standing Committee on Medical Literature of the AMERICAN MEDICAL ASSOCIATION reported at its third annual meeting, held in Cincinnati in May, 1850, concerning the first volume as follows:

"This volume, which contains nearly nine hundred pages, is taken up with the medical topography, the climate, the manners of the inhabitants, and the autumnal fevers of this vast region. Owing to the late period of its publication, the committee have been unable to examine the treatise thoroughly, and they might, therefore, rest contented with a bare announcement of its existence. But they are reluctant to do so, since even a superficial inspection of the work has convinced them that it belongs to the very highest rank of our medical literature, and may very probably come to be regarded as the most valuable original work yet published in America. It is certainly unrivaled in the amount and variety of its materials; its style is perspicuous, correct and elevated; and it appears to have been elaborated with great industry and care. Its distinguished author has raised a durable monument to his own name, and to the medical reputation, not only of the great valley but of the greater Union."

be actual variations in the disease as found in the Interior Valley, in the Atlantic States, and in Europe, is still open to discussion; and Drake's chapters are an important contribution to the study. The flora and fauna certainly present wide differences at different sections of the valley. It seems improbable that microorganisms should be exempt from the influence of climate and environment. It will not seem strange if shown that certain species of bacillus acquire at different latitudes, and in different soils, widely different degrees of growth and pathogenic virulence. There is considerable evidence in favor of the view that the bacillus communis coli, for instance, may from contact with certain organic matter, fecal or not, acquire the properties of the so-called bacillus of Eberth. Bacteriology is not ready as yet to dogmatize on such points. It is probable that we must take into account not only the susceptibility of the system (the soil) and the number of bacilli implanted (the dose of infection) but the virulence of the particular specimens of the bacillus present.

If I were to draw any inferences from Drake's description as to the relation between the typhoid he saw and that which we meet with to-day in the Middle Atlantic States, I should say that there were many more cases without eruption, while on the other hand grave nervous symptoms, hyperpyrexia, malarial complications and primary pneumonic lesions were unusually frequent.

Drake had arrived at a belief in the microbic nature of malaria, yellow fever and typhoid fever, as early as 1832, though of course his opinion was based purely on theoretical grounds. He states specifically that he had not seen the ingenious work of the elder John K. Mitchell until the year 1850; and hastens to make acknowledgment of the almost irresistible array of facts adduced by the latter distinguished author. He anticipated Woodward in the attempt to establish the existence of a *tertium quid* formed by the blending of typhoid and malarial infection. It seems to be an easy thing to fall into this mistake when one is dealing with typhoid and malarial fevers simultaneously on a large scale. The occurrence of a malarial complication of typhoid, and of a typhoid state in malarial fevers, is familiar; and it may be possible that the co-existence of the two microbes may so modify the blood and tissues as to influence the toxin and antitoxin developed and the consequent phenomena of the disease, but the accounts furnished by Drake, just as the later and more elaborate descriptions by Woodward, fail to convince that such modifications go far enough to constitute a specific difference which would justify the creation of another species of fever. Malaria, indeed, was the bane of the Interior Valley in those days; and I doubt if any one has enjoyed such opportunities as did Drake for studying all of its manifestations. Almost every page of his great work attests its prevalence; from the Gulf of Mexico up to the 47th degree of latitude (beyond which it became very rare); on the low and ill-drained lands near the rivers, and though in less virulent form throughout the bluff zone and back into the hilly regions; and over the Lake region, including extensive portions of New York State.⁴ Even at the elevation of 600 or 1,000 feet, malarial fevers were of frequent occurrence; and when extensive disturbance of the sur-

⁴ The swamps of the Chautauqua (sic) Summit in New York at an elevation of 1,400 feet were innocuous.

face of the soil was made, virulent outbreaks were to be feared. The distinguished French traveler, Volney, wrote that in a journey of 250 miles from Cincinnati to Detroit, begun on Sept. 8, 1796, in a company of twenty-five persons, they did not encamp one night without one at least of the party being seized with a periodical fever. On arriving in Detroit only three of the party were in health, and on the ensuing day the Commander, Major Swan and himself, were seized with a malignant fever.

On the lower reaches of the valley there were places where malaria was so pernicious and the sanitary conditions so shocking that we can not criticise Dickens for the harrowing account he published in "Martin Chuzzlewit" in 1843. Drake describes a town which was projected under the name of Florida, but which may well have been the original of that most misnamed Eden to which young Martin and the faithful Mark Tapley were lured by the wiles of land agents. It was at the estuary of the Escambia River, where the silt brought down by that stream had generated a marsh several miles in width, while the pine lands, which usually conferred immunity, lay to the leeward. In 1766, sixteen French Protestant families, consisting of sixty persons, were sent at the expense of the English government to this deadly spot. When the hot months arrived, all but fourteen perished; and the survivors lingered only a few months longer with shattered constitutions. In spite of this, many years later, in 1832, a new town was laid off to be called Florida; and between twenty and thirty wooden houses were built and tenanted by as many families. Their history, says Drake, may be told in a few words. Year after year they were assailed by autumnal fevers of the most malignant character; the spot was at last called a graveyard; and being abandoned by those who survived, I found, on passing through in 1843, but two families remaining.

"Do you consider this a swamp, Sir?" inquired Chollop gravely of Mark Tapley at Eden.

"Why yes, Sir," returned Mark, "I haven't a doubt about it."

"The sentiment is quite European," said the Major, "and does not surprise me. What would your English millions say to such a swamp in England, Sir?"

"They would say it was an uncommon nasty one, I should think," said Mark, "and that they would rather be inoculated for fever in some other way."

"European," remarked Chollop, with sardonic pity. "Quite European."

It was just such swamps as that of Eden which abounded formerly in many of the counties of England, and the medical literature of England in the last century teemed with discussions of the resulting malaria. Just as drainage and cultivation have almost eradicated it there, so did Drake and every intelligent observer know that the same agencies would inevitably banish malaria in large degree from our great Interior Valley. How swiftly this good work would progress under the vast immigration of the ensuing fifty years, not even Drake in his most sanguine moments would have ventured to predict. Meanwhile, it was the great cause of mortality or infirmity of constitution, especially in the southern portions of the valley; and the medical practice of the entire region was powerfully influenced by the views entertained regarding its nature.

I am aware that some of Drake's contemporaries, possibly influenced by envy of his national fame and great authority, insinuated that he was a mere theorist and speculator, and a reckless practitioner. Dr. Gross, who had the best opportunities of knowing him and his practical ability, gave this testimony: "I have great confidence in his professional acumen. I saw enough of him in the sick chamber to satisfy me he had a most minute and thorough knowledge of disease and of the application of remedial agents. There was no one whom I would rather have trusted in my own cases, or in that of a member of my family." No additional testimony, however, is needed by any one who will carefully study his own writing. Everywhere is manifest the accurate observer, the clear-headed thinker, the practical man who can not be led by mere authority and who will not lapse into routine. The truth is that Drake was ahead of his time—at least of that time in his region—as much in his practice as he was in other things. When he first began the study of medicine with Dr. Goforth, of Cincinnati, at the age of 15 years, he showed so much ability that in four years he was admitted to partnership. He was thus engaged in practice, not only without a diploma but without ever having listened to a single lecture, for over a year, when he scraped together enough money to go to Philadelphia and take a course of lectures at the University of Pennsylvania. Before leaving Cincinnati, his instructor and partner presented him with an autograph diploma, setting forth Drake's ample attainments in all the branches of the profession. This was the sole pretense of a license to practice which he possessed until his second visit to Philadelphia, eleven years later, in 1816, when he received his diploma at a special Commencement held purposely for him on May 11, more than a month after the occurrence of the regular Commencement.⁵ He was powerfully impressed with the brilliancy of Rush's lectures. He had, even as a lad, conceived a high admiration for the genius of this great teacher from the study of his writings; but his practical sagacity led him to modify his doctrines in accordance with the results of his own observations, instead of carrying them blindly to an extreme length as was done by only too many. We can well understand the mortality that attended all fevers, when we read in Drake's reports of the practice of his contemporaries, that for the gastric complications many physicians gave calomel in doses of a scruple or a drachm at short intervals; that even doses of half an ounce, or an ounce and a half several times a day were far from rare; that these doses were sometimes given to load down the irritable stomach and by their actual weight to prevent vomiting; that multitudes believed that when they did not obtain bilious discharges by ounce doses, it was because they were too timid in its administration; that in some cases even so much as a pound or a pound and a half were administered to a single patient. He quotes from the letter

⁵ A full explanation of this singular and highly complimentary occurrence is given in Dr. Meigs' interesting biographical notice of Drake (Trans. Coll. Phys. of Phila., 1893) in the form of a letter from Dr. Joseph Carson, the Dean of the Medical Faculty of the University. It appears that Dr. Drake submitted his thesis, at the close of the session, and left the city with the understanding that he should be notified in time to be examined and to receive his degree. The letter did not reach him and he returned to Philadelphia the day after Commencement. "Under these circumstances the Professors, considering the high literary accomplishments of Mr. Drake, the value of his late publication, his present eminence and future promise . . . examined him on April 30 and recommended him to the Board of Trustees for the special mandamus which was granted at the Commencement held as has been stated."

of a physician in Louisiana who wrote with playful hyperbole that in a recent epidemic, "he had drawn enough blood to float, and had given enough calomel to freight, the steamer *General Jackson*." Against this drastic and murderous practice, Drake exerted all his influence. He urged the external use of cool water in fevers to reduce excessive temperature; he rapidly came to advocate an expectant method of treatment conjoined with scrupulous attention to all hygienic details, because he found all special methods unsatisfactory. When we look around us to-day and witness the eminent schools of medical science in those Central States; the numerous distinguished practitioners, teachers and authors; the original publications of high scientific and practical value, we are amazed at the speed with which the medical profession here has advanced to a position of well organized and commanding strength. It is easy for you to-day to advocate prolongation and elevation of medical studies; to insist upon the adoption of rational methods of treatment; to secure substantial aid in the prosecution of scientific investigation. Let us never despise the day of little things. All the more should we honor those who were the pioneers in this wonderful march of progress; and who held aloft the standard of scientific truth and professional dignity under the most difficult conditions. Well do I remember the feeling words in which my revered friend, the late Samuel Freeman Miller (whose services in the cause of constitutional liberty rendered during so many critical years as Associate Justice of the United States Supreme Court place him in the rank with the immortal Marshal), spoke to me of the causes which led him to abandon medical practice and begin the study of law. He graduated at the Medical Department of Transylvania University, in 1838; but soon found the difference between the theory as taught and the practice as established in Kentucky so glaring, and the difficulty of securing a chance for more rational measures so insuperable that he was wretchedly unhappy. Drake felt these difficulties keenly, but his enthusiasm carried him through. When he was only 21 years of age he used cold affusions in a case of fever; the friends protested, and Drake called in consultation an old and respectable physician who highly approved the affusions, but said it was too hazardous to a physician's reputation and therefore should not be employed. "This advice," continued Drake, "contained something which we are all sufficiently predisposed to lay hold of. I accordingly adopted it, and have had repeated occasions for dissatisfaction ever since. The event of some severe cases of fever in the summer of 1812 determined me to revert to the disinterested and magnanimous views and motives of youth, and also to prescribe and enforce, in all dangerous cases, anything which I believed necessary, the antipathies of the sick and the obloquy of the intermeddling notwithstanding." I am sure that every one of us has been forced to face the same temptation; and it is well for us if we have shown the righteous determination of Drake. It is certainly not the least of Brandt's claims to our gratitude that while others before him had recognized the advantages of hydrotherapy in fevers, he alone insisted upon it so strenuously and repeatedly and with such impressive marshalling of facts, that at last a reluctant world was compelled to give heed.

I may not now enter into any extended discussion of this ever interesting question. My object has been

to show that Drake was a leader in this respect also. He appreciated the external use of cold water in fevers, in the phlegmasiæ, and as a means of rousing reaction in collapse. He quotes from the practice of a number of his correspondents to show that hydrotherapy made some headway in his time. The difficulties attending its thorough introduction into private practice have always been too great, however, for the average man to overcome; and all of us know that only of recent years and under the teaching of Brandt, of Jurgensen, of Liebermeister has it secured general adoption. In fact, even at the present day, this curious anomaly exists, that in nearly all hospitals thorough hydrotherapy is used in fevers, and in many of them the rigid Brandt method is applied as an unvarying, and therefore unphilosophical routine; while in private practice I fear there are comparatively few medical men who insist upon cool bathing, even when it is urgently indicated. If any rigid routine treatment of typhoid fever is to be used, the statistics leave no room for doubt that the Brandt method has yielded a larger percentage of recoveries than any other. The problem is still unsolved, however, whether the restriction of this method to certain groups of cases, and the employment of other methods in cases of different type, may not still further reduce the mortality. To this conclusion I believe we shall come at last. It is the opinion which some of the ablest clinicians are reaching. When we meet with such figures as the following, which give the results of the strict Brandt method in typhoid fever in the German Hospital of Philadelphia for five years, and show during 1890-91-92, 292 cases with 16 deaths, or a mortality of 5.5 per cent., while during 1893-94 there were 152 cases with 24 deaths, or over 15 per cent. mortality, it is difficult to avoid the conclusion that some of those who died might have fared better under another mode of treatment. We may be assured that hydrotherapy, like every other powerful remedy at our disposal, must be used with strict regard to the peculiarities of each case; and that extended observation will show it can not be employed in a rigid routine method in any disease, and especially in so complex a disease as typhoid fever, with the attainment of the best results practicable. I am convinced, for instance, that it is a grievous mistake to omit the use, in conjunction with hydrotherapy, of some suitable remedy adapted to the state of the affected mucous membrane, and to the septic condition of the intestinal canal. I doubt not that others have learned to use various remedies for this purpose with good results; as for myself, I must state that for so many years I have used nitrate of silver in every case of typhoid fever under my care, and with such apparent benefit, that I greatly prefer it to all other intestinal antiseptics; and, indeed, as you well know, it possesses extremely high antiseptic power, in addition to its remarkable local action on the mucous membrane.

I wish I might dwell at length on the admirable instruction of Drake as to the hygienic treatment of fevers; but this was but natural in one who saw more clearly than any one of his time, so far as I know, the supreme importance of hygiene both in preventive and remedial medicine.

Each age has its Jeremiahs, who lament the degeneracy of the time. It is probable that Nordau, who is the latest, is also the most learned and ingenious of these apostles of pessimism. But it is easy to

make out a strong case by collecting data which support a certain view and excluding all which are opposed. His book, which has had the vogue of a popular novel, will be scarcely more long-lived or influential. It is a poor business to oppose mere assertion to elaborate argument, as I am doing; but I have such deep and unchanging faith in the improvement, physical, intellectual and moral, of the race, that I can not let pass unchallenged what seem to me the specious and unsubstantial arguments of the pessimists. Thirty years ago many people were comfortably settled in their conviction that the attempt to establish on this continent an enduring, vigorous, native-born race was doomed to failure. The American climate was to prove too much for us; and those who survived the climate were to succumb to the enervating effects of luxury, or to fall in the deadly struggle for the almighty dollar. We can afford to laugh at these predictions now, when we see the splendid physique of the men and women of the rising generations; when we see the triumphant advance of our industrial and commercial position; when we see the development of a vigorous literary, scientific and artistic activity; when we see a progress in the wise and enlightened use of wealth which extorts the admiration of the world; and when we see our beloved institutions standing the stress of every storm and adapting themselves more and more marvelously to the growth of a community of 70,000,000 peaceful and prosperous freemen.

But in Drake's day the peculiarities of the climate were little heeded; the dress, especially of women and children, was usually unsuitable; athletic exercises were almost unknown; the excessive use of spirits and of tobacco was conspicuously frequent. Many of the early settlers brought with them the habits of life acquired in comparatively equable climates; it is needless to say they suffered from the sudden and violent changes here. Drake called attention to the obvious fact that the great Central Valley, lying between one of the hottest and one of the coldest seas of the globe, must forever be subject to sudden vicissitudes and wide extremes of temperature. He cited as examples of such extremes a yearly range of 117 at Cincinnati; of 126 at Montreal; of 134 at St. Louis. We have learned not only that these changes can be anticipated, but that with intelligent care their effects can be readily tolerated.

The most depressing feature of those early days is the fact that so little physical exercise was taken by young people of either sex. Says Drake: "A walk of a single mile is regarded as an enterprise to be remembered with self-complacency; and if, under necessity, extended to twice that distance, a hardship to be recounted for the purpose of exciting sympathy." If hard labor and exposure generate a few diseases, want of exercise and recreation is the remote cause of a far greater number; and the above account of the attitude of our people toward exercise before the era of athletic sports opened was applicable to the entire continent. To this lamentable absence of proper physical training, and to the effect of a climate which renders this training preëminently necessary to increase our resisting power, there were added the evil results of yet another national peculiarity, the universal prevalence of bad cookery and neglected mastication. Drake says: "The practice of rapid eating is universal among us; that it prevails everywhere, though not adopted by every indi-

vidual; the food is imperfectly masticated, and too much is taken." You will all remember Dickens' excruciatingly funny account of the dinner at Mrs. Pawkins' boarding house in New York, where dyspeptic individuals bolted their food in wedges, feeding not themselves but broods of nightmares, who were continually standing at livery within them; where the fowls disappeared as rapidly as if every bird had had the use of its wings and had flown in desperation down a human throat; where the sharpest pickles vanished, whole cucumbers at once, like sugar plums, and no man winked his eye; and spare men, with lank and rigid cheeks, came out unsatisfied from the destruction of heavy dishes, and glared with watchful eye upon the pastry. Allowing for the exaggeration pardonable in the courteous visitor who accepts our hospitality in order to write his book of travel at our expense, there was much unpalatable truth in the account. It did not need the prevalent malaria, inevitable in a new and fertile country, nor the damp, ill-ventilated dwellings that were only too frequent, to explain the prevalence of catarrh and anemia and defective nutrition, where such grave faults of personal hygiene were ignorantly practiced by the great majority. The same lesson has been learned here as in all parts of the world, that it is easy to overestimate the influence of climate, and that strict attention to the details of hygiene will insure a gradual attainment of high physical vigor even under adverse conditions. We have seen malaria diminish steadily and rapidly, and we shall see the prevalence of catarrh, with its vile habit of expectoration and its defective articulation, become a thing of the past, just as we are witnessing the replacement of the anemic light-weights of former generations by the most vigorous lads and lasses in the world. It has been my good fortune to be able for over thirty years to study on a large scale the physical and mental and moral conditions of the young people of America. I have no fear of contradiction on the part of any competing authority when I assert that these conditions have all changed decidedly for the better, and I venture the opinion that the improvement has corresponded to, and has been largely dependent upon, the specially conspicuous advance in their health.

No one of Drake's claims to the gratitude of posterity seems to me greater than that which is based upon his services to hygiene. When all around him were indifferent to it, he was unwavering in its advocacy. In one of his latest utterances, an address before the Medical Library Association of Cincinnati, in 1852, he thus bemoans the premature death of a large proportion of his medical contemporaries—then as now, often among the violators of the laws of health: "It is truly a sad thing that in the United States the progress of civilization and science shall so violate the laws of health as to shorten the lives of those who are laboring to promote it. I beseech you, gentlemen, to turn your minds to the correction of the errors of hygiene and education which lead to this melancholy result."

If space permitted, it would be well to show how rational and judicious were his views on the subject of phthisis, then already recognized as the scourge most to be dreaded in this country. The relation between the frequency of phthisis and ill-drained soil and damp and poorly ventilated buildings, subsequently worked out for Massachusetts by Dr. H. I.

Bowditch in a masterly manner, was clear to him; he recognized its infectiousness; he had learned that the main hope of averting its development or of checking its progress is to be found in careful hygiene; and he advocated strongly that phthical patients should seek a residence in dry, cool and elevated regions.

In estimating the influence which Drake exerted upon contemporary thought on these great questions, we must remember the exceptional opportunities he enjoyed for reaching the ear of the public, as well as of the profession. For many years his house was more resorted to by distinguished visitors than any other in the cities where he resided. He was the chosen orator on nearly all important public occasions—whether in the cause of temperance, of charity, of education, or of large public improvements. He founded the first medical journal in the interior valley in 1822. He was one of the founders of the Cincinnati College of Teachers, and some of his ablest addresses were delivered before that body. Somewhat after the example of the distinguished Caspar Wistar, of Philadelphia, he encouraged meetings of a literary and scientific character at his house on a stated evening of each week. But undoubtedly the work into which Drake threw himself with the greatest ardor, next to the preparation of his *magnum opus* on the "Diseases of the Interior Valley," was that of medical education.

Of his merits as a teacher, it suffices to quote Professor Gross' assertion: "Of all the medical teachers I have ever heard, he was the most forcible and eloquent." And as to the appreciation in which he was held throughout America, it will surely suffice to state that beginning with his first call to a professorship at Lexington, Ky., at the age of 31 years, he received no less than thirteen calls to professional chairs, and he actually occupied nine separate chairs in five distinct institutions. These institutions were Transylvania College, in Lexington, Ky., where he held two different chairs at different times; the Medical College of Ohio, of which he was the founder in 1819, and where he was elected a professor no less than three times; the Jefferson Medical College, at Philadelphia, where he filled the chair of the institutes and practice for one year; the Medical Department of Cincinnati College, which he organized in 1835; and the Medical Institute of Louisville, Ky., with which he was connected at two separate periods. Naturally, these frequent changes have seemed to require explanation; nor is the explanation difficult to furnish. It was certainly not from any lack of ability nor from any want of popularity with medical students. Gross, who was his colleague in two distinct faculties, declares that when he came to the Jefferson College he was the most popular professor in the institution long before the close of the session. Eloquence such as his, ready and off-hand, had not fallen from the lips of any teacher since the days of Rush. It may be asserted that each and every institution with which Drake was so connected enjoyed exceptional prosperity while he was in the faculty, and in most instances there was a marked reduction in the size of the classes immediately consequent upon his withdrawal. I have no doubt myself that his conduct was governed by lofty motives, and that each step was dictated by his intense desire to elevate the standard of medical education in the great interior valley, to the interest of which he had dedicated

his entire life and powers. Professor Meigs, who knew the facts, states explicitly that Dr. Drake accepted the chair of medicine in the Jefferson College with the express understanding that he should hold it for only one season, when he intended to return to Cincinnati to establish a Medical Department of the Miami University. He was essentially a leader and a pioneer. Of the other medical schools with which he was connected, he was either in whole or in part the founder and organizer. In all he strove earnestly for the adoption of a higher standard and for stricter methods than were approved. In each case he promptly sacrificed his personal feelings and interests, so soon as it appeared that the conditions were not favorable to honest and thorough education. No more uncompromising foe existed to ignorance and to dishonesty, and shams of all sorts. Persevering study, unswerving application, steady, hard work, had done great things for himself; he believed in them for all. He was an eloquent advocate of the public school system, and urged that compulsory education in certain branches (including physiology and anatomy) is in strict accordance with the spirit of our Constitution, and the most certain means of perpetuating them.

In 1832 he issued a little volume of practical essays on medical education—which I would gladly see reprinted and placed to-day in the hands of every medical man in the country. It is literally true that not one of the evils from which the profession has so sorely suffered since is overlooked, and not one of the remedial measures which we have striven to secure and apply is not brought forward and advocated. He points out with the unsparing finger of truth, the defects in the preparatory education of a majority of medical men. He denounces the wrong done by the reckless competition of needlessly numerous medical schools, wholly unendowed, and conducted far too largely in the personal interests of their faculties. He insists with caustic force upon the flagrant inadequacy of the curriculum then required, which covered two sessions of a little over four months in successive years, or even in a single year; and asserts that even three years of actual study with longer sessions is too short; that four years should be rendered indispensable, and that the regular course should be supplemented by summer lectures on auxiliary sciences. He demands that the didactic element in teaching shall be subordinated to such practical training as will develop the power of accurate observation. And finally he insists "that medical schools shall be placed under the supervision of the law, and thus rendered amenable to the sovereign power of the State; and further, that medical professorships shall be regarded as public offices, which are to be filled or made vacant for no other motive than the general good."

It is thus I would present to your consideration this noble-minded man, filled with the enthusiasm of genius and of devotion to humanity, and consecrated to the true interests of society and of medical science. He was decades ahead of his time. It must have been bitter to him to note that in the ensuing twenty years, from 1832 to 1852, the date of his death, there were no fewer than fifty-three medical schools organized in the United States. It would have been more bitter to him to know that the degradation of medical education was to continue unabated until even the possession of an American diploma should

become an opprobrium in foreign lands. But it is not necessary, thank Heaven, to fight over again the battle for higher medical education. It is true that the morbid process of multiplying medical schools has gone forward even more virulently than before; between 1853 and 1872 inclusive, sixty-one were organized; and from 1873 to 1890, only seventeen years, no fewer than 114 medical schools were established. The proportion of medical schools to population in other countries has varied little since the tables I published in 1876.⁶ Russia has 1 school to 14,000,000 people; Brazil 1 to 7,000,000; Austria and France each average 1 to between 5,000,000 or 6,000,000; Germany and Great Britain 1 to 250,000; but the United States, which in 1876 had 1 medical school to every 477,392 of her population, can now boast that in 1890 the ratio has risen to 1 in every 440,151. But, nevertheless, the battle for higher medical education has been fought and won. The profession has set the seal of lasting approbation upon those great schools which have had the courage to enforce the needed reforms; to exact a serious preparatory examination; to lengthen the period of collegiate studies to four full years; to insist upon careful grading of the courses, and upon ample practical instruction of each student both at the bedside and in laboratories; and to establish salaries for the professors so as to lessen their pecuniary interest in the size of their classes. Professional opinion has also demanded, with the cordial concurrence of the leading schools, that State Boards of Examiners shall exist in every State, so that the questionable custom shall cease of having the qualifications of candidates for the license to practice decided solely by the men who have taught them, and who are interested in their success. Not only has the profession contributed its indispensable and invincible support to the great pioneer schools in this movement, but the public has shown its appreciation by beginning to contribute to their endowment and by insuring ready and brilliant success to their graduates. The callow brood of half-fledged schools, with poor equipment and meager clinical facilities, must accept the useful but less ambitious duty of providing preparatory training in the non-practical branches to fit students for entering the stronger institutions for their advanced work and final degree.

This law of development is already so manifest that we may cease to distress ourselves about the continuing low standard of many of our weak schools. Let us address ourselves all the more courageously to the great objects so clearly in sight; to the further strengthening of the strong schools until in endowment and equipment and facilities they not only equal but surpass, if possible, the greatest schools of Europe; to strengthening the hands of the State Boards so that their examination shall actually demand a thorough and adequate education; to insistence upon such legislation in each State as shall stop the issue of charters save to creditable persons who shall give evidence of actual resources sufficient to establish the proposed school upon a strong and permanent basis. Let us go one step further and demand, in the name of the vast interests devolving upon the medical profession, of the assured advances already made in hygiene and medicine, of the absolute necessity for concerted and authoritative action in dealing with the problems which now confront us, and

which affect the happiness and prosperity and safety and life of every inhabitant of this country—let us demand, and let us persist in our united enforcement of the demand, that there shall be granted national recognition of preventive medicine, with a proper representation in the government at Washington.

What joy unalloyed would such a meeting as this have given Drake! To see his most glowing dreams more than realized; to see such a gathering representative of the entire country, in his beloved valley—drawn there not by its great natural attractions, not by the splendid prosperity of its cities, Detroit, Cincinnati, Louisville, St. Louis, Chicago, and a score of others; but chiefly by brotherly affection for her medical men and by admiration of her great schools which have so bravely and so successfully fought in the vanguard for the elevation of medical education and for the dignity and purity of the profession.

The great Mississippi waterway, which extends over four thousand miles, instead of dividing, united, and helps to weld into one, the great States between which it runs. From the mountains and highlands within its drainage area, it is now, as for ages past, carrying down to the Gulf, solid material at the rate of hundreds of millions of tons annually.⁷ The leveling down of the mountains is serving to fill up the Gulf, so that the delta of the Mississippi may in time extend to Yucatan. With equal certainty is the flood tide of human life pouring into and through this valley, doing its mission. Ancient barriers of class prejudice and race hatred melt down; the East is blended with the West, and the North with the South. To-day we plan for an extension of our medical relations far to the southward, until they shall meet our brethren of the South American Republics. Already we have effected the organization of the Pan-American Medical Congress which is the final expression of the consolidation of the profession of the entire continent. Our sister Republic of Mexico extends a cordial invitation to us to attend the second Congress in her capital in 1897. As chairman, *ex-officio*, of the Executive Committee of the Congress, I have the honor to announce this gratifying and courteous act. I am confident that all of us feel that the spirit of the times, the genius of this great region, the inevitable law of our national evolution, lead us strongly in that direction, and impose on us the duty of doing our full share to render that important meeting as brilliant a success as we have made of this delightful occasion.

ORIGINAL ARTICLES.

THE BATH IN MODERN MEDICINE.

Read in the Section on State Medicine at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY CHAS. H. SHEPARD, M.D.

BROOKLYN, N.Y.

The advance of modern medicine in the prevention of disease is gratifying to all whose studies have been in that direction. Preventive medicine touches the keynote of medical science, and its possibilities reach to the perfection of mental and physical manhood. It is in this line of medical research that the greatest good to the greatest number is to come. As mankind are enlightened they will seek necessarily,

⁷ Estimated at 362,000,000 tons a year, sufficient to make a square mile of new land, allowing for its having to fill up the Gulf to a depth of eighty yards.

more, and more, those who can teach them to observe mental and physical laws, that thereby they may secure a sound mind in a sound body; and, inasmuch as the onward march of sanitary science will bring about a condition in which the mere healer of diseases will be in less and less demand, a broader field will be found for the constantly increasing supply of graduated physicians in such work as instructors, lecturers, health inspectors, etc.

It is a hopeful sign that the study of medicine is to-day more concerned with the origin of disease than the verification of symptoms. By electroscopic explorations the physician is now provided with accurate methods of searching out disease, and to the microscope he is indebted for many important discoveries that have advanced the science of medicine to the plane of demonstration; that has given the germ theory of disease the importance it deserves, and contributed to the mitigation of human misery, as well as to the mastery of disease.

The living nature of contagious disease is beyond question, and it has been demonstrated that in the body of an individual thus attacked, there exist microbes capable of implanting themselves and multiplying in the tissues of a person predisposed to that disease.

The fermentations produced by the action of the microbes are toxic, and beside this there are soluble ferments which assist in the production of local lesions by breaking up living cells. The toxicity of intestinal matter is recognized as a poisonous product elaborated by these microbes. If by any reason their elimination is delayed or prevented, poisoning of the system necessarily follows from their absorption.

The human organism is a receptacle and a laboratory of poisons. Those that are formed by the disintegration of the tissues and those which are formed in the digestive tube are carried into the blood. Therefore as we know the blood is the necessary medium between the place of their formation and their elimination, man's only escape from them is by the cutaneous, renal, intestinal, and pulmonary emunctories. There is no other relief for any of the organs, and safety lies only in their normal action.

The liver protects from poisoning, by arresting on their way, before they pass into the general circulation, the poisons brought from the intestine by the portal vein, in order to neutralize or throw them back into the intestine. Then the excretory system expels the poisons which are in the circulation. It is claimed by some authorities that at least seven poisonous substances are thrown off through the urine, and all come from the blood, and that the man would die if his blood were to contain ten times as much poison as it does in its normal condition. If the skin or other eliminatory organ acts imperfectly, the patient is poisoned by the retention of the normal products, and if the kidneys perform the work of depuration insufficiently, the urine ceases to be toxic because of the retention of these impurities in the system. Man receives poisons in his food, creates them by disassimilation and forms them in his secretions, and toxic elaborations are carried on by the normal microbes which constantly inhabit the alimentary canal.

The nature of the alkaloid formed by whatever bacterium may present in the system is largely dependent upon the condition of the individual. The

nature of the soil alters the character of the microorganisms that flourish upon it.

If the whole digestive system was made a matter of careful consideration, its relations to every organ in the body intelligently understood, its needs and normal wants alone administered to, the prevalence of disease would be largely abated.

Disturbances of nutrition are responsible for many illnesses of an acute character, as well as the larger number of chronic diseases. The reaction of a disturbed nervous system induces temporary disturbance of nutrition. Fatigue from overwork or pleasure exposes the system to disease that in a normal condition would be entirely avoided. The first appearance of disease implies an essential deterioration of the organism. An imperfect action of the digestive organs may be inherited, but is more often produced by abnormal conditions. Many diseases that are marked by prominent nerve symptoms are but the first signs of poisoning due to defective nutrition. Man is as surely poisoned by the abnormal action of any function as by breathing mephitic gases or swallowing poisonous substances. Therefore the most important object in the treatment of disease is to secure some method whereby the system may be relieved of these poisons, and the earlier in the case this can be undertaken, the more simple the problem, and the easier of solution.

The fact that so many people are continually overloading their systems with excess of food is too apparent. Even though the stomach may be so weak as to pass on the offending substance, to be taken care of by the lungs, the kidney or the bowels, this excess is nevertheless foreign to the needs of the system. It becomes a poison, and is sure to cause what we call disease, the particular form depending upon the idiosyncrasy of the individual. That is why simple treatment so often relieves such a variety of diseases.

If disease, as we maintain, is naught but a vital effort for the purification and repair of the body, then whatever agency best promotes the work of elimination, at once secures this most desirable result.

The skin may be placed first on the list of eliminating organs, for the reason that it is the largest, enveloping all others, and that a larger proportion of the *débris* of the system is thrown off through the skin than by any other organ. After protecting the system by simply existing, its main function is elimination. Inasmuch as the kidneys, and in fact every organ of the body, are dependent for the perfect performance of their functions upon the character of the blood, as well as upon the circulation, none can be more important than the skin, because of this very depurating power. It is a most important fact, that a more powerful drain can be made upon the system through the skin, than by any other organ, and this without disturbing the harmonious working of any function.

The action of heat upon the blood internally, while passing through the capillaries of the lungs, and also upon the capillaries of the outside skin, is most salutary in destroying the virus of whatever disease may be present. There is no more powerful disinfectant than hot air, and a report recently made to the British Medical Association, demonstrates what hygienists and sanitarians have long contended for, that sunlight and fresh air prove of more avail

in the disinfection of tuberculosis than any other measures, and hot air is but the liberation of stored up sunlight.

While bacteriologists are not fully agreed as to the precise manner, or the agencies by which the blood carries on the warfare against disease producing bacteria, the weight of evidence favors the theory that the white corpuscles are the common defenders and scavengers, but all must agree that with a pure condition of the blood and a perfect circulation, its bactericidal power will be at its highest activity, and that this form of immunity is of all others the most desirable.

Thanks to the therapeutics which the body constantly exercises upon itself, man lives. The course to be pursued in the general therapeutics of self-poisoning is to prevent the poisons from being formed, to oppose their penetration into the system, and if they have been absorbed, to try to destroy them, or to stimulate the action of the liver, which is a physiologic destroyer of poisons, and further, to encourage the elimination of poisons by the skin, the lungs, the intestines, and the kidneys. Of one thing we may be certain, in the treatment of auto-infection, that if there is vitality enough to neutralize or throw off the poison, it will be done more readily and more thoroughly by relying upon and assisting the natural emunctories than by introducing other poisons to neutralize the first. Particularly is this true in regard to what are called tonics or stimulants. Whatever excitement they may arouse is so quickly exhausted and is derived at such a great expense of vitality as to make their use of more than doubtful utility.

In most diseases the active poison is the natural one, resulting from the more intense disassimilation, or from more rapid cell destruction, setting at liberty imperfectly oxidized material.

The use of vaccine, tuberculin, antitoxin, and even animal extracts, has been found to be attended with disadvantages. The most desirable in the list of artificial remedies seems to have some drawback, and though the search has been long and diligent, success in finding a panacea is as far off to-day as it was one hundred years ago. The mere list of fads that have had their day, to be laid aside for new ones, would fill volumes.

But there is one direction in which we can work with assurance of success, and that is in the matter of personal equation. By purifying and fortifying the body, we enable it to cope with the most virulent diseases. Unless this can be accomplished, sanitary science will have labored in vain.

The sickening and deceitful flood of nostrum advertisements can be overcome, and the community protected, only by disseminating the fundamental truths of sanitary science, and facts regarding hygiene, and its application to human needs. Physical health is necessary to perfect mental health, and as health is governed by certain well defined and easily understood laws, it follows that it is a moral obligation on every one, of sufficient capacity, to become acquainted with these laws and live in obedience to them. The amount of ignorance on these subjects is appalling, and calls for an unlimited amount of self-sacrificing work by every physician who considers the public good of more importance than mere personal gain. It is certainly better for the medical man to lead in this matter, than to leave

it to the charlatan, or to wait for the outside pressure of an enlightened public opinion that is sure to come.

While the practice of to-day is in accord with the most advanced thought, and certainly is a great improvement upon the sanguinary era when patients were bled to exhaustion, or when they went to their death in a state of intoxication, the time must come when many of the practices now in vogue will be superseded by a still more enlightened and scientific treatment.

An abundant use of pure air always produces a quickened activity of all the vital forces. Suitable exercises are certain to quicken the circulation and bring therewith corresponding benefits. The judicious use of water, both hot and cold, is universally attended with benefit to the whole system, and there is a charm about bathing that commends itself to the good sense of every individual, were it only for the feeling of purity which it engenders, but when there is added to that the reality of protecting the body from attacks of disease, as well as relieving it of discomfort and pain, then the use of the bath enters the realm of prophylactics and remedial agents. There are many kinds of baths, from the sponge, the river and the sea bath, up to the hot air or Turkish bath, and all have their place, though some are more capable of being utilized in a general way, and made more useful than others.

The natural elements, air and water, are indispensable to the existence of life, and when modified by another natural element, heat, they become the most powerful, most salutary and unfailing agents yet discovered for the preservation of life, and the alleviation of those numerous derangements to which life is exposed. This is no new principle or novel theory; on the contrary, it has been known, though at times imperfectly practiced, for thousands of years, throughout the globe, and is to-day, in spite of discouragement, receiving scientific and practical development.

All religious institutions were based upon the ceremonial of cleanliness. Baptism and bath are synonymous terms. The ancient history of Egypt, of Africa, of East India, China, Japan and Persia, all give ample testimony to the efficacy of the bath in the treatment of disease. Ancient Britain also gives abundant evidence of the same result. As early as the sixteenth century, publications were issued advocating the use of cold bathing in disease, and one authority of the seventeenth century says: "No part of physic is more ancient than cold bathing."

Suetonius relates that Cæsar Augustus recovered from a dangerous illness, after his other physicians had pronounced his case desperate, under the simple hydropathic treatment of his freedman-physician, Antonius Musa, who had been his domestic slave, and who had studied medicine while in the condition of servitude. He appears to have understood the curative properties of cold and hot bathing in relation to particular diseases, and to have been well acquainted with the efficacy of diet and regimen, which he also employed in the case of the Emperor. This event wrought a great change in the public sentiment regarding practitioners of medicine. Musa was rewarded profusely. He received a large sum of money, was exempted from all public taxes, was given the freedom of Rome, allowed to wear a gold ring, and his statue was placed next to that of Esculapius. In further honor of him, the professors of physic were

then, for the first time, admitted to the immunities of Roman citizenship.

That thermal springs which are found in every quarter of the globe, first suggested hot bathing, is shown by the fact that all of them have been utilized for that purpose, from remote antiquity, and by all people, from the rude untutored savage to the most civilized nations.

Heat is at once the simplest and the most powerful of all the agencies of nature. It is the heat from which is derived the most important part of the beneficial effects of warm bathing, and the superiority of air, in comparison with water, as the medium of a bath, is evident, for the reason that water can not be used for communicating heat to the body at a temperature much beyond 100 degrees, whereas air can be utilized for ordinary bathing at from 140 to 175 degrees, and for the remedial purposes much higher. It is this perfect command of temperature which the hot air bath places at the disposal of the scientific and skilled physician that constitutes its superlative merit.

The existence of the bath during thousands of years in every part of the world, gives abundant proof of its value, and it will be seen readily, that when the bath has been used as a curative in disease, the one great object in view has been to bring into play the action of air, water, and heat on the human body so as to excite perspiration.

From the fact that the form of treatment secured by the Turkish bath unites all the elements, making it a perfect combination of air, water, and different degrees of temperature, comes our belief and assertion that this form of bathing is bound to supersede all others, as being more complete and useful in every respect, and is eventually and inevitably to be recognized as the most potent agent in the physician's armamentarium. It is a process which will in a few minutes secure a general diaphoresis, bring the circulation to the extremities, equalize the arterial action, soothe disordered nerves, while it allays spasm immediately. It is obvious that such action would be of great service in every case of internal congestion, and in obviating diseases of the liver and kidneys. In the treatment of diseases of the joints, its efficacy is remarkable, also in all classes of cutaneous diseases. In bronchial or laryngeal inflammation the surface affected is instantaneously reached, and instances of gradual relief from chronic disorder, particularly gout and rheumatism, might be multiplied without end. At the same time it is an incomparable luxury, and most valuable as a means of training in health. In all diseases it is a remedy or palliative.

It is only necessary that the properties of the Turkish bath should be really understood to insure its adoption by an intelligent public. Its simplicity and natural action place it in antagonism to all empiricism. This bath stands alone on its merits, a great and acknowledged power. It will remain to diminish the pains and penalties that afflict the large majority of our fellow creatures, and to increase the good things that fortune showers upon us. It is at once the perfection and glory of all baths.

81 Columbia Heights.

WHY BALTIMORE IS A HEALTHY CITY.

Read in the Section on State Medicine, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY D. W. CATHELL, M.D.
BALTIMORE, MD.

Baltimore lies in latitude 39° 18', longitude 76° 36'. It is situated on the Patapsco River, one of the tributaries of the great Chesapeake Bay, which divides the State of Maryland into two portions—eastern and western, the city of Baltimore being on the western portion, about fourteen miles from the junction of Patapsco River with the bay. We have an excellent and large harbor for our shipping.

Baltimore covers an area of thirty-one and one-half square miles, and like Rome, may be said to lie on seven hills. Its soil is both healthy and favorable for building. The city has 99,987 houses, with an appraised value, including the ground, of \$274,000,000. Its population, as ascertained by the police census of 1894, is 496,315, of whom 422,568 are white and 73,747 are colored. It has 780 miles of paved streets, with 234 miles of rapid transit street railways, running 785 cars, some cable, some electric, each car being provided with a fender in front for the protection of life and limb, and all stop to take on or let off passengers at the near side of the streets, instead of crossing the street before doing so, and each must come to a full stop before crossing any intersecting railway. By these rules our street railway accidents are reduced to a minimum, and in addition to business, car-riding for pleasure is a source of both recreation and health to our people.

Our city has an inexhaustible supply of excellent water, chiefly from the Gunpowder River, kept in eight separate storage reservoirs, which have a total capacity of 2,274,000,000 gallons, the daily consumption of water being 45,000,000 gallons, while the daily capacity of supply is 300,000,000. This is one of our chief sources of health.

The rich and diversified soil, the swarming waters, and the teeming forests about Baltimore furnish an unsurpassed abundance and variety of food. Added to these, we have an unequalled climate for permanent residence, for neither the cold of our winters nor the heat of our summers continues long enough to entail deleterious effects on the general health. Our snows end with March and our autumn frosts begin with November.

Baltimore is chiefly surface drained, and although it has about thirty-five miles of underground sewers, the function of most of these sewers is to carry off storm water from certain localities.

The city has no slums, and comparatively few tenement houses, although, like all large cities, there are many thickly populated neighborhoods where many poor people live too closely huddled.

The mean temperature for 1894 was 55.9 degrees; the highest temperature of summer was 98 degrees F.; the lowest in winter was 7 above zero. Our average annual rainfall is 44 inches; the number of days on which rain and snow fell in 1894 was 134, and strange to say, the greatest monthly precipitation was in May, 7½ inches, and the least was in March, 1¼ inches.

The total mortality in the city of Baltimore for the year 1894 was 9,486, of which number 7,242 were white persons and 2,244 colored, being a marked decrease in comparison with the five preceding years,

INJECTION OF HERNIE.—Luton has recently reported (*Revue Mensuelle des Maladies de l'enfance*) that he has many times cured infantile hernie by injection of 1 gram of a solution of sodium phosphate and sodium sulphate.

notwithstanding a decided increase in population. Our death rate for 1894 was 20.84 per 1,000, but if the death rate per 1,000 were computed as in other cities, upon an estimated population, instead of the U. S. census of 1890, it would show a rate of only 19.04 per 1,000 for the whole population, which would make Baltimore rank high among the very healthiest cities in the world.

Among the 9,486 deaths there were 1,085 deaths of persons above 70 years of age.

Taking the different periods of life separately, there were:

Under 1 year	2,616
Between 1 and 2 years	669
" 2 " 5 " 	476
" 5 " 10 " 	255
" 10 " 15 " 	143
" 15 " 20 " 	316
" 20 " 30 " 	778
" 30 " 40 " 	780
" 40 " 50 " 	735
" 50 " 60 " 	801
" 60 " 70 " 	832
" 70 " 80 " 	701
" 80 " 90 " 	322
" 90 " 100 " 	59
" 100 " 110 " 	3

The ratio of deaths of children under 5 years of age to the total mortality was 39.5. In addition, there were 721 still-births during the year.

The death rate among our colored population is always greater than that of the whites. This I attribute chiefly to their few opportunities for advancement, compared with those of the whites, coupled with their meagre comforts, limited opportunities and relative lack of knowledge of sanitary laws. Thus, in 1894:

The annual death rate per 1,000 white population was	18.85
The annual death rate per 1,000 colored population was	31.60

Among the chief causes of death in 1894 we find:

Consumption	1,106
Pneumonia	790
Cholera infantum	440
Disease of heart	438
Cancer	264
Bright's disease	226
Typhoid fever	222
Diphtheria	198
Diarrhea	144
Influenza	132
Whooping cough	112
Accidents	109
Bronchitis	90
Scarlet fever	85
Childbed	82
Dysentery	72

The number of deaths in public institutions was:

Baltimore city jail	2
Penitentiary	15
Hospitals and asylums	976
Deaths reported by coroners, including inquests	770

During the year there were 777 interments in the two public cemeteries, Eastern and Western, at the public expense.

A comparison of the mortality in Baltimore for the past five years shows the following decreasing ratio:

	Ratio per 1,000
1890	22.41
1891	22.13
1892	21.77
1893	20.99
1894	20.84

The vital statistics of our race tell us that the average duration of human life is about thirty-seven years. Up to 1875 there were no reliable vital statistics kept in Baltimore; and I am ashamed to tell you that even now, almost at the dawn of the twentieth century, we have no complete record of the births; but of the 174,923 deaths that occurred in Baltimore, during the twenty years ending Dec. 31, 1894, we find the following large number of aged decedents:

Between 40 and 50 years of age	12,651
" 50 " 60 " " " 	12,752
" 60 " 70 " " " 	12,800
" 70 " 80 " " " 	10,779
" 80 " 90 " " " 	4,972
" 90 " 100 " " " 	759
" 100 " 110 " " " 	95
Above 110 years of age	13

Nature has done a bountiful share for Baltimore, and man has done much to aid her, and of this her physicians have done their full share. We have about four hundred and fifty regular practitioners in the city, beside quite a sprinkling of irregulars of all shades and colors. We now have laws regulating medical practice, which bid fair to be of great benefit to the community. Beside the great Johns Hopkins Hospital, we have scattered through the city and suburbs, the Hebrew Hospital, Bay View Asylum, Mount Hope Retreat, Spring Grove Asylum, Wilson Sanitarium, Samuel Ready Home, Maryland Blind Asylum and numerous other and well-managed hospitals and homes; some for the sick, some for the insane, and all for humanity, and each of these is doing its full share toward making Baltimore a healthy city.

In addition to all these, we have various sanitariums, retreats and homes for sick children, free excursions for the poor, asylums, etc., which I might describe and praise too, if time permitted, but if prevention is better than cure, then these institutions all unite to do a power of good.

Among other medical features, we have five regular medical colleges that send forth a total of about five hundred graduates yearly.

We have lovely suburbs, which teem with the summer homes of our wealthy citizens and the cottages of our middle classes; and our woods and parks, river and bay swarm with excursionists and picnickers during warm weather.

Within our city limits we have 861 acres of public parks, divided among Druid Hill Park, Clifton Park, Patterson Park, Riverside Park, Harlem Square, Lafayette Square, Union Square and a dozen others, each acting as a resting and breathing place for our people and each adds its share to Baltimore's healthfulness.

We are told by all travellers, that our Druid Hill Park is one of the most beautiful natural parks in the world.

We also have several hundred ever-flowing public drinking fountains scattered here and there about the city, which are a great source of comfort and health, to both man and beast, especially during the summer months.

We have a well organized and highly efficient Health Department. A brief synopsis will show the important duties and responsibilities devolving on these, our custodians of public health, in 1894. It has a permanent corps of twenty-two vaccine physicians, whose number is increased when emergency

requires. During 1894 they made 48,475 calls, and vaccinated 42,042 persons. Vaccination is compulsory, and no unvaccinated child is allowed to attend the public schools of Baltimore. This is another of our sources of health.

Our food inspectors inspect all food products, condemning any and all that are unfit for use. During 1894 they condemned 67,322 pounds of various kinds of meat and 1,449 pounds of poultry, thus sparing our olfactories and guarding our health.

Our milk inspectors examine milk, and spill into the streets all that shows by the lactometer a less specific gravity than 129, at 60 degrees F., or is proven by microscopic examination to be adulterated or dirty; and for these causes during the year 1894, 6,679 gallons were condemned and spilled. Our milk supply for the year consisted of about 8,000,000 gallons of milk and cream, brought to us by twelve railroads and seventy country wagons, added to that gotten from the 1,126 cows kept in the city.

We have an inspector of plumbing and drain work, whose duties and importance to the public health are obvious to all medical men; 3,595 inspections were made during the year.

We also have an inspector of buildings, whose duties require him to see that all new buildings are erected with regard to safety to life and limb, and every dwelling house erected, however small, is compelled by law to contain a bath-tub—another decided source of cleanliness and health.

There are two inspectors of covered gutters and sewer inlets, who make daily visits of inspection, cleaning and disinfecting wherever and whenever necessary. Thirty-six tons of carbolate of lime were used by the Health Department in 1894. Their value to the public health makes it money well spent.

Our coroners, five in number, are all physicians, and in addition we have two post-mortem medical examiners, who made seventy-three post-mortem examinations for the authorities during the year.

We also have a public morgue, to which 163 bodies were sent—127 white and 36 colored; 140 of these were males and 23 were females. Eighty-one of these were subsequently claimed and buried by their friends.

Baltimore has now a new and efficient quarantine hospital, with a disinfecting plant, equal if not superior to any in the country. This hospital is on the river, a few miles below the city, and is in charge of a quarantine physician and his assistants. Five hundred and three vessels were boarded and inspected during the year 1894, and twenty-four patients with infectious diseases were treated in the hospital. During the year, 7,692 unsanitary mattresses from emigrant steamships were destroyed in this port. Baltimore is the only American port in which they are totally destroyed.

The city has twelve sanitary inspectors, who examined and abated 20,582 nuisances during the year, and had 286 vacant lots drained and filled. It is also their duty to examine into all cases of contagious diseases: diphtheria, scarlet fever, croup, measles, smallpox, etc., and to disinfect the premises after recovery. In 1894, 1,977 cases were reported by the attending physicians, who are compelled by the laws to report every case. The importance of these rules in maintaining public health could scarcely be overestimated.

There were issued by the Health Department dur-

ing 1894, 59,923 notices and orders to place premises in more sanitary condition, and 74,874 permits to clean privies were given; and every year on the approach of warm weather all persons are compelled to place premises and privies in a sanitary condition.

In regard to night soil, 90,721 air-tight cart loads, equal to 18,144,200 gallons of liquid material, and 268,466 loads of garbage and ashes, were removed from the city in 1894, all by daylight, the former by what is known as the odorless system, to the two dumps, and were carried thence down the river in scows, and disposed of to agriculturists. There were also removed 169,915 loads of street dirt and sand.

In some portions of the city the streets are cleaned by sweeping machines, but the dirt is taken from the majority of streets, lanes and alleys by laborers, scraping and sweeping. The daily average number of loads of street dirt removed was 600; and beside this, during the year, 9,987 cart loads of refuse and filth were removed from the various sewers, sewer inlets, and covered gutters, and 1,105 cart loads of vegetable and other offal were taken from the various city docks, all with a view to maintain the public health.

In addition to garbage and dirt carts, we have covered wagons for the removal of dead animals, fowls, tainted meat, etc. During 1894, 45,211 of the former and 2,713 pounds of the latter and more than 112,000 fish, crabs and eggs were removed, and all done so quietly that probably many of our people do not even know of the existence of such wagons.

Our police force ably assists the health authorities in carrying out all laws relating to the public health. It consists of 808 officers and men, maintained in 1894 at a cost of \$825,000. To say that we have a model police organization with a most excellent detective service, would certainly be no exaggeration. We have seven police stations and to each station is attached one of the vaccine physicians and a patrol wagon. These wagons not only carry arrested persons from the signal-box nearest the point of arrest, but are also utilized for the humanitarian duty of carrying sick and wounded persons to their homes, or to the hospitals.

There are two abattoirs and quite a number of slaughter houses, all under private management. These are among our chief unsanitary features.

Baltimore is lighted by 1,039 electric lights, costing 35 cents each per night; beside there are 5,932 gas lamps and also 1,036 gasoline lamps, in small streets and alleys where there are no gas mains. These all conduce to safety of life and limb to pedestrians, and help to secure our persons and property against evil-doers.

A few additional words: I do not wish any one to infer that all of our improvements have been made at once, nor that they have suddenly dropped to us from the skies, or that they have been handed down one by one from the rainbow, as in fairy tales; far from it! They have cost much time, much labor, and much money. Our city has exerted herself and must continue to do so, for there are other great strides to be taken before she reaches sanitary perfection. But Baltimore is a progressive city, and when our brethren of this ASSOCIATION favor us with another session I hope to be able to report further and greater advances.

Among other things we must establish and maintain perfect supervision over our water supply, and

protect it against any and every possible source of pollution.

We must adopt a more rational and scientific method of disposing of our garbage, fecal matter and other offal, either by desiccation or cremation.

We must abolish our abominable privy vault system and adopt dry earth closets, or some other still better method.

We must legislate the 97 cow stables, with their 1,126 cows, and all other nuisances, out of the city, and keep them out.

We must abolish, together with all other pathologic industries, every private slaughter house, and place all abattoirs under such rules as insure full protection to the public health.

We must devise some method of securing perfectly accurate statistics of births.

Free public baths on an ample scale, centrally or conveniently located for the masses, should be established.

The unjust yearly tax of \$3 for each hose attachment for sprinkling and washing the pavements and streets in front of one's residence, should be forever abolished, because these promote the public health.

The dangers of every unsanitary lane and alley in Baltimore should be removed by making it smooth with asphalt.

We, also, badly need a public disinfecting plant for the city, and a city hospital for the care and treatment of the milder contagious diseases, *i. e.*, scarlet fever, diphtheria, measles, etc., while smallpox, yellow fever, cholera, etc., should continue to be treated at the quarantine hospital.

I am also strongly of opinion that our Health Department should be separated and isolated from all other city departments and placed in a building of its own, so that a citizen going in to pay his water bill, or to enter either of the many other departments adjoining, will incur no risk of encountering any one suffering with or coming from a case of contagious disease—a building where each function of the Health Department can be carried on separately.

Thus would I briefly attempt to point out a few of Baltimore's many advantages, and to give you a glimpse at her vital statistics and her sanitary agencies; and, also, to frankly tell you of some steps still required to push her up to the full measure of a perfect metropolis.

I shall mention one other great blessing we possess, and I am done; that is, that in addition to all else, *Baltimore is a lucky city*, for in addition to having hosts of worthy men and noble women, she escapes many of the sorrows that fall to some other communities, for she is neither subject to earthquakes nor volcanoes, tornadoes, cyclones nor blizzards, and neither war nor pestilence has ever laid its hand heavily upon her. Beside, she has suffered no great fires, no sweeping floods, no withering droughts, no ghastly famines, or other dire calamities. And thankfully appreciating these facts, *we, her citizens, "with malice toward none, but with charity for all,"* We, Her Citizens, are determined under God, to exert all the powers of our hands, and of our heads, and of our hearts, to make fair Baltimore, in the future as she is to-day, one of the healthiest and happiest cities in the world.

THE IMPORTANCE OF THE STATE GOVERNMENT CONTROL OF ARTIFICIAL AGENCIES THAT MAY BE PRODUCTIVE OF NOISES.

Read in the Section on State Medicine at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY AUGUSTUS P. CLARKE, A.M., M.D.

CAMBRIDGE, MASS.

DEAN AND PROFESSOR OF GYNECOLOGY AND ABDOMINAL SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, BOSTON, MASS.

The inhabitants of the American States have long been noted for their hurrying and bustling habits, for their ceaseless, restless activities, and for their all but immodest disposition when setting themselves about to accomplish a purpose, not to intrust the fact to the keeping of a silent herald. So marked have these characteristics become and so influential have they been in modifying the development of their personality that Europeans, surrounded by other amenities and pleasures, have fancied that the average American citizen is still but a son of the forest, that the noises incident to his movements are only the rustling of his feathery head-gear, that the implements of his trade are the disguises of the tomahawk, and that the acclamations expressed upon the success he attains are not unlike the war-whoop of his aboriginal predecessors.

After eliminating from our field of vision all the extravagances of imagination indulged in by trans-Atlantic personages, there is, nevertheless, much that having been borne along by our peculiar methods of action has become more and more the subject of the deepest concern, and requiring also for proper correction continued interest and coöperation on the part of all. Not the least among the factors inimical in no small degree to our health, comfort and repose, are the noises that are on all sides produced by artificial agencies. Perhaps in the decades that have preceded ours, a person would not have been deemed patriotic or public spirited had he entered his protest against occurrences which have been regarded as incidental to the affairs of the greater moment, but it must be remembered that the rapid multiplication of the agencies in question has been carried on much more with the view of enhancing private interest than of providing for the needs of the public at large.

The employment of the tramway system upon the streets of American cities was at first considered not only as an innovation, but also as an encroachment upon private rights; this system was at length endured and patronized by the abutters for the reason it was felt that those less favored might with greater facility be enabled to reach the more distant points of their destination. The introduction of the trolley cars into the larger cities is not only an encroachment upon private rights of the inhabitants, but the whole management of such ponderous machines, through the crude and unscientific principle of construction, is not only a waste of force, but its practical application becomes a veritable nuisance. Such a method of conducting travel we have reason to fear will to a very great extent continue to be so, on account of the insufferable noises that must necessarily result from the operating of such cars by the companies for the sole purpose evidently of gain. Such harsh, bewildering sounds, such fiendish, hideous clangor with which the ears of the would-be

sleeper must ever ring, can not but act injuriously upon his whole organism. Though legislative enactments thus far have not been put forth in the direction to lead to the abatement of the evil, yet there is no sufficient reason why the State should not take cognizance of any factor that may disturb to such a degree the health and comfort of mankind.

No good reason can be offered why boards of health should not be clothed with all necessary powers for the supervision of travel and of exercising a salutary control over all the means for accomplishing the same. Indeed, there is more reason why such powers should be delegated than there is for granting authority to institute measures against an apothecary or other dealer who may chance to sell a package of sal soda, or of sal tartar, or to dispense a vial of laudanum, or other quite unimportant article, which may not be up to some arbitrary standard of weight or measurement.

All must admit that there are unnecessarily made disturbing noises that should be prevented by legislative enactment. The numerous whistles and bells employed on railway trains are often deafening in the extreme, and thus become the source of much discomfort, not only to persons who may be suffering from severe illness, but also to the inhabitants of an entire neighborhood. The ringing of church bells, that betoken the coming or the presence of the parson, is often a merciless herald to those who may be too unfortunate to attend the meeting for the appointed service.

It is becoming more and more apparent that in our country, where the public affairs are sought to be managed by popular sovereignty, less attention is paid in response to the actual needs of the masses than in those countries where the will of the people exercises but little influence in the election of rulers. The hurrying through our streets, often at most unseasonable hours, of brick wagons, ice carts, milk teams, market men's loads, beer carts, and of the numerous other vehicles, all for private gain or for a syndicate's exchequer or for a company's till, is most uncongenial to all and is often prejudicial to that large number who are dependent for their activities on quiet and refreshing sleep.

Those who are weak, or who are suffering from peculiar idiosyncrasies, or whose proper psychic balance is dependent on favoring influences, should not be left to suffer through the capricious temper, or be brought under the power for gain of the heartless and unfeeling members of the community. I venture to say that in almost every municipality of our metropolitan district, or our Greater Boston, the daily noises incident to artificial agencies, to say nothing of the avoidable noises made by persons who have not the slightest regard for the public welfare, are frequently greater than what are heard in many of the larger European cities. When any complaint or remonstrance is presented to the officers of the law on account of the ruthlessness of such persons, the answer almost invariably returned is that noise is but a mere inconvenience. It has not been uncommon in my own practice, and I feel certain that it is not unusual in the practice of other physicians, to have patients who, while undergoing the effects of long and exhausting illness, are compelled to endure their full share of this brain paralyzing and nerve destroying agency.

It has long been a recognized fact that in man the

greater part of the impression that is received reaches the sensorium through the medium of the different special senses. Odors that are agreeable produce, for the most part, a salutary effect upon the organism; those that are disagreeable, when endured for long continued periods, exercise an injurious influence. Objects, especially articles of utility, presenting rich and beautiful colors are conducive to the health and strength of the person; the same may be said of all agencies that transmit through the several special channels of communication pleasing and agreeable impressions. Undue irritation or excitation of any one of the senses or of the organs of the body is liable to effect pathologic changes, either from producing immediate and serious derangement in the histologic elements, or from not allowing sufficient intervals for rest and recuperation. The intricate and delicate arrangement of the auditory apparatus is no exception; it can not repel the persistent assault from noises thus made upon it without becoming the center of a diseased condition. Persons who are exposed to such harassing attacks appear dwarfish, undeveloped, or with a retrograded intellect, morbid in their impressions, and if, perchance, they should rise to any considerable degree of activity, they would still be prone to relapse into a listless state that borders on neurasthenia, and to other varieties of the neurotic state.

When one comes to consider what hideous noises are endured by the inhabitants of our more densely crowded municipalities, it would seem that such people are, indeed, lacking in moral stamina; that they are really deficient in what is essential to the development of the higher attainments of mankind. It may be said, however, that the pursuing of the personal aims and ends of the individual tend to lessen interest in matters not directly conservative to such attainments; there then will be brought about no unity of action and no well directed opposition to encroachments on rights regarded only as public in the advantages which they insure.

In order, therefore, to overcome the several factors diverse to the higher accomplishments for the public welfare, and to elicit personal attention, irrespective of private enjoyment, for the support of such measures, it will become necessary to bring into operation other methods, to be carried out in all their details for the proper administration of affairs of state. The building of great public thoroughfares, and especially the grading of such avenues of travel, should be carried on more with the view of conserving all the elements of public health and convenience than of adding features that may be helpful or useful in merely one direction only. In this connection may be mentioned notable instances of the unwise policy so often pursued in the paving¹ of many of our most important streets with rubble stone, or with stones that have been broken into cubes or blocks, and then laid in the usual manner of doing such kind of work. Streets thus prepared become not only the source of great annoyance to the inhabitants by the loud rumbling, by the rapid driving over them of the many heavy wagons, which is often done at unseasonable hours, but they also become, as all sanitarians admit, the source of danger from being the receptacle of filth from drainage matter that continually gravi-

¹ See Medical News, of Philadelphia, August, 1893. See also the October number of the same year of the Buffalo Medical and Surgical Journal. In both of these journals the baneful effects of city noises are ably discussed.

tates into the interstices between the stones, that are laid in such a primitive manner. The employment of concrete, cement or asphalt,² or other similar material, on our streets, as is usual in some foreign cities, would be an improvement and would fulfill most of the purposes for which such streets are graded. The use of properly constructed vehicles, the regulation of the driving, and the hours allowed for the travel should be under the strict control of the government officers. Much of the noises of our street car system could undoubtedly be prevented by the more general adoption of underground ways, or, by what is a better system, the building of roads after the manner of the Ringbahn, of Berlin. If the latter should be adopted the stations might be at greater distances from each other. Tramways, with cars of light gearing, should be the only ones allowed for intramural service. While the fostering of a patriotic spirit should be encouraged and allowed the broadest latitude on all proper occasions for its true exhibition, its conservation should not be jeopardized by the government's yielding to the caprices of unthinking persons, as is so often shown by its resorting to vain and useless mockery in its attempts at public celebrations. On such occasions the discordant ringing of bells, the blowing of horns, the loud cracking and firing of torpedoes, the display of what may really be regarded as "antique and horrible," have helped to displace many of the better class of residents of our eastern cities, and have likewise been the source of much discomfort in their relationship, but unfortunate in their location and surroundings.

As I said before, I can recall as occurring in my own practice numerous instances of persons who have been victims of such public disorder, or instances of persons whose recovery has been materially retarded by the demonstrations of such public license. Have not the minority or the few people who thus suffer, some vested rights that the majority is bound to respect? Surely, the persons whom the physician for the most part is summoned to treat, belong to this latter class. It is in the interest of this class, and for the more unfortunate, generally, that the true physician was first led to choose for his life work the profession of medicine; that he ever seeks by the employment of all his energies to improve his talents for the attainment of the highest good. This he does that he may fulfill the mission to which he feels that he has been called by divine appointment.

REFORM IN MEDICAL EXPERT TESTIMONY.

Read in the Section on State Medicine at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY S. S. HERRICK, M.D.

SAN FRANCISCO.

The disagreement of doctors is both a proverb and a reproach: a proverb, as if it were constant and axiomatic; a reproach, as if it were needless, unreasonable and peculiar. If medicine were an exact science, men with equal opportunities for acquiring it might be expected to agree substantially, as they do in chemistry and physics; but the personal equation is a disturbing element in the mind of both physician and patient, of a variability defying the power of the differential calculus. That other people should disagree is a matter of course, and generally of no con-

sequence. Clergymen disagree widely in doctrines believed to affect supremely the eternal welfare of mankind, and in this land of liberty and toleration a large fraction look on with indifference, and the remainder with serenity. Lawyers are paid to disagree; their clients are not satisfied unless they are radical and stormy in variance; yet lawyers are loudest in complaining of the disagreement of doctors, especially when they may be supposed to be paid for it.

The above is said rather to explain than to justify the ground of complaint. Substantial agreement in medical testimony is very desirable and probably possible, though at present impracticable in particulars. This much by way of introduction to the special subject, which has reference to expert medical testimony in courts of justice.

"'Tis true, 'tis pity, and pity 'tis 'tis true," that the figure generally made by physicians as experts is embarrassing and often discreditable to themselves, and that the oft-repeated spectacle has brought reproach on our calling; but I hold that the fault is rather with the system of taking medical expert testimony than with the witnesses themselves. Their services are sought for the purpose of supporting the claims of parties in contest, and their opinions are always known beforehand by the lawyers who call them. If their views were not known to be more or less favorable to the party requiring them, they would be avoided rather than sought.

Furthermore, physicians are human, and can hardly escape bias in favor of a friend who happens to have a case in court, whether as client or attorney. He is asked by an interested party, friendly to himself, to give opinions, knowing that, if favorable, they would be more acceptable than unfavorable ones, and he is too apt to assume a partisan rather than a judicial frame of mind. The main check to such insensible bias is dread of cross-examination. Still more to be deprecated is the custom of paying a considerable fee to the expert by the party employing him. If this be given in advance, it is fairly presumed to secure the most favorable opinion possible; if not given beforehand, then it is expected that the honorarium will be according to the value of the testimony. In either case the fee is demoralizing to average human nature. On the other hand, expert testimony without a fee, either express or implied, is given grudgingly. Parties in court find themselves in a situation like that of people at a public table who feel constrained to fee waiters in order to secure good service. The comparison is humiliating to members of a liberal profession, but human nature varies less in kind than in degree in different stations. Here it is fair to remark that physicians are no more responsive to a pecuniary inducement than lawyers, or even clergymen. Pleading and preaching both have a recognized money value; the dispensers are not apt to depreciate their own worth, and sensible people pay them accordingly.

Under the existing practice of taking medical expert testimony, lawyers intend to use physicians for partisan purposes, and whatever moralists and the public at large may think of the consequences, the legal fraternity have no more right to find fault with experts than duelists have with each other's weapons. It is wrong for the law to allow medical men to be used as partisans in such controversies. An effectual remedy is needed for this abuse, both to spare the ex-

² Op. cit.

pert such degradation and to promote justice, and this we shall now consider.

The first and essential requisite is, that expert witnesses should never be chosen by parties in contest, nor by their legal representatives, either in civil or in criminal trials. If possible, their opinions on questions at issue should not be known beforehand. I would suggest that the court be authorized by law to summon a suitable number of persons to act in the trial as experts, that they be questioned as to any possible bias in the case, and that counsel on both sides have the privilege to object on such grounds, as in case of jurors, but without privilege of peremptory challenge. The court, jurors and counsel on both sides should then have a right to question the expert. Such a plan would give him a judicial position, more satisfactory to himself and vastly more conducive to fairness and justice. The law should allow adequate fees, according to the value of the expert's time in his ordinary business, to be fixed in the judgment of the court and included in the ordinary costs of trial.

I am clearly of opinion that legal counsel should not be allowed to suggest names of experts, nor to have anything to do in their choice beyond aiding in the discovery of any possible bias, and objecting for such cause. Neither should they be taken at hazard from a list of practitioners, as jurors are drawn from a polling list. A man competent to preside over a court may be trusted to select experts from the best of their class. In a city there is ample room for choice, but in a rural community it might be necessary to summon men from a distance.

The court should be authorized, in his discretion, to require one or more experts to listen to the testimony of ordinary witnesses, before giving their own opinions, for this course would obviously qualify them to understand the case and assist to a just and correct decision. This might be made optional with putting a series of hypothetical questions. In either event the same precautions should be used to guard against outside influence upon the experts as are taken with the jury, and for the same reason.

Since the foregoing was written, I observe that the Illinois State Medical Society has proposed a legislative act authorizing the judges of the Circuit and Superior Courts to appoint experts in medical and other sciences, for the purpose of giving opinions upon the evidence as presented in hypothetical form in both criminal and civil trials. The term of appointment is to be one year, and the judge may summon as many as three in one case. They are to be subject to cross-examination, but only upon points touched in their opinion. I think it safer that experts in an important trial be selected for the occasion and at the opening, so as to preclude their being tampered with by interested parties beforehand. Their opinions should be no more forestalled or anticipated than those of the court and jury.

This matter is one for each individual State to settle within its own jurisdiction; likewise for the national government within the purview of the federal courts. It would be well for a suitable example to be set by a Congressional act applying to trials in federal courts, and then we might hope that the several States would take like action so as to make the practice substantially uniform throughout the country. In my judgment it would be fitting and helpful for the AMERICAN MEDICAL ASSOCIATION to urge upon Con-

gress some such measure as the one here briefly outlined, not only for the credit of our profession, but still more in the interest of justice.

THE PREVENTION OF ASIATIC CHOLERA.

Read in the Section on State Medicine, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY ELMER LEE, A.M., M.D., PH.B.

CHICAGO.

Asiatic cholera is one of the pestilential diseases that remains to menace the happiness and prosperity of the human race. In civilized countries epidemics are more and more rarely occurring, but cholera is still a dreaded and fatal disease in periodical epidemics of wide extent in civilized Europe. To-day the disease prevails almost continuously in some portion of southern Europe and western Asia. The people in these countries are of two notable classes; those of the highest, but the majority of the lowest intelligence. Superstitions offer obstacles that so far have prevented the development of prophylactic measures against ravages of epidemic cholera. When a people such as are the occupants of southern Russia, threaten to murder the priest of the parish because he endeavors to introduce, for their use in times of cholera, so simple an agent as carbolic acid, it is not strange that preventive measures make slow headway. The Russian populace during the last epidemic of the year 1892, actually murdered a physician in cold blood, simply because of his profession. They believed that he, with other members of the profession, was indirectly the cause of their suffering and death. Mobs attacked the hospital barracks, dragged the patients into the open places, laid them on their backs in the hot sun, destroyed the hospital, threatened the lives of doctors and nurses, and in one instance a doctor was martyred. In another instance, in order to save his life, at the hands of these sadly superstitious people, it was necessary to place a physician in a coffin and carry him as if dead to the outskirts of the town. Even in more enlightened portions of civilized countries, grave difficulties present themselves to important measures relative to protection of human life in times of epidemics.

It is a long time since there has been an epidemic of the cholera in the United States, but it is perhaps an open question whether our own people in some instances would behave in the most enlightened manner. While it is agreed by the profession universally, that it is desirable to prevent epidemics, it seems everywhere to be scarcely possible to meet the laudable desire. Up to the present time, there have been and there are a number of propositions concerning the prevention of Asiatic cholera. The success of measures of prevention has not realized the expectations of the advocate who has proposed them. A most notable and widespread interest and enthusiasm was produced ten years ago by Ferran, of Valencia, Spain. The Doctor heralded to the world that by the use of his attenuated cholera germs, the disease was both quickly and surely curable, as well as preventable. His proposition received almost universal consideration, but to-day the proposition receives absolutely universal neglect. This is the sad history of the great hope that was extended throughout the civilized world, that at last a great man had discovered a method equal to the require-

ment. Expectations ran high, the medical press, as well as the secular, was filled with seemingly strong and convincing facts that went far to establish the value of Dr. Ferran's proposition; but alas! as have so many propositions during our own brief generation, it waned and to-day is only remembered on account of the notoriety of the failure. Since his day, other equally intrepid investigators have had propositions to advance. Some of the propositions have been worthy of serious consideration, some of them have been ridiculous. In every instance the proposal to protect human life from the contagion of cholera has consisted of some foreign element to be introduced into the blood circulation. The principle underlying the introduction of foreign substances into the circulation is that of antagonism. Some of these substances proposed to be introduced into the body have been animal substances, many of them mineral. The disposition of the moment, especially the disposition of European investigators, is along the line of animal viruses. These viruses are of two kinds: the newer kind is the sterilized toxins of the disease to be prevented; the older form consisted of attenuated bacilli. Both forms have sadly failed to prevent the disease feared.

The latest proposer of a virus of animal nature that would prevent Asiatic cholera is Professor Haffkine, of the Pasteur Laboratory, a Russian by birth and education. The Doctor is an intrepid experimenter, a faithful observer, and a profound bacteriologist. His great and untiring efforts seriously deserve a better fate than the results of latest experiments warrant. Encouraged by the hope of success, he has visited the home of Asiatic cholera in India, and a great many of the natives and members of the native army, were inoculated against cholera. The report of the results of his inoculations, show that 70 per cent. of the inoculated subsequently contracted cholera, whereas the percentage of the natives not inoculated who contracted cholera did not exceed 67 per cent. This is truly disheartening, but it was what was to be expected. Inoculation by animal viruses predisposes to Asiatic cholera, the opposite result to that which is desired. Inoculation against cholera has signally failed in the hands of each successive prophet. The virus subcutaneously introduced produced retrograde metamorphoses similar to the effect of the disease itself. The experiments in Calcutta by inoculation during the past three years have shown better results, but the conclusion is valueless for the reason that that community has not been visited by Asiatic cholera during the entire period of the experiment. If the attenuated germ and the sterilized product of the germs, or the sterilized product of the disease itself, after the conscientious trial of a generation fails, what hope remains along this particular line? There is nothing left to be tried, and it appears to me the case is hopeless in this direction. My own conviction honestly revealed, denies any prospect of a realization of such hopes.

A still later earnest, intelligent, educated enthusiast in our own country comes forward with a new theory. Dr. Reginald Leach, a worthy and honored graduate of Dartmouth, proposes to prevent Asiatic cholera by a process of introducing arsenious acid into the circulation. His conclusion is the result of theoretical deduction. The proof of the value of the deductions has not yet been established, but the high standing

of Dr. Leach entitles him to our most respectful consideration. He assumes, and in his assumption he has my concurrence, that to prevent a disease such as cholera, an agent is required which is in itself able to cure that disease. This is good reasoning; this is from my standpoint literally and actually true. Now, as to the selection of the remedy. The Doctor holds with me that the propositions of Pasteur, of Behring, Haffkine, Hammond, Ferran, and others of that class are faulty, because they use an animal toxin for their preventive measure. An animal toxin, the Doctor says, is necessarily uncertain in its dynamic force, owing to incidental and unavoidable causes. In addition to that, the morbid products of vicious character are liable to accompany the curative animal virus, owing to the impurity of the source from which it is to be taken. Consequently, Dr. Leach proposes to use a definite unvariable mineral of known strength, a mineral which can be weighed and the dose made exact. He reasons that there is some analogy between Asiatic cholera and malarial disorders, and that this mineral substance likewise is able to exert its peculiar protecting influence. Virchow has stated that there is some analogy between the effect of poisoning by arsenic and the disease, Asiatic cholera. Upon this basis of analogy, the theory is constructed in part, that that remedy which produces an analogic disease to cholera may be the remedy which will cure a prototype of that analogy. Another conclusion entertained is that while the morbid products of disease used as viruses for inoculation produce retrograde disturbances of the human body, on the contrary, arsenic is said by Bartholow, as the Doctor's authority, to produce tonic and reconstructive effects. Theoretically, this may or may not be true. Practically, the conclusion has not been determined. It is a serious question in my mind as to whether it ever can be proved to be true. The claims for prophylactic effect of arsenic are being investigated by certain colleagues in Lucknow and some other parts of India. Whatever may be the result, it is too much to hope that the prevention of Asiatic cholera can be secured by introducing any corrosive mineral substance into the circulation. Arsenic is an intense corrosive, and whatever its influence may be, its action is that of a foreign corrosive substance. It has by right and by nature no natural place in the human organism. The reasoning from the point of theory by Dr. Leach is clear and deeply interesting and worthy of consideration. The whole subject has been plainly presented to me by the Doctor in the form of a personal letter, but it is too important a document to be retained by me as a private paper. It is my wish that it be included in the Transactions of this Section for publication in the regular way.

The prevention of cholera must necessarily be along two lines: 1, the measures instituted and executed by the State; and 2, those means and measures to be carried out by the individual. The enforcement by the State of modern sanitation, modern hygiene, the principal feature of both the preceding, being a free supply of pure water for public and private use, constitute the wisest and the best provision as a public policy. The application of rules of strict and severe and unyielding quarantine measures is neither humane nor is it necessary.

Cholera is a preventable disease; but to prevent cholera requires cooperation between the directors

and the directed. Education and the growth of intelligence alone will secure protective coöperation. What can we do in a place where its citizens, when commanded by the authorities to restrict their use exclusively to sterilized water, reply as they did along the banks of the Volga in Russia, that they will not do so because God Almighty did not intend them to drink boiled water, for if he had he would have boiled the water himself. The day when sufficient intelligence will inspire the motive for coöperation between the authorities and the masses is somewhat nearer but still a long way off.

Personal prophylaxis against cholera would avail much if the result of personal intelligent instruction. Victims of cholera are chiefly persons who are themselves victims of vicious appetites or vicious habits. The excessive use of alcoholic beverages is without an equal as a chief factor in preparing the organism for an invasion of cholera. Excessive use of tobacco likewise weakens the system and invites cholera. Unscientific cooking and the too frequent use of animal foods are productive of a condition of body which encourages cholera. The insufficient consumption of water, and especially pure water, is of all factors the most conducive to the acquirement of this disease. One preventive which would be a universal prophylactic against Asiatic cholera is the condition not as frequently found as it should be, which is known by the name of good health. Pettenkofer, of Munich, showed by his experiments upon himself, that with normal secretion of gastric juice, a tumblerful of cholera bacilli could be taken with mirth and impunity. Gastric juice is a corrosive substance secreted in the normal stomach, that attacks and cuts to pieces quickly and surely, every organic particle of matter that comes in contact with it. It is fully taught and fully believed that cholera is produced by organic germs which enter the stomach through the mouth in the contaminated water which is drunk, or in the food which is consumed. The sentinel, in good health is vigilant and absolutely prevents every form of organic substance from passing the threshold into the human citadel. But if the guard who stands watch at the door is stupefied and rendered impotent by his own vicious habits, he will permit the foe to enter, and the house to be invaded. Healthy tissue, together with a healthy mind, is the prophylaxis universal as to time and to place against every invasion of the system by Asiatic cholera.

It was my experience during a stay of six weeks in the Oboukoff Hospital in St. Petersburg, to see many cases of Asiatic cholera. There were 600 persons afflicted with cholera at the time of arrival. The cases of cholera were principally among the lower or lowest classes. These poor people live badly, eat poorly, and drink excessively; but instead of drinking pure water, they substitute a Russian liquor, and frequently while under its influence they drink water during the heat of the day from the filthy canals which divide the city into three parts. These canals are so foul that they resemble to some extent the Chicago River. Fish can scarcely be kept alive for even a few days in them. Very many of the men who came to the hospital sick from cholera, contracted the disease through their ignorant use of the contaminated water from the canals of the city. The preventive measure that is universally employed, and which commended itself because of its good results, was the provision

for a supply of boiled water for all the inhabitants. It is wise in observing to take note of a measure so simple, yet so generally recommended as the use of pure water during epidemics. This sensible measure is the only likely preventative of Asiatic cholera. During the prevalence of the epidemic in Hamburg, Altoona, a division of the city, was supplied from a different system of waterworks, from that of Hamburg, and while cholera raged in Hamburg to the extent of 21,000 cases in five weeks, there were no cases of cholera in Altoona, which was only separated from Hamburg by the difference in having a separate waterworks which supplied filtered water as against unfiltered water to the residents of the infected city. Pure water will save Hamburg from future epidemics of cholera.

100 State Street.

LETTER FROM DR. LEACH.

PARIS, TEXAS, April 6, 1895.

Dr. Elmer Lee, 100 State Street, Chicago, Ill.,

My Dear Doctor:—Your very welcome favor of the 3d inst. came to hand but shortly, and I hasten to reply that against your very large practical experience with the disease, I can not pit my remedy (as yet but partially tested) as a curative; nor do I so wish to do, for I hastily acquiesce in the verity of your special plea for absolute cleanliness in the treatment of Asiatic cholera, and I also have my apology to offer for some unmeant abstruseness which seems to have slipped into my letter of the 29th ult., for I did not then, nor ever, mean to commend arsenious acid, nor any other form of arsenic, as anything else than the remedy, *par excellence*, as a prophylactic against this disease; believing, always, that with absolute cleanliness, followed by the judicious exhibition of the proper drug, this disease may be reduced to the status of, at least, that now held by the more loathsome variola or possibly to something even better still, for I am at least sufficiently enthused with the belief in arsenization vs. cholera to make any reasonable sacrifice for the pleasure of personally testing the alleged efficacy of my drug to prevent; but to date I have been handicapped by a succession of misfortunes which have wellnigh buried me in that oblivion it seems the desire of the majority to relegate us, and the misfortune of all such who are adventurous in medicine to that point where those who dare but follow pronounce each temerous.

I assure you, therefore, that I appreciate to the utmost, the honor of the attention you have thus far bestowed upon my hypothesis, and trust it may be my good fortune ere long to forward you some more convincing news from the East, of the efficiency of my chosen drug as a prophylactic against this fell destroyer of our fellow beings; meanwhile, I trust you will excuse me when I acknowledge a timidity in asserting views diametrically opposed to the generally accepted theories of the day as presented by Pasteur, Haffkine, Hammond, Behring and others, but at the same time accord me the privilege of the paradoxical position of apparent temerity in asserting my views on arsenization as the only true prophylaxis against cholera (as you have seen it) I believe logical reasoning can arrive at; and accredit me with the desire only to better our standing as preventers of disease, however attained.

As you say, my theory is clever and engaging, please do me the further honor of reading something more of the same which will more fully acquaint you with the wherefore I am so confident of its ultimate good to mankind; and then, if you please, reward me with your further correspondence upon this very intensely interesting subject.

Granting that you will continue to read to the end, I take great pleasure in stating that I find, in reading up on my opponents (inoculation of animal virus) that Toussaint and Chaveau first recognized the fact that not only the attenuated disease germs, but also the sterilized products of bacterial life, could communicate immunity, but Behring says the acquired immunity is of a relatively short duration and the dismal results of Haffkine at Lucknow show that he there lost over 70 per cent. of the inoculated, while there was a mortality of less than 67 per cent. among the uninoculated, showing a morbid condition we would wish to avoid in alleging prophylactic virtues of anything; therefore please note that while I shall attempt to show the fallacy and even dangers of other hypotheses on the prevention of Asiatic

cholera, I do not do so till I feel confident I have something logically correct as a substitute; and, therefore, not as an iconoclast but as a simple investigator do I propound my own theory to you as to all others, hoping only now to sufficiently interest those who may have the ear of public opinion; that tests may be made where such is possible, and the sooner the better, as the more certain of something tangible and reliable.

We know that Virchow first promulgated that "many cases of acute arsenical poisoning are not distinguishable by their symptomatology or morbid anatomy from cases of epidemic cholera;" that Farrington proclaims that arsenic "excites intestinal disease which is almost identical with cholera, even the organic growths of cholera are found in the discharges from the arsenic proving;" also that since 1873 sulphuric acid (as I wrote in my last) has held a high place among the alleged preventive measures against this form of cholera. Therefore in handling this much mooted question I ask your forbearance and a reservation of verdict until I have presented more testimony than I felt it my privilege in my letter of the 29th ult.; and in doing this you will please note I shall attempt to faithfully present all sides of the question; at the same time claiming most for arsenic as the preventive of the disease, as well as the superiority of drugs over all kinds of animal viruses as preventatives, because I am with you in my conviction that the whole principle now underlying allopathic practice is incorrect, and I say so though I am a graduate of Dartmouth College also that I do not now follow the precepts of my alma mater.

Though this may seem already long I have but just begun, yet shall try and not burden you with a novel method of cure, but only present a prophylactic measure as different from a curative as is hygiene from medicine, yet as allied in significance and utility. I follow the same general trend of thought as that of all our illustrious predecessors in preventive medicine (for there is but one royal road to success) but am constrained to choose a drug instead of their inoculation with the animal viruses or antitoxins, for I choose more measurable substance, which, in exhibition as a prophylactic against cholera, is within our power to control by regulating the dosage and within our ken in most probable effect; at the same time eliminating possible idiosyncrasies in persons of unusual susceptibility; but even in them prepared to meet any untoward symptoms with a known antidote such as we have not for the animal viruses.

I choose a drug because of the fact that extraneous noxious agencies (such as natural diseases and animal viruses) possess subordinate and often extremely conditional powers, while drugs possess absolute and unconditional powers far superior to the former in their ability to produce morbid discordancy or the antitype of the prominent, uncommon and characteristic signs and symptoms equal in number to the disease to be prevented which must be the power of any protective to protect. I choose arsenic, therefore, because, as Hippocrates says: "Experience has demonstrated that only that remedy will prevent a disease that possesses the power of curing the disease feared, and which can produce reaction in the system which is directly antagonistic to the disease and its influences." Though I do not claim that the inoculation process with the sterilized viruses will not cure the disease feared, I do assert that in a system that might otherwise demonstrate cholera, that inoculation with animal viruses can not produce reaction directly antagonistic to the disease and its influences, but on the contrary, with cholera, I claim that the inoculation process (contrary to the same process in smallpox) weakens and makes more susceptible to the influences of the natural disease each one inoculated, and by virtue of its similar powers of destructive metamorphosis to the action of the disease, epidemic cholera.

I choose arsenic, also, because long before the profession was dominated by the manufacturing chemist, arsenic was known to be one of the most potent remedial agents in combating this disease, and is even now quoted by Bartholow as "one of the numerous remedies proposed for the cure of this disease," and by others as "indicated in all stages of the disease;" and as it is tonic in effect and a reconstructive, both of which are diametrically opposed to the destructive metamorphosis at work in the cholera patient or him likely to become such. I choose my drug also because, as Wm. Henry Porter says: "The arsenites (that is the molecular elements which constitute the arsenites) are intensely irritating and poisonous to all forms of protoplasmic life, both animal and vegetable. At the same time they enhance the accumulation of tissue throughout the whole animal economy, and when this is done diseased processes all through the system

are in part or completely removed and more or less of a new normal or healthy activity is brought to all parts of the body."

I choose arsenic, also, because authority and experience teach us that the human economy is more susceptible to drug action and the vital force more responsive to its magic touch than to any miasm or perversion of nature's laws; therefore, while I acknowledge that sterilized products of bacterial life might communicate a like immunity, accord me the privilege of stating that many may be the imperfect results of chemic action in this process rewarding us with such prognoses as awaited Haffkine at Lucknow and Lady Montague in England where, in either instance, the results were such as could not be predicted by the most gruesome pessimist of that time or of this; affecting as they did such monstrous mortalities that thanks to Jenner many were saved.

As Behring says of his antitoxin: "The acquired immunity is of a relatively short duration," so I assert of Haffkine's inoculation, and likewise acknowledge a probable short immunity from arsenization, for I accept authority for the statement that "the effects of arsenic continue in the system from a few hours to four weeks, or longer, according to the size and frequency of the dose," yet while the effects of inoculation are not known positively they are of arsenic, and so far as yet demonstrated the results show for the former more of destruction than protection, while for arsenic more for protection and none for destruction. In this, I take no account of the 200 cases reported by Simpson from Calcutta, where there had been no danger of infection for over three years previous to his inoculations. Such misleading reports can have no effect, pro or con, upon the actual prevention of this disease, and their publication as made in American newspapers and medical journals is simply wrong, to say the least; for a prophylactic to command the courtesy of the name must protect a majority of those alleged to be protected, and only where disease and danger to infection is active and imminent and not in situations where it may have existed in the past but has not since reappeared.

In such times as these, therefore, when we are seeking after the true preventive for each preventible disease, with a loyal but misguided enthusiast in the Orient sending to our Western civilization only the immediate results of a most pernicious though seemingly very plausible theory, we can and do realize and recognize the sacrifices of the investigator into the occultness of disease, more especially this of epidemic cholera, yet only to the successful discoverer of that protective which will protect all, be that what it may, can we honestly render our respectful acknowledgments. To return to the why and the wherefore of the proposed substitution of arsenic for all others as a preventive of cholera we recall the facts relative to cases of supposed cholera at Cincinnati in September, 1892, and of similar cases at Little Rock in the following month, wherein the auxiliary diagnosticians of the microscope and chemic analysis were required; and in the first instance showed similar though not identical germ life to Asiatic cholera in the milk drunk by those victims, while in the second instance chemic analysis demonstrated arsenical poisoning at Helena while the microscope showed the Little Rock cases to be those of so-called winter cholera. In all exemplifying bacteriology the acme of diagnosticians is germ diseases (after the germs are admitted) and Asiatic cholera and arsenic poisoning are, as Virchow so aptly states, indistinguishable (oftentimes) by their symptomatology and morbid anatomy from each other (except, as stated,) by the auxiliaries here noted.

If these be facts, and I believe all know them as such, then truly a drug is eminently superior to any animal virus or if there can possibly be a better process than the one of Haffkine or Ferran (with the excreta of the cholera patient, sterilized or not) why not a drug which we have known in effect for the past century, instead of risking a repetition of our certainty to infection with the disease feared, as well as some possible worse disease. Experience has shown recently in India that there is more danger to the inoculated than to those where no precaution against infection was made, and remembering the results of inoculation from 1721 to 1783, and that the process of sterilizing can be unsuccessful at times (the cause of Haffkine's late failures) then why place ourselves and patients in the unfortunate position of Lady Montague and her enthusiastic collaborators, when they produced (of course unintentionally), a condition which may best be described by that trite old simile of the early English and known as: "the groans of the Britons," in which they are made to say: "The barbarians on the one hand drive us into the sea; the sea, on the other, throws us back upon the

barbarians; and we have only the hard choice left us of perishing by the sword or by the waves."

If this appears far-fetched, my dear Doctor, look at the results in Haffkine's Lucknow inoculations in which it was supposed the sterilization of the virus there used was faulty, and if such was the case there, it is but fair to presume that in any of the "hair splitting" processes of eliminating individual or family characteristics or diseases from the excreta of the cholera patients, we may never have a truly sterilized immunizing virus containing only the comma germs and their toxic results or combinations. For example, let us look upon an imaginary threatened epidemic of the disease and in the following personal manner, wherein you will imagine yourself in imminent danger to infection because your nearest neighbor has the disease. You each use the same well for obtaining your supply of drinking water and your families exchange the ordinary courtesies of such relationship; but you know him or at least suspect him the domicile of syphilis, scrofula or tuberculosis. This is the only case thus far, and inoculation as now promulgated, the only preventive measure known to the profession.

If Scylla and Charybdis presented such fearful obstacles to the usually undaunted ancients, which of these seems the more favorable to you? the Scylla of the hardened syphilitic or the possible swirling, twisting and contorting Charybdis of Asiatic cholera? for in this, maybe a little overdrawn simile, you see inoculation against cholera as it might exist and the consequent predicament of our people. This is in fact the only view to take of inoculation as it exists, as shown by the grievous experience of our colleague in India; yet, despite all this, we find the leaders of preventive medicine of to-day forgetful of the near past, and the wave of a more certain and accessible prophylactic which is offered in arsenization, of which I had the pleasure in my letter of the 29th ult., of reporting so much of what is good and none of a like character to the inoculations of my unfortunate colleague.

If, then, Pasteur prevents hydrophobia with a virus which presents symptoms in the inoculated almost identical with the rabies canina, and Jenner's vaccine may, and sometimes does, exhibit such a similarity to true smallpox as to question the purity of the virus, and it be a fact, as Virchow says, that arsenic produces a condition which may preclude a positive differential diagnosis with cholera to produce this effect, then the arsenious acid must actually occupy the exact space or place in the animal economy or affect the intestinal pabulum in a like manner (as I think I wrote you before) as would true Asiatic cholera, (and it matters not which is the solution) to there demonstrate its certain effect. Therefore, by the willful arsenization of men up to a condition of slight physiologic effect of the remedy, such, for instance, as is produced by the animal virus, this process must and will effectually prevent that one so treated simultaneously demonstrating in himself the disease feared, and just as surely, and upon exactly the same hypothesis that we presume and logically conclude that the vaccinated can not suffer simultaneously the full virulence of variola; yet in this we need not be more void of common sense in our expectations of arsenization than of vaccination (already sufficiently tested to satisfy a big majority) as facts simply verify, in the latter, that personal idiosyncrasy in the well is quite a factor in the equation, and that such affects its prognosed results as in the administration of different remedies to the sick. Therefore not every one arsenicized, more than every one vaccinated, will be protected against disease more than is to be expected of otherwise positively indicated remedies prescribed, as they all are, according to our fallible diagnostic powers and prognosing hopes.

These, then, are some of my reasons for promulgating what Gibier so aptly pronounces my "theoretically perfect" hypothesis, and the reason for my choice of a drug in preference to any animal virus. Because I believe that through a drug alone, exhibited into the system and that system made responsive to its physiologic effect, and so kept while danger lasts, may we be protected, and finally emancipated from the ravages of epidemic or Asiatic cholera. By this method alone may we hope for relief from the pernicious theory of inoculation advocated by the gentlemen referred to; and by drug effect alone may we hope to keep off indefinitely the possible dangers far worse than the probable epidemic disease; and by drug effect alone practice truly aseptic prophylaxis against this disease.

If, then, the sterilized products may become dangerous through some unknown cause, why should we advocate further a process which, at best, can but effect an equal immunity with arsenious acid which latter is long known as

to effect, where positive antidotes are the public property of all inquiring minds and named in all medical works pertaining to the subject of arsenic and its compounds. Why, then, inoculate at all, while the alleged acquired immunity is of so relatively short duration, and while a more certain and safer effect may be had by arsenicizing, which demonstrates truly one more long known fact that two diseases, though different in kind (drug and miasm) but very similar in their manifestations of signs and symptoms will always extinguish each other, whenever they meet in the system, for the superadded morbid potency (drug) takes possession chiefly of the same parts in the organism heretofore affected (or hereafter to be affected) by the weaker morbid agency (disease). This is thereby deprived of its power of action and is consequently extinguished or prevented.

In arsenization we therefore have a safe, sure and accessible prophylactic; for such a process must demonstrate true asepsis and the power to produce a like condition to that intended to prevent, as well as a condition directly antagonistic to the disease and its influences. All of which Bartholow unconsciously affirms when he says: "Arsenic is, with but a few exceptions, destructive to animal and vegetable germ life and is a reconstructive and a tonic to the system, yet in lethal doses produces symptoms similar to epidemic cholera." To all this I add that I note with pleasure that you agree with me that Haffkine's inoculation theory, like Ferran's, must fail under test, but what must also be the verdict of all others in the case of inoculation as practiced, filled as it must be necessarily with provisional possibilities of other and worse diseases than Asiatic cholera. What of this inoculation process in comparison with arsenization which must not only protect the inoculated or arsenicized, but also protect all coming into his presence, as well as those who, by virtue of their environment, might ingest particles of his ejects? In the arsenicized is one less germinating center and one less germinating medium for the rapid incubation and dissemination of the comma bacillus and its toxins, thus sterilized beyond any possibility of a doubt and the result unaccompanied by any wail of possible failure in the process, such as came from India after the demonstration of such a fearful mortality.

Therefore, if we are to have protection against cholera through a process yeplept vaccination or inoculation (as predicted by von Pettenkofer), and none can be more efficacious or expeditious, it can be done in but the one way, and that is by arsenization of each and every suspect or patient (in the first stage), or person subjected to possible infection, as well as to all others seeking protection, and this should be repeated after four weeks at the longest if danger to infection remain. So by arsenicizing with ivory points charged with doses of the one-thirtieth of a grain of pure arsenious acid (such as are made at the Lancaster County Vaccine Farms), each one thus brought under the sufficient effect of the remedy may experience a successions of symptoms resembling an attack of cholera in miniature, yet with few, if any, of the distressing symptoms usually incident to true cholera. At most, there will be but slight diarrhoea, with burning at the epigastrium and under the eyelids, and a ringing and roaring in the ears, as is common after dysentery, diarrhoea, or profuse fluxes of any sort; but in inoculation with the ofal of the cholera patient most of these symptoms are more pronounced in that each must, perforce, suffer a mild and sometimes even a virulent attack of the actual disease. Under slight physiologic effect of arsenic, one has but taken a dose and acquired its effects, such as has been common practice (in prescriptions during the past century) for chronic malarial cachexia and skin diseases of a germ origin, and is still an almost diurnal prescription for such maladies with the "regular" doctors.

Such constitutional effect of the drug may be produced when there is no especially imminent danger to infection, by the ingestion of from 2 to 5 drop doses of Fowler's solution, repeated every two hours till the desired effect is acquired; or the same may be effected by hypodermic administrations in like dosage and repeated until like effect is acquired; but all this, like successful vaccinations, should be done only under the prescription and immediate supervision of the physician, who holds ever ready, in dialyzed iron, an antidote to any possible idiosyncrasy in the applicant; and such none may possess against the inoculations with any degree of certainty of action; for once inoculated or ingested, the cholera germ or miasm takes its own course, and often the life of him experimented upon.

From some comes the common wail of fear for those thus arsenicized, but to all I respectfully request a comparison of the mortality at Berlin alone, before and after the intro-

duction of vaccination, yet this process of protection counts some victims. Compare the mortality from cholera and from Haffkine's inoculation and that from arsenic poisoning (in the hands of the physician when purposely prescribed); compare also the possible dangers incident to inoculation (even to those who survive the process) to the process of arsenization as I propose it, and of all these choose the lesser evil, if evil it be to try and avoid disease; compare the actual increased mortality from inoculation against that where it was not practiced at all and therein alone see the fallacy of a theory in relation to the practice of which we speak; and then remember that inoculation calls for a first case, with all its possible accompanying dyscrasie, its entire lack of effective antidotes and its frequent mortality. While arsenization calls for the ingestion or other manner of acquiring a slight physiologic effect of arsenious acid (a drug in daily use the whole world over), and that in this process there need be no first case from which to obtain the virus, for this drug is known to all medical men, who know its effects and its antidotes, while few know cholera and its effects, and fewer know its antidotes.

Let me, therefore, my dear Doctor, review your favor of the 3d inst., and remind you first that where you find the consensus of opinion to have been against good results from the use of drugs during the epidemic in Europe in 1892, that I believe you have only been able to hear from one side of the profession, and that side used much too large doses, thereby augmenting the diseased condition by adding drug disease, whereas by the judicious administration of much reduced doses you would have probably come out of that epidemic much more in favor of continuing the good old-fashioned drug medication. I am also truly pleased to find one more who shall acknowledge, with you, that "adding to an already overburdened and disordered blood new and additional foreign and disturbing substances is the principle underlying allopathy, but it is not the correct principle involved in curing disease." I would respectfully cite you to one Professor Brunton (medical author, editor and examiner), who acknowledges a like empiricism in the allopathic practice, which is claimed to be the only scientific process of medicating our fellows; and as above stated I am pleased to add that I am one with you in encouraging absolute cleanliness in the cholera patient. But do not forget that drugs will do much more than the majority of practitioners. I now respectfully and forcefully present my allegations in detail and shall appreciate much your further consideration of this most interesting subject, especially as I can see that through your disinterested interest you further promulgate this hypothesis, which is thus far "incontrovertible except by test," and which has thus far stood firmly against all adversities.

I conjure you, my dear Doctor, to write of this subject while you have the ear of the entire profession, as I am but yet little known; also do me the honor of an early answer and your candid opinion as to the theory as thus far propounded, and believe me,

Yours very truly,

REG. LEACH.

THE PROPRIETARY SYSTEM AND ITS REMEDY.

Read in the Section on State Medicine at the Forty-sixth Annual Meeting of the American Medical Association, held at Baltimore, Md., May 7-10, 1895.

BY F. E. STEWART, M.D., PH. G.
DETROIT, MICH.

THE PROPRIETARY SYSTEM.

For the purpose of promoting progress in science and the useful arts the Constitution of the United States gives Congress the power to grant to authors and inventors for limited times the exclusive use of their respective writings and discoveries. Hence our copyright and patent laws.

A patent is a contract between the government, representing the public at large, and the inventor. The consideration moving from the government is the granting of the exclusive use of the invention for a limited time. The consideration moving from the inventor is the invention of a new and useful article, and the giving to the public full knowledge of it by a proper application for a patent, so that, when the pat-

ent expires, the public may manufacture the invention. The wisdom of such a law seems apparent, for by it inventors are stimulated to produce new and useful articles, capital is protected during the working and marketing of the invention until the investment becomes remunerative, knowledge is increased, and the archives of the Patent Office become a great public library and industrial exhibit, free to the use of the public, and commerce is promoted by valuable additions to the list of marketable commodities.

A trade-mark is a "commercial signature" employed to distinguish one brand of an article from another brand of the same article on the market. Its use does not confer on the user any exclusive right to the manufacture and sale of the article upon which the trade-mark is branded. In law, the trade-mark has two uses. One is to designate ownership, illustrated by the common method of branding horses and cattle so often seen on the ranches of the great West. Another use is to designate the source of emanation or of manufacture. For this reason the lumberman brands his logs with a trade-mark, or the manufacturer of pottery stamps his wares with peculiar marks or signs. In the same way the manufacturers of silk, linen and other fabrics use the words "Lyon," "York Mills," etc., as trade-marks, to distinguish their various brands of goods from other brands of the same articles on the market. But these uses of the trade-mark do not vest in the users the right to the exclusive handling, or manufacture and sale of the articles upon which the trade-marks are branded. The man who brands his cattle with a trade-mark does not acquire thereby a monopoly in cattle; neither does the use of trade-marks by potteries, silk manufacturers, makers of linen and other fabrics, vest in the users the right to exclude others from making and selling the same commodities.

Another use of the trade-mark has sprung into being as a development of modern times—a use not contemplated by law. The method to which I refer is the registering at the Patent Office of the only name by which an article is known, as a trade-mark on said article. This use of the trade-mark has created what is known as the proprietary system. This system should not be confounded with the patent system, as it is, in principle and practice, directly opposed to it, as a further consideration of the subject will show.

The monopoly created by registering the only name by which an article is known as a trade-mark upon such article is unconstitutional, illegal and unscientific. These charges I now proceed to prove.

The monopoly is unconstitutional because unlimited in nature. *Congress has no power to grant perpetual monopolies.* I grant that the right to use a trade-mark can not be limited by law. But, as I said before, when one puts his commercial signature on his goods he acquires thereby no exclusive right to the manufacture and sale of articles so marked. No monopoly whatever can result from the *proper use* of a trade-mark. Only its misuse or abuse creates the so-called proprietary system.

The monopoly is illegal, for there is no law in the statute books of the United States designed to protect the new use of the trade-mark. On the contrary, the courts have decided that when a new article of commerce is born it must be provided with a name; and that any one has a perfect right to manufacture and sell the article under the name by which it is

known to the public provided the article is not patented.¹ In case the article is patented no one has a right to make and sell it under that name or any other name until the patent expires. Furthermore, the name, by use becomes descriptive. A name is descriptive if commonly used by the public in designating the article when purchasing it.² And it is an axiom of law that a descriptive name can not be a trade-mark. An absurdity that might occur by misusing a trade-mark in this way illustrates the subject very well. The trade-mark law permits the employment of the same trade-mark as many times as there are classes of articles. The word "Lyon," for example, can legally be used as a trade-mark on logs, silk or tin-plate. In the same manner the word "Lactopeptine" may be branded on a cow with just as much propriety as upon a medicine. The very impossibility of such a thing occurring demonstrates most clearly the name lactopeptine is not a trade-mark when applied to the well-known article so-called, but its proper or descriptive appellation, the present manufacturer to the contrary notwithstanding.

The monopoly is unscientific because it is protective of secrecy. While in many instances the ingredients of proprietary medicines advertised to the medical profession are given, their true, or working formulas, whereby the public (pharmacist) may manufacture them are rarely published. The disadvantage of this to pharmacy must be apparent to any thoughtful mind. Pharmacy is the *science* of preparing medicine. Therapy is the science of applying medicine to the cure of disease. *Materia medica* is the name given to the collection of substances used as medicine. These three were formerly classed under the general term pharmacology, or the science of drugs. Pharmacy, then, is a branch of medical science, and should be represented in scientific medical literature alongside of therapeutics and *materia medica*, as a part of that science. But the proprietary system stands directly in the way of it. How can pharmacy have its place in medical science when the knowledge of it is locked up in trade secrecy? How can we have a scientific nomenclature to pharmacy when many of the new medicinal compounds are introduced under "proprietary" names which can have no place in science? The proprietary system more than any one thing prevents pharmacy being recognized as a science, and its practice as a profession.

Finally, the patent law was designed to promote progress in science and the useful arts by encouraging inventors to invent new and useful things, and to "publish full knowledge thereof whereby the public may manufacture the invention when the patent expires." The proprietary system, on the contrary, hinders progress in science and the useful arts by putting in its place a system of secrecy and perpetual monopoly. Many physicians object to the open limited monopoly of the patent law as injurious to the welfare of sick humanity. Are we to indorse the proprietary system which is far worse, both in principle and practice?

THE REMEDY.

The main objections to the proprietary system are its secrecy, the unlimited duration of the monopoly, and the unscientific nature of its nomenclature. The great thing in its favor is that it protects the invest-

ment of capital better than the patent law. Very few manufacturers with whom I am acquainted would object to a reasonable time limit being set on the monopoly. All manufacturers would agree to the adoption of a scientific nomenclature as far as I know. But there are very few who would care to throw their processes open to unrestricted competition. And it seems hardly fair to ask it. Yet, unless some kind of compromise is adopted between what might be called equity and expediency, the objections I have named remain in force.

Nothing can be done in this struggle with wealthy nostrum proprietors, unless the legitimate manufacturing interests will cooperate with the medical profession. Therefore, the establishment of some basis of cooperation is essential to success. Secrecy of composition is incompatible with scientific prescribing and should be prohibited; there is no special objection to allowing processes and methods of manipulation to come under the patent or copyright laws.

Now, I have a compromise to suggest which, it seems to me, would overcome the difficulty. In my trip across the continent with a large party of medical men for the purpose of attending the annual meeting of the AMERICAN MEDICAL ASSOCIATION held in San Francisco, I suggested the plan to various prominent physicians, who, in the main, agreed in regard to its desirability. It is to *permit* an inventor of a new and useful medical compound to retain the name and secret of manufacture of his invention for a limited time, provided the true working formula thereof be placed in the hands of a national committee of physicians and pharmacists, and the article marketed only under the sanction of the committee. In other words, let the system remain as it now is, only with the exceptions that a censorship shall be exercised over the market by a committee of competent physicians and pharmacists, the monopoly to be limited in time, and the system to be made scientific by providing it with a proper nomenclature and by the final publication of every invention whereby all pharmacists may manufacture the same when the patents expire.

I use the term *permit* advisedly. The present position of the trade is in every respect one of assumption, not permission. Pharmacy can never rank as a profession until the proprietary system is abolished, or some compromise of the kind I have suggested be adopted. Either point once gained then it is time for the medical journals to recognize pharmacy as a profession and invite the pharmacist to contribute the results of his researches to the medical journals. Pharmacy now only appears in the advertising pages of the medical journals, which are torn up when the journals are bound. Under such a system there is danger of the pharmacy of the nineteenth century becoming to a great extent a lost art for want of a literature. There are pharmacists who are taking the position I have mentioned now, and they should be admitted as members of county medical societies as honorary members, or active, if they take the medical degree.

Then let every manufacturing house open a scientific department manned by competent physicians and pharmacists, who can be held responsible to the profession for their utterances, and for the representations made by respective houses in labels, in circulars, in advertisements, and in the contributions of these houses to scientific literature. It would be

¹ Brown on Trade-marks.

² *Ibid.*

well if the members of these scientific departments were graduates in medicine as well as in pharmacy. They could then join the AMERICAN MEDICAL ASSOCIATION, become members of the section on materia medica and pharmacy, and contribute to the scientific proceedings, thus promoting the interests of both pharmacy and therapeutics.

At the present time there are quite a number of medical journals pretending to be independent, but really organs of various manufacturing houses. I can see no reason against, and much in favor of a manufacturing house issuing a journal as its organ; but I have nothing but condemnation for the pretender who sails under false colors as a purely scientific journal. Such a journal as *Squibb's Ephemeris*, for example, issued above board as the organ of Squibb's manufacturing establishment, but filled with scientific articles, the work of investigators in his laboratory, or elsewhere, is a valuable addition to our list of journals.

The question of the day at the recent meeting of the AMERICAN MEDICAL ASSOCIATION at San Francisco was, shall the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION advertise proprietary medicines? I would have the JOURNAL draw the line and admit only those whose true formulas are placed in the hands of a committee and under the restrictions I suggest. However, it must be agreed that such indorsement must not be construed as a recommendation and used for advertising purposes. And I would add another restriction, and that is, do not advertise any proprietary medicines which are advertised to the public in the newspapers.

Now, as to the complexion of the committee, I would suggest that it consist of one member each of the AMERICAN MEDICAL and American Pharmaceutical Associations, and one member each from the medical departments of the Army, Navy and Marine-Hospital service, to which might be appropriately added as chairman, the Commissioner or Secretary of Public Health, if such an office is finally created by Congress.

DOES ALCOHOL EVER ACT AS FOOD, OR AS A GENERATOR OF ANY NATURAL FORCE IN THE LIVING BODY?

Read in the Section on State Medicine, at the Forty-sixth Annual Meeting of the American Medical Association, held at Baltimore, Md., May 7-10, 1895.

BY N. S. DAVIS, M.D.
CHICAGO, ILL.

Ever since Baron Liebig, of Germany, laid the foundations of organic chemistry by his two essays read before the British Medical Association—one on "Chemistry in its Application to Agriculture and Physiology" in 1840, and the other on "Animal Chemistry as Applied to Physiology and Pathology" in 1842, the assumption that the nitrogenous elements of food were appropriated to the growth and repair of the organized structures of the body and non-nitrogenous elements underwent oxidation or combustion, generating heat, has been accepted and incorporated into all our literature, both professional and non-professional. Consequently, the non-nitrogenous proximate elements of our food have been and still are almost universally regarded as fuel for supposed combustion or *respiratory food*, and not as furnishing material for the growth and repair of organized tissues. This arrangement of food elements into two

classes by Liebig and his followers was founded on no experimental proof, but rested solely on the analogies of composition. The starch, sugar, gum, cellulose, etc., being composed of the three primary elements, carbon, hydrogen and oxygen, and capable of uniting with additional oxygen outside of the living body constituting combustion, it was assumed that the same union with more oxygen took place in the living body and thereby evolved the heat characteristic of the animal.

As all this class of proximate food elements was composed of carbon united with hydrogen and oxygen in proportion to form water they were called carbohydrates. And as alcohol in its elemental composition was strictly analogous it was unhesitatingly placed at the head of the list of carbohydrates or heat producing foods. I found so much difficulty in reconciling many facts connected with the diet of different individuals and communities with this theory that as early as 1850 I instituted a series of direct experiments for determining the actual influence of both the carbohydrates and nitrogenous elements of food on the processes of heat production and tissue repair. The results of these experiments were embodied in a paper that I read before the AMERICAN MEDICAL ASSOCIATION at its annual meeting in Charleston, S. C., 1851, and were such as convinced me that both carbonaceous and nitrogenous elements of our food furnished materials for tissue growth and repair; and that the animal heat was the result of molecular changes constantly taking place in the tissues; while the presence of alcohol neither promoted tissue repair nor heat evolution, but retarded both.

Böcker, of Germany, had previously demonstrated experimentally that the presence of alcohol in the living body diminishes the sum total of eliminations and excretions and therefore retarded the molecular or metabolic changes in the tissues. These results were verified by further experimental researches by Dr. W. A. Hammond and several others, as set forth in his work on hygiene published in 1863. It is worthy of note that all these early investigators as well as those of more recent date, found that the alcohol, instead of undergoing digestive changes in the stomach like starch, sugar and other carbohydrates, was rapidly absorbed into the blood and with it permeated all the tissues and reappeared more or less in the excretions, while the products of combustion, *i.e.*, carbonic acid and heat, were both diminished. It became evident, therefore, that it could not be longer regarded a respiratory or heat producing food. But the fact that its presence uniformly retarded tissue metamorphosis and lessened the products of waste, having been well established, it was at once assumed that such retardation of tissue waste was equivalent to the same amount of actual nutrition, and therefore the alcohol must be regarded as *indirect food*.

This view was adopted by Dr. Hammond, who asserted that if the presence of a moderate amount of alcohol in the blood lessened the amount of waste products to the extent of four or six ounces in twenty-four hours, it rendered that much less food necessary, and hence he placed it with several other substances, in a distinct class of *indirect foods*. He was led by his own experiments to acknowledge that both the nitrogenous and non-nitrogenous or carbohydrate elements of our food were capable of entering more

or less into the formation of tissue and both capable of heat production; a position still more fully sustained by Dr. F. W. Pavy in his recent work on the "Physiology of the Carbohydrates."

The theory so plausibly advocated by Dr. Hammond that alcohol by retarding the molecular or katabolic changes in living tissues, actually became indirect or accessory food, rapidly acquired wide popularity and caused both medical and magazine writers to designate it the "savings-bank" or the "conservator" of the tissues, and gave a marked impetus to its use in the treatment of all diseases characterized by predominance of waste over that of nutrition. And though Dr. Hammond and all the more reliable experimenters agree that the presence of alcohol diminishes the animal temperature, many others still assert that it is mainly oxidized or "burnt up in the system," and that it "is a conservator of tissue, a generator of vital force, and may therefore be considered as food." (See Essay on the "Physiological Actions of Alcohol," by Dr. D. Cerna.)

Considering the very large amount of alcohol consumed by the people in the form of fermented and distilled liquors, the question whether it is capable of ever acting in the living body as food, either direct or indirect, or of generating vital force, is one of the greatest importance in its relations, both to the public health and to its therapeutic value as a medicine.

That alcohol undergoes no digestive or molecular change in the stomach, but is rapidly absorbed and mixed with the blood, has been demonstrated so completely that it does not need further discussion. That, while in the blood it does not furnish any material for either the growth or repair of any of the organized tissues, and consequently does not act as direct tissue food, is conceded with equal unanimity. That it does not act as respiratory or heat producing food, by uniting with oxygen or being "burned up" in the blood or tissues is proved by: 1, the fact that the temperature of the body diminishes in direct proportion to the quantity used until life ceases at a temperature from 5 to 10 degrees below the natural standard of health; 2, the fact that no investigator has been able to find any increase of the well-known products of its oxidation, namely, either aldehyde, carbonic acid, or acetic acid, although diligently sought for; and 3, the fact that it displays a much stronger affinity or attraction for the hemoglobin, albumin and water of the blood and tissues than for oxygen at the temperature of the living body. If it be thus conceded that the alcohol does not act in the living body as either direct tissue or respiratory food, does its known power to retard or lessen the ordinary katabolic processes, justify the inference that such retardation is in any physiologic sense equivalent to the same amount of nutrition, and that it is therefore an *indirect food*? In other words, is retarding katabolism or tissue disintegration, physiologically equivalent to the same amount of anabolism or tissue building? If it is, any person ought to be able to live well on notably less ordinary food by taking regularly a given quantity of alcohol, opium, tobacco, or any other agent capable of retarding the tissue waste, and yet be able to do the same amount of work, mental and physical. But the abundant facts of human experience in every climate, in every relation of human life, and every kind of occupation, deny the truth of the supposition. Again, if retardation of waste was in any proper sense equivalent to nutrition, an individual ought to be

able to live much longer on nothing but diluted alcohol, as in fermented and distilled liquors, than he could on pure water alone. But while we have quite a number of examples of men living on nothing but water forty or fifty days, I have never seen or learned of a well authenticated case of a man taking, or receiving into his system, nothing but diluted alcohol for half of that length of time, without becoming sick with either gastro-duodenitis, nephritis or delirium tremens.

It is not necessary, however, to appeal to the facts of human experience in determining the question before us. A careful study of the conditions and processes necessary for both tissue building or nutrition, and tissue waste or disintegration in all the higher orders of animals, will show that neither process can be materially retarded without retarding or preventing the other. Both processes take place only in bioplasm or vitalized matter supplied with oxygen, water and heat. Neither the assimilation of new material, food, nor its use in tissue building can be effected without the presence of free oxygen and nuclein or corpuscular elements of the blood. And without the presence of the same elements we can have no natural tissue disintegration and removal of the waste. The processes of tissue building and tissue disintegration are, therefore, so intimately related and dependent upon the same materials and forces that neither can be either hastened or retarded from day to day without influencing the other. When alcohol or any other substance, introduced into the blood, retards the tissue waste, as shown by the diminished amount of excretory products, it must do so by either diminishing the amount of free oxygen in the blood; by impairing the vasomotor and trophic nerve functions; or by direct impairment of the properties of the nuclein or protagon elements of the blood and tissues.

The popular idea, both in and out of the profession, is, that the alcohol by further oxidation in the blood lessens the amount of oxygen to act on the tissues, and generates heat or "some kind of force." Those who advocate this theory of saving the tissues by combining the oxygen with alcohol, seem to forget that in doing so they are diverting and using up the only agent—oxygen—capable of combining with, and promoting the elimination of all natural waste products as well as the various toxic elements causing disease. But the theory that alcohol directly combines with the oxygen of the blood by which it would be converted into carbonic acid and water with evolution of heat, is completely refuted by the well-known fact that its presence in the blood diminishes both temperature and elimination of carbonic acid as already stated. Physiologists of the present day very generally agree, that the capacity of the blood to receive oxygen from the alveoli of the lungs, and convey it to the systemic capillaries and various tissues, depends chiefly on its hemoglobin, protein or albuminous and saline elements.

Both experimental and clinical facts in abundance show that alcohol at all ordinary temperatures displays a much stronger affinity for these elements of the blood and tissues than it does for oxygen. And when present in the blood, it rapidly attracts both water and hemoglobin from the corpuscular and albuminous elements of that fluid, and thereby diminishes its reception and distribution of oxygen. We are thus enabled to see clearly how the alcohol

diminishes the oxygenation and decarbonization of the blood and retards all metabolic changes both of nutrition and waste without itself undergoing oxidation with evolution of heat. Consequently, instead of acting as a shield or conservator of the tissues by simply combining with the oxygen, the alcohol directly impairs the properties and functions of the most highly vitalized elements of the blood itself, and thereby not only retards tissue waste but also retards the highest grades of nutrition and favors only sclerotic, fatty and molecular degenerations as we see everywhere resulting from its continued use.

Can an agent displaying such properties and effects be called *food*, either direct or indirect, without a total disregard for the proper meaning of words? And if not, can it act as a generator of vital or any other natural force in the living body?

The recognized physiologic forces belonging to the human body are, vital force; heat force, muscular force and nerve force. Vital force is that property of bioplasm or vitalized proteid matter, that is manifested in such molecular or metabolic changes as constitute nutrition, secretion and excretion, or growth and decay. Consequently the best test or measure of the *vital force* in any body, is the degree of activity of its metabolism; and yet it has already been shown that one of the most marked effects of the presence of alcohol, is the diminution of this same metabolism, and with it a loss of heat also. That it does not generate or increase muscular force or contractility, but the reverse in a marked degree has become so well known, that entire abstinence from its use has become an imperative rule in *all* intelligent training for exhibitions of the greatest muscular strength and endurance. Nerve force is manifested in two ways, namely, sensory, or acuteness of sensibility, and conducting or transmitting. That alcohol diminishes both these functions of nerve structure in direct proportion to the quantity present in the system, has been demonstrated by its use as an anesthetic, and by the application of instruments for the actual measurement of the acuteness of sensibility and the rate of transmission, under the influence of doses varying from 4 c. c. to 100 c. c. From the foregoing review it will be seen that alcohol when present in the system positively diminishes vital force as measured by molecular or metabolic activity, reduces temperature, lessens muscular force, and impairs nerve force both transmitting and sensory, in direct proportion to the quantity used. And yet, simply because a large part of the alcohol taken has not been actually reproduced in the excretions and eliminations, a large proportion of writers continue to assert that it "must, therefore, be oxidized in the body, thus serving the purpose of a food and in this manner generating *force*."

The same writers when asked what kind of *force* is generated, quote Dupré as having "shown that 1 gram of alcohol oxidized in the organism yields 7,184 heat units, while the same weight of lean beef evolves only 1,482 heat units." And therefore "two ounces of alcohol generate a *force* equal to that generated by a little over nine ounces of lean beef;" thereby leaving us to infer that heat is the force generated. And still the stubborn facts of both experiments and daily observations, show that nine ounces of beef a day maintains a man's temperature and other forces quite well, while on two ounces of alcohol per day

his temperature diminishes together with every other known physiologic force manifested in the living body. And if it continues to be used daily for a number of years, instead of "conserving," it results in molecular degeneration in almost every tissue of the body, as seen in all cases of chronic alcoholism.

But why so persistently assume that the alcohol *must* be oxidized in the system, when it is fully demonstrated that it displays a much greater affinity for the water, albumin, hemoglobin, and nuclein of the blood and tissues than it does for the oxygen? Is it not quite possible that it is held in molecular or atomic combination with the protein elements named? And is not such a supposition much more in harmony with all the facts belonging to the subject?

Certain it is, that in its origin and its effects on the functions and structures of the living body, it is wholly unlike every other substance recognized as food. Instead of being a natural product of either vegetable or animal growth, alcohol is the well-known active toxic product of bacteriologic culture, neither digestible nor capable of assimilation, but pervading readily all parts of the system, and producing effects closely analogous to those produced by ether and chloroform, and usable for the same purposes. Then why longer delude the public and aid in deteriorating the public health, by calling it either a food or a generator of some kind of imaginary force?

PERITONEAL SUPPORTS—(LIGAMENTUM PERITONEI).

BY BYRON ROBINSON.

PROFESSOR OF GYNECOLOGY POST-GRADUATE SCHOOL,
CHICAGO.

(Continued from page 418.)

The lesser bag extends in young subjects from the cardiac end of the stomach to the pelvis and from the transverse fissure of the liver to the spleen. Beside this wide extension of the sac does not long remain. The cavity begins to lose its completeness at the lateral circumference during childhood. Coalescence encroaches upon its borders. Adhesions of its closely applied walls begin early on the lateral edges. This coalescence appears to me to be the result of local peritonitis. However, coalescence occurs in distinct localities of the lesser sac, so far as my examinations are concerned. These definite localities are: (a), the pars omenti colica; (b), the ligamentum phrenico-colicum; (c), the omentum colicum Halleri; (d), on the posterior surface of the ligamentum gastro-lienalis. So far as regards the pars omentum colicum, every anatomist knows that it coalesces. Its two double-bladed layers become adherent in early adult life. No explanation of this cohesion has attained general recognition. It appears to me that the coalescence is due to peritonitis and the only reasonable explanation which I can offer is that as the folds of the omentum lie on the bowel, microbes or their products pass through and induce peritonitis in the pars colica omenti; I mean that portion of the omentum below the transverse colon, in other words I mean the colic part of the omentum. The blades of the pars colica can be definitely separated in children and sometimes in adolescence, but as a rule the blades coalesce early and in places almost completely. I have found in autopsies that

patches of the pars colica omenti would be adherent to the bowel surface due to local peritonitis, and there was no doubt that the infection had passed from the bowel lumen through its walls. Others may argue that the colica part of the omentum coalesces from absorption of the endothelial layers and consequent adhesions, the absorption being due to lack of nourishment. His's followers would say the serous endothelium being not genuine, acts just like connective tissue cells and coalesces when and where it chooses, but they do not tell us why the coalescence rules so frequently in the pars colica omenti and not other places. Another explanation I offer myself, but not so reasonable as the first is, that the double blades of the pars colica omenti lie on a movable digestive tube and it might induce enough friction by peristalsis to cause a (plastic) peritonitis. The region of the ligamentum phrenico-colicum and gastro-lienale may be taken together and constitute the chief coalescence found so frequently

diverticle. One can find simple adhesions, cicatricial bands and depressions or narrow-necked sacs constricted off. The chief place for constricted off sacs are in the ligamentum phrenico-colicum. Some of the sacs may be completely closed. Multiple adhesions occur immediately to the left of the septum bursa omentalis. Adhesions of various kinds, cicatrices, peritoneal depressions, sacculations and completely closed off spaces may be found at the right end of the lesser omental cavity along the flexuri coli hepatis or Haller's omentum. Hence, these coalescences which occur, as a rule, in the above named localities of the lesser omental sac limited its size in the adult. They allow considerable encroachments on the border surfaces, lessening materially the circumference of the sac. The coalescence occurs at the lateral edges or places where friction or infection are liable to arise. As regards the neck of the sac, orificium epiploicum, I have found it closed in two of the many subjects examined. It nearly

Fig. 43 (After Henle, 1873) represents a horizontal section of a new bone through the under border of the 1st lumbar vertebra, Va 1 to show the disposition of the peritoneum and viscera. The section passes through Winslow's foramen and the bursa omentalis. The upper surface: 1, aorta; 2, posterior liver lobe; 3, left kidney; 4, ligamentum phrenico-lienale or better vena splenic ligament. I have found it well marked in many bodies; 5, spleen; 6, ligamentum gastro-lienale; 7, pylorus; 9, ligamentum suspensorium hepatis; 10, beginning of duodenum with its transverse portion; 11, cut surface of the liver whose overhanging border fell under the gall bladder; 12, cystic duct; 13, sharp border of the ligamentum hepatico-venale together with the portal vein and hepatic artery; 14, orificium epiploicum; 15, sharp border of the ligamentum hepatico-venale; Observe that the real entrance to Winslow's foramen is bounded by the gastro-hepatic ligament and the hepatico-venal ligament; 16, right kidney; 17, pancreas; 18, vena cava. This excellent diagram shows well the disposition of the peritoneum and the relations of viscera.

at the left end of the lesser omental sac. I have found some coalescence at the left end of the lesser omental bag in nearly every adult body. The spleen is the organ around which the adhesions chiefly occur. Infection and constant motion must induce the peritonitis. The dilatation and contraction of the stomach (movement), the proximity to the flexura coli lienalis where infection is apt to arise from sharp foreign bodies abrading the mucosa as they pass around the acute bowel flexure, and the disturbances of the spleen, may account for so much and so frequent coalescence found in the left end of the lesser omental sac. The coalescence takes on peculiar forms in the left end of this peritoneal

always admitted one or two fingers and hence varied in size, but I can not, so far, report definite adhesions distinctly around the mouth of Winslow's foramen, except in two cases which were closed. Of course the gall bladder region is a great peritonitic region, but its inflammation belonged to the gall bladder or the flexura colica hepatis and occasionally to the pylorus and not to the hiatus Winslowii. In several cases adjacent inflammation made it appear that the foramen was closed, but careful investigation showed that it was not, but free from cicatricial tissue.

In the adult omentum or mesogaster there are three segments that may call for a few remarks. There is

1. The mesogaster which belongs to the stomach more strictly. It arises in the mid-dorsal line and passes to the greater curvature. But in the adult this purely stomach segment of the mesogaster is somewhat changed on account of the left blade of the mesogaster being displaced toward the left and the right blade following and becoming fixed against the posterior dorsal wall, that is, the mesogaster forms a part of the parietal peritoneum of the dorsal wall from displacement toward the left. The stomach mesogaster also forms part of the lesser omental cavity. It contains also between its blades, the body and tail of the pancreas. In an adult dog one can note the mesogaster exactly in the mid-dorsal line. It has never shifted its blades to the left and become part of parietal peritoneum of the dorsal wall by displacement or coalescence. This condition of part of the mesogaster becoming part of the dorsal parietal peritoneum in man is no doubt due to the liver pushing the stomach to the left, and forcing the stomach so strongly against the mesogaster that it displaces it (or possibly coalesces it).

Fig. 44 (modified from Testu) illustrates the formation of the great omentum and its relations to the transverse colon. Hep, liver; S, stomach; 1, gastro-hepatic omentum; 5, bursa omentalis; P, pancreas; 2, gastro-colic omentum of the future in which is directed an arrow; D, duodenum; 3, mesocolon; T. c. transverse colon; 4, mesenterium; I, small intestine. The author does not indicate that the lower or anterior blade of the mesogaster and the upper (anterior) blade of the mesocolon is drawn out but this figure suggests that these two layers coalesce.

2. The next segment of the mesogaster, which is altered in the adult, but is a distinct portion of it is the mesoduodenum. In the adult the mesoduodenum appears to be absent, but it is an error to consider it absent. My dissections show the mesoduodenum present. In its mesentery, one can find the head of the pancreas, the lymphatics and nerves and blood vessels all arranged just as in the mesentery of the small intestines. The blood vessels show arcs and arcades, but the mesoduodenum in the adult consists of only the membrana mesenterii propria minus the two shining serous endothelial layers which cover other mesenteries. But the membrana mesenterii propria is a true mesentery though it lacks the shining endothelial layers. The mesoduodenum reaches from the pylorus to the flexura duodeno-jejunalis. It must be remembered that every portion of the bowel must possess the membrana mesenterii propria because it is the neuro-vascular visceral pedicle on which its

life depends. The open spiral ring, molded to fit the vertebral column, known as the duodenum, is no exception to the unalterable rule of possessing a membrana mesenterii propria though it does not possess the not absolutely necessary endothelial layer.

3. The third segment of the mesogaster is the anterior layer of the great omentum, *i.e.*, the pars omenti colicum or the pendulous portion of the blades below the colon. This part becomes the omentum colicum Halleri and ligamentum hepato-colicum on the right side. On the left side it merges into the ligamentum phrenico-colicum. In the middle it forms close relations with the transverse colon. The relations of the left end of the great omentum with the ligamentum phrenico-colicum and flexura coli lienalis I have gone over in the relation of the spleen to the peritoneum, as well as its right relations to the ligamentum hepato-duodenale et hepato-colicum and omentum colicum Halleri.

Fig. 45 (after Testu, 1892, modified) represents the relations of the mesogaster and mesocolon transversum just before coalescence. The figure suggests coalescence of the superior blade of the transverse mesocolon and the anterior (lower) blade of the mesogaster. The displacement theory is not entertained in the sketch; Hep, liver; 1, gastro-hepatic omentum; 5, bursa omentalis; S, stomach; P, pancreas; D, duodenum; 3, mesocolon transversum; T. C., colon transversum; 4, mesenterium; I, small intestine. The arrow shows the mesogaster elongated. The anterior blade of the mesogaster and the superior blade of the mesocolon would need to coalesce according to the figure. According to the displacement or readjustment theory they would be drawn out.

(To be continued.)

SOCIETY PROCEEDINGS.

Mississippi Valley Medical Association.

Abstract of the Proceedings of the Twenty-first Annual Meeting, held in Detroit, Sept. 3, 4, 5 and 6, 1895.

The Association convened in the Strassburg Academy, and was called to order by DR. H. O. WALKER, of Detroit, Chairman of the Committee of Arrangements.

Prayer was offered by the REV. MARCUS A. BROWNSON, of Detroit.

DR. WALKER then introduced MAYOR PINGREE, who paid an eloquent tribute to the medical profession, and extended a cordial greeting to the Association.

The ADDRESS OF WELCOME on behalf of Detroit physicians was made by DR. J. HENRY CARSTENS, of Detroit.

DR. WALKER presented the President of the Association, DR. WM. N. WISHARD, of Indianapolis, who delivered the PRESIDENT'S ADDRESS.

He said the importance and advancement of Detroit were

represented by the standing and intelligence of the local physicians. He referred to the beginning of the four years course in medical colleges, and said that the fear that the new rule would operate to the disadvantage of the smaller schools was unfounded. The President urged the advisability of publishing the records, papers and discussions in some manner to make them accessible to all members. He recommended a permanent executive committee, and regretted that the large number of papers necessitated the holding of two meetings at the same time. He commended the preparations for the convention, and pledged his earnest efforts to the promotion of the profit and pleasure of the convention.

The reports of the Secretary and Treasurer were read and accepted.

The reading of papers was proceeded with, the first one being read by Dr. THOMAS HUNT STUCKY, of Louisville, entitled

THE GOLD COMBINATIONS AS ALTERATIVES.

At a meeting of the Medico-Chirurgical Society of Louisville, April 5, 1894, the author had the pleasure of exhibiting a series of cases who had been taking the preparations of gold and arsenic, known to the profession as *arsenauro* and *mercauro*. He was under the impression at that time that the good effect claimed was produced in three ways: 1, by stimulation of the secreting glands of the stomach; 2, by the probable alterative effect upon these secretions; and 3, that probably there was a local antiseptic influence exerted. The class of patients in which he had used the preparations were people afflicted mostly with consumption, Bright's disease in its various stages, chronic hepatic troubles, and convalescents. He made it a rule with all these cases to withdraw all medicines except the combinations of gold and arsenic. He had selected from a series of cases four or five, which he detailed.

Case 1.—Patient, a male, 60 years of age, with tuberculosis. History good. Eight drops of the mercuric bromid of gold and arsenic were given hypodermically every four hours, this treatment being continued for two months. No deleterious results were noticed. On the contrary, he is decidedly better; physical condition, color, appetite and bodily strength improved.

He reported a few cases out of a large number to demonstrate, in his judgment conclusively, that by the combinations of gold and arsenic we have an agent acting as neither of the minerals do when administered separately, or in other words, we have an entirely new agent in so far as therapeutic action is concerned.

The author then dwelt at considerable length upon the chemic differences between the chlorid of gold and sodium, and the bromid of gold and arsenic (*arsenauro*) with reference to their therapeutic action and subsequent elimination. He believes that in the action of the combination of bromid of gold and arsenic, it is entirely different from any therapeutic agent known. As compared with *mercauro*, iodin or the combination of iodids, the action of gold in the combinations named is greater and intensified; that these combinations enter into the circulation as gold and arsenic, and spend their force and exert their influence in an alterative way upon the glandular system; that a marked alterative effect is exerted upon all scleroses (non-malignant); that it is not only a blood-maker, but a blood-builder; that it not only increases the quantity, but the quality of the corpuscles; that under its use hemoglobin is markedly increased; that it is eliminated by the kidneys; that they produce no irritation either when given per orum or hypodermically.

Cases corroborating the beneficial and curative effects of the preparations mentioned by the essayist were reported by Drs. A. P. Buchman, I. N. Love, and Wm. F. Barclay.

The following paper was read by Dr. Wm. F. BARCLAY, of Pittsburg:

LEGITIMATE PHARMACY.

He defined legitimate pharmacy as that which meets the necessities and demands of the regular medical profession and the people. The medical profession is entirely separate and distinct from pharmacy. Medicines are divided into four classes; patented, proprietary, non-proprietary and secret. There are a large number of cures, mixtures and tonics bearing the name of their originators and deserving of consideration as proprietary preparations. Pharmacists and physicians are interdependent and should work together. Legitimate pharmacy has called into service educated and able men, but the incompetent and dishonest have got in,

too, and can not be too severely condemned. Pharmacists make errors, but physicians are careless, too, in writing prescriptions. Physicians should not favor any particular pharmacist and should not receive pay from them. On the other hand, it is unworthy and unprofessional for pharmacists to prescribe drugs or medicines. Legitimate pharmacy should protect the people from the nostrum-makers. Physicians have a right to require the highest skill and competency upon the part of the pharmacist, both for their own interest and the good of their patients.

Dr. F. E. STEWART, of Detroit, read a paper on

COD-LIVER OIL.

He considered the powerful stimulant action of cod-liver oil on nutrition, also demonstrating with specimens the difference in the color of oil digested from fresh livers and that prepared from putrid livers; the former being pale, golden or light brown, according to the number of hours digested, and the latter dark brown. The darker oils contain more extractive matter. Dr. Stewart said the text-books contained many errors regarding the preparation of cod-liver oil.

DISCUSSION.

Dr. I. N. LOVE, in the discussion, conceded the merits of the paper, but expressed himself as rather skeptical as to the value of cod-liver oil. He declared that there was danger of our getting too professional, and said that that which brings relief to the patient is to be commended. He favored proprietary remedies which have come to the profession through pharmaceutical channels.

GYNECOLOGY AND ABDOMINAL SURGERY.

Dr. TOD D. GILLIAM, of Columbus, Ohio, read a paper entitled

UTERINE FIBROIDS—WHEN TO OPERATE.

The medical and electrical treatment of uterine fibroids is to-day in a very unsettled state. While it can not be denied that amelioration or even recovery has followed such lines of treatment, there has not been that degree of uniformity in results calculated to inspire confidence. To the author's mind, there is no better field for a competent observer, than the study of the natural history of uterine fibroids. It will enable us to determine the true value of so-called curative agencies. It will insure a more certain prognosis. It will give the proper cue to surgical interference. If, out of 100 cases, 90 suffering women can be restored to lives of usefulness and happiness, would it not be better to give them a chance? No surgeon is justified in doing hysterectomy or the more serious operations for uterine fibroids when the patient has not experienced sufficient trouble to make it a menace to her life.

Dr. L. H. DUNNING, of Indianapolis, Ind., read this paper:

TUBERCULAR PERITONITIS.

In the domain of surgery there is no more attractive study than tubercular peritonitis. The mode of invasion, forms of the disease, diagnosis and treatment were considered in the paper, and finally a brief history of five cases was given.

Tubercular peritonitis, with effusion, is now universally considered a surgical disease. Even in the acute suppurative cases, abdominal section yields a sufficient number of successes to render its employment imperative. Senn excludes all forms of the disease from surgical treatment except the exudative form. Manclaire gives as the chief contra-indications to surgical treatment, the generalization of the lesion, and the existence of profound systemic infection. Linder analyzes the results in 205 operations, with a mortality of 75 per cent. The deaths resulting in most of these cases were from collapse. In cases of involvement of the tubes and ovaries, they should be extirpated. His experience, in two cases leads him to the belief that we should, if possible, avoid using silk ligatures in tying the pedicle when it is necessary to remove the uterine appendages.

Case 1.—Mrs. A. B., aged 56 years, consulted the author concerning the extirpation of a fibroid tumor of the uterus. She had passed the menopause five years previously, but the tumor had gradually increased in size. At the time of examination, it had reached the umbilicus. There was a small amount of fluid in the abdomen, and on opening it probably a quart of clear straw-colored fluid ran out. The peritoneum and intestines were studded with innumerable small grayish deposits of the size of a millet seed. Similar deposits thickly studded the serous covering of the tumor. The intestines were agglutinated, but were not adherent to the tumor. After removal of the tumor by supravaginal hysterectomy, and ventrofixation of the stump, the abdominal cavity was

irrigated, and then leaving the drainage tube just behind the stump, the abdominal incision was closed. Recovery.

In *Case 2*, a diagnosis of ovarian tumor had been made and examination revealed an accumulation of fluid in the abdomen which was encysted. The uterus was fixed and an immovable mass was outlined in the pelvis upon the right side, which the author believed to be a small ovarian tumor surrounded by inflammatory exudates. An exploratory incision was made, and three gallons of dark fluid evacuated from the abdominal cavity. A small tumor was felt in the pelvic cavity. The incision was enlarged, the tumor enucleated, and the pedicle tied off, together with the Fallopian tube. The left tube and ovary were likewise extirpated. On exposing the abdominal and pelvic cavities to view, it was seen that the viscera were thickly studded with small grayish deposits. Microscopic examination demonstrated the presence of tubercle bacilli. Patient now, eleven months after operation, in good health. Two of the five cases reported by the author terminated fatally.

DISCUSSION.

DR. GILLIAM, of Ohio, believes that where we have tuberculosis of the ovaries and tubes, it is better to remove the uterus, too.

DR. J. FRANK, of Chicago, asked whether any of the members, who had operated for tuberculosis of the peritoneum, had noticed a recurrence, or how long the patient was immuned from further attack.

DR. HUMISTON, of Cleveland, Ohio, reported two cases, upon which he had operated successfully.

DR. R. S. SUTTON, of Pittsburg, had seen a good many cases of tubercular peritonitis, upon several of which he had operated successfully. Until within a year he had been in the habit of washing out the cavity with hot water, but now he pays no attention to it, but simply opens the abdomen and cleans out everything. He is convinced that while hot water does no harm, it does no good in that it has no influence upon the disease. He believes in removing as far as possible, all diseased organs.

DR. HENRY O. MARCY, of Boston, operated in 1887 for the first time on a case of tubercular peritonitis, the patient making an easy recovery. He had operated several times since then for this disease with excellent results.

DR. A. H. CORDIER, of Kansas City, Mo., called attention to the fact that Mr. Wells, as early as 1862, operated for tubercular peritonitis, simply incising the abdomen and draining, thus curing his cases. He thinks that drainage is the principal thing that brings about a cure of this disease, but how, is not definitely settled. He said the theory had been advanced by Dr. Morris, of New York, that it is due to the admission of saprophytes into the peritoneal cavity.

DR. BAYARD HOLMES, of Chicago, related an interesting case of adhesive peritonitis cured by operation.

The paper was further discussed by Dr. W. S. Caldwell, of Freeport, Ill.; Dr. Entriken, of Findlay, Ohio, and Dr. B. M. Ricketts, of Cincinnati, Ohio.

DR. DUNNING, in closing, said that Linder's observations were the most complete of any, and he found very little tendency to recurrence of the disease where it was primary and of the adhesive form; but where the disease was secondary and of the adhesive form, there was a strong tendency to recurrence. His own experience had not been sufficiently extensive to furnish reliable data in this regard.

DR. BAYARD HOLMES, of Chicago, was the author of this contribution:

HYSTERECTOMY FOR PUERPERAL SEPSIS—WHEN SHALL IT BE PERFORMED? WITH A REPORT OF FOUR CASES.

The paper was divided into five parts: 1, a report of four cases of puerperal sepsis, treated by four different methods; 2, the pathology of puerperal sepsis in various stages; 3, curettement in the hands of its advocates; 4, puerperal sepsis as a cause of death in Chicago, New York, Brooklyn, and in the Charity Hospital at Berlin, with an abstract of 79 deaths from puerperal sepsis in 6,635 cases.

The first case was a multipara, 26 years of age, of Irish extraction, having a history of tuberculosis of the lungs, confined under unfavorable circumstances, with retained placenta, post-partum hemorrhage, delivered without an anesthetic with the hand of a physician, arrest of a hemorrhage, gradual sepsis, failure of curettement, and death seven weeks after confinement.

The second case was a woman 30 years of age, normal confinement, with sepsis appearing upon the fourth day, of mild character, gradually increasing until six weeks after delivery. Temperature was high, pulse rapid, and symptoms of peritonitis with obstruction of the bowels. Laparotomy.

Removal of the right broad ligament, tube and ovary; drainage through the vagina; death after eight days without peritonitis, from phlebitis and pulmonary embolism.

The third case was in a multipara with gonorrhoeal history, an abortion followed by pelvic inflammation, peritonitis and obstruction three weeks after delivery. Removal of both tubes and abdominal drainage; death after ten days without peritonitis through phlebitis and pulmonary embolism.

The fourth case was a multipara, 32 years of age, delivered by a midwife, with a bad history of puerperal infection, rapid onset of a mild infection, no curettement. Obstruction of the bowels, vomiting six weeks after delivery, with evidences of peritoneal effusion. Laparotomy; removal of the uterus and its adnexa, abdominal drainage and recovery. This uterus and these appendages were carefully examined microscopically. There was evidence of necrotic endometritis, suppurative endometritis, suppurative metritis, suppurative lymphangitis in both tubes with abscess of the ovarian ligament upon the right side and adjacent peritonitis. The blood vessels throughout the broad ligaments were found indicating a progressive infective thrombosis. The uterine tissue was filled with pus cells occupying the perivascular and lymph spaces with occasional obliteration of large blood vessels. A great number of mastzellen were found throughout the infected tissues. The author held that the progress of puerperal infection was in this case through infective thrombosis and suppurative lymphangitis, and that the removal of both tubes and drainage would have been ineffectual. He then proceeded to recount the pathologic findings in cases of non-infected puerperal women dying from accidental causes during the first, third and sixth weeks after labor, and also cases dying at somewhat similar times after labor, stating the comparison of the normal and the abnormal uterine and peri-uterine tissues.

Fourth division. In the city of Chicago, during the years 1881 to 1894 inclusive, there were 2,127 deaths from puerperal fever. In New York during six years ending May 31, 1880, there were 250,000 deaths, of whom one-sixth were females, and 2,236 of these deaths were due to the pregnant state. Of these, 1,250 were due to puerperal infection. In Brooklyn, with 112,000 deaths during the same period, 53,000 were females, and of these 867 died of the puerperal state, 462 dying of puerperal sepsis. These figures show the importance of the subject.

The question of treating puerperal infection by evident or curetting was discussed by presenting the work of its own advocates, showing that out of 7,600 cases of labor in the hands of one of the advocates of curettement, 101 were treated by repeated curettement and irrigation. Of these ninety-six recovered and five died.

An abstract of the history of these five cases was presented, showing that there was every reason to believe that after curettement had failed, hysterectomy would have proved efficient in saving the patients.

A series of 6,635 cases of confinement occurring in the Charity Hospital in Berlin, under the care of Hensoldt, Schwarze, Huenermann and Hochselter during four successive years were then analyzed. Seventy-nine deaths from all cases occurred. Of these deaths, thirty-three resulted from puerperal sepsis, and in order to fully understand the possibility of these cases, a short epitome of the history of each was presented, showing that only 3 out of 633 cases were of such character as to give rise to the suspicion that they might not have been saved by an hysterectomy.

The author gave the following conclusions: 1, puerperal sepsis has its origin in the endometrium, and usually travels by the lymph channels or by the thrombosed blood vessels and the lymph channels together; 2, it still causes almost one-half of the deaths which occur in the puerperal state; 3, curetting is ineffectual in many cases of puerperal sepsis; 4, the removal of an infected broad ligament and the drainage of a pelvic abscess or peritonitis is often ineffectual; 5, hysterectomy should be performed, therefore, in such cases of puerperal infection as do not yield to uterine curetting and irrigation; 6, hysterectomy should be done whenever peritonitis is present in the course of puerperal fever; 7, hysterectomy should be performed in cases of puerperal mania where there is a history of endometritis without uremia; 8, hysterectomy may not be helpful in the course of diphtheritic vaginitis and endometritis; 9, hysterectomy may not be helpful in cases of rapid early infection; 10, it may not be useful in cases of septic phlebitis reaching outside of the pelvis.

DR. WM. H. HUMISTON read a paper entitled

A METHOD OF PREVENTING THIRST FOLLOWING CELIOTOMY.

He said: No one who has had any experience in the after-

care of abdominal cases will deny the important place that thirst occupies. It is the one prominent, annoying and distressing symptom, and I know it can be overcome. This is my method of procedure:

The patient should have the usual preparation for celiotomy; i. e., diet, daily baths, cathartics, etc. For three days prior to operation, order the patient to drink one pint of hot water an hour before each meal and on retiring, thus drinking two quarts of water each twenty-four hours, the last pint to be taken three hours before the time set for operating. Do not omit to give the water the day previous to the operation, while the patient is restricted to a limited amount of liquid nourishment and the bowels are being unloaded. We thus restore to the system the large loss of fluid occasioned by the free catharsis, and we have the great satisfaction of seeing our patient pass through the trying ordeal of the first thirty-six hours after the operation in comparative comfort, with no thirst, a moist tongue, and an active renal function, represented by an excretion of from twenty-eight to fifty fluid ounces of urine during the first twenty-four hours, catheterization being seldom necessary. This is in keeping with the full character of the pulse noted.

The above details I have recently carried out in twelve cases. To eleven, chloroform was administered; to one, ether. The time required to complete the operation varied from ten to fifty-five minutes. Whether the case was one of sclerotic ovaries or a pus case with universal adhesions of all the pelvic structures, the result has been uniform and highly satisfactory, thirst being allayed and excretion stimulated.

I believe this method will prove to be efficient in the hands of abdominal surgeons generally, and I publish it early, with all confidence that the twelve cases that I have had will soon be fortified by the reports of many hundreds, and that by it we may avoid a condition that is and has been distressing alike to the patient, surgeon and nurse.

DR. MILES F. PORTER, of Fort Wayne, Ind., read this paper:

CELIOTOMY IN GENERAL SUPPURATIVE PERITONITIS, WITH THE REPORT OF A CASE.

The author first quoted Prandin, who says regarding general puerperal peritonitis: "The women die, no matter what the form of treatment employed." Dr. Baldy says: "To my knowledge, there has never been reported an undoubted case of general purulent peritonitis from any cause whatever, in which an abdominal section or any other line of treatment has succeeded in saving the patient's life." That the mortality of general septic peritonitis is large all will agree, but that it is always fatal is certainly not true. Dr. Porter then reported the case, and closed by saying that the object in writing the paper was to assist in arousing a sentiment against the too prevalent idea that in general septic peritonitis death is inevitable, and to encourage in these cases prompt operative interference.

DR. A. H. CORDIER, of Kansas City, Mo., presented the subject of

PERITONEAL IRRIGATION AND DRAINAGE.

In which he said that the latest works on abdominal and pelvic surgery contain, like the older text-books, very short and misleading articles on the indications for peritoneal irrigation and drainage, and still less explicit are the directions how to use these agents for good, intelligently and correctly. This diversity of opinion among authors leaves the inexperienced beginner in a position of perplexity and doubt as to the special course he is to pursue in his early work. The same principles hold good in draining the peritoneal cavity that are applicable to other parts of the body. No surgeon, with all the antiseptic precautions possible to be used in opening a diffuse abscess of the thigh or other part of the body, would think of such a thing as at once closing a wound hermetically, leaving many broken-down shreds of diseased tissue dangling in the abscess cavity. He might have irrigated the cavity thoroughly with a 1 to 1,000 solution, yet he would not feel it safe to close the wound until after he had made counter-openings and introduced a drainage tube, this being as near ideal surgery as it is possible to obtain in these cases. Freshly boiled distilled or filtered water, cooled to 102 or 110 degrees F., should be used in irrigating.

The author drew the following deductions: 1, drainage is a life-saving process when properly used; 2, to use it is not an admission on the part of the surgeon that his work during the operation is imperfect; 3, the use of the tube alone does not produce or leave any condition that favors the development of hernia; 4, the omentum, or other structures,

do not become entangled in the openings in the tube; 5, a small sized flint glass tube, with small openings and open end, should always be selected for pelvic drainage; 6, the tube does not produce fecal fistulae; 7, the tube should be used when in doubt as to the absence or presence of drainage indications; 8, to depend upon microscopic findings as to whether a given case should or should not be drained is seemingly scientific, but is neither necessary nor practicable; 9, gauze drains should rarely be used, and should always be supplemented by a glass drain; 10, there is no danger of infecting the patient through a tube if the attendant is properly instructed.

DR. J. HENRY CARSTENS, of Detroit, followed with a paper entitled:

THREE CASES OF HYSTERECTOMY FOLLOWING CELIOTOMY FOR PUS TUBES.

The author summarized his remarks as follows:

"1. It seems to me in the light of my present experience in cases of bilateral pus tubes that a more perfect and complete operation can be performed by abdominal section, with less danger of injury to the bladder and intestines, and with smaller mortality and better ultimate results.

"2. That in certain cases a better immediate result is obtained by vaginal hysterectomy and drainage, but these cases frequently require a second operation to remove the ovarian tissue and parts of the tube, which at first in many cases can not be removed, before a perfect ultimate cure is established.

"3. Where the sympathetic and other nerves are affected, the cause is not in the uterus, ovaries or tubes alone, but part in each. We are unable to state which organ is at the bottom of the trouble. Sometimes it may be only one, sometimes the other, sometimes two or all three; hence, in such cases I would say:

"4. In many cases with marked nervous symptoms, the best results are obtained only after the complete removal of every particle of the generative organs—that is, uterus, tubes and ovaries—be this accomplished at one, two or three operations, per vagina or by abdominal section."

DISCUSSION.

DR. R. S. SUTTON, of Pittsburg, favored abdominal section for pus tubes. He maintained first and foremost that a uterus deprived of its appendages is of no use. Second, that it is an organ, if left, which is liable to tuberculosis, gonorrhoea, syphilis, discharges, adhesions, etc. When it is decided to remove the appendages, the uterus also should be taken out.

DR. GILLIAM, of Columbus, Ohio, argued against the removal of the uterus with the appendages in order to save life, the objection being that shortening of the vagina resulted.

DR. B. M. RICKETTS, of Cincinnati, believes total extirpation will be relegated. The dangers are cystocele, hernia, increased danger of prolonging the operation, and shortening of the vagina.

DR. HENRY O. MARCY, of Boston, favored retaining the cervix when it is healthy, and pointed out the reasons why it should not be removed. It helped materially in acting as a support to the vault of the vagina.

DR. HOLMES, of Chicago, in discussing Dr. Cordier's paper, said that drainage was a sort of vicarious redemption for poor surgery. Whenever it is impossible to make a wound clean we must drain, and sometimes we drain when the wound is clean, but we are unable to arrest the hemorrhage. He could conceive of no other indication for drainage, whether in the abdomen, the brain, or any other part of the body, than failure to meet one great indication of wound treatment—to keep the wound clean.

DR. GEORGE W. CALK, of St. Louis, read a paper entitled

TWO SUCCESSFUL OPERATIONS FOR TRAUMATIC INSANITY.

The author said that insanity due to injuries of the head is of rather infrequent occurrence. In 2,200 cases of insanity, treated by Kiernan, 45 were of traumatic origin; while Hays records 61 due to the same causes, out of 2,500 cases. Schlager reports 500 cases of insanity due to concussion of the brain. The author then considered the causes and symptoms.

Case 1 was a male, 26 years of age, carpenter by occupation. Family history good. No case of insanity or of serious nervous disease had ever been present. June, 1885, the patient received a blow from a club in the hands of a negro, the wound inflicted being midway between the fissure of Rolando and the external occipital protuberance, slightly to the left of the median line. It was treated as an ordinary

scalp wound, as it suppurated for three months. Four years after the inception of the wound, he complained of severe pain in the left parietal and occipital regions of the head. October, 1888, he was sent to an insane asylum, where he remained sixteen months. His condition improved, he returned home, but was again sent back to the asylum, where he was detained five months. Four months later he was brought to Dr. Cale, who diagnosed traumatic insanity; advised operation, which was consented to. Recovery.

Case 2 was one of acute mania, following a trauma. Operation performed the same as in Case 1. Recovery.

DR. WILLIAM FULLER, of Grand Rapids, Mich., had operated on two cases of insanity, due to traumatism, one in Montreal in 1870. The patient was discharged from an insane asylum as incurable. When the dura mater was opened, there escaped some serum. A few days subsequent to the operation, the patient was rational, but as soon as the wound closed up the hallucinations returned. He then punctured the brain in two or three different directions with no result except to establish drainage. The man died two months later, and a post-mortem examination revealed a tubercular abscess in the fissure of Sylvius, containing about two teaspoonfuls of pus. The other case was due to syphilis, and was relieved by the removal of the pressure from that disease.

DR. J. FRANK, of Chicago, reported an interesting case of insanity in which he trephined, removing a large piece of bone. A piece of the brain was also excised for examination, and seemed to be healthy. The patient, after being in an insane asylum for five years, made a complete recovery, and took up the thread of life where she left it. She continued in this way for one year, then relapsed. What was the reason of her recovery? In opening the dura, there was a gush of cerebral fluid. Dr. Frank firmly believes that it is not the depression of the skull which produces the bad result, but that at the time of the injury there is a chronic inflammation of the meninges, or a slow inflammatory process, which throws out cerebral fluid. This fluid may be in the ventricles between the dura and the brain, or in the tissues of the brain filaments themselves, and the theory of concussion, held by the profession, he believes is erroneous. He had repeatedly made experiments on dogs by rapping them on the head and rendering them insensible, and immediately thereafter, effusion was found.

DR. MAAS, of Detroit, thought we were in the dark as to the exact cause of the insanity in many cases, and that there was evidently some vasomotor disturbance.

DR. MAAS then read a paper which was largely a statistical one, in which he pointed out the comparative value of the medical and surgical treatment of appendicitis.

DR. WILLIAM E. WIRT, of Cleveland, Ohio, read a paper on THE USE OF DRY HEAT OF HIGH TEMPERATURE IN THE TREATMENT OF JOINT DISEASES.

Shortly after reading a description of this treatment in the medical journals, the essayist encountered a case of rheumatoid arthritis, in which he resorted to this method. The treatment was followed by great improvement in the motion of the joint, and in the comfort felt by the patient. He also reported a case of rheumatism of a year's standing, in which there was more or less fixation. He broke up the adhesions, made use of the high application of heat, and raised the temperature to 290 degrees, which was followed by decided improvement in the ease with which the patient could move the joint and the relief from pain.

DR. CARTER S. COLE, of New York, presented a paper on
ULCERS OF THE LEG; ALL CAN BE CURED.

What constitutional conditions obtain that favor morbid states, or that retard a return to a healthy state, such a diathesis receives its proper treatment, whether or not ulcers exist. For systematic purposes, ulcers of the leg were designated by the author according to their appearance as healthy, irritable, indolent, etc. In intractable cases, he is inclined to place foremost thorough washing with soap and water and good scrubbing with a stiff bristle hair brush. If the ulcer be inflamed, irritable or painful, anesthesia may be required for this and subsequent steps. The next step is a thorough cleaning out of all soft granulations, and the base of the ulcer with a sharp curette. The edges of the ulcer are freed from their attachment, and in many cases with a curved sharp bistoury he nicks the circumference at intervals of about one-quarter of an inch. If much hemorrhage follows, a pad of gauze wrung out of a 2 per cent. solution of carbolic acid is placed over the wound, and a firm compression bandage from the toes to the knee applied, the wound having been previously cleansed with the carbolic solution. The

dressing, when used, is allowed to remain for twenty-four or forty-eight hours, after which he considers the ulcer to have become a simple one, and amenable to treatment as follows: no further lotion is used. The wound is wiped off with dry cotton, and over and completely covering it, he places strips of diachylon plaster to protect the ulcer. Over the surgeon's plaster he applies a pad of sterilized gauze, held in place by strips of rubber adhesive plaster, or often simply by a bandage. He then uses a firm muslin bandage from the toes to the knee, making equable compression. Bandaging should be carefully done. Sometimes he uses two bandages three inches wide and eight yards long. This bandage is not removed unless the discharge comes through, or the leg becomes painful, or the bandage gets loose. When he re-dresses the ulcer, he again uses simply dry absorbent cotton to cleanse the wound, and proceeds as before. Often after two or three dressings, the bandage may remain five to seven days without being disturbed. In some cases a thin scum forms on the ulcer, which must be removed by going over the surface lightly with a curette. With this treatment, in ordinary cases about three weeks will suffice for an ulcer of even a dozen years standing. In extraordinary cases, as much as six weeks may be necessary.

DR. EUGENE FULLER, of New York city, presented an article on

HOW TO DIAGNOSTICATE SEXUAL DERANGEMENTS IN THE MALE.

The author endeavors to impress upon the profession the fact that in the majority of instances, sexual derangements in the male are caused by pathologic processes in or about the seminal vesicles, and further, that they accomplish their results by interfering with the mechanism of ejaculation. He calls attention also to the fact that this side of the question has been almost wholly neglected by preceding writers on sexual disorders, who have devoted themselves largely to psychologic conditions in this connection, the result being that the great majority of the profession associate sexual disturbances with some radical mental defect. Sexual derangements in the male should be diagnostically arranged in four classes: 1, those dependent on seminal vesiculitis; 2, those dependent on neuroses; 3, those dependent on primary mental disease on degeneration; 4, those dependent on general malnutrition and debility. The order of this classification corresponds to the frequency with which these different forms of diseases are encountered in practice. In explanation of the first class of causes, the writer states that it is needless to go into details, since he has recently reviewed that subject very fully in his book, just published.

Where seminal vesiculitis exists, there is generally a previous history of urethral or bladder inflammation, sexual abuse and the like, all of which are agents tending to produce localized inflammation in the seminal vesicles.

The second class of causes either inhibit or excite the sexual center by means of reflex nervous action.

The third class of causes includes the different forms of paranoia, in which the sexual sense exists in a perverted form.

The fourth class of causes is a small one. It includes individuals, generally young or middle-aged, who make complaint that they are capable of little sexual exertion and that feelings of prostration and exhaustion result whenever coitus is attempted.

Dr. Fuller then takes up the clinical examination. In conclusion, the writer makes some special remarks on the different appearances that the varying grades of seminal vesiculitis present to the sense of touch, and calls attention to the fact that in cases of extensive perivesiculitis, involving both sacs, an inexperienced examiner is liable to err in diagnosis, mistaking the condition for hypertrophy or inflammation of the prostate. The author holds that to become perfected in the feel of the seminal vesicles, the finger needs as much practice as does that of the gynecologist in feeling the ovaries and tubes. To obtain the necessary practice, he advises the genito-urinary surgeon to make it customary to examine in this manner every male case coming into the clinic until all normal and pathologic conditions can be fully appreciated.

DR. S. P. COLLINGS, of Hot Springs, Ark, read a paper on
CHRONIC SEMINAL VESICULITIS WITH HEMORRHAGE.

He said there has apparently been little known of the pathologic condition of the seminal vesicles until within recent years. The usual cause of this trouble is the extension of gonorrhoeal inflammation from the prostatic urethra through the ejaculatory duct into the vesicle itself; at least, there is usually a history of a former gonorrhoea with a chronic deep urethral trouble remaining. The vesicles are

sometimes involved in very acute and severe gonorrheal inflammation with or without the implication of the cord and epididymus. They may also be involved with a tubercular inflammation, although practically never primarily.

One observer reports a case in which the autopsy showed that the vesicle was primarily involved. The most important symptom is the disturbance of the sexual function. The character and appearance of the seminal fluid is more or less changed. Its consistency is so increased at times that it is gelatinous. The diagnosis of subacute or chronic seminal vesiculitis would be difficult to make, were we to depend entirely upon symptoms in reaching a conclusion. They are vague and at times misleading except the appearance of the blood in the semen, which, if thoroughly mixed with it, would determine a diseased condition of one or both vesicles at once. The author reported two cases, discussed the treatment as applied to them, as well as that generally used in the subacute and chronic forms.

In conclusion, he said that if inflammation of the vesicle occurs in one whose urethra is strictured, cure the stricture before we can hope for permanent results in vesical treatment.

DR. C. T. DRENNEN, of Hot Springs, Ark., read a paper on

SYPHILIS AND ITS TREATMENT.

The author spoke more directly of the treatment of this disease in connection with the use and abuse of certain so-called antisiphilitic remedies. He said, we are unable as yet to form definite conclusions as to the usefulness of serotherapy in the treatment of syphilis from the most recent researches, but the reports are quite encouraging, and there is hardly a doubt but that it possesses value in at least the tertiary lesions. Fournier believes the good effect to be due not to any specific, but to its rehabilitary effect upon the system. The author said, in closing, that the hot water at Hot Springs was well known to exert an influence peculiar in its effects for good, and in it we had a veritable Mecca for syphilis. That its action is eliminative, stimulative and antiseptic, and that larger doses of mercury and the iodid of potassium can be given without harm is known to the writer, based upon experience and observation; that its exact or specific action is unknown, and that its value is attested to by the multiplied thousands throughout the country, are propositions that are incontrovertible.

DR. WILLIAM T. BELFIELD, of Chicago, described and presented an instrument for the purposes of securing asepsis in bladder and prostate operations.

DR. THOMAS H. MANLEY, of New York city, read a paper on

THE ELEMENT OF VASCULAR COMPRESSION IN FRACTURE TREATMENT.

The author considered at length the anatomic structure and vascular function as related to fracture. The extent of damage borne by the vessels in a given case of fracture will primarily depend upon the degree and quality of force applied and the line of treatment adopted. In a series of experiments made during the past year on the blood and blood vessels, under a multiplicity of conditions in the lower animals under anesthetics, one question which the author spared no pains to definitely determine was whether in fracture, as a general rule, the circulation to the distal part of the limb was retarded in cases of fracture. Without entering into detail on the great diversity of vascular phenomena observed in a frog's webbing under the microscope, after single, multiple and compound fractures were produced, it will suffice to say that with few exceptions, immediately and for a considerable period of time after the bone was broken, the circulation in the capillaries and the smaller arteries was completely arrested. In several it was found that for several days all the smaller vessels were motionless, and in a few they so remained until after the fractured ends of the bones united. These experiments were extended to the mammalia, the shafts of the limbs of pups, kittens and adult dogs, of different ages and various sizes.

DR. H. O. PANTZER, of Indianapolis, Ind., read a paper entitled

THE SIGNIFICANCE OF FISSURE FRACTURES OF THE ARTICULAR ENDS OF THE LONG BONES.

He reported a case of fissure fracture involving the outer third of the head of the radius, having loose attachments to its body. An excessive callus had likewise developed in its site, without affecting union. This splinter and callus were removed, when re-position of the joint was easily attained. The crepitus felt at the first examination and the failure to find it again, should have suggested fissure fracture in the opinion of the author. When the first dressing was removed,

the limb seemed to present a perfect condition, and to promise full restoration. These prospects were changed as soon as passive and active mobilization was begun. The probability is that the attempts at mobilization for this kind of injury was begun too soon, and that they were at least partially responsible for the subsequent unfavorable developments. The author concludes that when undue painfulness and subsequent swelling with no gain or even a loss of mobility attends the efforts of mobilization after kindred lesions, we should delay further efforts at mobilization. The possibility of a fissure fracture should be considered in determining the diagnosis and treatment of all cases of joint injury.

DR. E. W. ANDREWS, of Chicago, contributed a paper entitled "Imbrication or Lap Joint Method—A Plastic Operation for Hernia." (See JOURNAL June 15, p. 934.)

DR. CHARLES A. L. REED, of Cincinnati, presented a paper on

FURTHER OBSERVATIONS ON THE RADICAL CURE OF RUPTURE BY THE INTRAPELVIC METHOD, WITH ILLUSTRATIVE CASES.

In what essential particulars does this intrapelvic method differ from the several methods of radical operation now in vogue? It differs, in the first instance, in the fact that it is intrapelvic, while the others—Bassini's, Halsted's, McBurney's, Macewen's—are extrapelvic. The essential point of difference between Dr. Reed's operation and that of Bassini, consists in: 1, leaving undisturbed the extremely tense fascia composing the anterior wall of the ring; 2, in leaving the cord in the position which Nature designed for it, and entirely protected by the normal fascia; 3, in closing the internal ring on the inside of the pelvis, and in protecting it by a strong peritoneal pad; 4, in avoiding the menace to virility arising from a transplantation of the cord, its possible constriction by an artificial ring of tense fascia, and its necessary investment by an inflammatory exudate; 5, in increasing the resistance of the parts by fortifying the fascia comprising the anterior wall of the ring, and by increasing and making permanent the obliquity of the cord within its normal canal.

The advantages of the operation consist in securing by the unfolding of the redundant but attenuated median fascia, the formation of a column which, when consolidated by inflammatory adhesions, has a certain retentive and supportive power the influence of which is of value in preventing recurrence. The anchorage of the recti in the median line restores the retentive power of the wall.

DR. HENRY O. MARCY, of Boston, followed with a paper entitled

SURGICAL TREATMENT OF HEMORRHOIDS.

This paper was in the nature of a reply to the strictures cast upon the Whitehead operation by Dr. Edmund Andrews, of Chicago, in a paper read before the last meeting of the Illinois State Medical Society. Dr. Marcy believes that if in the statistics given by Dr. Andrews the names of the operators were mentioned, most of the disastrous results will be found to have followed the work of incompetent men. His results had been excellent in those cases in which he had done the Whitehead operation, slightly modified by himself.

DR. JOHN RIDLON, of Chicago, read a paper on

CLUB FOOT,

which he defined as a distortion of the foot in its relation to the leg. The simple and compound varieties of club foot were dealt with. Nearly all of the congenital cases present the compound variety—equino-varus; a few present equino-valgus; rarely there is seen a simple calcaneus. Of simple equinus, the author had met with but a single instance, and of simple varus and simple valgus, he had seen none. Of the acquired variety, simple equinus is by far the most frequently found; next in frequency we find simple valgus; then equino-varus; calcaneo-valgus, equino-valgus, simple varus, and varus in one foot and valgus in the other. The acquired deformity occurs more than three times as frequently as the congenital form. The etiology of the congenital forms was next dealt with, as well as of the acquired forms. Then followed the symptoms, diagnosis and prognosis.

The treatment of club foot is mechanical or operative, or both mechanical and operative. Both these measures were dealt with at length.

DR. E. E. TULL, of New York, read a paper on "Vaginal Castration." The author claimed for this method a lower mortality, a shorter convalescence and a wider adaptability as it may be practiced in cases too weak for abdominal section.

DR. F. J. GRONER, of Grand Rapids, Mich., read a paper entitled

A NEW PHASE OF CELIOTOMY.

He related a suit for malpractice which had just been terminated in Grand Rapids. The suit was begun against a doctor some time ago, and was for \$50,000. The defendant died, but the court held that the cause of action survived, and that the suit could be brought against the estate. The jury returned a verdict for \$10,000. The author claimed that he knew there was no malpractice because he was interested in the case and knew just what was done in the operation. He found fault with the laws which permitted a suit against a doctor to survive his death, and be a menace to the widow and children. The speaker thought that the next Legislature should remedy the law. He had the draft of a bill prepared which he thought would remedy the present law, and which he read.

DR. J. FRANK, of Chicago, read a paper on RESULTS OF FIVE YEARS' EXPERIENCE WITH INTRA-ABDOMINAL SHORTENING OF THE ROUND LIGAMENTS.

Since his last publication, November, 1889, he had had the opportunity of performing this operation seventeen times, with only one failure, and without any deaths. All of the seventeen cases operated upon were for retroversion, prolapsus, and retroversion with prolapsus of the uterus.

Technique of the operation: the median incision is made a trifle lower than for ordinary celiotomy, the round ligament is caught up anteriorly with a sharp or blunt hook, and is then held taut by an assistant. A small, full curved needle threaded with fine silk is then passed through the loop of the round ligament and is brought back in the reversed manner through the other half of the loop. No portion of the broad ligament is included in any of the sutures. Too much stress can not be placed upon this particular procedure of passing a needle through a part of the cord and not around it, for in passing the needle around the cord there is danger of strangulation, as the blood and nerve supply would be entirely shut off by this faulty method of placing the sutures around the ligament.

About 50 per cent. of the cases have been under the observation of the author since the time of operation, which in some instances has been as long as two years, and in all of these the uterus retains its corrected position. This operation should be performed in preference to any other in all cases where the uterus is prolapsed or immediately falls back upon replacing it with a uterine sound, and where pessaries and tampons afford no relief, clearly showing that there must be some force which does not permit the uterus to remain in its normal position.

DR. THEODORE A. MCGRAW, of Detroit, delivered the

ADDRESS ON SURGERY,

which appeared in our last issue. (See p. 387.) He selected for his subject: "The Present State of Our Knowledge of Cancers and Tumors."

(To be continued.)

SOCIETY NEWS.

Litchfield County (Conn.) Medical Society.—The annual meeting of the Litchfield County, Conn., Medical Society will be held at Litchfield on October 8. Papers will be read by Drs. J. W. S. Gouley and Charles Phelps of New York City, J. C. Kendall of Norfolk, and Charles Page of Litchfield.

F. H. WIGGIN, President.

American Orthopedic Association.—Program of the ninth annual meeting, to be held at Chicago, September 17, 18 and 19:

The President's Address, John Ridlon, Chicago.

The Treatment of Fractures from an Orthopedic Standpoint, A. M. Phelps, New York.

Joint Disability following Fractures, James Kerr, Washington, D. C.

Observations on the so-called Congenital Dislocations at the Hip Joint; and the Success of Dr. Buckminster Brown's Treatment by Recumbency with Extension for two years, Wm. Adams, London, Eng.

On the Surgical Treatment of Congenital Dislocations of the Head of the Thigh Bone, Bernard Brodhurst, London, England.

Operative Treatment for Congenital Dislocation of the Hip, Wm. E. Wirt, Cleveland.

A Case of Double Congenital Knee Luxation, H. L. Taylor, New York.

Congenital Absence of R radii, with Operation, S. L. McCurdy, Pittsburg.

The Report of a Case of Congenital Dislocation of the Shoulder, and an Operation for its Relief, A. M. Phelps, New York.

Treatment of Slipping Patella, E. H. Bradford, Boston.

Club Foot, R. W. Lovett and John Dane, Boston.

A Case of Talipes Varus following Section of the Biceps Cruris Tendon. Neurorrhaphy after six years, without benefit, E. Muirhead Little, London, Eng.

A Case of Unusual Varoid Deformity of the Foot. (Illustrated.) E. Muirhead Little, London, Eng.

Removal of Astragalus for Talipes Valgus, James E. Moore, Minneapolis.

Tendon Transplantation in the Treatment of Paralytic Deformities of the Feet; A Report of Cases, Joel E. Goldthwait, Boston.

A Report of Seventy Cases of Splicing of the Tendo-Achilles, H. Augustus Wilson, Philadelphia.

Treatment of Rigid Flat-Foot by the Localized Hot-Air Bath, W. J. Walsham, London.

A Study of the Weak Foot with Reference to its Causes, its Diagnosis and its Cure; with an Analysis of One Thousand Cases of so-called Flat-Foot, Royal Whitman, New York.

Metatarsalgia, L. A. Weigel, Rochester.

One Thousand Cases of Lateral Curvature of the Spine, Treated by Posture and Exercises Exclusively (without mechanical supports), Bernard Roth, London.

The treatment of Lateral Curvature of the Spine without Corsets, Noble Smith, London, Eng.

The Treatment of Scoliosis by Light Gymnastic Exercises, James K. Young, Philadelphia.

On Forceful Correction and Corrective Jackets in the Treatment of Scoliosis, Bernard Bartow, Buffalo.

The Use of Mechanical Supports in Treatment of Scoliosis, L. A. Weigel, Rochester.

Spasmodic Wry Neck, Noble Smith, London, Eng.

Spasmodic Wry Neck, T. H. Myers, New York.

Bone Drilling in Arthritis and Osteitis, Noble Smith, London, Eng.

The deformities Produced by Acute Inflammatory Lesions in Bone, Roswell Park, Buffalo.

Some Considerations of the Mechanical Arrangements around the Hip Joint, H. M. Sherman, San Francisco.

A Review of the Treatment of Hip Disease, B. E. McKenzie, Toronto.

Some Remarks Concerning Hip Disease, with Especial Reference to the Deformity, A. B. Judson, New York.

Presentation of Hip Joint Brace, S. L. McCurdy, Pittsburg.

Operative Measures in Caries of the Spine, E. H. Bradford, Boston.

Caries in Adults, R. G. Brackett, Boston.

Ambulatory Treatment of Pott's Disease, R. W. Lovett.

Spondylitis (?) followed by Hysterical Spine and Chorea, A. B. Hosmer, Chicago.

The Rawhide Corset Spinal Brace, B. E. McKenzie, Toronto.

The Anterior Spine Brace, J. C. Schapps, Brooklyn.

New (anterior) Spine Brace, with exhibition of patients, A. E. Hoadley, Chicago.

The Use of the Plaster Jacket in Caries and the Effect of Position on the Spine, E. G. Brackett, Boston.

The Causative Relation of Suppuration to Tubercular Meningitis in Joint and Spine Diseases, Samuel Ketch, New York.

A Study of the Interior Forms and Burrowings of Lumbar Abscesses, Edmund Andrews, Chicago.

How the Orthopedic Surgeon should Treat Abscesses (tubercular and purulent), A. M. Phelps, New York.

Excision of the Knee as an Orthopedic Measure, W. O. Plimpton, New York.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 86 FIFTH AVENUE, CHICAGO, ILLINOIS.
W. H. LOWDERMILK & CO., WASHINGTON AGENT.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 86 Fifth Avenue, Chicago.

SATURDAY, SEPTEMBER 14, 1895.

MEDICO-LEGAL CONGRESS AT NEW YORK.

This convention, held under the auspices of the New York Medico-Legal Society, began its session September 4, under the presidency of Dr. H. W. MITCHELL, in the United States court rooms, New York City. A gathering of physicians, lawyers and judges, and the reading and discussion of fifty-eight papers on widely varying topics of medical jurisprudence, extending over a period of three days, is an event of unusual interest.

DR. FORBES WINSLOW, the eminent alienist of London, was the star guest of the occasion, and read the opening paper on the "Progress of Lunacy during the Present Century." This will appear in full in next week's JOURNAL. He is reported to have said "that in Great Britain on Jan. 1, 1895, there were 91,081 persons registered as of unsound mind, an increase of 2,014 over the number a year before." He complimented the United States on its magnificent institutions for the insane, and said he was looking forward with pleasure to visiting them. He was inclined to lay great stress upon newspaper publicity as a cause of the present great prevalence of suicide, while recognizing the same tendency of this form of lunacy to act epidemically that is well known to have been the fact in past ages. Respecting certain emotional factors he spoke as follows:

"There is no passion of the mind which so readily drives a person to suicide as remorse. To live is horror; the infuriated sufferer feels himself an outcast from God and man, and although his judgment may still be correct upon other subjects, it is completely overpowered upon that of his actual distress.

"In England the great majority of the cases of

insanity among women can clearly be traced to unrequited and disappointed affection."

DR. T. D. CROTHERS, Chairman of the Section on Inebriety and its Legal Relations, read a paper on "Inebriety" which was discussed by DR. WINSLOW and others.

DR. OGDEN DOREMUS attacked the system now in vogue for testing milk used by the Board of Health in this city. He cited a number of instances in which adulterated milk satisfied the requirements of the Board, and attacked the law which specified that skimmed milk shall not be sold in this city. He gave the testimony of physicians to the effect that many invalids can not drink unskimmed milk. Skimmed milk, he said, is a healthful diet. He doubted if its sale was forbidden in any other city in the world.

PROF. A. H. MOTT read a paper entitled "Somatic Death by Poison." PROF. CHARLES A. DOREMUS followed in an elaborate examination of "Two Remarkable Cases of Chronic Poisoning." A paper on "Ptomaines," written by PROFESSOR VEIGH, of Harvard, was read by PROFESSOR MOTT. PROF. M. C. WHITE, of New Haven, Conn., rehearsed the details of a trial, in which the case turned upon the identity of arsenics from various sources, illustrating his contentions by photographs. PROF. R. OGDEN DOREMUS exhibited vials of arsenic tending to establish the fact that parcels of arsenious acid obtained from different sources, or from different manufactories, may be distinguished.

DR. PAUL GIBIER made an earnest defense of the worth of vaccination, illustrating it by an appeal to history. These remarks were elicited in rejoinder to a paper by one of the lady members who took the occasion to enter her protest against compulsory vaccination and its so-called errors.

DR. GIBIER read an address on "Bacteriology" which caused quite a flutter, inasmuch as he pointed out the fact that anarchists and other criminals are likely to turn their attention from chemic to bacteriologic studies, for the procuring of a sure and safe (to themselves) means of murder. He said, "there are two aspects of this branch of science, the civil and the criminal."

"Concerning the criminal phase, he said that he was asked by a certain man as to the resultant traces if bacteria were injected into a person. The person was told that certain effects might result from such an injection which could lead to discovery of the cause. But he afterward found that his questioner was a man of doubtful reputation, and his suspicions were at once directed toward the possibility that would-be murderers might resort to bacteriology with deadly effect. In many instances death could be caused by such injection, and the evidence would be hardly discoverable."

"Already desperate men have shown that they are willing to devote infinite labors to the accomplishment of their purposes. Anarchists had pursued elaborate chemic studies. There was no reason for believing that they would not, if they thought it worth their while, devote themselves with all zeal to a study of bacteriology, whereby their designs could be accomplished. A bomb thrown into this city

would cause less harm than a few microbes thrown into the source of water supply."

At the end of the first day, the following were among the permanent officers elected: President, CLARK BELL; Medical Vice-Presidents, T. D. CROTHERS, R. OGDEN DOREMUS, PAUL GIBIER, W. B. OUTTEN, IRVING C. ROSSE, FORBES WINSLOW, H. LOUISE THOMAS; and FRANK H. CALDWELL, of Florida; Secretaries, MORITZ ELLINGER, F. B. DOWNS, ALBERT BACH, CLARENCE A. LEIGHTON, CHARLES A. DOREMUS, of New York; Treasurer, GEORGE CHAFFEE.

A resolution was passed at the close of the session expressing the belief of the conference that medical and law schools should include medical jurisprudence in the curriculum, and that examination in the subject should be made compulsory. Another resolution provided for the appointment of a Standing Committee on Medical Jurisprudence by every National and State Bar Association.

Dr. W. X. SUDDUTH was chairman of the Department of Experimental Psychology, and Dr. G. P. CONN Chairman of the Section on Medico-Legal Surgery. Dr. H. A. MOTT presided over a Section on Medico-Legal Chemistry. PROFESSOR M. C. WHITE was Chairman of a Section on Legal Microscopy. Judge A. H. DAILEY, and HON. M. ELLINGER each presided over special sections.

The New York Medico-Legal Society, through its energetic Secretary MR. CLARK BELL, projected and carried out this Congress, which was undoubtedly the largest and most successful public discussion of Medical Jurisprudence ever held.

The Congress ended with a reception and banquet at the Press Club.

MENTAL HYGIENE OF WOMEN.

One of the papers read before the Medico-Legal Congress lately in session in New York, was an urgent plea by a woman, MRS. CONNORS, to the medical and legal professions to do something to cure the marked emotional tendencies of her sex. She asserted that on the physician rested largely the responsibility for this state of affairs, and that if our profession did its whole duty, much of the evil of which she complained would cease to exist. That women are invalids because encouraged to be such by the doctors is a libel on the medical profession, and is probably never intended to be said except by certain irresponsible writers. But that they are humored in their invalidism may perhaps be more justly charged, though any unqualified and absolute condemnation even of this course may be a mistake. When female ailments are not a palpable organic fact, they are the indications of a psychosis, the efficient moral treatment of which may be a serious question, and one may err as much in any attempted brusque repression as in the following the

fancies of the patient and admitting to some extent, even, the reality of her troubles.

In a recent publication ("The New England Invalid," Shattuck Lecture, for 1895), DR. ROBERT T. EDES discusses this subject very fully and instructively. He concludes that the condition of nervous invalidism is very possibly connected with actual changes in the neuron, analogous to those that have been demonstrated by HODGE as the result of fatigue, thus indicating a rational possible pathology of neurasthenia in both sexes. Emotional weakness is only one symptom of the disorder, and that it is most observable in woman is due to the natural constitution of the sex as well as to social conditions and environment. The "new woman," so far as she is to be realized, will not at once throw off all tendencies in this direction that she has acquired through the ages by heredity, and nervous enfeeblement will undoubtedly exhibit itself in her by special manifestations due to this as well as to the structural peculiarities of sex.

With this basis of heredity, DR. EDES holds, the fully developed condition, ranging in all its forms from pure nervous exhaustion to hysteria and insanity may be acquired at any time, but especially in early life, either gradually or as the result of disease or shock. Its treatment must be based on a careful diagnosis by exclusion of all actual organic disorder, and must then consist in restoring the exhausted nerve elements by proper nutrition and rest, and the appropriate moral treatment which must be individual in the full sense of the word, and to be successful requires unlimited tact on the part of the physician. In this, as DR. EDES says, expectant attention is for therapeutic purposes, a much better thing than argumentative and combative attention; it may be worse policy often to tell a neurotic woman that her ills are imaginary than it is to enlist her vanity in the therapeutics of her supposedly remarkable symptoms. Woman's psychic weaknesses may be thus, in a measure utilized as a counteracting influence to her physical ones, and humoring her ailments be a direct aid to their cure. When a woman feels ill, she thinks she knows it, even if it is not possible to find any tangible objective reason for it.

Women are by their physiologic organization more inclined to be emotional than men, and the prevalent systems of education and the conventional social usages probably increase to some extent this tendency. The "new woman" may throw off these latter, but she can not relieve herself of her physiologic handicap of more delicate response to sensory impressions.

The New England invalid, studied by DR. EDES, is a type too common in our older settled communities, but is largely the result of heredity and the selective process due to emigration. The alarmist note of

Mrs. CONNORS, while indicating a present evil, would have applied even more forcibly, it is probable, in the past few decades than now, in the greater portion of our country.

THE AMERICAN ORTHOPEDIC ASSOCIATION.

The ninth annual meeting of the American Orthopedic Association will be held in Chicago on the 17th, 18th and 19th of the present month. Some fifty papers, many of unusual interest, are promised in the program which appears elsewhere in this issue of the JOURNAL. Mr. BERNARD ROTH, of London, England, will contribute a report on 1,000 cases of lateral curvature of the spine treated by posture and exercise. Mr. WILLIAM ADAMS, of London, a paper on the mechanical treatment of congenital dislocation at the hip, and Mr. BERNARD BRODHURST, of London, on the operative treatment of the same displacement. Dr. H. AUGUSTUS WILSON, of Philadelphia, will report on seventy cases of splicing the tendo-Achillis. Dr. ROYAL WHITMAN, of New York, whose writings on flat-foot are classic, will discuss the subject of weak-foot, its cause, diagnosis, and cure. Every surgeon who has read the prize essay on hip disease by Dr. R. W. LOVETT, of Boston, will be interested to know that, in connection with Dr. JOHN DANE, he will present an essay on club-foot; this will be discussed by Dr. A. M. PHELPS, of New York.

A study of the origin and growth of this society might be of interest to those connected with similar special societies. When it is remembered that very few men have any special interest in orthopedics, and that the number of subjects upon which the orthopedist may write is also very limited, one marvels at the well-attended meetings and the 400-page volume of Transactions which the Society publishes annually. We are inclined to think that the vigorous growth of the Association is due in no little extent to the rigid requirements for admission, the high annual dues and the generous expenditure in the publication of the Society's Transactions.

THE COMPLAINT OF THE MANUFACTURING CHEMIST.

For many years there have been complaints that the druggist in filling prescriptions either disregarded the wishes of the prescriber *in toto*, or only made a pretense of using the particular preparation designated in the prescription.

One chemist in St. Louis recently informed the JOURNAL that by an actual test in more than one-half the cases where his preparation was asked for, the article obtained was not his own make. Other manufacturers have made the same complaint. Professional sentiment could crush this business of substitution if once concentrated on this question. If Dr. SMITH writes for "JIBB's Ether," "KIBB's Chloro-

form," or "MAUDLIN & Co.'s Fluid Extract," if JIBBS, KIBBS and MAUDLIN & Co., are reputable manufacturers it should be furnished. When Dr. SMITH writes a prescription and Druggist A receives it, A is bound in honor to either furnish the exact brand called for, or to privately communicate with Dr. SMITH, and explain *why* he can not do so. There is no more reason why it should not be recognized as dishonesty to substitute one article for another, than there is reason to condone any other method of obtaining money under false pretenses. Common honesty requires that a prescription should be filled with the identical articles named therein, and any druggist who makes a business of substitution should be promptly dropped by the profession.

At least, the Illinois Legislature at its last session seems to have so regarded it, for a penalty was enacted on all pharmacists who should substitute one drug for another.

CHRISTMAS WEEK, 1897.

Our Mexican confrères have authorized PROFESSOR PEPPER to announce that the second Pan-American Medical Congress will be held in the City of Mexico Christmas week, 1897.

In Mexico, the week of the Nativity is the week of festival and rejoicing. The Christmas chimes peal merrily; the city is in holiday garb; entertainment, good fellowship, and overflowing hospitality characterize the season.

Business, while not actually suspended, is carried on only so far as is absolutely necessary for the purposes of commerce and public comfort.

The management have done wisely in choosing Christmas week as the one in which shall be held the second Pan-American Medical Congress.

CORRESPONDENCE.

The Code—Another Reply to *Amicus Veritatis*.

CANTON, OHIO, Sept. 11, 1895.

To the Editor:—The gentleman writing the open letter to you and signing himself *Amicus Veritatis*, reminds me of a ship at sea without a rudder, or a man out on the sea of professional life without a conscience, roaming about seeking whom or what he may devour from a non-professional or commercial standpoint. If the writer were to take up the Code and be determined to read and understand it in the same spirit as it was given us, in accordance with the Golden Rule, he would, I am sure, entertain a more exalted opinion of our profession. I read the communication very carefully, and laid it aside with a silent expression of pity for the writer.

Respectfully, S. A. C.

PUBLIC HEALTH.

Anthrax in a New Jersey Dairy.—Representatives from the New York City Board of Health have visited a section of Cumberland County, New Jersey, for the purpose of investigating an outbreak of anthrax among cattle, and its relation to the milk supply of that city. They reported the dis-

ease to be in a limited area, and the affected cattle to be under the supervision and control of the State Dairy Commission, so that none of the products of the infected herd can be shipped.

Crematory for Refuse in New York City.—On September 5, a new crematory for the incineration of city refuse, except garbage and ashes, at Twelfth Avenue and Fifty-third Street, began operations. Three car-loads of material were burned, and the inventor of the system said he was well satisfied with the result. If this system is adopted by the city it will require five or six plants conveniently located to dispose of all its refuse. The capacity of the first plant, when working night and day, is estimated at sixty tons.

Disinfection in Typhoid Fever.—Even when the fecal discharges of a typhoid fever patient are properly disinfected, which is by no means so much the rule as the exception—especially in country districts—little or no attention is paid to the disinfection of the urine. Wright and Semple, however, in a recent issue of the *London Lancet* (July 27 ult.) draw attention to the frequency with which the typhoid bacillus may be found in the urine of such patients; they, themselves, have found them in six out of seven cases examined. It is suggested further that their presence will help to clear up the diagnosis of doubtful cases and to explain the serious kidney complications which are not uncommon in typhoid fever. The late complications of the disease, regarded by some observers as due to the coli communis, are also probably caused by the wide-spread diffusion of the typhoid bacillus.

Cholera Mortality in Japan.—In view of the present prevalence of Asiatic cholera in Japan, the following summary¹ of the ravages of this disease in the land of the Mikado have a timely interest. When cholera first appeared in Japan is not known, but it is supposed that it was in 1822. Between 1858 and 1860 the disease again made its appearance, but there are no returns for those years. They are, however, complete from Jan. 1, 1877 up to July 19, 1895:

Year.	Cases.	Deaths.	Year.	Cases.	Deaths.
1877.	13,816	8,027	1887.	1,228	654
1878.	902	275	1888.	811	460
1879.	162,637	105,786	1889.	751	431
1880.	1,580	618	1890.	46,019	85,227
1881.	9,889	6,287	1891.	11,142	7,760
1882.	51,681	33,784	1892.	874	497
1883.	909	434	1893.	633	364
1884.	900	414	1894.	546	314
1885.	18,772	9,310	1895 (to July 19)	7,901	4,804
1886.	155,923	108,409			

"A Burning Fiery Furnace."—In the discussion on the cremation of garbage and town refuse in the British Medical Association at its recent meeting, Brigade-Surgeon Pringle, M.D., took occasion to call attention to the fact that the subject is a very ancient one. In the East in many places fires are still used, as they were centuries ago, as the great sanitary measure of the city, and the Tobhet or Tophet of Jerusalem, or as Milton calls it, "black Gehennum, styled the type of hell," was the place of burning refuse, where "the fire was never quenched;" and the burning fiery furnace of the plain near Babylon was only a vast receptacle for burning the city refuse; and the fact of those who threw in the Hebrew captives being burnt was due, no doubt, to some defect in the draught-shutters, by which the flames instead of passing up the chimney rushed out at the door. The plan on which this vast cinerator was built is what is seen now in the East where bricks, etc., are burnt for the purpose of securing a draft in that windless land.

Severe Punishment for Milk Adulteration.—It appears that one of the new police magistrates of New York city has been for years interested in chemistry. His brother justices hav-

ing delegated to him the trial of the adulterated milk cases, he has instituted an unusually severe line of discipline against dealers found guilty by the inspectors of the Board of Health. Fines of \$100, with ten days' imprisonment, were among some of the heavy sentences imposed; the lighter grade of sentences was a fine of \$25, with or without five days' imprisonment. This latter sentence was the exception, whereas under the old régime the light punishment was almost the invariable rule, except in the case of second or third offenses. The Health Officers are especially desirous of getting convictions of certain wealthy wholesale dealers and jobbers in low test milk, and the court, in some instances, suspended sentence as to the smaller dealers found guilty for the purpose of securing the coöperation of the latter in bringing the former to justice. This action, if carried out to a successful issue, will have the effect of striking at the fountain head of much of the impoverished milk supply of that city. The court pointed out the fact that the City Board of Health had received very little aid and comfort from the State Dairy Commission in combating the evil of adulterated milk. On this point the magistrate is reported to have remarked: "It is incomprehensible to me why this Commission, which receives such a large sum of money from the State, does not at least lend a hand in stopping this traffic in impure milk. The Commission, so far as I can learn, appears to confine itself to chasing people into boarding houses and arresting them for selling or eating oleomargarine, which is much better than much of the alleged creamery butter in the market."

The counsel for the accused had been carefully primed for his work, and sought to entangle the Health Board's chemists by asking them what sort of milk a cow would give that was bothered with Texan flies, and what was the difference in the milk from a high-fed Jersey and a low-fed Holstein; but the fines fell heavily "all the same."

Leprosy in Cape Colony and India.—The Commission appointed by the Cape government to study the question of leprosy has finished its labors and made its report. According to the census of 1891, the total number of lepers at the Cape was 625—366 men and 259 women—or a proportion of 4.77 per 10,000 inhabitants. Of this number 532 were born in the colony, 41 in the countries of Africa, 1 in Asia, and 51 were Europeans, or of the white race. Among the latter were four individuals who were not born in the colony and were only attacked after arrival in South Africa. The disease seems to have markedly increased, for in January, 1895, the number of lepers was 1,177, or nearly double that of four years previous. As regards frequency, it is found most often among the Hottentots; then come the mixed races, next the Malays, and lastly the Kafirs and Europeans. The Commission is of opinion that the theory of contagion is the only one capable of satisfactorily explaining the increase or diminution of the disease. Moreover, the mode of living in the country favors the spread of the disease. No instance of transmission by vaccination has come under the notice of the Commission. However, the disease is, as noted above, most prevalent among the natives, who are opposed to vaccination. As regards the influence of heredity, the Commission, while neither affirming nor denying it, is of opinion that it occurs but very rarely. No treatment is of any avail; isolation is to be insisted upon and furnishing notice of the existence of lepers should be made obligatory upon landlords, physicians, etc. It is interesting to note that the report of the Commission in India, appointed for a similar purpose, gives exactly opposite results. In 1891 there were 126,361 lepers in India, 31,069 of whom were women. The Indian Commission declares that the dangers of the propagation of leprosy are considerably exaggerated and regards the disease as non-contagious, hence there is no necessity for obligatory isolation, with the exception of vagabonds. The Indian Commission, moreover, recommends the exclusion of lepers from certain occupations. The questions of the heredity and of the contagious nature of leprosy are far from being settled definitely. On the one hand are Zombaco Pasha, Armauer, Hansen and Ehlers; on the other, the Cape and Indian Commissions which arrive at diametrically opposite conclusions.¹

¹ Abstract of Sanitary Reports, Sept. 6, 1895.

¹ La Semaine Medicale, July 31, 1895.

Health Reports.—The following health reports have been received at the office of the Supervising Surgeon-General Marine-Hospital Service:

SMALLPOX—UNITED STATES.

Louisiana: New Orleans, August 3 to 31, 2 deaths.

Michigan: Kalamazoo, August 17, 1 case; Calhoun, August 24, 1 case.

Tennessee: Memphis, August 1 to 31, 3 cases.

Texas: Eagle Pass, September 4 to 8, 5 cases, and 3 deaths. Total smallpox cases and deaths among refugees at Camp Jenner, near Eagle Pass, 177 cases, 55 deaths.

SMALLPOX—FOREIGN.

Cairo: July 23 to August 5, 3 deaths.

Calcutta: July 20 to 27, 5 deaths.

Constantinople: June 1 to 31, 39 deaths.

Dublin: August 17 to 24, 3 cases.

Gibraltar: August 11 to 18, 1 case.

Havana: August 24 to 31, 2 deaths.

Hong Kong: July 20 to 27, 1 death.

London, Eng., August 17 to 24, 6 deaths.

Montevideo: July 27 to August 3, 1 case.

Naples: August 16 to 23, 1 case, 1 death.

Nice: July 1 to 31, 1 death.

Nogales: August 31, 1 case, 1 death.

St. Petersburg; August 3 to 10, 4 cases, 1 death.

Prague: August 3 to 17, 2 cases.

Rio de Janeiro: August 3 to 10, 68 deaths.

Rome: June 22 to 29, 1 death.

YELLOW FEVER—FOREIGN.

Brazil: Rio de Janeiro, August 3 to 10, 7 deaths; Santos, August 3 to 10, 2 cases.

Cuba: Havana, August 22 to 29, 90 cases, 30 deaths; Matanzas, August 21 to 28, 12 cases; Santiago, August 17 to 31, 44 deaths; Santa Clara, August 24, 2 cases; Santa Domingo, August 24, 2 deaths; Sancti Spiritu, August 24, 30 cases.

Puerto Rico: San Juan, August 3 to 24, 21 cases, 14 deaths.

CHOLERA—FOREIGN.

China: Hong Kong, July 28 to August 3, 2 deaths.

France: Cognac, August 17 to 24, 1 death.

India: Calcutta, July 20 to 27, 9 deaths; Bombay, July 27 to August 2, 1 death; Singapore, July 16 to 22, 44 cases, 37 deaths.

Japan: Nagasaki, August 5 to 12, 40 cases, 30 deaths; Osaka and Hiogo, August 3 to 10, 243 cases, 179 deaths; Yokohama, August 2 to 16, 36 cases, 27 deaths.

Turkey in Asia: Aleppo, July 17 to 24, 24 cases, 21 deaths; Hamah, July 22 to August 3, 20 cases, 5 deaths; August 7 to 10, 1 death.

BOOK NOTICE.

Report of the American Humane Association on Vivisection and Dissection in Schools. Chicago, 1895.

This pamphlet consists mainly of replies to circulars sent out by the Humane Association in regard to the benefits and propriety of vivisection in the teaching of children. Naturally, they are nearly all condemnatory—in fact, there is very little to be said in any way for the practice. It is a very different thing from experimental investigation, and young children can, and readily will take physiologic facts on trust without practical demonstration, which will, at the best, be likely to be very imperfectly appreciated.

The tendencies of children to torture animals need checking, and vivisection under the sanction of instruction is, with them on the whole, liable to do harm rather than good.

NECROLOGY.

ROBERT L. VAUGHT, M.D., of Chattanooga, Tenn., was born May 24, 1863. He was drowned August 28 ult., while bathing in the Great Kanawha River at Henderson, W. Va. He was spending his vacation at the home of his nativity and when the news of his death reached his friends and relatives, both far and near, sorrow was general. Professionally and socially but few physicians enjoyed the popularity he

attained. Dr. Vaught was graduated in medicine March, 1884, at the Medical Department of the University of Nashville and Vanderbilt University, and served one year as interne to the City Hospital of Nashville, located in Chattanooga. At the time of his death he was professor of anatomy in the Chattanooga Medical College; Member of the Chattanooga Medical Society; Tennessee State Medical Society and the AMERICAN MEDICAL ASSOCIATION. He left an aged mother and an only brother beside other relatives and numerous friends who mourn his untimely death.

HENRY W. RAND, M. D., of Brooklyn, N. Y., August 31. Dr. Rand was born in Nova Scotia in 1851 and was graduated at Acadia University in 1873. He received his degree as Doctor of Medicine in the Bellevue Hospital College of Medicine in 1877. In that year he was appointed resident physician at the Brooklyn Hospital, and later visiting surgeon to the Brooklyn Orthopedic Infirmary, filling this position for several years. He was visiting physician to the Home for Destitute Women and Children for several years and had charge of the department of women's diseases at the Atlantic Avenue Dispensary. In 1884 he was appointed attending surgeon of the Long Island College Hospital, and in 1890 to St. Johns Hospital, filling both places at the time of his death. —N. E. Wright, M.D., Berea, Ohio, September 10. He was a native of Ohio, and was 61 years of age. —M. H. Murphy, M.D., Scranton, Pa., August 4, aged 32. —H. C. Reid, M.D., Mariposa, Cal., September 7. —C. V. Jones, M.D., formerly of Indiana, at San Jose, Cal., September 7, aged 40 years.

MISCELLANY.

Jefferson Medical College.—The chair of pathology in the faculty of the Jefferson Medical College in Philadelphia is vacant.

An Illegal Practitioner Sent to Jail.—In New York city, the lawyers employed by the County Medical Society have secured the conviction of a "Doctor" Ruffo for practicing medicine without a license and registration. He was sentenced to a three months' term in the penitentiary.

Medical Students in Holland.—The universities of Holland have an attendance during the current collegiate year of 2,940 students, of whom 1,486 are studying medicine, distributed as follows: 624 at Amsterdam; 349 at Leyden; 277 at Utrecht; and 236 at Groningen.

Parisian Practice.—Mons. X, according to *Le Journal de Medicine de Paris*, consulted his physician, saying that he was not feeling at all well, being tormented nightly by "bad dreams," and especially by visions of women in "the altogether," *a la* Trilby and Mother Eve. "That is easily remedied," replied the doctor. "Every night before retiring you will take an infusion of fig leaves."

Treatment of Phlegmonous Inflammations.—In the lesser phlegmonous inflammations alcohol dressings abort the inflammatory process and in the graver forms they cause the rapid formation of a circumscribed abscess filled with thick pus. Alcohol of 60 to 90 degrees is to be used. The skin of the inflamed area is cleansed with ether; if there is any open wound it is covered with powdered iodoform; then a thick, even layer of cotton soaked with alcohol is applied with a proper protective over it; this latter is pierced with holes or slits so as to allow evaporation of the alcohol and prevent any caustic action. The dressing is kept in place for twenty-four hours and must be renewed daily for some days after the disappearance of all tumefaction.¹

To Examine Medical Students.—Springfield, Ill., August 31.—The Illinois State Board of Health has issued a call for examinations to be held in Chicago, September 16 and 17, of all matriculates in medical colleges not graduates of some literary institution. The branches used in examinations are reading, writing, grammar, geography, arithmetic, composition, elementary physics and United States history. The questions are furnished by the faculty of the State University, who will rate the papers and issue certificates to successful applicants. These examinations have heretofore been

¹ Gaz. Med. de Paris, No. 28, 1895.

conducted by the faculty of different medical colleges. The State Board decides that every applicant for matriculation should submit to the same examination conducted by disinterested persons.

The regulation, while in some respects desirable, would have been in better taste if this institution were not the identical one that had a somewhat shady project on foot to buy for the State one of the medical colleges of the city. As the President of the Board of Health favored the scheme, and was at the same time a member and alleged stockholder of the medical college in question, this action, taken after the colleges not in the secret had already issued their announcements, smacks of favoritism and should be revoked.

Dr. John S. Billings, U. S. Army.—*L'Union Medicale* of August 31, says: "Surgeon-General Billings, of the United States Army, has asked to be retired in the month of October. This very distinguished confrère will leave the Army Medical Museum, of which he is administrator, and the library of the Surgeon-General's office, of which he is librarian, institutions which have been made what they are by his ability and devotion.

Before taking his retirement Surgeon-General Billings hopes to terminate the last volume of the Index Catalogue, an immense and precious work for which the entire medical profession should be grateful to the Government of the United States, its Army Medical Department, and above all to Dr. John Shaw Billings. In retirement Dr. Billings will not cease to work. He has accepted the Chair of Hygiene at the University of Pennsylvania.

Clinical and Bacteriologic Researches on Osteomyelitis.—Carrow has studied seventy cases of osteomyelitis from a clinical and bacteriologic point of view—thirty-one acute the rest chronic. The age of the patients with the acute variety was from nine months to 20 years; with the chronic from 3 to 22 years. Thus the disease seems to be one of youth. In these cases the disease had lasted from four days to four weeks before surgical intervention. The length of time influences the character of the exudate, which is sometimes mucous, sometimes muco-purulent, sometimes altogether purulent. Of the thirty-one acute cases both limbs were involved fifteen times, and six times in the thirty-nine chronic cases. In twenty cases it was possible to trace the source of infection either to an infectious disease, a suppurating wound, an ulcer of the leg, or a carious tooth. The rôle of dental caries was proved by the identity of the organisms in the teeth and in the osseous lesion. The pus was examined in twenty-six cases; in eleven the *S. aureus* was found; in six the *S. albus*. In thirteen cases the blood was examined with nine positive results. In these cases a large number of staphylococci were found beside a number of streptococci. Pus from an osteomyelitic foyer containing staphylococci injected into animals in many cases produced osteomyelitis. The same experiments with the colon bacillus, Eberth's bacillus and Löffler's bacillus were negative. With the streptococcus it was possible to cause medullary abscesses in animals. Immunizing animals with serum from the osteomyelitic ones or with weak cultures succeeded in a certain measure. The serum appeared to confer a greater immunity than the cultures against staphylococci of medium virulence; but both were powerless against staphylococci of increased virulence from passage through a successive series of animals.¹

Trendelenburg's Method for Varicose Veins.—Trendelenburg's researches on the formation and growth of varicose veins in the lower limbs have shown that the trouble lies, not in the difficulty which the blood experiences in circulating in the veins, but in the pressure of the column of blood heaped up above—that is, in the saphenous vein, a column whose weight rests on the peripheral veins on account of the weak valves of the saphenous. Trendelenburg's method—ligature of the saphenous at the upper part of the thigh—is based on this theory. Perthes, operating on forty-one cases, had thirty-

two definitive cures. He had some relapses, due to the vein becoming permeable again some time after the operation; consequently, the author recommends resection of a few centimeters of the vessel. The successes of this method are remarkable—not only for the effect they have on the disappearance of pain, but also for the improved local conditions. Varicose ulcers were notably ameliorated in a short time by ligature of the saphenous. This method appears worthy of adoption; its advantage over Madelung's method—extirpation of the varices—consists in the much greater facility with which it may be performed.¹

Damages Recoverable for Breach of Contract for Sale of Practice.—The losses recoverable on breaches of contract are those directly connected with and arising from the breach. In case of the breach of contract for the sale of an established business, and its good will, damages may be given on proof of the diversion of the business from the purchaser, or the basis for damages might be furnished by proof of acts or conduct on the part of the vendor causing loss of the business to the purchaser, entitled to all the income, and to the aid of the vendor in securing the income. But for the breach of a contract of sale of a physician's practice, the Supreme Court of Louisiana holds (*Rigney v. Monette*, decided March 25, 1895) that damages for the amount the purchaser claims he would have made from professional practice given up, relying on the contract, do not arise from the breach complained of, and are not within the measure of damages fixed by the law in such cases.

Rivals of the Doctor.—A French physician figures out in *La Médecine Moderne* that the doctor is lucky if he sees one sick person in five, and that, as things now go, of all human beings doctors will soon be those who will see the fewest sick people. What with the strong-minded individual who does not believe in doctors, but "knows it all" himself; the mother, grandmother and mother-in-law, each of whom doctors all the children, big and little; the water-, faith-, mind- and other "curists"; the volunteer, who has an "infallible remedy" for every ailing friend and acquaintance; and, finally, the prescribing druggist—it is doubtful if even one in five of the sick reach the doctor's office or ever send for him. He concludes that "the medical profession, which certainly ranks far above many other callings, is in reality a very inferior one in regard to material things, and from this point of view many trades necessitating manual labor often soar far above it. If we want a coat we can not do without the tailor, nor without the shoemaker for a pair of boots; yet in that which appertains to the art of healing any ignoramus can be a formidable rival to us; so that not only have we, in the race of life, come to struggle against other medical men, but also against a multitude of individuals with various crotchets who enrich themselves by filching the fees out of our very pockets."

American Medicine's "Chief Ornament" in Edinburgh.—According to a personal note in *Leslie's Weekly*, August 29, Dr. Mitchell, of Philadelphia, has fallen heir to the mantle of Dr. Holmes—in the estimation of the Scotsmen—for it says, in effect, that the doctorate of laws recently conferred on Dr. S. Weir Mitchell, of Philadelphia, by the University of Edinburgh, is the second he has received, the first coming from Harvard; but it was left for the Scotch university to do him the extraordinary honor of referring to him as the "chief ornament to medical science in the New World." In addition to his great attainments as a physiologist, Dr. Mitchell has the unique distinction of maintaining a practice in London as well as in Philadelphia. He is one of the numerous physicians of celebrity, of whom Smollett and Oliver Wendell Holmes were examples, who have excelled in letters as well as medicine. Dr. Mitchell is well known both as poet and as novelist, and it is not unlikely that a "run" on one of his books would have pleased him even more than the Edinburgh degree.

Bellevue Hospital.—The Commissioners of Public Charities and Corrections have lately asked the members of the Fourth Division of Bellevue Hospital to form an organization for the purpose of giving instruction to graduates and third year students. The medical staff of the Fourth Division consists of Drs. C. L. Dana, George B. Fowler and Alex. Lambert. The surgical staff consists of Drs. J. W. S. Gouley, Chas. Phelps and W. F. Fluhrer. The gynecologist is W. Gill Wylie. The following communication, from the commissioners, and the answer thereto are given for the information of the profession:

DEPARTMENT OF PUBLIC CHARITIES AND CORRECTION, COMMISSIONERS' OFFICE.

NEW YORK, Sept. 3, 1895.

Gentlemen:—I am directed to transmit the following proceedings of the Board, at a meeting held this day:

Resolved, That the seven members of the Fourth Division of Bellevue Hospital be requested to form, without delay, an organization for practical instruction to graduates in medicine and third year students, in the hospital and the bureau of medical and surgical relief for out-door poor.

Resolved, That the members of the fourth division shall be empowered to draw, from the institutions subject to the division, all necessary clinical material.

Resolved, That the commissioners will heartily cooperate with the fourth division in carrying out the scheme of instruction.

Resolved, That certificates issued, to those who shall have attended instruction, and signed by the seven members of the fourth division, shall be countersigned by the commissioners, and shall bear the seal of Bellevue Hospital.

By order,

G. F. BARTON, Secretary.

NEW YORK, Sept. 6, 1895.

To the Commissioners of Public Charities and Correction:

Gentlemen:—At a meeting of the Fourth Division of Bellevue Hospital, held on the fourth day of September, your communication was presented and read. The members of the division desire to express their high appreciation of the step you have taken, in the interest of the hospital and of the people at large, in thus adding to the usefulness of the vast amount of clinical material in Bellevue. They have therefore resolved to accept your invitation to become a teaching corps, have formed the organization which you requested, and have further resolved to begin, on or about the first of October, the courses of instruction instituted by your honorable board. Each course of instruction shall continue six weeks, and not less than five courses shall be given annually.

Very respectfully,

479 Fifth Avenue.

W. F. FLUHRER, M.D., Secretary.

The Kings County Hospital, New York.—A legislative committee has recently been investigating certain charges against the management of the public institutions, for the pauper sick and insane, in the county called Kings, of which the great city of Brooklyn is the center. Since the temporary adjournment of the inquiry, a report by the medical officers of these institutions has been drawn up, a part of which is quoted below so far as it relates to the county hospital above named. The report, addressed to the commissioners of charities who are in charge of the county buildings, is a kind of half-hearted attempt to meet, without answering, the charges that have been made year after year in about the same tenor, but without any material or permanent advantage.

The charges set forth that the hospital was overcrowded, uncleanly, unsanitary, and that drunkenness and abuse of patients by male nurses were common. The report, after setting out the objects of the physicians' investigations, as stated above, says:

"Overcrowding. This hospital of thirty years ago is compelled to receive all comers, residents of the county, suffering from no matter what disease (contagious diseases alone excepted). The building is compelled to shelter more than double the number of patients it was intended to accommodate. The hospital is overcrowded, and must remain so until the authorities of Kings County either enlarge the present building to double its size or, what the staff considers a better plan, build a new hospital elsewhere.

"Uncleanliness. Uncleanliness is not an unnatural result of overcrowding, nevertheless the staff have been surprised at the cleanliness of the institution. The wards and corridors are as clean as paint, kalsomine, soap and water can make them, as visitors can easily see for themselves.

"Unsanitary condition of buildings. The plumbing itself is in very fair condition, apart from its location in the wards.

"Nurses. With regard to the nursing at the hospital, it is as good as can be expected under a system which does not provide for a training school.

"Night service. In regard to having a medical officer on duty at night, it may be said that the internes at the hospital are on duty continuously and answer night calls as promptly as day calls.

"Visiting staff. As the present staff have made during the last year over sixteen hundred visits to the hospital it can hardly be said that the patients have lacked proper medical or surgical treatment. Constantly diminishing appropriations, however, have forbidden anything more than temporary repairs for a number of years."

Have We Too Many Doctors?—Our contemporary, the *Medical News*, in its issue of July 27, editorially discusses the comparative standing of the American medical profession; and, among other wise and timely remarks, refutes the trite and senseless charge that, because its numbers are disproportionately large, therefore the quality of the profession must be poor. It is pointed out there are other factors to be taken into consideration beside that involved in the statement that this country has 1 physician to every 500 inhabitants, while England has only 1 to 2,000, France 1 to 3,000, Germany 1 to nearly 4,000, and Spain and Russia 1 to 7,000 of population. There is the law of supply and demand for one thing, and the density of population for another. One competent physician, says the *News*, is probably capable of properly performing the medical services required by 1,500 or 2,000 people—provided, that they live within a radius of three miles of his office; and for an even larger number within a mile. But what about the district where he would have to drive forty miles to reach 500 people? A physician is as absolute a necessity to a "cowboy" town or mining-camp of 300 people, with no other medical aid within fifty miles, as to a factory town of 5,000. Indeed, many a "superfluous," poorly educated, uncouth country doctor, out on the frontier, with his clientele scattered over two counties, who loves his patients and profession, commands as much of our admiration and respect, deserves as well of his country and is as "necessary" in every way and sense of the term as the most scholarly and polished consultant of a European center. If we were to divide this country and England each into geographic settled districts, each requiring the residence of a physician, nearly two-thirds of our "excess of doctors" would disappear at once. Furthermore, it is argued, "the number of physicians is a good index of the intelligence of a race. And as civilization becomes more complex and the whole field of preventive medicine—scarcely surveyed as yet—is added to our domain, a still higher proportion of skilled, intelligent advisers will be demanded by the community."

Hospital Notes.

GROUND has been broken at Kankakee, Ill., for a \$10,000 emergency hospital building. The institution, although a private one, will be under the charge of Sisters of Charity. —It has been stated that over \$5,000 has been subscribed for the erection of the proposed German Hospital at Buffalo, N. Y.—Work has been begun upon the new wing of the Buffalo General Hospital.

Washington Notes.

HEALTH OF THE DISTRICT.—The report of the Health Officer for the week ended August 31, is as follows: number of deaths—(still-births not included): white, 59; colored, 52; total, 111. Death rate per 1,000 per annum, white, 16.71; colored, 31.08; total, 21.41. Death rate per 1,000 per annum for corresponding week last year, 16.78. Still-births: white, 2; colored, 6; total, 8.

GARBAGE DISPOSAL.—After many months of investigation and study by the Health Officer and the Commissioners, the question of garbage disposal in the District is at last settled. It is to be destroyed by cremation and the "Smith furnace" is the one adopted as being the most satisfactory. The question of location of the plant is now the all absorbing item. As usual, protests and indignation meetings are springing up, opposing any location suggested by the authorities.

REPORT OF THE WOMAN'S DISPENSARY.—The report of Dr. Magruder Muncaster, secretary of the Woman's Dispensary, for the past fiscal year states that the allowance from the Commissioners is \$500, and that the amount received from other sources is \$362.25, making a total of \$862.25. Out of a little less than that the dispensary has compounded and given away 4,099 prescriptions; treated 123 male and 1,060 female medical cases, 52 male and 189 female surgical cases, made 816 external applications and attended 3,568 patients. While the dispensary has sufficient wards for the accommodation of many who require hospital treatment, it is a source of regret that it has been compelled to close the hospital portion for several years, owing to lack of funds to pay for nurse hire and provide proper food. For this purpose there is asked an increase of \$1,000 in the appropriation.

REPORT OF THE U. S. HOSPITAL FOR INSANE (ST. ELIZABETH).—The fortieth annual report of the board of visitors to the Government Hospital for the Insane has been received at the Interior Department. The admissions during the past fiscal year were 371, more than ever before except during the last two years of the war. The whole number under treatment, 2,052, is larger than ever before. The recoveries during the year were 98 and deaths 179. A mortality of 10.73 per cent. of the average number of inmates and 8.72 per cent. of the whole number under treatment. More than half the sickness is charged to the flats of the eastern branch of the Potomac, which lie exposed to the sun. Additional buildings are now under construction, which will relieve the present crowding. The estimates for current expenses during the coming fiscal year are \$368,500, divided between the District appropriation and the sundry civil bills in the proportion of \$104,049 to the former and the remainder to the latter. This is on the basis of \$220 per capita for an average of 1,675 inmates. The other appropriations recommended are as follows: general repairs, \$20,000; rebuilding shops, \$7,000; laboratory extension, \$1,500; electric fans and resistance coils, \$6,000; heating apparatus for new buildings, \$4,500; renewing and fireproofing floors, \$2,500; kitchen and dining rooms, \$2,400. The extension of the laboratory is necessary for the important pathologic work, which is being carried on in connection with the treatment of the inmates.

WATER METERS TO BE USED.—The Commissioners have decided that all large consumers of water shall use meters, after October 1 next. The rates will be 3 cents per each thousand gallons, payable quarterly. A number of rules and regulations have been adopted with penalties for their violation. The principal penalty is the cutting off of the water and a \$2 charge for turning it on afterward.

AGRICULTURAL CHEMISTS ASSOCIATION.—About sixty government chemists met during the week at the lecture room of the National Museum. It was the Association of Official Agricultural Chemists, and included many of the State chemists of the various States, beside a large number of other government workers and those interested in agricultural education. The meeting was called to order by H. A. Huston, the president. The object of the Association is to secure uniformity and accuracy in the modes and methods and statements of analyses relating to fertilizers, soils, cattle foods and dairy products. The annual meeting usually lasts three days, and is made the time for presenting papers of general interest to the members. The Secretary of Agriculture was present at the opening and made a short but instructive address.

REPORT OF THE WASHINGTON HOSPITAL FOR FOUNDLINGS.—Dr. Z. T. Sowers, President of the Washington Hospital for Foundlings, yesterday submitted his report. He states that the average number of children during the year was thirty-four. The expenses have been greatly increased and the directors ask that the appropriation for 1896-97 be increased to \$7,000, as the indications are that the number

of applications for admission will be greatly in excess of any previous year. Attention is called to the fact that there were twenty-three deaths during the year, while during the year ending June 30, 1894, there were thirty-four deaths.

THE PUBLIC SERVICES.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from August 31, 1895, to September 6, 1895.

Leave of absence for two months, to take effect on or about September 15, 1895, is granted Captain William C. Gorgas, Assistant Surgeon.
1st Lieut. Alexander S. Porter, Assistant Surgeon, is relieved from duty at Fort Keogh, Montana, to take effect on the expiration of his present sick leave, and ordered to Fort Huachuca, Arizona, for duty.
Major Joseph K. Corson, Surgeon, granted leave of absence for two months.
Captain Leonard Wood, Assistant Surgeon, is relieved from duty at Fort McPherson, Georgia, and ordered to report in person to the Attending Surgeon in this city, for duty as his assistant.
Captain Marlborough C. Wyeth, Assistant Surgeon, is relieved from duty at the Army and Navy General Hospital, Hot Springs, Arkansas, and ordered to Fort Huachuca, Arizona, for duty.
Captain Julian M. Cabell, Assistant Surgeon, upon the expiration of his present sick leave, will be relieved from duty at Washington Barracks, D. C., and ordered to report to the Surgeon-General.
1st Lieut. Frank T. Merlwether, upon the expiration of his present sick leave, will be relieved from duty at San Diego Barracks, California.
1st Lieut. Charles E. B. Flagg, Assistant Surgeon, upon his return from duty in the field, will be relieved from duty at Angel Island, California, and ordered to Fort Hancock, Texas, to relieve 1st Lieut. Francis A. Winter, Assistant Surgeon. 1st Lieut. Winter, on being thus relieved, is ordered to Fort Grant, Arizona, for duty, relieving 1st Lieut. George M. Wells, Assistant Surgeon. Lieut. Wells, on being thus relieved, is ordered to Fort Mason, California, for duty, relieving Captain William L. Kueedler, Assistant Surgeon. Captain Kueedler, on being thus relieved, is ordered to San Diego Barracks, California, for duty.
Captain Walter D. McCaw, Assistant Surgeon, is relieved from duty at the Presidio of San Francisco, California, and ordered to Fort Ringgold, Texas, for duty, relieving 1st Lieut. Champe C. McCulloch Jr., Assistant Surgeon. Lieut. McCulloch, on being thus relieved, will report in person to the Commanding Officer, Army and Navy General Hospital, Hot Springs, Arkansas, for duty at the Hospital.
1st Lieut. George M. Wells, Assistant Surgeon, granted leave of absence for two months, to take effect on his relief from duty at Fort Grant, Arizona.

Marine-Hospital Changes. Official list of changes of station, and duties of Medical Officers of the U. S. Marine-Hospital Service, for the sixteen days ended August 31, 1895.

Surgeon John Vausant granted leave of absence for thirty days, August 24, 1895.
Surgeon W. H. H. Hutton detailed as chairman board for physical examination of officers revenue cutter service, August 22, 1895.
Surgeon Fairfax Irwin detailed as chairman board for physical examination of candidates revenue cutter service, August 30, 1895.
P. A. Surgeon C. E. Banks detailed as member board for physical examination of candidates revenue cutter service, August 30, 1895.
P. A. Surgeon G. B. Young, upon expiration of leave of absence, to report at Bureau for temporary duty in laboratory, August 28, 1895.
P. A. Surgeon B. W. Brown detailed as recorder board for physical examination of candidates revenue cutter service, August 30, 1895.
E. K. Sprague detailed as recorder board for physical examination of officers revenue cutter service, August 22, 1895.
Asst. Surgeon J. B. Greene to proceed from Washington, D. C., to Wilmington, N. C., for temporary duty, August 22, 1895.

ADDRESSES.

SUICIDE AS A MENTAL EPIDEMIC.

Read before the Medico-Legal Congress, at New York City, Sept. 5, 1895.

BY FORBES WINSLOW, M.B. AND LL.M. CANTAB., D.C.L.
OXON., M.R.C.P. LOND.

SENIOR PHYSICIAN TO THE BRITISH HOSPITAL FOR MENTAL DISORDERS,
EUSTON ROAD, LONDON; LATE LECTURER ON INSANITY,
CHARING CROSS HOSPITAL, LONDON.

The question of suicide is one which for some time has occupied public attention. During the present year, in consequence of the alarming increase of suicide, I have decided to choose this subject for our consideration, hoping that perhaps what I shall place before the society may prove of interest to its members and draw their serious attention to a grave question.

All human actions are under the influence and power of example more than precept, and consequently self-destruction has often been justified by an appeal to the laws and customs of past ages. An undue reverence for the authority of antiquity induces us to rely more upon what has been said or done in former times than upon the dictates of our own feelings and judgment. Many a mistaken individual has formed the most extravagant notions of honor, liberty and courage, and, under the impression that he was imitating the example of some ancient hero, has sacrificed his life. He may possibly urge in his defense that suicide has been enjoined by positive laws and allowed by ancient custom; that the greatest and bravest nation in the world practiced it, and that the most wise and virtuous sect of philosophers taught that it was an evidence of courage, magnanimity and virtue. The force of example is one which appeals to the mind of certain individuals, but is in itself based solely on a fallacy.

No inferences deduced from the consideration of the suicides of antiquity apply nowadays, as we live under a Christian dispensation. Our notions of honor, of death, and of courage are in many respects so dissimilar from those which the ancients entertained that the subject of suicide is placed entirely on a different basis. History is replete with examples of moral and criminal epidemics during the past centuries. The force of example and imitation is very great among a certain class of our humanity.

The fourth century is remarkable for the rapid increase and spread of superstition, the reinstatement of image worship, the adoration paid to relics, and the many pious frauds of the so-called monks; the fifth century for the epidemic of climbing to the top of heights and there remaining. Simon, a monk, adopted as a mark of sanctity the singular device of spending thirty-seven years of his life on the top of a high pillar. Led by a false adoration and utterly ignorant of true religion, the inhabitants of Syria and Palestine followed the example of this fanatic

and, what is more incredible, this practice continued in vogue until the twelfth century. The rise and spread of Mohammedanism in the seventh century is one of the most remarkable instances of the rapid propagation of ideas and principles.

STRANGE FANCY IN TENTH CENTURY.

In the tenth century a very strange fancy seized upon men's minds. They imagined that the end of the world was close at hand, and multitudes forsook their daily vocation, both civil and domestic, and gave their property to the church, and repaired to Palestine, where they imagined that when the end did come they would be in greater safety. An eclipse of the moon or of the sun was considered as the immediate precursor of the end of all things, and many tried to bribe the Deity by great gifts to the church. In a word, no language is sufficient to express the confusion and despair which tormented the minds of miserable mortals on this occasion. Consequent upon this we have, perhaps, the most extraordinary epidemic for which fanaticism ever is responsible, for vast multitudes left for the Holy Land, and not a meteor fell across the skies but sent whole hordes on the same delusive errand. Scarcely had this excitement departed when the plague, or black death, of the fourteenth century, set in, which appeared in 1333, in China, and passing over Asia westward, and over Europe and Africa, carried off about one-fourth of the population. In Europe it is supposed that 25,000,000 fell victims to this dire pestilence. All epidemic diseases have their moral aspect, and this one was attended by a constellation of fanaticisms and delusions such as man had never witnessed before or since. The specific moral aberrations connected with this period were:

1. The rise and spread of the flagellants, or whippers.
2. The wholesale murder of the Jews on the suspicion of having poisoned the water.
3. The dancing mania.

In Mayence alone, 1,200 Jews were slaughtered by the flagellants, and with this epidemic was associated witchcraft, which then existed and was gradually increasing. The dancing mania in 1374 consisted in persons joining hands and jumping about frantically for hours together, and falling down ultimately in a state of exhaustion. This epidemic was tried during this century in the form of the "Shakers" in the New Forests, but so far as my recollection goes, the best antidote to the revived nonsense was the police court of the district, which evidently had the desired effect.

In the sixteenth century demonomania existed largely, a belief that they were possessed by the devil, and many were burned at the stake in consequence. Our present century has been full of epidemics of one sort or another. I will just name, *en passant*, spiritualism. There are three kinds of individuals

who believe in this, but, not desiring on this occasion to begin a controversy on the subject, I will not refer to them.

Incendiarism, infanticide, kleptomania, homicide and suicide have all during this century been epidemic at one time or another, the force of imitation being so great, and acting prejudicially on weak-minded persons or on those predisposed to mental disorders. In the time of the Ptolemies, a Stoic philosopher preached so earnestly and eloquently on the contempt of life and the blessings of death that suicides became frequent. The ladies of Miletus committed suicide in great numbers because their husbands and brothers were detained at the wars. At Lyons there was an epidemic of drowning among the women. No cause could be assigned for this. It was ultimately checked by the order of the authorities that the bodies of all who drowned themselves should be publicly exposed in the market place. The epidemic was stopped at Miletus by a similar device.

REASONS FOR THIS YEAR'S EPIDEMIC.

An order was made that the bodies of those who hanged themselves should be dragged through the town by the same rope with which they had accomplished their purpose. At Rouen, in 1806, at Stuttgart, in 1811, and at the Valois, in 1813, there are histories of suicide as a powerful epidemic. In 1844 there was an epidemic of voluntary mutilation in the French army, numbers of soldiers being self-mutilated and for no reason. Suicide from poison has often occurred epidemically.

Having thus shown that suicide has during various ages been connected with an epidemic, I would draw the attention of this society to the fact of the recent epidemic which has taken place during the present year, especially during the spring of the year, the alarming character of which is my excuse for drawing your attention to the question of suicide to-day. Speaking generally, the reasons for this epidemic appear to me to be as follows:

1. The great publicity given by the press in publishing revolting details of crime and trials, thus reacting perniciously in the minds of weak-minded persons.

2. Insufficient power of the legislature in suppressing such publicity.

3. The liability to act epidemically in the same way as I have previously mentioned in past ages.

To the medical philosopher nothing can be more deeply interesting than to trace the reciprocity of action existing between different mental conditions and affections of particular organs. Thus the passion of fear, when excited, has a sensible influence on the action of the heart; and when the disease of this organ takes place independently of any mental agitation, the passion of fear is powerfully roused. Anger affects the liver and frequently gives rise to an attack of jaundice; and in hepatic and intestinal disease, how irritable the temper is!

Hope, or the anticipation of pleasure, affects the respiration; and how often do we see patients in the last stage of pulmonary disease entertaining sanguine expectations of recovery to the very last!

As the passions exercise so despotic a tyranny over the physical economy, it is natural to expect that the crime of suicide should often be traced to the influence of mental causes. In many cases it is difficult

to discover whether the brain, the seat of the passions, is primarily or secondarily affected. Often the cause of irritation is situated at some distance from the cerebral organ; but when the fountain head of the nervous system becomes deranged, it will react on the bodily functions, and produce serious diseases long after the original cause of excitement is removed.

It is not our intention to attempt to explain the *modus operandi* of mental causes in the production of suicidal disposition. That such effects result from an undue excitement of the mind can not for one moment be questioned. Independently of mental perturbation giving rise to maniacal suicide, there are certain conditions of mind, dependent upon acquired hereditary disposition, or arising from a defective expansion of the intellectual faculties, which originate the desire for self-destruction.

SOME CAUSES FOR SUICIDE.

Some idea of the influence of certain mental states on the body will be obtained by an examination of the various tables which have been published, in this and other countries, respecting the causes of suicide, so far as they could be ascertained. The table for London is as follows:

Indication of Causes.	Men.	Women.
Poverty	905	511
Domestic grief	728	524
Reverse of fortune	322	283
Drunkenness and misconduct	287	208
Gambling	155	141
Dishonor and calumny	125	95
Grief from love	97	157
Disappointed ambition	122	410
Wounded self-love	53	53
Envy and jealousy	94	53
Remorse	49	37
Fanaticism	16	1
Misanthropy	3	3
Causes unknown	1,381	377
Total	4,337	2,853

According to a table formed by Falret of the suicides which took place between 1794 and 1823, the following results appear: of 6,782 cases, 254 were from disappointed love, and of this number 157 were women; 92 were from jealousy, 125 from being calumniated, 49 from a desire without the means of vindicating their characters, 122 from disappointed ambition, 322 from reverses of fortune, 16 from wounded vanity, 155 from gambling, 288 from crime and remorse, 723 from domestic distress, 905 from poverty, 16 from fanaticism.

In considering the influence of mental causes, we shall, in the first instance, point out the effects of certain passions and dispositions of the individual on the body; then investigate the operations of education, irreligion, and certain unhealthy conditions of the mind which predisposes the individual to derangement and suicide.

There is no passion of the mind which so readily drives a person to suicide as remorse. In these cases there is generally a shipwreck of all hope. To live is horror; the infuriated sufferer feels himself an outcast from God and man; and, though his judgment may still be correct upon other subjects, it is completely overpowered upon that of his actual distress, and all he thinks of and aims at is to withdraw as much as possible from the present state of torture, totally regardless of the future.

In England the great majority of the cases of insanity among women in our establishments devoted to

the reception of the insane, can clearly be traced to unrequited and disappointed affection. This is not to be wondered at if we consider the present artificial state of society. We make "merchandise of love;" both men and women are estimated not by their mental endowments, not by their moral worth, not by their capacity of making the domestic fireside happy, but by the length of their respective purses. Instead of seeking for a heart, we look for a dowry. Money is preferred to intellect; pure and unadulterated affection dwindles into nothingness when placed in the scale with titles and worldly honors.

JEALOUSY A MIND DISTURBER.

Few passions tend more to distract and unsettle the mind than that of jealousy. Insanity and suicide often owe their origin to this feeling. One of the most terrific pictures of the dire effects of this "green-eyed monster" on the mind is delineated in the character of Othello. In the Moor of Venice we witness a fearful struggle between fond and passionate love and this corroding mental emotion. Worked upon by the villainous artifices of Iago, Othello is led to doubt the constancy of Desdemona's affection. The very doubt urges him almost to the brink of madness; but when he feels assured of her guilt and sees the gulf into which he has been hurled, and the utter hopelessness of his condition, he abandons himself to despair.

The great increase of the crime of suicide has been referred by many able physicians of the present day to the political excitement to which the minds of the people have been exposed of late years. In despotic countries suicide and insanity are seldom heard of. The passions are checked by the nature of the government, the imagination is not elevated to an unhealthy standard, every man is compelled to follow the calling in life to which he was born and for which he had capacity, and on this account the evil and corrupt dispositions of the mind are to a certain extent kept in abeyance. In republican governments the greatest latitude is allowed to the turbulent passions; all mankind are theoretically placed on an equality, the man "whose talk is of bullocks" considers himself as fit to carry on the complicated business of government as he whose education, associations and experience tend to qualify him for the duties of a legislator.

In proportion as men are exposed to the influence of causes which excite the passions, so will they become predisposed to mental derangement in all its forms. The French and American Revolutions increased considerably the crime of suicide. It has been said that during the Reign of Terror statistical evidence does not show that self-murder was more common than at any other period. Perhaps the alleged infrequency of suicide may be attributed to the circumstance of the French people having been so busy killing others that they had no time to think of killing themselves.

More than the average number of suicides may not have really occurred during the crisis of the Revolution, but it is an undisputed fact that before and after that political convulsion, self-destruction prevailed to an alarming extent. Disappointed hopes, wounded pride and vanity, blighted ambition, loss of property, death of friends, disgust of life, all came into active operation after the turbulence and bloodshed of the Revolution had somewhat subsided.

These passions working upon minds easily excited, and not under the benign influence of religion, it is almost natural to expect that great recklessness of life should be exhibited. Such facts demonstrate to us the folly of uselessly exciting the passions of the people, and raising in their minds exaggerated expectations from political changes.

There is no more frequent cause of suicide than visceral derangement, leading to melancholia and hypochondriasis. It has been a matter of dispute with medical men whether hypochondriacal affections have their origin in the mental or physical portion of the economy. Many maintain that the mind is the seat of the disease, others that the liver and the stomach are primarily affected, and the brain only secondarily. In this disputed point, as in most others, truth will generally be found to lie between the two extremities. That cases of hypochondria and melancholia can clearly be traced to purely mental irritation can not for one moment be disputed, and that there are many instances in which the derangement appears to have commenced in one of the gastric organs is equally self-evident. Whatever may be the origin of these affections, there can be no doubt of their producing the most disastrous consequences.

HEREDITARY CHARACTER OF SUICIDE.

With reference to suicide, there is no fact that has been more clearly established than that of its hereditary character. Of all diseases to which the various organs are subject there are none more naturally transmitted from one generation to another than affections of the brain. It is not necessary that the disposition to suicide should manifest itself in every generation. It often passes over one and appears in the next, like insanity unattended with this propensity. But if the members of the family so predisposed are carefully examined, it will be found that the various shades and gradations of the malady will be easily perceptible. Some are distinguished for their flightiness of manner, others for their strange eccentricity, likings, and dislikings, irregularity of their passions, and excitable temperament, hypochondriasis and melancholia. These are often but the minute shades and variations of a hereditary disposition to suicidal madness.

A gentleman suddenly, and without any apparent reason, cut his throat. The father had always been a man of strong passions, easily roused, and when so was extremely violent. The brother was a man of impulse; he always acted by fits and starts, and therefore never could be depended upon. The sister had a strange, unnatural, and superstitious horror of particular colors and odors. A yellow dress caused a feeling approaching to syncope, and the smell of hay produced great nervous excitement. The grandfather had been convicted of homicide, and had been confined for over two years in a mad-house. Andral relates the case of a father who died from the effects of disease of the brain; the mother died sane. They had six children, three boys and three girls. Of the boys, the oldest was a man of original mind; the second was very extravagant in his habits, and was ultimately confined in a mad-house; the third was extremely violent in his temper. Of the girls, one had fits of apoplexy; one became insane; the third died of cholera, not, however, until she exhibited indications of mental aberration.

A case more singular than the last is recorded. All

the members of a particular family being hereditarily disposed, exhibited, when they arrived at a certain age, a desire to commit self-destruction. It required no exciting cause to develop the fatal disposition. No wish was expressed nor attempt made to overpower the suicidal inclination, and the greatest industry and ingenuity were exercised by the parties to effect their purpose. In two cases the propensity was subdued by proper medical and moral treatment, but, just in proportion to its being suppressed did the idea of suicide appear to fix itself resolutely in the mind. The desire came upon the individual like the attacks of intermittent fever.

A. K., a man aged 57, was twice married. He was a shoemaker by trade, but, not having received any education, his wife was compelled to keep all his accounts. He had experienced, when young, a blow on the head, which occasionally gave him pain. He became very intemperate in his habits, and at particular intervals he exhibited an uncontrollable temper, quarreled with everybody, neglected his business, abused his wife, and became extravagant and melancholy. During the paroxysm he would exclaim: "Oh, my unlucky head! I am again a lost man!" When the attack subsided he returned to his business, was affectionate to his wife and family, most humbly begged for her pardon for having ill-treated her, and expressed the greatest contrition for his conduct. These attacks came at regular intervals. He procured a piece of rope for the purpose of hanging himself, and for some months carried it about with him in his pocket for that purpose. During one of his fits he effected his object. His grandfather had strangled himself, and his brother and sister had attempted suicide.

DANGEROUS EFFECT OF FALSE PRIDE.

A common cause of suicide is a feeling of false pride. Owing to the ridiculously false views which are taken of worldly honors, the idea which a sickly sentimentality infuses into the mind, this feeling is engendered, to an alarming extent, through the different ranks of society. This constitutes one great element which is undermining and disorganizing our social condition. A fictitious value is affixed to wealth and position in the world; it is estimated for itself alone, all other considerations being placed out of view.

We can not conceive how this evil is to be obviated, unless it be possible to revolutionize the ideas which are generally attached to fame and worldly grandeur. It is difficult to persuade such persons that the end of fame is merely

"To have, when the original is dust,
A name, a wretched picture, and worse—bust."

There is a nameless, undefinable something, that the world is taught to sigh after, is always in search of, a moral *ignis fatuus*, which is dazzling to lead it from the road which points to true and unsophisticated happiness.

Among the causes which operate in producing the disposition to commit suicide, we must not omit to mention those connected with erroneous religious notions. M. Falret justly remarks that the religious systems of the Druids, Odin, and Mahommed, by inspiring a contempt for death, have made many suicides. The man who believes that death is an eternal sleep scorns to hold up against calamity, and prefers annihilation. The skeptic also often frees himself

by self-destruction from the agony of doubting. The maxim of the Stoics, that the man should live only so long as he ought, not so long as he is able, is, we may observe, the very parent of suicide.

The Brahmin, looking on death as the very entrance into life, and thinking a natural death dishonorable, is eager at all times to get rid of life. The Epicureans and Peripatetics ridiculed suicide as being death caused by fear of death.

M. Falret, however, goes perhaps too far when he asserts that the noble manner in which the gladiators died in public not only familiarized the Romans with death, but rendered the thoughts of it rather agreeable than otherwise.

Misinterpretations of passages of Scripture will sometimes lead those who are piously inclined to commit suicide. M. Gillot hung himself at the age of 75, having left in his own handwriting the following apology: "Jesus Christ has said that when a tree is old and can no longer bear fruit it is good that it should be destroyed." (He had more than once attempted his life before the fatal act.) Dr. Burrows attended a nobleman who, for fear of being poisoned, though he pretended it was in imitation of our Saviour's fast, took nothing but strawberries and water for three weeks, and these in very moderate quantities. He never voluntarily abandoned his resolution. He was at length compelled to take some nutriment, but not until inanition had gone too far; and he died completely attenuated. When sound religious principles produce a struggle in the mind which is beginning to aberrate, the contest generally ends in suicide.

CLIMATE AND ITS EFFECT ON SUICIDE.

Among the causes of suicide the foggy climate of England has been brought prominently forward. The specious and inaccurate conclusions of Montesquieu on this point have misled the public mind. The climate of Holland is much more gloomy than that of England, and yet in that country suicide is by no means common. From the following tabular statement we see that the popular notion of the month of November being the "suicide month" is founded on erroneous data. The average number of suicides in each month for years may be taken as follows:

January	213	July	301
February	218	August	296
March	275	September	246
April	374	October	198
May	328	November	131
June	336	December	217
Total	3,133		

It has been clearly established that in all the European capitals, when anything approaching to correct statistical evidence can be procured, the maximum of suicide is in the months of June and July, the minimum in October and November. Temperature appears to exercise a much more decided influence than the circumstances of moisture and dryness, storms or serenity.

M. Villeneuve has observed a warm, humid and cloudy atmosphere to produce a marked bad effect at Paris, and that so long as the barometer indicated stormy weather this effect continued. Contrary, however, to the opinion of Villeneuve, it appears that by far the fewer number of suicides occur in the autumn and winter at Paris than in the spring and summer.

When the thermometer of Fahrenheit ranges from 80 to 90 degrees, suicide is most prevalent. The English have been accused of being the beau-ideal of suicide people. The charge is almost too ridiculous to merit serious refutation. Suicide is not an offense that can be deemed cognizable by the civil magistrate. It is to be considered a sinful and vicious action. To punish suicide as a crime is to commit a solecism in legislation. The unfortunate individual by the very act of suicide places himself beyond the vengeance of the law. He has anticipated its operation. He has rendered himself amenable to the highest tribunal, namely, that of his Creator. No penal enactment, however stringent, can affect him. What is the operation of the law under these circumstances? A verdict of *felo-de-se* is returned, and the innocent relatives of the suicide are disgraced and branded with infamy, and that, too, on evidence of an *ex parte* nature. It is unjust, inhuman, unnatural and unchristian that the law should punish the innocent family of the man who in a moment of frenzy terminates his own miserable existence. It was clearly established before the alteration of the law respecting suicide, the fear of being buried in a cross-road and having a stake driven through the body had no beneficial effect in decreasing the number of suicides, and the verdict of *felo-de-se* now occasionally returned is productive of no advantage whatever, and only injures the surviving relatives.

If the view which we have taken of the cause of suicide be a correct one, no stronger argument can be urged for the impropriety of bringing the strong arm of the law to bear upon those who court a voluntary death. In the majority of cases it will be found that some heavy calamity has fastened itself upon the mind, and the spirits have been extremely depressed. The individual loses all pleasure in society, hope vanishes, and despair renders life intolerable and death an apparent relief. The evidence which is generally submitted to a coroner's jury is of necessity imperfect, and although the suicide may, to all appearance, be in possession of his right reason, and have exhibited at the moment of killing himself the greatest calmness, coolness and self-possession, this would not justify the coroner or the jury in concluding that derangement of mind was not present.

MINDS OF SELF-MURDERERS DISTORTED.

If the mind be overpowered by "grief, sickness, infirmity, or other accident," as Sir Matthew Hale expresses it, the law presumes the existence of lunacy. Any passion that powerfully exercises the mind, and prevents the reasoning faculty from performing its duty, causes temporary derangement. It is not necessary in order to establish the presence of insanity to prove the person to be laboring under a delusion of intellect—a false creation of mind. A man may allow his imagination to dwell upon an idea until it acquires an unhealthy ascendancy over intellect, and in this way a person may commit suicide from an habitual belief in the justifiableness of the act. If a man, by a distorted process of reasoning, argues himself into a conviction of the propriety of adopting a particular course of conduct without any reference to the necessary result of that train of thought, it is certainly no evidence of his being in possession of a sound mind. A person may reason himself into a belief that murder, under certain circumstances not authorized by the law, is perfectly

just and proper. The circumstances of his allowing his mind to reason on the subject is a *prima facie* case against his sanity. At least it demonstrates a great weakness of the moral constitution. A man's *morale* must be in an imperfect state of development who reasons himself into the conviction that self-murder is under any circumstances justifiable.

We dwell at some length on this subject, because we feel assured that juries do not pay sufficient attention to the influence of passion in overclouding the understanding. If the notion that in every case of suicide the intellectual or moral faculties are perverted, be generally received, it will at once do away with the verdict of *felo-de-se*. Should the jury entertain a doubt as to the presence of derangement—and such cases may present themselves—it is their duty, in accordance with the well-known principle of British jurisprudence, to give the person the benefit of that doubt, and thus a verdict of lunacy may be conscientiously returned in every case of this description.

Having, we think, clearly established that no penal law can act beneficially in preventing self-destruction—first, because it would punish the innocent for the crimes of the guilty, and, secondly, that, owing to insanity being present in every instance, the person determined on suicide is indifferent as to the consequences of his action—it becomes our province to consider what are the legitimate means of staying the progress of an offense that undermines the foundation of society and social happiness.

If we are justified in maintaining that the majority of the cases of suicide result from a vitiated condition of the moral principle, then it is certainly a legitimate mode of preventing the commission of the offense to elevate the character of man as a moral being. It is no legitimate argument against this position to maintain that insanity in all its phases marches side by side with civilization and refinement; but it must not be forgotten that a people may be refined and civilized, using these terms in their ordinary signification, who have not a just conception of their duties as members of a Christian community. Let the education of the heart go side by side with the education of the head; inculcate the ennobling thought, that we live not for ourselves, but for others; that it is an evidence of true Christian courage to face bravely the ills of life, to bear with impunity "the whips and scorn of time, the oppressor's wrong, and the proud man's contumely," and we disseminate principles which will give expansion to those faculties that alone can fortify the mind against the commission of a crime, alike repugnant to all human and Divine laws,

"And make us rather bear the ills we have,
Than fly to others that we know not of."

CHAIRMAN'S ADDRESS.

Read in the Section on Diseases of Children, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY EDWARD H. SMALL, A.M., M.D.
PITTSBURG, PA.

We are met together in the sixteenth annual meeting of the Section on Diseases of Children, which was the sixth Section to be formed in the AMERICAN MEDICAL ASSOCIATION.

This Section was organized under the chairmanship of Dr. S. C. Busey of Washington, in the city of New

York, in 1880, with an attendance of about forty members. At this first meeting but five papers were read, and the discussion was carried on by some ten gentlemen. Since then the fortunes of the Section have varied. At one time, interest in it had so declined that a motion was offered that the Section be done away with. Fortunately, this motion was not passed.

The best meeting that the Section ever held was that in Milwaukee in 1893. The program arranged for this present meeting has been gotten up to as great an extent as possible on the lines of the Milwaukee one.

Although the report of the Committee on Revision of the Constitution was not adopted at the meeting in San Francisco last June, still it has been thought best to follow the provisions of the proposed revision, as much as possible, in making arrangements for this present meeting of our Section. Accordingly I shall appoint at the close of this first session a Nominating Committee, consisting so far as may be, of ex-chairmen of the Section who are present. This committee is expected to make its report at tomorrow's afternoon session. It will then report nominations for chairman and secretary.

The Executive Committee is composed of the three last chairmen of the Section.

Provision has been made to have all the papers and discussions of the Section, together with lists of its officers and members, and the rules adopted for the conduct of its work, republished from the JOURNAL, in convenient form for preservation.

The services of a competent stenographer have been secured to take full and accurate reports of all discussions.

Letters have been sent to many physicians eminent in pediatrics throughout the country, soliciting papers for this present meeting, and it is hoped that the program made up from the papers thus obtained, and the discussions upon them will be interesting and profitable.

The rule that papers must not consume in reading more than twenty minutes, and that no member shall occupy more than fifteen minutes in the discussion of any paper or papers will be enforced.

The following resolution, adopted in 1888 was printed in the preliminary program, which was sent to all the gentlemen expected to take part in the proceedings of this Section and to others, viz.: "That in future each delegate or permanent member shall, when he registers, also record the name of the Section, if any, that he will attend, and in which he will cast his vote for Section officers." This was done in the hope that more members of the ASSOCIATION would identify themselves with our Section.

The General Business Committee of the ASSOCIATION is composed of the Executive Committee of the several Sections. This committee was created to take from the general sessions of the ASSOCIATION, much of its routine work, so that members of the ASSOCIATION can devote more time to the proceedings of the various Sections.

Would it not be well also to have but one annual address delivered before the general session of the ASSOCIATION—that of the President on the first day, and have the three other annual addresses (those on General Medicine, General Surgery and State Medicine) delivered before the Sections in which they respectively belong?

In San Francisco last year, on the first day of the

meeting a motion was passed that the hour of meeting of the general session be changed from 10 A.M. to 12 M., in order that all members might be able to be present. If an annual address, not to exceed one hour's time were to be given each day at 12 M., and the regular routine business also carried out, this would not leave enough time to get lunch and then return for the afternoon Section work.

An amendment is to be voted on at this meeting, offered in 1892,—“That Thursday morning's general session be omitted, and the time be devoted to sectional work.” This has the same object in view as the above suggestion.

If the three annual addresses were to be given in their respective Sections, instead of in the general sessions, then the general sessions could be held at noon each day, except the first, when the President's address is given and when the Sections do not hold any session, and the Sections could thus have a two and one-half, or three hours' session both morning and afternoon of each day.

The good to be obtained from the AMERICAN MEDICAL ASSOCIATION must come from its Sections, and all efforts should be directed to make the work of each a success.

At the Milwaukee meeting in 1893, it was moved and carried that this Section have a dinner at its next annual meeting. Unfortunately so few attended its meetings in San Francisco that the dinner was never heard of. I would be glad at any session to entertain a motion to have a dinner at our next annual meeting.

ORIGINAL ARTICLES.

THE EARLY HISTORY OF VAGINAL HYSTERECTOMY.

Delivered before the Chicago Medical Society, March 18, 1895.

BY N. SENN, M.D., PH.D., LL.D.

PROFESSOR OF PRACTICE OF SURGERY AND CLINICAL SURGERY, RUSH MEDICAL COLLEGE; PROFESSOR OF SURGERY, CHICAGO POLICLINIC; ATTENDING SURGEON PRESBYTERIAN HOSPITAL; SURGEON-IN-CHIEF ST. JOSEPH'S HOSPITAL, CHICAGO.

Every great operation in surgery has a period of evolution of varying duration. Each marked advance in medicine and surgery is preceded by attempts which led to the elucidation of old ideas or the conception of new ones. All great discoveries are overshadowed by the labors of a host of earnest and progressive workers which ultimately crown the efforts of a favored few. Nearly all of the improvements in medicine and surgery which have characterized the present progressive age are only a repetition of the work of our professional ancestors. Many a so-called modern operation is only a recent and not always an improved edition of the operative technique as devised and described by one of the old masters. These remarks apply with special force to vaginal hysterectomy. The operation of removing the carcinomatous uterus through the vagina, so recently developed to its present state of perfection, was planned and performed by men who have long since departed, but whose names will always be intimately associated with the interesting history and gradual development of this operation.

There can be no doubt that the first ideas which led to the plan of removing a diseased uterus through the vagina were based upon the results which followed the unintentional removal of the uterus in cases of

mistaken diagnosis. All of the early operations were done for prolapse or inversion of the uterus. The idea of removing the uterus through the vagina originated with Soranus, who was a distinguished obstetrician in Rome during the reign of Emperor Hadrian. The first authenticated description of removal of the uterus through the vagina was given by Berengarius, of Bologna, in 1507. Like all of the early cases, we are ignorant as to the exact pathologic conditions for which this operation was made, but there can be no doubt that part of the uterus was removed. J. Schenck a Grafenberg (1617) relates a number of cases in which the uterus was removed through the vagina, in whole or in part, by ignorant persons who had not the faintest ideas as to the nature of the difficulty or of the extent and gravity of the operation. In 1792 Laumonier removed an inverted uterus below a ligature. The patient died six weeks after operation. The post-mortem showed cicatricial obliteration of the vagina, absence of the uterus; the ovaries and tubes were found on the side of the rectum. Baudelocque examined the specimen later and found that the inversion was caused by an intra-uterine growth and explained that the operation was limited to the removal of the tumor, and that the uterus was removed later by the application of a ligature which opened the peritoneal cavity and caused the fatal suppurative peritonitis. Beyerlé, on the other hand, asserted that the entire uterus was removed at the first operation. Other cases of vaginal removal of the inverted uterus, with or without the presence of a uterine tumor, have been reported by Bardol, Marc-Antoine, Petit de Lyon and Widmann. Cases of unintentional, partial or complete vaginal hysterectomy are also related by Sclevogt, J. Ramsbotham, Fignet and Blasius. Instances of partial or complete removal of the uterus in which the organ was rudely removed by midwives have been reported by Hildanus (1646), Wrisberg (1785) and Bernhard (1824). In the case reported by Bernhard the inverted uterus was removed by the midwife with a razor, the profuse hemorrhage was controlled by the introduction of fragments of ice into the vagina, and the woman recovered.

Cases of intentional removal of the uterus by surgeons have been recorded by Zwinger, Vieussen, Baxter, Faivre, Alexander Hunter, Joseph Clarke and Johnson. In Zwinger's case the amputation was made soon after delivery after preliminary ligation. Death two days after operation. The post-mortem showed that the middle portion of the uterus had been removed. In Baxter's case the uterus was amputated in the same manner five weeks after delivery. Recovery six weeks after operation. Faivre applied a ligature to the recently inverted uterus which sloughed and was detached on the twenty-seventh day after ligation, followed by recovery of the patient.

Johnson cut off the uterus below the ligature and his patient made a good recovery. In a second case of recent inversion of the uterus, the same surgeon applied a ligature to control the profuse hemorrhage. The hemorrhage ceased and the ligature was removed two days later. The hemorrhage returned, when the uterus was again ligated, and fourteen days later the fundus and tubes were detached in the form of a slough, after which the patient made a satisfactory recovery.

Windsor (1819) operated on a case of chronic inversion by tying a silk ligature around the uterus.

He tightened the ligature more firmly every evening and on the twelfth day after the ligature had cut its way nearly through the tissues, he cut off the uterus below the ligature without incurring any hemorrhage. The specimen removed was three inches in length and consisted of the uterus, round ligaments and a portion of the tubes and ovaries. After a protracted illness the patient ultimately made a favorable recovery. In Weber's case the inversion was caused by an intra-uterine tumor, hastened by a midwife, who made an attempt to remove the tumor by traction. Weber ligated the fundus of the uterus, tightened the ligature daily, and cut off a piece below it four and one-quarter inches in diameter, and an inch and a half in length. The specimen removed contained portions of the tubes. Eight days after the application of the ligature the ligated mass sloughed off. The woman recovered without any untoward symptoms and remained in good health a year after the operation.

Rheineck operated on a similar case. The patient was a multipara, 41 years of age. The entire uterus was removed by the use of a ligature. A careful examination after recovery of the patient showed no trace of the uterus. In many of the cases operated upon before 1800, the diagnosis was uncertain, but in most instances the operation was performed for simple or complicated inversion of the uterus.

Vaginal hysterectomy for malignant disease of the uterus dates back to the year 1812, when Paletta appears to have removed the entire organ. The extent of the disease is unknown, but the tumor occupied the lower segment of the uterus. Paletta did not know that he extirpated the entire uterus until he examined the specimen after the completion of the operation. The patient suffered for nine months from pain in the back and hips and a copious sero-sanguinolent vaginal discharge. The cervical portion of the uterus was the seat of an ulcerating tumor. The operation was performed April 13, 1812. By the use of obstetric forceps and the hand, the uterus was brought down to the vaginal outlet. The upper part of the vagina was incised with a pair of curved scissors. After separating the lower segment of the uterus a hard body could be felt at the base of the tumor. This hard body proved to be the fundus of the uterus which remained in connection with the tumor. The patient died at the end of the third day. Paletta did not intend to remove the entire uterus with the tumor, and the extent of the operation became evident only after the completion of the operation upon careful examination of the specimen removed. The more general use of improved vaginal specula about the beginning of the nineteenth century enabled the surgeons to make an earlier and more accurate diagnosis in affections involving the vaginal portion of the uterus and rendered the organ more accessible to direct surgical intervention. To Osiander, of Göttingen, more than to any one else, belongs the credit of popularizing the use of the vaginal speculum as a diagnostic resource and as an aid in operations upon the lower segment of the uterus. As early as 1808 he resorted to the speculum and curved scissors in the removal of uterine polypoid growths. To the same surgeon also belongs the honor of having devised and practiced for the first time, supravaginal amputation of the carcinomatous cervix uteri. The first operation of this kind he performed in 1801. The carcinomatous cervix as large as a child's head,

which filled the vagina, was drawn through the vaginal outlet with a pair of Smellie's obstetric forceps. The greater part of the tumor was torn away from the cervix, an accident which was followed by profuse hemorrhage. As the uterus could no longer be drawn down by the use of forceps, he inserted, with curved needles, four traction sutures at the vaginal insertion, placed at an equal distance apart. The needles and sutures were brought out through the cervical canal at a level corresponding with the internal os. By gradual and careful traction upon the sutures, the lower segment of the uterus was brought down to near the vaginal outlet. With Pott's fistula knife the carcinomatous cervix was then amputated. The hemorrhage, which was quite profuse, was controlled by applying a sponge dusted over with a styptic powder. The patient was convalescent four weeks after the operation. The experience with this case led him to devise another method to enable him to render the uterus more accessible in cases in which the cervix was so much diseased that it could not be drawn down by the use of forceps or traction sutures. This modification of his first procedure consisted in grasping the cervix with the fingers of one hand and pressure of the hand of an assistant upon the abdominal wall above the uterus, and removal of the cervix with curved scissors. For the purpose of removing carcinomatous tissue from the cavity of the uterus he invented a curved chisel. The application of Smellie's obstetric forceps, as an aid in performing vaginal hysterectomy, led to the invention of traction forceps by Museux and Récamier. The reports of Osiander's attempts to remove the carcinomatous uterus through the vagina soon reached France, and his operative procedures were modified by Dupuytren, Lisfranc and other French surgeons.

Dupuytren dragged the uterus toward the introitus vaginae with tenaculum forceps and amputated the cervix with curved scissors. Lisfranc exposed the cervix with the aid of a bivalve speculum, grasped it with his tenaculum forceps, removed the speculum and by gradual traction brought the diseased part within easy reach. In the case of fungous growth he used the fingers of the left hand in making pressure against the blades of the forceps to prevent tearing. The amputation was made with a curved bistoury guided by the fingers of the left hand.

Hatin used a bivalve speculum and a traction forceps of his own invention, the teeth of which grasped the interior of the uterus as well as the external surface of the vaginal portion. Forceps of a complicated structure for vaginal hysterectomy were also devised by Canella and Colombat. The results of partial vaginal hysterectomy for carcinoma, as practiced by Osiander and his immediate followers, were as could be expected most discouraging. Osiander's cases, twenty-three in number, died sooner or later after the operation. The work of the French and Italian surgeons yielded no better results. In all of the cases the diagnosis was made and the operations done long after the disease had passed beyond the limits of the parts removed. A speedy local recurrence and death within a year after the operation were constant occurrences in all of the cases. The local and regional dissemination of carcinoma of the uterus were not well known at that time and the operative procedure was usually limited to the part of the tumor and uterus which projected into the vagina.

Dupuytren reported twenty-nine cases of vaginal removal of the carcinomatous cervix with fifteen deaths, but a later report by Pauly left only one recovery. The unsatisfactory results of the operation induced Dupuytren later to abandon it almost entirely and to substitute for it the potential cautery. The authenticated history of intentional complete extirpation of the uterus for carcinoma dates back to 1813. In 1810, Wrisberg discussed the propriety and feasibility of vaginal hysterectomy in a prize essay read before the Vienna Royal Academy of Medicine. Two years later, Paletta removed the uterus through the vagina for carcinoma. He did not intend to remove the entire uterus, and the fact that the entire organ had been removed only became apparent after the completion of the operation by a careful examination of the specimen removed.

The first deliberate and well-planned vaginal hysterectomy for carcinoma was made in 1813 by J. C. M. Langenbeck, of Göttingen, the uncle of the late distinguished surgeon B. von Langenbeck. The paper of Wrisberg and Paletta's case encouraged him to undertake this difficult task. His patient was a Mrs. Oberschein, 50 years of age, the mother of several children, with the general health but little impaired. She had suffered for some time with a lancinating pain and a burning sensation in the region of the uterus. The uterus had gradually descended toward the vaginal outlet. The suffering became so severe that the patient begged for an operation. Uterus prolapsed. On examination the cervix was found of a stony hardness, nodular and ulcerated. The cervical canal very vascular, ulcerated and from it escaped a bloody and exceedingly fetid discharge. The irritating vaginal discharge had caused erosions of the external genital organs. The ulceration of the cervical canal extended deeply into the cavity of the uterus. Digital exploration of the cervical canal and uterine cavity revealed an ulcerated surface with great induration of the cervix and body of the uterus, and was followed by free hemorrhage. Through the inverted vagina the uterus could be felt as a firm body which could also be distinctly felt by rectal examination. As Langenbeck had no precedent to follow, he had to devise his own plan for the removal of the entire uterus upon which he had decided. The operation was performed in the following manner: the patient was placed with the pelvis upon the edge of the bed with the thighs separated and the feet resting upon two stools. The operator properly seated between the thighs dissected the vagina from the cervix, the dissection was continued until the peritoneal envelope of the uterus was reached. The dissection was made with special care not to open the peritoneal cavity by directing the edge of the knife against the uterus; and separating the tissues as far as this could be done with the handle of the scalpel. To reach the fundus of the uterus, the broad and round ligaments and the Fallopian tubes had to be divided. In his first report of this case he maintained that he removed both ovaries with the uterus, but from later information gained by examination of the specimen and repeated examinations of the patient, he corrected this statement. Two round hard excrescences connected with the uterus gave rise to this wrong impression. The last part of the operation consisted in the subperitoneal enucleation of the fundus of the uterus. He had no one to assist him except a gouty surgeon who, when called upon to render much

needed aid, could not rise from his chair. Toward the end of the operation the hemorrhage became alarming, when the following conversation, occurred: Langenbeck: "*Herr, so humpeln Sie doch jetzt herbei.*" Assistant: "*Ich kann nicht.*" With severe hemorrhage and approaching collapse of the patient and no one to assist him, prompt action on the part of the operator became a matter of urgent necessity. With the left hand, Langenbeck grasped and compressed the bleeding part, and with the right hand he passed a needle armed with a ligature through the tissues behind the bleeding point. Having only one hand at his disposal the ligature was tied by grasping one end between the teeth and the other with the right hand. At this stage the patient appeared to be dying. Dashing cold water over the face revived her. The long wide vagina was now pushed in an upward direction by introducing the whole hand. Above the vagina was a deep pocket, the walls of which were composed of the peritoneal investment of the uterus. Vagina and peritoneal pouch were continuous with each other and no opening into the peritoneal cavity could be detected. Through the peritoneum the intestinal coils could be distinctly felt. To prevent the inversion of this peritoneal bag by pressure against it of the intestines, a sponge was inserted. In spite of the critical condition of the patient at the close of the operation she made an uneventful recovery. If we remember that this, the first complete vaginal extirpation of the carcinomatous uterus was made without an anesthetic, without assistance, and without the use of hemostatic forceps, we can easily conceive the difficulties which the operator encountered and grant him willingly the well merited and hard won honor of having established an important surgical operation. Langenbeck's trials, however, only began at the completion of the operation. Death of the patient would have brought him undeserved censure; her recovery excited the envy of his colleagues which followed him to his grave.

The history of medicine and surgery is replete with similar incidents. The originator of every marked improvement in medicine and surgery has, during his lifetime, received but little recognition for his labors on part of his colleagues. Professional jealousy has always selected for its target the men conspicuous by their honest, unselfish work. Langenbeck's report of his successful operation aroused doubt and a bitter criticism among his contemporaries. Upon his return from Cassel, where the operation was performed, he visited his friend Osiander, and related to him the particulars of the operation. Osiander doubted the possibility of complete removal of the uterus and adnexa without opening the peritoneal cavity, as was first claimed by Langenbeck, and said that he would advise all of his patients who desired to have the uterus enucleated to consult Langenbeck.

Jörg doubted the veracity of the description of the operation. Langenbeck invited his friends to examine the patient after her recovery. The invitation was accepted by Mende and von Siebold. Mende made the examination twelve years after the operation. The patient was in perfect health at that time, and the most careful examination satisfied Mende that the entire uterus had been removed. Von Siebold made the examination Oct. 4, 1829. He indorsed the statements made by Mende in every respect. The testimony furnished by his trusted friends did not succeed in allaying the suspicions of a doubt-

ful profession. Unfortunately the specimen was lost at the time of operation and could not, therefore, be utilized to verify and support Langenbeck's claims. His assistant died soon after the operation, and his testimony was, therefore, not available to substantiate the operator's position. Nothing was left for Langenbeck to do but to await patiently the opportunity to fortify himself by the results of a post-mortem examination upon his patient. The patient died of senile marasmus June 17, 1839, twenty-six years after the operation. The post-mortem was made by Dr. Neuber in the presence of three other prominent physicians. The bladder, rectum and vagina were removed together and placed in alcohol. No adhesions were found in the abdominal cavity and no signs of recurrence in any part of the body. The specimen is described in Max Langenbeck's dissertation, "*De totius uteri extirpatione*," Göttingen, 1842. The upper part of the vagina and the empty peritoneal pouch formed by the enucleation of the uterus were found inverted and formed a swelling in the vagina which reached as far as the labia majora. Inspection of the peritoneal surface showed the Fallopian tubes, their cut ends terminating in the peritoneal pouch. The inverted pouch appeared between rectum and bladder as a globular depression, the surface of which did not show signs of scar tissue anywhere. Langenbeck places great stress on the peritoneal hernial protrusion, as a positive demonstration that the uterus was enucleated without opening the peritoneal cavity. Both ovaries were found in their normal relations with the fimbriated extremities of the tubes. The description of the operation as given by Langenbeck is corroborated by the results of the post-mortem, and the case will always remain in history as the first intentional complete vaginal extirpation of the uterus.

The second complete extirpation of the uterus per vaginam was performed by Sauter Jan. 28, 1822. Billroth and others have repeatedly wrongly quoted Sauter's name as the originator of the operation of vaginal hysterectomy when, as the records show, his operation was performed nine years later. Sauter's case differs from Langenbeck's, in that the uterus was not prolapsed and the peritoneal cavity was freely opened during the operation. The patient was 50 years of age, and the cervix was found extensively ulcerated. Sauter intended to make an artificial prolapse, as suggested by Wenzel, by the employment of tenaculum forceps, and then remove the uterus by enucleation after the example of Langenbeck. In the attempt to bring the uterus down with the curved index finger, the papillomatous excrescences broke off, which gave rise to considerable hemorrhage. The vagina was now cut off from the cervix by a circular incision and another attempt made to bring the uterus down by traction forceps, one blade of which was inserted into the cervical canal and the other placed upon one side of the cervix. Making in this manner strong traction upon the uterus, the attempt was made to separate the bladder from the uterus by the finger and handle of scalpel, but this did not succeed. The piece of the cervix grasped with the forceps was torn off and after working for half an hour he concluded to remove the uterus in its position by the use of a curved scalpel. Two fingers of the left hand served as a guide to the knife, and with it the uterus was detached from the bladder. The whole hand was then

inserted into the peritoneal cavity, and with it the fundus of the uterus was seized. In the attempt to draw the uterus down, the intestines escaped and, after replacing them, a repetition of the same manipulation caused the same accident. He finally succeeded in dragging the fundus of the uterus through the opening after which it was separated from the remaining attachments. The intestines did not prolapse after the removal of the uterus; urine escaped involuntarily. The opening contracted into a funnel-shaped space with the apex directed upward. A few days later urine escaped through the vagina, showing that the bladder had been injured during the operation. After closure of the peritoneal cavity the opening in the bladder was discovered. The patient recovered from the immediate effects of the operation, but died on June 31 of the same year.

The post-mortem showed that the peritoneal cavity was closed. A large opening in the posterior wall of the bladder communicated with the vagina. A number of limited intestinal adhesions, ovaries in their normal location, tubes indistinct.

The experience with this case led Sauter to make the following suggestions: horizontal position of the patient; complete evacuation of rectum and bladder. Pressure by the hand of an assistant over the abdomen above the pubes in the direction of the pelvis. Incision of vaginal vault between uterus and bladder with scalpel with a short convex blade. Enlargement of this opening around the whole cervix with the same knife. Section of the broad ligaments close to the uterus with curved scissors, guided by the fingers. Separation of uterus from the rectum with curved scissors; at last, bringing down of the uterus with the whole hand and separation of remaining attachments.

The third complete vaginal extirpation of the uterus was made by Elias von Siebold, April 19, 1823. The patient was 38 years old. To prevent injury to the bladder, a catheter was inserted and held in place by an assistant. The same assistant compressed the abdomen above the pubes in the direction of the pelvis. The vaginal vault close to the cervix was incised with Savigny's fistula knife, first on the right side of the cervix, guided by the two fingers of the left hand. The opening was then enlarged sufficiently for the introduction of a finger; after this, section of the vaginal insertion all around and close to the cervix; the broad ligaments were divided between two fingers close to the uterus with a small pair of polypus scissors. The uterus was now detached on the right side. To effect this also on the left side, two fingers of the right hand were inserted, and using them as a guide the opposite side was separated with Savigny's knife and Osiander's chisel. A finger was now inserted into the cervix, and with another pressure made from without, whereupon the remaining attachments of the vaginal vault on the right side were torn and the uterus slipped from between the fingers. The intestines could be felt, but did not prolapse. The uterus was now so high that it could only be felt with the tips of the fingers. Attempts to bring it down by the insertion of the assistant's fingers into the rectum and the use of Boer's excerebration forceps proved a failure. The operator satisfied himself that the only way in which the uterus could be brought down would be by the insertion of the whole hand into the peritoneal cavity. As the vaginal entrance was too narrow, the peri-

neum was incised. The opening in the vaginal vault had also to be enlarged, which was done with Savigny's knife. The hand was now inserted, the fundus of the uterus grasped, and the organ drawn down into the vagina, after which the left broad ligament was divided in the same manner as on the opposite side. Death sixty-five hours after the operation. The post-mortem showed inflammation of the small intestines; fibrous exudations upon the peritoneal surfaces; rectum and bladder intact.

The second case, operated upon after Sauter's method, was by Holscher Feb. 5, 1824, a patient upon whom Prael had performed previously Osiander's operation. The patient was placed in the dorsal horizontal position upon an obstetric chair. As the uterus could not be brought down with the hand and a brass needle twelve inches in length, the carcinomatous cervix was excised in order to reach the fundus of the uterus more readily. The vaginal vault and the broad ligaments were divided with an amputating knife, guided by two fingers, close to the uterus; first on one side, then on the other. Death in less than twenty-four hours.

Wolff operated according to Sauter's method May 5, 1824. The patient was 60 years of age and insane. In this case the operation was greatly facilitated by complete prolapse of the carcinomatous uterus and inversion of the vagina. The incision of the vaginal vault was first made in front, then on both sides. The ligaments and tubes were then brought forward and divided some distance from the uterus, after which the uterus was separated from the rectum. The wound was sutured and the inverted vagina replaced. Death two days after operation.

In 1830 Delpech combined vaginal with abdominal hysterectomy, being five years later than Langenbeck's first laparo-hysterectomy. At the vaginal vault Delpech incised the tissues between the bladder and cervix with a knife of his own invention. The separation of the loose connective tissue and the tearing of the peritoneum was done with the finger. After enlarging the opening sufficiently to insert two fingers the abdomen was opened above the pubes by making first an oval skin flap, after which the linea alba and peritoneum were incised. The operator then inserted a finger through the wound between uterus and bladder, which was used as a guide in dividing the broad ligaments, after which the uterus could be sufficiently mobilized from above to sever the remaining attachments safely.

The fifth total extirpation of the uterus after Sauter was made by Elias von Siebold upon a patient 30 years of age July 25, 1825. He rendered the uterus more accessible prior to dividing the broad ligaments by passing a silver needle with a steel point armed with a strong thread through the cervix, using the thread as a guy rope. The patient died two days after the operation.

The sixth total vaginal hysterectomy for carcinoma was made by Langenbeck upon a servant, 28 years of age, August 5, 1825. As a preliminary step, the perineum was incised for the purpose of widening the vaginal opening sufficiently to permit the introduction of the whole hand to grasp the uterus before the division of the right broad ligament. After placing the index finger of the left hand in the vaginal vault between the cervix and the rectum, it was utilized as a guide to Osiander's hysterotome, with which an incision was made into the pouch of Douglas. This

opening was dilated until the whole hand could be introduced with which the fundus was grasped, and pressed in a downward direction, placing the broad ligaments on the stretch. After section of the right broad ligament, the uterus could be brought down beyond the rima pudendi, which made it easy to divide the remaining attachments. He places great stress on opening the peritoneal cavity behind and not in front of the uterus, as by doing so the bladder is exposed to less risk of being injured. He also insists that the large pelvic vessels should be protected by making the incisions close to the uterus. As an additional safeguard to protect the bladder and the urethra, a catheter is held in proper position in the bladder by an assistant. The hemorrhage was not severe. After the completion of the operation a sponge was inserted into the vagina, and for the abdominal pain twenty leeches were applied without any material benefit following. The patient died on the second day. The post-mortem revealed that the small intestines in the pelvis were covered by coagulated blood and a plastic exudate.

The seventh total vaginal extirpation of the uterus after Santer was made by Récamier, July 26, 1829, which, according to Gendrin, was the first operation of this kind in France. He modified Sauter's procedure only in so far that he ligated the uterine arteries in the lower part of the broad ligaments before dividing them higher up. His patient was 50 years of age. With two tenaculum forceps he gradually brought the carcinomatous cervix as far as the vulva. The vagina in front of the cervix was incised with a probe-pointed bistoury (convex), and with the index finger the loose connective tissue between bladder and cervix separated as far as the peritoneum. The opening was enlarged with the bistoury sufficiently to enable him to insert two fingers; the peritoneal cavity being opened, the fundus of the uterus was grasped and the upper part of the broad ligaments was then divided one-third from above downward, without causing much hemorrhage, after which between thumb and index finger the lower part of the broad ligament, first on the right, and afterward on the left side, was seized and with a curved tunneled needle armed with a ligature, the ligament was transfixed and tied, thus securing the uterine arteries. The broad ligaments were then divided above the ligature. The uterus could now be brought out of the vagina and its attachments with the rectum were easily separated. The operation was completed in twenty minutes. Complete healing of the wound twenty-seven days after operation.

The eighth vaginal extirpation of the entire uterus was made by Langenbeck, August 18, 1829. This was his fourth complete extirpation of the uterus, and his third *per vaginam*. It differed from his preceding cases in that the Douglas pouch was opened first and the uterus removed piecemeal to the fundus, which did not appear to be diseased. Hemorrhage slight. The patient recovered from the immediate effects of the operation, but died on the eleventh day. Intestines reddened in places. Only a small fragment of the fundus remained. A rectal fistula with irregular margins was found as the immediate cause of the fatal peritonitis.

The ninth complete vaginal removal of the uterus was performed by Roux, Sept. 20, 1830. The patient was 50 years old and the method employed Récamier's. Death soon after the operation. The same surgeon

performed his second operation five days later, following the same plan with a similar result.

The eleventh vaginal extirpation of the uterus was performed by Récamier Jan. 13, 1830, upon a woman 35 years of age. At the completion of the operation the intestines escaped into the pelvis; they were reduced and the wound sutured. The patient died on the second day from what was believed to be secondary hemorrhage from the internal spermatic artery.

Blundell made the twelfth vaginal hysterectomy Oct. 16, 1830. The woman was 47 years old. Cervix much enlarged and ulcerated. Patient's general health greatly impaired. The uterus was exposed with the rectal speculum of Weiss, which was removed after grasping the cervix with tenaculum forceps. After bringing the uterus well down into the vagina a second forceps was applied, and by an assistant making traction upon both of them the uterus was brought within easy reach. An incision was made between the cervix and rectum with an ordinary scalpel, after which the opening was enlarged with a probe-pointed bistoury. The next step in the operation consisted in making a transverse incision in front of the cervix, separation of uterus from bladder, during which the latter was opened. The fundus of the uterus was grasped with the hand, and into it was inserted a sharp hook, with which it was drawn in the direction of the vagina, after which both broad ligaments were severed. Hot fomentations and thirty leeches relieved the abdominal pain. A return of the pain was met by the application of twenty leeches. Four weeks after the operation the patient was convalescent, but the vesico-vaginal fistula remained.

Dubled suggested that after liberating the cervix by vaginal incision, and after bringing the uterus well down into the vagina by the employment of tenaculum forceps, the broad ligaments should be ligated without previous partial division, as was done by Récamier. After this has been done the uterus is so freely movable that the diseased part can be readily excised. He insisted that the operation should be limited to the removal of diseased tissue. He carried this method into effect once, but his patient died twenty-four hours after the operation. In 1839 Langenbeck performed a supravaginal amputation of the uterus for carcinoma. The patient was 44 years old. The cervix was grasped with two volsellum forceps, and by continued traction it was brought down to the vulva. A circular incision around the cervix was made and the dissection carried upward extraperitoneally as far as the body of the uterus, where the amputation was made. The patient made a good recovery, and at the time she left the hospital the wound was completely cicatrized.

I have given you this brief outline of the early history of vaginal hysterectomy, to show the value of a retrospective view in these times of unrest in medicine and surgery. In the laudable ambition to devise new operative procedures, the surgeons of the present day often ignore the work of our forefathers. New operations are devised and described which were conceived and practiced, or, at least, recommended years ago. Honesty and justice demand that credit should be given to whom it belongs. From what I have said it is evident that the uterus has been removed through the vagina for inversion and prolapse for more than a century. The credit for removing the carcinomatous cervix by the same route unquestionably belongs

to Osiander. This operation was later improved by M. Langenbeck, who made, for the first time, the supravaginal amputation of the cervix for carcinoma in 1830, an operation which was later revived and popularized by Schroeder. Langenbeck and Sauter were the pioneers in establishing vaginal hysterectomy for carcinoma. Langenbeck enucleated the uterus in 1813 and his patient recovered and finally died of senile marasmus at the age of 84. Sauter removed the entire uterus *per vaginam* successfully in 1822 by an operation which, with some slight modifications, is practiced to-day. Of the first twelve cases of complete vaginal hysterectomy, only three recovered, a mortality of 75 per cent. Extraperitoneal enucleation of the uterus has recently been described as a new operation, but those conversant with the history of surgery will always link Langenbeck's name with the origin of this operation. The great mortality which attended the first attempts to remove the uterus through the vagina were due to hemorrhage and infection. The improved means and technique in prophylactic hemostasis and the introduction of aseptic surgery encouraged Czerny to revive and improve vaginal hysterectomy in 1878. Since that time the operation has been modified in various ways, and has now become an established procedure in the treatment of well selected cases of carcinoma of the uterus, but the honest student will always connect the early history of this operation with the names of Osiander, M. Langenbeck and Sauter.

BRIGHT LIGHT IN THE SCHOOL ROOM A
CAUSE OF MYOPIA, AND A METHOD PRO-
POSED FOR THE ESTIMATION OF
THE QUANTITY OF LIGHT.

Read in the Section on State Medicine, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY A. G. FIELD, M.D.
DES MOINES, IOWA.

The object of this paper is to ask attention, briefly, to the physiologic results of regular use of the eyes in bright light, and more especially to raise the question as to whether progressive myopia in school children is not attributable to a large extent to such use. Also to propose a method of estimating the quantity of light in a given place or room with some approach, at least, to mathematical exactness.

The prevalence of myopia among school children attracted the notice of observers more than thirty years ago. Cohn examined the eyes of 10,000 school children and reported over 2 per cent. myopic in the elementary departments, over 10 per cent. myopic in the intermediate departments, more than 19 per cent. myopic in the high schools, and more than 26 per cent. myopic in the gymnasium. The showing discloses an almost regular ratio of increase from the lower to the higher grades. More recent statistics show an increase since that time of from 25 to 50 per cent. in the number of myopic pupils in the higher German schools. In other words, the longer school life continues, the larger is the percentage of myopia. While Germany leads the world in the intensity and persistency of school work, as she does also in the percentage of myopics, the same conditions, though in a less degree, are shown by the statistics of every civilized people.

Some country schools show as low as 5 per cent. average including 1 per cent. myopic in the elementary departments, but in all, the percentage increases rapidly with the continuance of school life. The causes assigned are: 1, bad air; 2, inheritance; 3, general debility; 4, unnatural posture; 5, use of eyes during partial congestion of the blood vessels of brain; and 6, the use of eyes upon fine print or upon

objects in too near proximity. Most of these causes are amenable to improvement to a greater or less degree, and it is fair to assume that the suggestions presented have been acted upon in the sanitary management of schools. We are, therefore, at this state of the inquiry, confronted by two circumstances which stand out very conspicuously: 1, the employment of measures suggested to remedy or diminish the prevalence of myopia; and 2, its progressive increase everywhere during school life.

Cohn placed as first in the list of causes, "bad light," meaning dim light and, as far as known, the same prominence has been given to that cause by all writers and teachers down to the present time. As a matter of course, Cohn advised more light, and that advice has been followed in the construction of school houses. He recommended one square foot of glass area to five of floor area, and he believed that if school houses should be constructed with a square foot of glass area to every square foot of floor area, that the benefits would be very marked. The proportion of glass area to floor area in school houses in my own vicinity, in some cases is as high as one to five, and the intensity of the light in them is intolerable to many eyes if exposed to it for any considerable length of time without proper shading.

Another cause of myopia named and universally admitted is the use of the eyes upon fine print or upon objects in too near proximity. During a personal visitation to many of these schools a very common custom with scholars was observed—that of laying the book flat upon the desk for study with the face over it. This position necessarily brings the eyes within from five to seven inches of the printed page, and I need not say that such position would meet with universal condemnation. The use of the eyes in this position requires shortening of focus, by increasing the convexity of the crystalline lens by a prolonged contraction of the ciliary muscle, an elongation of the eyeball because of the change in the conjugate foci of the lens; in short, a strained condition of the whole accommodative apparatus of the eye—a condition of temporary myopia. Practically the same thing happens to the eye when used in a bright light even upon distant objects, the immediate effect of which is to stimulate contraction of the pupil. In contraction of the pupil, the marginal rays—those most refracted by the lens are cut off, in effect limiting the action of the lens to its central portion, and landing the image beyond the normal position or distance. The posterior wall of the retina recedes by the action of the recti muscles to receive the image, the ball is elongated, and we have again induced or temporary myopia, just as we have in near or close vision.

The fact is best illustrated by the action of the photographic lens of the rectilinear type, in which the front combination represents the cornea and anterior chamber of the eye, the posterior combination the crystalline lens and the posterior chamber, while the retina is also represented by the ground glass screen. With a large stop, we focus upon a given object and move the screen until we have the image sharp upon it. We, then, without moving the object or screen, remove the large stop and substitute a small one. We contract the light opening in the lens, just as the pupil of the eye is contracted in viewing small objects, using the eye in near vision, or by exposing it to a bright light. We now observe the image upon the screen

and find that the use of the small stop has moved the image—it is no longer sharp upon the screen, because it has receded, and we shall have to move the screen back to where the image is, to get a sharp view of it on the screen. In other words, we must elongate the camera box, just as the recti muscles elongate the eyeball in myopia, to get a sharp image upon the retina. The frequent or forced production of temporary myopia results in a condition, chronic and permanent, and too often progressive. The remedy suggests itself; a thoroughly regulated and modulated light in the school room, a proper seating and frequent interchange of pupils with reference to light, and the substitution of charts and black-boards to the greatest possible extent, for books, in the school room.

The words bright, and dim, are used in this paper as substitutes for the more commonly used words, "bad" and "good" as indicating a measure of light, and possibly they may be the better words. But after all there is a vagueness in the meaning of such words which ill becomes a study that aims at, and demands, precision in terms used, as well as in methods and results. At best, only comparative or relative degrees of intensity are expressed by such words. I therefore propose a method of estimating with a very considerable degree of exactness the intensity or quantity of light, and not only of estimating it, but of recording it. It is by the use of sensitized paper. The sensitiveness of this paper depends upon the quantity of nitrate of silver contained in a given quantity of water in the bath. The standard formula is sixty grains to the ounce of water. Albuminized paper floated upon this bath and dried in the dark has a sensitiveness represented by two in the scale of a sensitometer. We have in the paper an instrument at once certain in effect, uniform in action and convenient to employ. The degree to which the paper is browned or darkened when exposed to a given light is a definite measure of the intensity of that light. I have shades of brown each resulting from exposure of different pieces of the sensitized paper one hour on a bright day, in the light of rooms in which the proportion of glass area to floor area varied from 1 to 1, to 1 to 20. (Scale color slips omitted.)

By the application of this method to the determination of quantity of light in the school room, the teacher may know not only the average light value of her room, but of the various parts of it, and at various times of day on different days. With such knowledge, she will be enabled to properly regulate the light by the use of suitable shades and also to seat her pupils in such parts of the room as are best adapted to individual needs and idiosyncrasies. In placing the slips for the estimation of the light value of a room, the mean distance of the slips from the windows is to be taken as the distant line of the area estimated. A scale similar to the one here presented should in all cases be provided for comparison in the use of such slips, and the degree of browning during one hour of exposure should range only from two to four of the scale. This will represent a safe and yet sufficient light, except in special cases and for short periods of time. The slips immersed in a combined toning and fixing bath for ten minutes and then rinsed in two or three changes of clean water become permanent.

I desire it understood, however, that this paper is not for the purpose of establishing a standard of light, for school rooms, which can only be done after

careful concerted observations and experiences, but to furnish a suggestion for the formulation of such standard. Much might be said of the wide range in the diversity of school house architecture, and the imperative need for uniformity of construction upon the best and most thoroughly matured plans under State supervision, including general rules for lighting, heating and ventilating the same. This, however, would be foreign to the scope and purpose of this paper, which seeks to draw attention to two points only:

1. That the use of the eyes in bright light, so constantly recommended as prophylactic, as a matter of fact causes temporary myopia which if persisted in as a habit, or from necessity, soon becomes chronic and permanent as is shown in the history of school life everywhere.

2. That the proper use of light as of heat and other natural agencies by the animal economy requires a means for its quantitative estimation. This can be accomplished with a considerable degree of accuracy by the use of sensitized paper.

THE GOLD IN GARBAGE.

Read in the Section on State Medicine, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY DOUGLAS H. STEWART, M.D.

NEW YORK.

The quest of the Middle Ages was for the stone that would turn lead into gold, but the aim of the nineteenth century seems to be the transmutation of waste into wealth. As a natural consequence, the elaborate and expensive utilization works of Europe, and the various processes of dealing with American garbage have been established.

Everybody believes in the gold in a dust heap, but as yet it has not materialized. In the light of practical experiment it seems quite as far from realization as the philosopher's stone—also once an object of universal belief. There is not, to my knowledge, a single public municipal system that is run at a profit in the disposal of garbage, no matter what its promises on paper or in the theoretical stage have been. Every system being subsidized—or costing in operating expenses from 7 cents a ton upward to a dollar or more. Every practical test points directly to a loss, and the problem seems to present only one factor for solution, viz., "how to make this loss as small as possible." Roughly speaking, the attempts at extracting gold from garbage may be divided into four methods:

1. The most wasteful, sea disposal.
2. The most offensive, hog-feeding or fertilization.
3. The most economical to operate, reduction.
4. The most sanitary and complete, cremation.

There is still another method, proposed by an Englishman in the *Leeds Mercury*. He seriously writes about his plan—of domesticating crocodiles in England, in order to have them eat up the garbage and refuse thrown into the rivers. This is no more humorous than some of the schemes proposed for New York. For instance, bear in mind, the simple sanitary fact that water transportation and sea disposal of garbage are unqualifiedly stupid and wasteful, and repeated handlings are unnecessary and costly.

Our ex-Mayor appointed a committee of five to investigate and report on the garbage systems of the United States and England. Let me call your atten-

tion to their report which is quite as humorous as the crocodile hatchery and just as seriously intended.

1. They say: "An intolerable nuisance is created at each garbage dump, from foul odors arising from the garbage, and from the winds blowing the lighter material about, and again, while towing to sea, the escape of a considerable proportion of the material to the defilement of the harbor.

"2. Even with the most improved methods of loading, and the best character of boats, the practice of depositing the refuse at sea is reprehensible from every point of view.

"3. We believe that this material could not be deposited at sea at a less distance than two hundred miles without contaminating the Long Island beaches.

"4. The commission was very reluctant to indorse any untried system."

You see, this is all very earnestly expressed, but here comes the humor. After condemning dumps the commission suggests building new ones—instead of doing away with them altogether. After condemning sea disposal, they provide for its continuance instead of its extinction. After condemning boats, they say, let us build propellers. After setting a two hundred-mile limit—some of them now talk fifty miles. After expressing reluctance to indorse any untried system, they do indorse an untried experiment—the garbage propellers invented by one of their number. In short, either the report does not bear out the facts or the facts do not bear out the findings. I do not mean to attack the committee at all, but simply to give you an instance of how little we inconsistent islanders of Manhattan know of the scientific position of the age on the garbage problem. And you may be surprised, but I can assure you that the report of the commission was received almost without comment and quite seriously.

New York and Brooklyn still dump their ashes into the sea—and from dock to ocean the freight is very nearly \$500,000. Occasionally the scows sink—thus in 1893 New York alone deposited eight boats and 2,557 cart loads of refuse, on the bottom of New York Bay. There was a bill introduced into the Legislature calling for an appropriation for dredging out the harbor.

It seems to be the fate of cities, located on islands, to become narrow and provincial in their ideas, and when once the conceit of having the "best in the world" is fairly fixed, their commercial position is on the wane. Therefore New York and Brooklyn, to-day, have nothing to teach other cities on the garbage question, except possibly what to avoid. The English cities show us the value of reducers. Some of our own neighboring towns furnish evidence in cremation, and others are living monuments to the results of the pig-feeding and fertilizer plan—but New York and Brooklyn have the most expensive method of making carrion soup on our neighbors' beaches.

Why there is not a perpetual injunction granted by the courts, I do not understand. The details of the garbage disposal of New York can be expressed in three words: nuisance, failure, and waste.

We come now to the second method: hoggerly and fertilization. The hogs are killed by the broken glass in household swill, and no farmer or gardener will put domestic garbage on his land more than once. It is much cheaper for him to dig a large hole back of his house and bury his own household rubbish, as it is in no sense of the word fit for a fertil-

izer. The popular belief is, that it is a rich and valuable manure, but ask your farmers what the average house production is worth per ton, and you will find, that, what everybody knows, is not so—in this case. The cities that have filtered their swill through hogs and cattle are praying for relief, and this method may be compared to sea disposal thus: less waste, more nuisance, and as great a failure.

It is a long step from the pig-stye to the third method—reduction. Perhaps one of the largest and best equipped of reductors is the Southampton. This will work at a loss of 7 cents per ton, with cheap labor, great economy, and the utilization of every possible bit of rubbish. The most popular of these machines in America seems to be the Merz.

As far as odor is concerned, the Merz has not had a fair chance, because the cities operating it would insist on storing the garbage in open sheds around the plant itself. Naturally, the neighborhood had the full benefit of the putrefaction. There is no reason why the operation should not be perfectly odorless. But in deriving gold from garbage this process is a dismal failure. It requires a large sum of money to erect a plant. One large enough for New York is estimated at nearly a million and a half of dollars. The grease obtained has so little real value that in some places it does not pay to run the extractors. In Paterson, N. J., after the first Merz plant burned, the system was replaced with the extractors omitted. The St. Paul plant which was burned has never been rebuilt. I am told that the Buffalo works are run at a profit—and yet I find the city paying an annual subsidy of \$35,000. I am informed that the St. Louis plant begins to pay, and I find the city paying \$1.80 per ton for having the garbage disposed of. I find so many complaints that it is feared that the machinery, costing \$400,000, will have to be removed. The plant pays 12 per cent., according to the builders, but the stock is selling at 60. Mr. Frenzel, of ex-Mayor Gilroy's commission, estimates the profit of the utilization companies at \$2 per ton—but there is something very strange about this, because I can not find a single municipal plant that pays. The utilization plants of Providence and Cleveland promised much, and have failed utterly.

The cremation furnaces can perform their work satisfactorily, with proper manipulation. The Engle crematory at Des Moines, burns 145 cubic yards and a dead horse in twenty-four hours at an estimated cost of 10 cents a yard. Those who are interested in the Merz process know that ten times, or even twenty times this sum, is not a high estimate for the work necessary to handle a ton through the various manipulations required.

Now it is evident that if we can "Utilize," with as small an expenditure as cremation requires, with a minimum amount of handling, and turn it into a product which has a ready sale on the spot, thus saving the cost of transportation, then we shall go far toward obtaining the hidden wealth. To do this, we must have, first, an odorless and economical furnace—one that has stood the test of long and continued experience preferred. Instead of allowing the heat to escape at a great loss, convert it into steam. Tests in England show an average temperature of 1,646 degrees in the garbage furnace—this is the result of actual measurement with the pyrometer. The result of burning one pound of garbage is sufficient to evaporate one pound of water. The steam produced is

utilized to run machinery for various mechanical purposes, such as making card-board, etc. The English people are obliged to be very economical, and the garbage shows a much smaller amount of carbohydrates and fats than ours. Hence, it seems reasonable to take for granted that the production of steam may have a greater percentage to waste burned, in this country than over there. In my search for an odorless furnace I met, among many, with the Rider, which has given satisfactory service to Allegheny and Pittsburg for about eight years. Perhaps it is the simplest and cheapest of all. A committee of investigation from Newport, R. I., had the curiosity to inquire whether the odors came out of the chimney, and one of their number, Mr. James A. Eddy, in his letter just before me states: "I went at once to the top of the stack and tested the matter, but there was no odor, gas, or offensive smell and I returned satisfied that the combustion was complete. We were all satisfied, and recommended the adoption of this furnace to our city."

Then, to my surprise, I found the Duquesne tannery running four acres of machinery with one of these furnaces, burning tan bark, but, as well, offal of various kinds. Their bills were \$4,000 a year for coal before putting in the furnace and \$100 a year after. As to the ability of garbage to make steam, that has been proved, but I will just add an instance quoted from a letter from Dr. Dunn, ex-President Pittsburg Board of Health. He went to the tannery, found the boiler pressure at eighty pounds; he stopped the fuel and had charged into the furnace three tons of decayed melons, potatoes and fruit, two tons cow manure, ten barrels cesspool matter, and two tons butcher's offal. In all about ten tons bad smelling material. This was entirely consumed in two and one-half hours, with no reduction of power, without odor or smoke, and the gauge still registering eighty pounds. After such a test, let us take for granted, that an odorless, steam-making, garbage furnace is an accomplished fact.

Now, if we can convert our garbage into power, we have something that will bring its price in large cities, everywhere and always. Have the furnaces centrally located to decrease cost of hauling. Steam rents in New York for from \$50 to \$100 a horse-power per year. Each furnace can readily make from 200 to 250 horse-power—day and night. Thus each one has an earning capacity of \$10,000 a year, on a supply of sixty tons of refuse a day.

The cost of labor and fuel is easily covered by 25 cents per ton, or \$15 a day, or \$5,475 a year, leaving a net earning margin of \$4,000 after deducting for repairs and emergencies. Of course, all expenses would be lowered by using cinders for fuel—in practical operation.

I always hesitate in giving facts and figures because they always bring to my mind Josh Billings' keen proverb: "Nothing will lie like figures except facts," or, as one medical man put it, in a city far away: "The garbage disposal here is a political reduction method by which fibs, untruths and plain lies are reduced to statistics."

If we are to have public disposal, I can find nothing better than the plans given before the Academy of Medicine, in my address delivered two days before the report of the Mayor's commission. Inventors have again and again shown to Mr. Harold P. Brown and myself, working plans of steam-making garbage

furnaces, the adoption of any one of which would eliminate scows and propellers, and save the city \$1,000 a day in cutting off this single item of expense.

The fuel value of New York garbage is largely in excess of that in European waste. As Dr. Thomas H. Manley once said to me: "Half of Vienna could live out of New York's ash barrels." In Austria, domestic economy is a stringent necessity, hence the constant presence of the vegetable can, the stale bread tin, the grease pot, and the soup kettle in the kitchen. With our population, canned soup is often bought and the hydrocarbons go into the swill pail. Here is a desperate evil, for it is an axiom of political economy that waste makes want. Unfortunately, the law can not step in and force thrift upon our citizens. Will domestic disposal of all garbage help us? It will help the city by doing away with the great expense of gathering and transportation, but, if the disposer is handy, will not our servants and our poor be more apt to put the drippings and grease into it, rather than take the trouble to fry out the fat for cooking purposes? Shall we not be saving the public purse at the expense of many private ones? The best way seems to be to keep the gold out of the garbage, rather than to attempt to get it out after it has been thrown in. And for this reason I should suggest that the public schools for girls give two hours each week to kitchen economics; let them teach only theory out of some good practical common-sense book, and you may be quite sure most of the little scholars will prove missionaries and reformers of the doctrine of thrift in the next generation, and many of them will be able to save 5 cents out of every dollar earned by the head of the house. Now, therefore, let us investigate the waste at its source—the cook. It is absurd for us to tell that domestic to save albuminoids, carbohydrates, and fats, for she could not understand, but we can find out how she manages to waste them, and how they can be utilized.

Albuminoid or nitrogenous: pieces of bread, cold rice, cold corn-meal, cold potato, cold beans, oatmeal, hominy, sour milk, beets, squash, cabbage, turnips, onions, peas, parsley, asparagus, carrots—these are all "no good," and go into the swill pail first of all.

Carbohydrates and fats: meat, poultry and fish in bits, bones, fat, drippings, and pork and sausage fat, mutton tallow, vinegar and fruit syrups, jellies, preserves—all these are thrown away.

Consult a good cook-book and see what this means: bread can be used for puddings, for griddle cakes, for stuffing meat and fish. It can be dried and powdered, serving the same culinary purposes as cracker dust. Rice, cold corn-meal, cold potatoes, cold hominy can be made into griddle cakes, gems and muffins. Sour milk makes doughnuts, gingerbread, pot cheese, and griddle cakes. The green vegetables may be made into hash and into vegetable salads. Meat, poultry, fish, and bones will make soups, gravies, and many made dishes; fat can be used for shortening bread and gingerbread. Pork fat of all kinds is useful for frying purposes. Tallow has many manifest applications. The farmers use it from head to foot—from hair oil to boot grease—not forgetting chapped hands and soap grease. The fruit skimmings and sweetened vinegar will take the place of wine in sauces. Jelly and preserves will make puddings and pies.

I should suggest a large printed card, hung over the range, for Bridget's information, and embodying

the use of every scrap which she enjoys putting into the refuse heap, and have her live up to the directions. You will reduce your garbage to such an extent that there will be little trouble in dealing with it, the effort to utilize it will not pay, and the burning of it will not be wasteful. But your citizens will lose the nervous anxious worry, and be able to lay by a "little money for the rainy day." It seems much more reasonable to stop the entrance of gold into garbage than to spend much money to recover a portion of the waste.

Since writing the above, the furnace invented by Mr. A. W. Colwell has been tried in New York. This consists of a steam-making crematory, and although it has been in operation but a short time, yet both from an economical and sanitary standpoint, it promises well. We can not sell a pound of manure in this city, hence the large "paper" earnings given to this product by the "Reduction" people are plainly nonsense. Garbage has fuel value only.

THE INFLUENCE OF ALCOHOL UPON URINARY TOXICITY, AND ITS RELATION TO THE MEDICAL USE OF ALCOHOL.

Read in the Section on State Medicine, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY J. H. KELLOGG, M.D.

BATTLE CREEK, MICH.

The biologic test for the urine, perfected by Bouchard, is a most important addition to our means of studying disease processes in the body and the effects of various infectious and toxic agents upon the animal organism. Bouchard demonstrated what had previously been suspected, that urea is not the most important toxic agent of urine, although the most abundant excretory product. His researches demonstrated the fact that urea is only very slightly toxic in character, and that it, in fact, serves a very important and useful rôle in the economy by stimulating renal activity, acting thus as a true physiologic diuretic. The experiments of Bouchard and Rogers have shown very clearly that the urine contains more than half a dozen toxic agents, most of which are far more important in character than urea. Urea is, however, a useful measure of these agents under ordinary circumstances, that is, when the urine contains only the normal toxins; but, under unusual morbid conditions produced either artificially for experimental purposes, or naturally as the result of an infection of some sort, the quantitative determination of urea is no longer a reliable guide, in fact, it may give no suggestion in relation to grave morbid processes resulting in the formation of large quantities of toxic substances and a consequent condition of general toxemia. The same is true with reference to the various other modes of examining urine in common use.

The biologic test of the urine does not require a chemic examination of the urine, hence does not depend upon the chemic recognition, by reagents, of minute quantities of chemic substances, the reactions for which may be obscured by the presence of other known or unknown substances, but makes a direct determination, both quantitatively, and, to some extent qualitatively, respecting the toxic character of the urine in both normal and pathologic conditions.

The following is the method: the urine collected for a definite time, and, if necessary, calculated for twenty-four hours is carefully neutralized and then injected at the rate of 1 c.c. per second into the venous system of a rabbit which has previously been carefully weighed; the weight of the patient must also be known. The exact quantity required to cause the death of the rabbit, and the symptoms occasioned as the result of the injection are carefully noted. The following are obtained, directly or indirectly:

1. The amount of urine required to kill a kilogram of rabbit.

2. The number of kilograms of rabbit which might be killed by the total amount of urine produced in twenty-four hours.

3. The amount of rabbit which might be killed by the quantity of toxic substances produced in twenty-four hours by each kilogram of the patient. The latter quantity is termed the urotoxic coefficient, and is represented normally by the fraction .44, that is, the quantity of urine produced in twenty-four hours by each kilogram of normal human being is capable of destroying the life of .44 kilogram of living being, consequently, if these substances were retained within the body by failure of the kidneys to eliminate them, death would result, approximately in about two and a half days. Clinical observation with reference to the effects of complete suppression of the urinary function agree with the results of experimental study.

I have employed the biologic test a very considerable number of times, some hundreds of times in all, and am fully satisfied with regard to its reliability and accuracy. It is, indeed, a most remarkably delicate test of the condition of the system in general, and of the renal function in particular. A few observations which I have made will serve to illustrate the value of these means of investigation. In a case of tuberculosis the toxicity of the urine was found to be double the normal. Among the most prominent symptoms occasioned by the injection, was a very great rise in temperature, the elevation in temperature amounting to over 3 degrees C. In a considerable number of tests made, in which the urine of a patient suffering from typhoid fever was employed, the toxicity of the urine was found to be greatly increased in every instance, and occasioned a marked elevation of temperature. In a case of intermittent fever of malarial origin, the urotoxic coefficient of 2.36 was found during the paroxysm, the coefficient of being .76 before, and .78 after. This observation seems to show that during the paroxysm of malarial fever there is produced by the parasites of this disease a febrile substance to which the febrile action is due. This subject the writer has considered at length elsewhere.

One of the most interesting observations I have made was in a case of idiopathic epilepsy; the urine employed was collected while the patient was just recovering from a succession of epileptic seizures, having been in what is known as the epileptic state, or static epileptics for nearly thirty-six hours. The urine was found to be extremely toxic, the degree of toxicity being three times the normal. The rabbit died in convulsions which were distinctly epileptiform in character.

The biologic test applied to the urine of pneumonia, erysipelas, scarlet fever, diphtheria, and all other infectious maladies shows a marked increase in the toxicity. When the patient is doing well, that is,

when the poison is being eliminated by the kidneys. In pneumonia, for example, the toxicity of the urine may be considerably diminished during the first few days, but when the critical period is passed and favorable symptoms make their appearance the toxicity of the urine is found to be three or four times the normal.

Delicate chemic investigations of the urine which have been made by Gauthier, Brieger, and others, have revealed the presence in the urine of definite organic compounds which possess characteristic toxic properties. Chemic researches, when sufficiently refined and delicate thus agree with the biologic test, but the modes of investigation employed are too troublesome to be ordinarily used, hence the value of the biologic test.

The above mentioned observations, and many others, having fully established my confidence in the biologic test as a reliable mode of investigation, I determined to make an experiment for the purpose of determining the influence of alcohol upon urinary toxicity. The subject of the experiment was a healthy man of 30 years, weighing 66 kilos. For fifty days prior to the experiment he had taken a carefully regulated diet and the urotoxic coefficient had remained very nearly uniform. The urine carefully collected for the first eight hours after the administration of 8 ounces of brandy diluted with water, showed an enormous diminution in the urotoxic coefficient, which was, in fact, scarcely more than half the normal coefficient for the individual in question. The urine collected for the second period of eight hours showed an increase of toxicity, and that for the third period of eight hours showed still further increase of toxicity, the coefficient having nearly returned to its normal standard.

The bearing of the results of this experiment upon the use of alcohol in pneumonia, typhoid fever, erysipelas, cholera and other infectious disorders will be clearly seen. In all the maladies named, and in nearly all other infectious diseases, which includes the greater number of acute maladies, the symptoms which give the patient the greatest inconvenience, and those which have a fatal termination, when such is the result, are directly attributable to the influence of the toxic substances generated within the system of the patient as the result of the presence of the specific microbes to which the disease owes its origin. The activity of the liver in destroying these poisons, and of the kidney in eliminating them, are the physiologic processes which stand between the patient and death. In a very grave case of infectious disease, without this destructive and eliminative activity the accumulation of poison within the system would quickly reach a fatal point. The symptoms of the patient vary for better or worse just in relation to the augmentation or diminution of the quantity of toxic substances within the body.

It is the recognition of this fact which has led to the recent general revival of hydrotherapy in the treatment of acute febrile disorders. Water applied externally stimulates cutaneous elimination, and, employed freely internally by water drinking and the introduction of water in quantities into the colon to be retained for absorption, aids liver and kidney activity. If the patient dies, it is because his liver and kidneys have failed to destroy and eliminate the poisons with sufficient rapidity to prevent their producing fatal mischief among the delicate mechanisms of the body.

In view of these facts, is it not a pertinent question to ask how alcohol can be of service in the treatment of such disorders as pneumonia, typhoid fever, cholera, erysipelas and other infections, since it acts in such a decided and powerful manner in diminishing urinary toxicity,—in other words, in lessening the ability of the kidney to eliminate toxic substances? In infectious diseases of every sort, the body is struggling under the influence of toxic agents, the result of the action of microbes. Alcohol is another toxic agent of precisely the same origin. Like other toxins resulting from like processes of bacterial growth, its influence upon the human organism is unfriendly; it disturbs the vital processes; it disturbs every vital function, and, as we have shown, in a most marked degree diminishes the efficiency of the kidneys in the removal of the toxins which constitute the most active factor in the diseases named, and in others of analogous character. If a patient is struggling under the influence of the pneumococcus, or Eberth's bacillus, Koch's cholera microbe, or the pus-producing germs which give rise to erysipelatous inflammation, his kidneys laboring to undo, so far as possible, the mischief done by the invading parasites, by eliminating the poisons formed by them, what good could possibly be accomplished by the administration of a drug, one of the characteristic effects of which is to diminish renal activity, thereby diminishing also the quantity of poisons eliminated through this channel? Is not such a course in the highest degree calculated to add fuel to the flame? Is it not placing obstacles in the way of the vital forces which are already hampered in their work by the powerfully toxic agents to the influence of which they are subjected?

In his address before the AMERICAN MEDICAL ASSOCIATION at Milwaukee, Dr. Ernest Hart very aptly suggested in relation to the treatment of cholera the inutility of alcohol, basing his suggestion upon the fact that in a case of cholera the system of the patient is combating the specific poison which is the product of the microbe of this disease, and hence is not likely to be aided by the introduction of a poison produced by another microbe, namely, alcohol. This logic seems very sound, and the facts, in relation to the influence of alcohol upon urinary toxicity or renal activity, which is elucidated by our experiment, fully sustain this observation of Dr. Hart.

It is also easy to show the important bearing of the fact to which we have called attention upon the relation of alcohol to chronic disease. Alcohol is doubtless, at the present time, much less frequently prescribed as a remedy in chronic disease than a quarter of a century ago.

In a recent number of the *British Medical Journal*, Dr. Lauer Brunton, the eminent English physiologist and neurologist, in mentioning the fact that death from chloroform anesthesia rarely occurs in India, but is not infrequent in England, attributed the fact to the meat-eating habits of the English people, the natives of India being almost strictly vegetarian in diet, partly from force of circumstances doubtless, but largely also, no doubt as the result of their religious belief, the larger proportion of the population being more or less strict adherents to the doctrines of Buddha which strictly prohibit the use of flesh foods.

The theory advanced by Dr. Lauder Brunton in relation to death from chloroform poisoning, is that the patient does not die directly from the influence of chloroform upon the nerve centers, but that

death is due to the influence of chloroform upon the kidneys, whereby the elimination of the ptomaines and leucomaines naturally produced within the body ceases, their destruction by the liver also ceasing, so that the system is suddenly overwhelmed by a great quantity of poison and succumbs to its influence, its power of resistance being lessened by the inhalation of the chloroform.

The affinity between alcohol and chloroform is very great. Both are anesthetic. Both chloroform and alcohol are simply different compounds of the same radical, and the results of our experiment certainly suggest the same thought as that expressed by Dr. Brunton. How absurd, then, is the administration of alcohol in conditions in which the highest degree of kidney activity is required for the elimination of toxic agents.

Another thought is suggested in this same connection, namely, the absurdity of injecting alcohol in a case of threatened death in chloroform anesthesia. Notwithstanding the extensive use of alcohol for this purpose during many years, can any person testify that he has seen a single life saved by it? The evident danger of establishing the alcohol habit by such a use of the drug doubtless influences most intelligent physicians sufficiently to lead them to consider it better for the patient to forego any possible benefit which he might receive from the use of alcohol, rather than become a confirmed inebriate. Nevertheless there are still many practitioners who recommend to certain classes of patients the habitual use of beer or wine or some other of the so-called light liquors with the idea that by their use nutrition may be improved, and appetite, digestion, or assimilation increased, or some good be accomplished in some way which no one has attempted to explain.

In a certain proportion of these chronic cases there is a tendency to tissue degeneration. Modern investigations have given good ground for the belief that these degenerations are the result of the influence of ptomaines, leucomaines, and other poisons produced within the body upon the tissues. It is well known that many of these toxic agents, even in very small quantity give rise to degenerations of the kidney. It is this fact which explains the occurrence of nephritis in connection with diphtheria, scarlet fever, and other infectious maladies. Dana has called attention to the probable rôle played by ptomaines produced in the alimentary canal in the development of organic disease of the central nervous system.

It is thus apparent that the integrity of the renal functions is a matter of as great importance in chronic as in acute disease, hence any agent which diminishes the efficiency of these organs in ridding the system of poisons, either those normally and regularly produced, or those of an accidental or unusual character must be pernicious and dangerous in use.

In conclusion, I desire to say that this paper is not claimed to be an exhaustive study of the subject presented, but simply a preliminary report of a work which I have begun, and which I hope to continue in the same line, with the expectation of securing still other interesting and valuable results.

A Retort a la Puffendorf.—Swell of the Period: "Oh! doctor, I have sent for you, certainly; still I must confess I have not the slightest faith in modern medical science."

Doctor: "Oh! that doesn't matter in the least. You see, a mule has no faith in the veterinary surgeon, and yet he cures him all the same."—*Tagliche Rundschau.*

THE TREATMENT OF TYPHOID FEVER WITHOUT ALCOHOL.

Read in the Section on State Medicine, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY W. H. RILEY, M.D.

BATTLE CREEK, MICH.

The purpose of the present paper is to give, briefly, an outline of the method of treatment of typhoid fever as used by the writer in a considerable number of cases.

A consideration of the pathology of this disease does not properly come under this head, but we wish simply to call attention to the well-known fact that typhoid fever is a germ disease. The germ which causes this fever has been generally supposed to be the bacillus of Eberth. More recent bacteriologic studies rather indicate that the bacillus coli may also cause the disease. These germs are usually carried into the body in food or drink, and lodging in the small intestines begin to grow and multiply, and by their life produce poisonous ptomaines which are absorbed and carried by the circulation to all the organs and tissues of the body. It is these ptomaines thus carried to all parts of the body that are largely the immediate cause of the pyrexia and attending symptoms. The organisms which produce these poisons for the most part remain in the intestines, although they have also been found in the spleen.

The indications for treatment are:

1. To remove or destroy the cause (to eliminate the germs and ptomaines from the body).
2. To sustain the vital and resisting powers of the patient.

If the patient is seen early in the disease, it has been my practice to immediately put him to bed and give a free dose of magnesium sulphate. This is preferably given in the morning or forenoon, and may be repeated once or twice on successive days. Beside this the patient should have a large enema of water at a temperature of from 75 to 80 degrees Fah. and this may be repeated daily, or even oftener, for some time, if necessary, to keep the bowels empty of poisonous substances.

The salines and enemas thus used, carry out bodily a large number of germs and ptomaines that are present in the intestines; and further, the salines, by producing an increased secretion of the mucous membrane of the intestines, tend to disentangle and set free many of the germs that have found a lodging place in the walls of the intestines.

For the elimination of the ptomaines which have been absorbed into circulation and carried to the tissues, nothing is better than the internal use of water. From three to five pints should be drunk during every twenty-four hours. It should be taken in small quantities, six to eight ounces every hour or two during waking hours, except when food is taken. We will refer to this point more in detail later.

A consideration of the general care of the patient properly comes under the second head of the indications for treatment as given above. The patient should be put to bed in a large, light, well-ventilated room. At least two sides of the room should communicate directly by windows with out-of-doors, in order that the room may be properly ventilated. All unnecessary articles of furniture, such as carpets, couches, upholstered chairs, pictures, etc., should be removed.

The room should be thoroughly cleaned before the patient is put in it. There should be two beds in the room for the use of the patient. These should be preferably narrow, and so placed in the room that there is a free approach to both sides of the bed, for the convenience of the nurse in giving treatment. Iron bedsteads are preferable to wooden. The bedding should be firm, yet soft and smoothly drawn. There should be just sufficient covering to protect the body. The patient should be changed from one bed to the other daily. This may be done by placing the two beds side by side and carefully moving the patient from one to the other. The sheets on the bed from which the patient has been taken should be washed and disinfected at each change of the beds, and all other bedding should be thoroughly aired and exposed to the sunlight.

The patient should have the care of a thoroughly educated, careful and competent nurse; one who understands perfectly the various methods of using water in the treatment of fevers.

There is no other single remedy that I consider so valuable in the treatment of fever as the internal use of water. As above stated, the patient should drink six or eight ounces every hour during the waking hours, except for about two hours after food is taken. The water should be thoroughly sterilized, and as a rule may be taken either cool or hot. Ice water is objectionable. Hot water is often preferable. This is a simple remedy, but nevertheless is efficacious. It should be given to the patient whether he calls for it or not, and should be considered an important part of his treatment. When water is taken into the stomach and absorbed into the circulation, it throws into solution the ptomaines which have been absorbed from the intestines and are present in the circulation and tissues, and thereby puts them in a favorable condition for elimination. It increases the activity of the kidneys, and thus hastens and increases elimination of the poisons in the system.

In the early stage of the fever, when the pulse is full and the action of the heart increased, it is best to give the patient cool water. Later in the disease, when the action of the heart is weak and the patient feeble, it is best to give the water hot.

Winternitz, many years ago, demonstrated that hot water taken into the stomach acted as a cardiac stimulant, and the increased heart's action is immediate, or at least before the water has time to absorb, which indicates that the hot water in the stomach acts reflexly as a cardiac stimulant. The water after absorption also increases the circulation by filling the blood vessels and increasing arterial pressure. The writer has frequently noticed a decided increase in the fullness and rapidity of the pulse after a patient has drank a glassful of hot water.

The external use of water also forms an important part of the treatment. The patient should be sponged off with tepid water every hour or two when the temperature is 103 degrees or above. When the temperature is less than this, it is not necessary to sponge the body so frequently. Sometimes a hot sponge bath is more efficacious in reducing the temperature than the tepid or cool bath. The sponge bath reduces the temperature, relieves many of the distressing nervous symptoms, is refreshing to the patient, and promotes sleep. The temperature of the body may also be reduced by the use of cool compresses placed over the abdomen and changed frequently.

The matter of diet is an important factor in the treatment of typhoid fever. The diet should be aseptic, easily digested, and should contain the necessary food elements. Probably no one article of diet meets all these requirements as well as sterilized milk. The patient should take from two to three pints daily. The milk is best taken four times during the day at intervals of four hours, taking eight to ten ounces at a time. Should the patient become tired of the milk, gluten gruel may be substituted at times for the milk. A new preparation known as malted gluten, manufactured by the Sanitarium Health Food Company, Battle Creek, Mich., would probably be preferable to gluten, as it is more soluble, and consequently more readily assimilated.

The diarrhea and bowel symptoms, when present, may be relieved by the application of hot fomentations to the abdomen, warm or hot enemas, and 20 grains of subnitrate of bismuth given every four hours.

The patient should be kept as quiet as possible, and should be turned in bed at intervals, to prevent hypostatic congestion and the formation of bed-sores. The bony prominences which are apt to become eroded should be sponged frequently with a solution of tannic acid in equal parts of alcohol and water; a drachm of the tannic acid to a pint of alcohol and water is about the proper strength to use.

By the methods outlined above, that is, by the free use of water internally and externally, by keeping the intestines thoroughly emptied of poisonous material, by the free and frequent use of enemas, by proper feeding and careful attention of a good nurse to the patient and his surroundings, the duration of the fever may be shortened, and the severity of the disease lessened; heart failure and other complications will seldom occur, and the patient will in nearly every instance make a good recovery.

The best method to pursue to prevent heart failure is to keep the poisons which are generated in the bowels and absorbed into the body, and which are the direct cause of the heart failure, eliminated from the body. Should the heart become weak, it may be effectually stimulated by giving hot water to drink, applying heat to the heart in the form of a fomentation, and the application of fomentations to the upper spine.

In the treatment of a large number of cases of typhoid fever, extending over several years' practice, the writer has never made use of alcohol internally to support the action of the heart or for any other purpose.

The number of cases of death from typhoid fever coming under the writer's observation, where the method of treatment pursued has been similar to that indicated above, have been very few, and a much smaller per cent. than in practice where alcohol has been used as a "cardiac stimulant." The writer believes that the use of alcohol in the treatment of typhoid fever is not only useless, but absolutely harmful.

More Oysters Called for in Chicago.—The poet, or song-writer, on the staff of the *Chicago Tribune* is manifestly and urgently observant of the fact that oysters may be eaten in September; he says:

"The oyster now is on our shore, Maryland, my Maryland. Li-tum-ti-tum-ti as before, Maryland, my Maryland. Ritoooral-looral o'er and o'er, tra-la-la-la abundant store, hi-umpty bumpty send some more, Maryland, my Maryland."

REPORT OF THE TREATMENT OF SIX GRAVE CASES OF TYPHOID FEVER WITHOUT ALCOHOL.

Read in the Section on State Medicine at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY KATE LINDSAY, M.D.
BATTLE CREEK, MICH.

The use of any remedy empirically declines always in proportion to increased knowledge of facts and the approach to exactness in medical science in all its branches. When the treatment of disease consisted almost entirely of a medication of symptoms and no fixed rules or indications regulated the giving of drugs, many remedies were used because of precedent and without any other virtue to recommend them for the cure of disease. At the present, when rational ideas about the causes, course, and all other phenomena of disease are found, collected and classified from actual knowledge of these subjects, and the progressive medical mind is not satisfied with the therapeutics of the past, many remedies and methods of treatment, some of them very popular, have been superseded by other and more rational methods of dealing with disease. Preventive medicine has come to the front in many departments of healing, notably in surgery, obstetrics, and the stamping out of many contagious diseases, until we know just what result may be expected from a given, proven line of treatment. No surgeon of to-day would be satisfied with what made glad the hearts of the surgeons of thirty or less years ago. When the house surgeons reported a wound discharging laudable pus freely, it was taken as an evidence that all was well with the patient, and very satisfactory to physicians and nurses. To-day a ward full of laudable pus-discharging wounds would be a signal for sanitary investigation, and an inquiry as to who had sinned, the physician or nurses. What has been the violation of the law of surgical cleanliness in the matter of the preparation for the operation and the dressing of the wound? What, or who was unclean? Patient, attendants, instruments, air, or operating room or ward? And the signal also for a thorough cleansing and disinfecting of everything, and increased care and cleanliness to prevent further extension of the wound infection is indicated.

About a quarter of a century ago the visiting obstetrician of the obstetrical ward of a large city hospital directed the house physician in a case of puerperal septicemia to give hypodermic injections of morphin until the patient was narcotized within an inch of her life, which inch slipped away within forty-eight hours, notwithstanding the house physician's faithfulness for the uterus and adnexa were exhibited to the students within that time. The uterine mucous necrosed in spots, shreds of decaying membranes and clots of blood all told the story of a toxic center from which floods of ptomaines and other morbid elements passed by way of the absorbents and blood currents to every part of the body, completely stopping all assimilation and arresting all functional activity. To-day a similar case would be treated by curetting, flushing and disinfecting, like any other abscess, getting rid of the morbid matter and microbes, and with them the heart failure and other dangerous symptoms for which the heroic doses of morphin or alcohol were given.

Now, latest investigations of the bacteriology of typhoid fever indicate that during the first ten or

fifteen days, typhoid bacilli are found in blood and excretions, later streptococci predominate, causing the pyrexia of the second, third and fourth weeks, the critical period usually in a typhoid fever case, the time when some authors consider alcohol the principal resource of the physician for impending heart failure. (See Osler's "Practice of Medicine," page 38.)

Now to do away with the necessity for the use of this very objectionable drug we have to locate the toxic centers, as in the case of the septic wound and uterus, and devise some safe method of cleansing and disinfecting it, to be as successful as a physician as the surgeon of to-day, in preventing this secondary infection, or of lessening the amount and formation of toxins to that extent that the bodily vital energies will not be overpowered in the conflict with them. The chief toxic center is evidently the intestinal tract, especially the termination of the ileum. The ulceration, necrosis, perforation and hemorrhage, are most frequently found in the last twelve inches of the small intestines, and may extend into the large intestines. The ulcerated surface and open vessels increase the facility for the poison to find an easy entrance into the structures of the body. The microbes, blood clots, necrosed tissue, and pus furnishing abundant supply of toxic matter, which, saturating the system, overpower and stop the activity of the functions of all the organs of the body, causing degeneration of tissues, and death is said to take place from heart, lung, or brain failure, when the failure involves every other organ as well.

Regarding the intestinal tract as any other abscess at this time the physician should seek for methods of treatment or remedies which will remove the morbid matter and destroy, or at least inhibit their action, thus decrease the fever and stimulate the circulation. Secondary toxic centers often develop in the course of this disease, notably in the glands, lungs and depending organs. The hypostatic congestion resulting from lying in one position causing stasis of blood, death and necrosis of tissues, both of the external and internal organs. All vessels connected with the dying tissues carrying toxins to other parts of the body, fermenting food in the stomach and bowels, suppurating glands, phlebitis of the femoral veins, are all examples of this secondary infection, and are accountable for the heart failure and collapses so often fatal during the second, third and fourth weeks of typhoid fever. The six cases I now report will be illustrations of the good effect of rational measures to prevent and meet these complications. It is not said to be the best that may be discovered in the near future, but better than the mere empirical administration of any narcotic or other drug, the action and therapeutic value of which is so much disputed as alcohol at the present time. It also indicates a line of clinical experimentation in the line of intestinal antiseptics, and cleansing and elimination of the alimentary tract, also means to avoid and overcome the blood stasis and death of tissue in the weak dependent organs of the body, liable to stagnation from obstruction or position. The old idea that in peristaltic action lay the great danger of increase of the hemorrhage and perforation of the bowels is giving way to the more rational view that gaseous distension and septic absorption are what bring about fatal results from these complications, and that the moderate peristalsis of the

intestinal walls lessens these dangers by closing the gaping ends of the injured vessels and expelling the septic matter and foul gases. To meet these indications I have found lavage of the bowels, even during hemorrhage, with water of 105 to 110 degrees, or even hotter, given in moderate quantity of from one pint to three, to give great relief by freeing the large intestines of blood clots, fecal matter, and other morbid matter, and also increasing peristaltic action in the small intestines, favoring the expulsion of gas, the heat stimulating the circulation in the peripheral vessels of the intestines, and overcoming the tendency to blood stasis.

Ice bags alternated with fomentations were used over the abdomen externally, and heat, or hot and cold to spine. The extremities were kept warm. From 10 to 30 minims of turpentine in an ounce of gum acacia or starch water increased the efficiency of the enemas and aided in expelling the gas and checking hemorrhage.

The tendency to hypostatic congestion and bed-sores was prevented by frequent change of position and the use of hot and cold to spine, by fomentations and compresses to spine, or better still, hot fine spraying, or alternate hot and cold spray. In one grave case, spraying was kept up for about twelve hours with only short intermissions. The heart was stimulated by heat over it, whenever depression and collapse threatened. From a series of 120 cases of continued fever lasting three weeks and over, not influenced in any way by quinin, the six cases reported below were selected from fifteen very grave cases. These six reached the extremely critical condition.

Case 1.—A. C., age 26; nurse; supposed to have contracted the disease from a 2-year-old child she was nursing. Temperature taken when she went to bed, Dec. 12, 1887, 103 degrees, 6 A. M. Had been feeling indisposed for about a week, with slight and increasing evening temperature and some chilly sensations, but no well-defined chill. From that date until December 24, temperature ranged very steadily between 104 degrees P. M. and 103 degrees A. M., with two or three exceptions, where it rose evenings to 105 degrees, and mornings fell for a short time to 101.5 degrees F. The 20th and 21st there was moderate hemorrhage from bowels, checked by ice to abdomen and heat to spine, and astringent enemas of moderate temperature were given. December 22, one-half pint of blood passed, also at 9 A. M. and 4 P. M.; 7 P. M. to 10 P. M. about a pint of blood clots passed. Patient now began to have marked symptoms of heart failure and indication of hypostatic congestion and bed-sores. Enemas were now given frequently of a higher temperature, and the hot applications made to spine and over abdomen. The gaseous distension was finally overcome, and with the removal of the distension and improved heart action and circulation in all parts of the body, the patient's condition began to improve, although she continued to be indifferent to her surroundings and passed all discharges in bed until December 31, when temperature was normal for the first time, and never reached 101 degrees. A very slow but steady convalescence followed, until Jan. 18, 1888, when unwise friends gave her a full meal of meat, rice pudding, and other hearty food for dinner, causing a severe pain in bowels and stomach, vomiting and purging, and an attack of acute gastritis ensued. Temperature rose from 98.2 degrees A. M. to 103 degrees 6 P. M. the same day. It ranged between 100 degrees morning and 103 degrees until January 27; at that date it reached the normal temperature morning, and evening kept below 102 degrees. February 1 patient was discharged from treatment. For several days patient was nourished by nutrient enemata during relapse. Never reached the danger line, as during the ulcerative stage of the fever.

Case 2.—C. F., young man, age 24, also nurse, contracted fever from a patient he was nursing. Had been feeling unwell for about two weeks, but did not wish to give up, as he wanted to attend college during the winter. Had had a rise of temperature ten days when he took to bed with fever 104 degrees. Had hoped the fever was malaria, and tried to

keep it off with antiperiods. Soon after going to bed the ocher-colored discharges and bloating tympanitis and muttering delirium of typhoid were well marked. Temperature followed the regular typhoid curve of 104 degrees P. M. and 103 degrees A. M. Middle of second week several severe hemorrhages occurred. Patient's condition became critical, but after free lavage of the bowels and the removal of a great amount of blood clots, sloughs, and other morbid matter his condition began to improve. Unfortunately a new nurse took charge of the case at this time, and fearful of producing another hemorrhage, allowed patient to remain on back for about twelve hours without change of position, when the hardening of the tissues over the hip bones and shoulder blades showed that there were extensive areas of dead tissue, and the patient's condition once more became critical from absorption and hypostatic congestion of lungs, spine and all depending organs. It was at this time the twelve-hour-long spray was given. Respiration became very rapid at this time, also pulse rapid and feeble. Under the spray they improved, but the respiration continued 40 and above for about a week. Extensive sloughing of the indurated tissues took place, but under the continued stimulating effect of the spray and antiseptic treatment, healthy granulations soon began to form and the patient recovered, the fever lasting from Dec. 18, 1887, the day he took to bed, until March 1, 1888. When he finally recovered there was extensive atrophy of voluntary muscles, involving the adductors of thumbs and of thighs especially. These muscles were never completely restored, either in size or function.

Case 3.—Miss E. P., college student, age 20, came into the boarding hall of college at opening of college year, middle of September, 1888. Felt tired and unable to begin her studies when the college course opened, but thought by resting a few days would be better. At the end of a week the college preceptress became anxious about her and brought her to a physician, who had her temperature taken and found it 103 degrees. The most distressing symptom at this time was an intense continuous headache, frontal and occipital, which was relieved neither by bromid, antifebrin, antipyrin, or hot and cold applications. It finally abated somewhat under the use of ice and galvanism. Opiates seemed to aggravate. The temperature course was about the same as the other two cases reported. Tympanitis, diarrhea, rash, and sloughing of Peyer's patches ensued. The hemorrhage was slight, but gaseous distension was very marked and required frequent enemata and mild salines with salol bismuth, and other eliminative and antiseptic measures to keep the patient at all comfortable. There was great nervous prostration and a tendency to hypostatic congestion, causing labored breathing and a quick, feeble pulse. The applications of hot and cold to spine were often the only thing which procured her any rest. After these treatments she would sleep for from one to four hours. There was always great tenderness of scalp and tendency of the head to draw backward. After a very critical week, the fourth of her illness since taking to bed, all the symptoms seemed to improve, and for about ten days pulse became strong, about 85 to 90; temperature near the normal line; appetite improved, and discharges from bowels became more normal; only head symptoms remained, and she had delusions of having threads or splinters in her throat. One morning in the middle of the sixth week of her illness she asked her nurse for the bed pan. The nurse went to the closet to get it, when the patient screamed out: "O, nurse, come quick, quick!" When the nurse got to her she was unconscious, face flushed and livid, complete paralysis of all the muscles of the body, and every evidence of rupture of blood vessels in the brain, and the formation of an extensive clot. She died of brain failure and compression in twenty-eight hours, being the only fatal case of the series.

Case 4.—Miss C. D., age 22, dressmaker, called at my office Oct. 12, 1888, about noon. Complained of feeling badly for about ten days. Had chilly feeling in the morning; felt hot and feverish at night; no sweating; nose bled freely. Took temperature, found it 104 degrees F. Had not sought any medical advice before. She was put to bed and treatment to reduce the fever began at once. Her case pursued a course very similar to No. 1. The free hemorrhage from bowels with evidence of secondary infection and heart failure, and to meet these indications treatment was the same, save there was no relapse. Was discharged with normal temperature Dec. 9, 1888.

Case 5.—A. S., a young girl, age 12. Very frail, orphan, parents both died young, but cause not known. Patient had complained of feeling unwell for a number of days. On Oct. 21, 1894, physician first called to see her. Temper-

ature found to be 104 degrees. As she was reported to have had a chill early in the morning of that day and also two days before to have had chill, fever and sweating, she was given a cathartic, warm bath and 12 grains of quinin in divided doses of three grains each. This treatment was continued three days without any influence on the fever whatever, which followed the regular course of evening rise to 104 degrees and morning decline to 102.5 degrees, though sometimes it rose to 106 degrees for a short time. Was very nervous. October 26, had a moderate hemorrhage from bowels; suffered greatly from distension and gas. Hemorrhages repeated the 27th; gas still very troublesome; abdomen hard; grasped throat and struggled for breath; heart's action bad, pulse quick, weak, irregular. Turpentine was now added to the enemata, 15 minims to a pint of water. This relieved the bowels of the gas, and a large amount of blood clots, fecal matter and sloughs, when patient became much more quiet. There was at this time the formation of small bed-sores, but under hot and cold sprays they soon healed. Heart when weak was stimulated by heat and electricity. The other complications were purulent otitis media of left ear, on eighteenth day with exacerbation of temperature from 99 to 106 degrees in a few hours, with free discharge of pus from ear, and disinfecting; recovery from this was complete. But the fever was prolonged, a series of boils keeping up a moderate rise of 100 to 101 degrees until Dec. 10, 1894, when patient was discharged with normal temperature, and improving rapidly.

Case 6.—Miss E. R., age 41, school teacher. Seen first Oct. 16, 1894. Seemed in a dazed condition mentally. Had been out walking, started at 9 A. M. and became confused. Remembered going into a colored church; did not remember coming out. When she came to consciousness found herself in the house of a friend. This lady stated that at 1 P. M. she came into her house, looked and acted strangely, not seeming to recognize any one, but asked if she might lie down on a couch and rest. Fell asleep and did not waken until 3 P. M., when she seemed more rational, but was surprised to find herself in her present surroundings, and as to how she got there. Returned to her boarding place looking so ill that a physician was called. It was then learned from a friend that she had been having diarrhea for two weeks, with fever every evening. Evidently a case of walking typhoid fever. The fever in this case was never high, seldom above 103 degrees F., ranged from that to 101 degrees on a few occasions. The principal feature was the disturbance of the sensation. Soon after taking to bed, passed discharges from bowels and bladder involuntarily; was not unconscious, but had many delusions, one that continued after she first suffered from it a number of days, the result of a complication. She imagined she was in bed with a corpse which always lay on her right side. This began October 29, and nurse at that time in report describes eyes as glassy and patient very delirious. A thorough physical examination of right side revealed a tumor under lower border of short ribs about the size of an orange. This continued to increase in size and to grow downward. Whole right side became edematous, and there was every evidence of a deep abscess, though exact location could not be made out. Patient was now very critical, and to complicate matters hemorrhage from the bowels, free, but not in quantities to be dangerous of itself. The usual gaseous distension and sloughing of Peyer's patches, and a complete inability of the stomach to retain food or even water. These complications were treated by lavage of bowels with the turpentine enemata. Lavage of the stomach was also given, resulting in the removal of a great amount of dark green matter. Patient could then retain a small amount of malted milk, the first nourishment by stomach for three days. But her case was now very critical, and the propriety of an operation was considered. The urine had been examined from time to time with nothing special but changes due to tissue waste from the fever. Now it contained pus, albumin, and blood corpuscles in great amount. The pus found, described in urinary reports, as in balls and bunches, and by the nurse a sediment, stated to be a quarter of an inch thick on bottom of bed pan; evidently the abscess had opened either into a ureter or the bladder. This relieved the profound nervous depression which seemed to threaten the patient's life. Respiration during the rapid filling of abscess became slow and labored, often not more than eight to ten a minute. Pulse also was slow and weak; in fact, never was 90 all through the fever which was peculiar to this case, as in all the other cases pulse was 120 to 140 and 160 during critical periods, but in this case at critical stage it went down to 65 and 70, very compressible, and almost imperceptible, with free discharge from abscess, which continued in the

amount of two to four ounces a day, as measured in the bottom of a glass jar, from Nov. 5 until Nov. 24, 1894, when it began to be less in amount, soon became intermittent and finally ceased altogether after December 3. Convalescence was slow, and patient has not fully recovered yet, April 30, 1895, but has gained her usual weight, 140 pounds. There seems to be no evidence of any return of abscess.

This patient was stimulated during stage of depression, as the others, by endeavoring to keep up the heart's action and stimulate the action of the peripheral vessels by applications of both heat and cold alternating, a hot fomentation of ten minutes followed by the short application of an ice bag, or two douche pails, one full of water 120 degrees and the other 32 to 60 degrees used alternately for a minute or two each. Sometimes a continuous hot spray was most soothing, sometimes one of 80 degrees. At the same time every effort was made to discover and cleanse, if possible, the toxic centers. Careful dieting and experiments with fluid foods, often malted or peptonized and the use of cold water treatment to reduce temperature when high, and other remedial measures in common use were applied, save narcotics and alcoholic stimulants. Knowing fully that there is much yet to learn in medicine, and knowing also that but few men, even of reputation in the profession, have faith for that future when the prevention and treatment of disease by the physician shall bring as certain results as the surgeon now expects, I will close, trusting that I have at least indicated the direction that investigations and experiments should be made if we can ever expect to successfully do away with the use of alcohol in the treatment of disease—do away with the need of this, and other harmful drugs, by substituting more rational and successful methods of treatment.

SHOULD ALCOHOL BE USED IN THE TREATMENT OF DISEASE?

Read in the Section on State Medicine, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY H. D. DIDAMA, M.D.

SYRACUSE, N. Y.

[ABSTRACT.]

After showing that: 1, alcohol is not a food; 2, does not promote digestion; 3, does cause gastric disturbances; 4, alcohol does not increase muscular strength nor promote physical or mental endurance, Dr. Didama continued:

Observation in by-gone days and accurate recent experiments seem to establish these statements beyond successful contradiction.

It is true that, from the time when the patriarch Noah indulged in the fermented juice of grapes which grew in his own vineyard, down to the latest newspaper advertisement, tradition has claimed that wine—alcoholic wine—not only makes glad the heart of man, but gives strength to the weary and heavy-laden, endurance to the sons of toil, consolation and joy to the broken-hearted, and brilliancy to the sluggish intellect. But the testimony of army officers, of insurance companies, railroad corporations, Arctic explorers, and even football and other fighters, is practically unanimous that total abstainers bear extremes of heat and cold, sharp conflicts, long marches, exposures to storms and malaria and infection better, and recover from fatigue and illness more speedily and thoroughly than those do who bounteously or

sparingly partake of the flowing bowl. The same testimony confirms your own observation, that the likelihood of recovery from serious diseases is much diminished by addiction to the use of alcoholic beverages.

The answer of the apologists and advocates is this: Conceding that alcohol is neither directly nor indirectly a food; that it does not promote digestion nor fortify the system against the pestilence that walketh in darkness, nor against the destruction that wasteth at noonday; that its habitual use impairs not only the resisting but the recuperative power of the system; and admitting more than this, even the utmost that is charged against the drinking habit by the advocates of temperance and is well known by the medical profession, that alcohol is the prolific parent of pauperism and wretchedness, of vice and crime and disease, and that the taint of all these may be and often is transmitted to the third and fourth generation; are not the prevalent opinions true, founded on the practice of observing medical men, that the results of modern, accurate, scientific experiments prove beyond controversy that, in the treatment of disease, alcohol is not only useful but so necessary that its judicious employment more than counterbalances all the evils conceded or asserted to be outflowing from or generated by the moderate, and even the immoderate drink habit?

The prevailing opinion of the great majority of wise and otherwise physicians—an opinion founded in part on personal observation and perhaps in greater part on the oral or printed dicta of other physicians—is that alcohol is a stimulant, that it gives strength to a flagging heart, that its use is eminently proper in pneumonia and typhoid fever, when the pulse is weak, and that, in these and all other diseases, the amount administered should constantly increase as the pulse grows weaker; and also that in diphtheria heroic doses are not only justifiable but almost omnipotent in rescuing the patient from the jaws of death.

Years ago a celebrated Brooklyn physician advocated the free use of brandy in this dread disease. This practice—modified in some instances by substituting whisky or wine for brandy—has been pursued extensively throughout this country and foreign lands. An eminent doctor, of large and varied experience in a children's hospital in New York, heartily indorses the practice, and asserts that large doses of alcohol have little or no intoxicating effect on diphtheritic infants. In one of the latest books on children's diseases, a writer declares that the reason why whisky so often fails in the treatment of diphtheria is because it is not given in larger quantities.

Recent and carefully conducted experiments made by competent scientists of world-wide reputation seem to demonstrate that alcohol should be classified with ether and chloroform as an anesthetic, rather than a stimulant. Among these scientists may be mentioned Martin, Ringer, Davis, Sainsbury, Richardson, Reichert, one of whom declares that "alcohol diminishes the sensibility of vasomotor and cardiac nerves as certainly as two and two make four."

As you all probably know, Dr. H. C. Wood asserts, as a result of repeated experiments, that the injections of alcohol in advanced chloroform anesthesia failed in every instance to increase the size or strength of the pulse, and that on several occasions they aided materially in effecting its extinguishment. His em-

phatic advice is: "In accidents during anesthesia avoid the use of all drugs except strychnin, digitalis and ammonia . . . and remember that some, perhaps many, of the deaths which have been set down as due to chloroform and ether, have been produced by the alcohol which has been given for the relief of the patient."

Dr. Frank Payne, Vice-President of the London Pathologic Society, affirms that alcohol is a functional and tissue poison, and that there are no proper or necessary uses of it as a medicine.

Testimony of this sort, the result of experiment and clinical experience, is rapidly accumulating. My limited time will permit me to quote only the matured opinion of Prof. Nathan S. Davis, whose high eminence as a scientist, a lecturer in the Chicago Medical College, an author of numerous medical works, an upright, level-headed, successful and beloved physician, is known and gladly acknowledged by the profession throughout this country and in Europe. Jan. 9, 1895, was his seventy-eighth birthday anniversary. After an entire disuse of alcohol personally and in practice for forty years, and after a long series of experiments, he unhesitatingly declares that alcohol is an anesthetic instead of a stimulant; that as a result of this property it makes the one who uses it feel warmer when he is cold and cooler when he is warm without altering his temperature; that it makes him less sensitive to pain; that in collapse and shock and failing pulse it does not afford relief; that when given with strychnin and digitalis, the stimulating effect is always from these latter articles and is diminished by the alcoholic association; and that wine and beer are diluted poisons, never necessary, never advisable.

Some of the members of the ASSOCIATION have enjoyed during the past year the pleasure of inducing a considerable number of confiding and grateful patients to abstain totally from the use of alcohol as a beverage, and have themselves totally abstained from administering it as a medicine. I think it safe to affirm that the practice has been satisfactory to all the parties concerned.

In the treatment of diphtheria, it has been the custom of not a few physicians, to administer Rhine or Moselle wine in decided preference to brandy or whisky. The comparatively beneficial effects noted must be attributed to the considerable amount of vegetable acid in the wine and not to the small portion of alcohol. There is reason to hope that unfermented wine, which contains all the desirable qualities of the grape with none of its harmful properties, will supersede the intoxicating variety.

The free use of alcohol in the treatment of diphtheria, throughout Europe and in some American cities has been almost universal. The mortality, according to reported statistics, has been appalling. The deaths in the metropolis at home have been 47 per cent., while in Paris, Berlin, and other cities abroad, they have reached the enormous number of more than 60, in 100 cases.

If the antitoxin treatment, which is under hopeful but still somewhat unsettled consideration, shall be proved to possess all the merits which it discovers and friends claim, there will be no excuse for continuing the employment of alcohol in the treatment of diphtheria.

Curiously enough, in the last report from abroad which has just been furnished by Dr. Rabot of Lyons,

the success of antitoxin in curing and preventing the dreadful disease is considered by the Doctor as specially "brilliant," the mortality in forty-seven cases being but 34 per cent., while the mortality in 1893 was 50 per cent. And the reporter significantly and jubilantly adds: "No alcohol was given."

It is just possible that some incredulous cavalier will suggest that the more favorable outcome—bad enough as it still is—was because the customary alcohol was not used; and he may even insinuate that the result might have been equally good if the antitoxin also had been omitted.

PERITONEAL SUPPORTS—(LIGAMENTUM PERITONEI).

BY BYRON ROBINSON.

PROFESSOR OF GYNECOLOGY POST-GRADUATE SCHOOL,
CHICAGO.

(Continued from page 456.)

The mesocolon dextra et sinistra as peritoneal supports are of much importance to surgeons. The right and left colon have been declared to exist and not to exist by various writers. The following remarks I assume to make after the examination of about two hundred cadavers, the last one hundred for the special purpose of tabulating mathematically the existence and length of the right and left mesocolon. The Scotch anatomist, Symington, declares he never saw a descending mesocolon. Treves examined one hundred cadavers and asserts that there is a descending mesocolon in 36 per cent. of subjects and an ascending mesocolon in 25 per cent. of subjects. Toldt claims one descending colon in twenty subjects. Gray declares that an ascending mesocolon exists "sometimes" and a descending mesocolon more frequently. Lesshaft claims that mesocolon descendens exist on an average once in every six subjects and that the mesocolons increase with age, *i. e.*, as the viscera prolapse the mesocolons become more apparent. Abey in his excellent "Anatomic" is inclined to deny the existence of a mesentery for the vertical colons. In the seventeenth German edition of that classical work of Hyrtl, one can read on page 715: "*Man kann insofern nur unrichtig von einem mesocolon ascendens und descendens und einem mesorectum sprechen.*" (One can only incorrectly speak of a mesocolon ascendens and descendens and a mesorectum.) One of the greatest of anatomists, Henle, ascribes no mesentery to the vertical colons, asserting them to be fixed to the posterior abdominal wall by connective tissue, immovable. Quain's ninth edition states: "The investment may be complete with a resulting right mesocolon," and "the membrane (peritoneum) invests (the left colon) much in the same manner as the right." The variation of opinion in regard to the existence of the mesentery to the vertical colon is due to what one understands by a mesocolon: 1, it depends how much dragging is performed on the bowel; 2, it depends on the distended or contracted condition of the bowel; 3, it depends on how close the blades of the mesocolon must be to be named mesocolon. After the careful examination of fetuses, children and adults, I consider a mesentery to the vertical colons as an abnormality, as an exception. The solving of the problem of the existence of a mesocolon dextra et sinistra must depend on observations through fetal, adolescent and adult life. In the second half of fetal life the growing kidneys appropriate the vertical mesocolons so

much that the posterior surface of the right and left colons become more or less fixed to the connective tissue of the dorsal wall. So far as my examinations are concerned the colons never regain their mesentery. It is true that I have in perhaps 3 to 4 per cent. of cases found a partial mesocolon at the upper end of the descending colon, but in such cases the descending colon was generally in a contracted state. At the lower end of the right colon it is often very free, *e. g.*, when the cecum lies on the pelvic floor. But in such cases the peritoneum does not depart from the posterior surface of the colon for several inches above the entrance of the ileum. The lower end of the left colon is generally quite fixed where it crosses the psoas muscle. In certain very spare youthful subjects the connective tissue behind the colon, especially the left, is very loose and extensible. But such subjects lost their fat rapidly. In such cases it is easy to demonstrate a mesocolon descendens by slight traction on the bowel. The degree of extensibility of both right and left mesocolon is considerable and should always be taken into account. It is a rule that the colon ascendens is minus a mesocolon at birth and the bowel is fixed to the dorsal wall. It is a very common and general rule that the colon descendens has no mesocolon at birth and that the bowel is fixed to the dorsal wall. This rule is, according to my experience, established for both vertical colons at the fourth fetal months.

The great utility of mesocolons or no mesocolons has lost its chief significance at present, on account of the impunity of safely entering the peritoneal cavity. Lumbar colotomy or colotomy by entering the bowel on its surface not covered by peritoneum is rare at present, in fact, frequently difficult to perform.

My investigations convince me that the normal vertical colons of man possess no mesentery. These portions of the large bowel are connected with the dorsal wall by connective tissue. They lost their posterior serous covering by the growing kidney having taken and appropriated it to return it no more. The transverse colon possesses a four inch mesentery, short at either end and elongated in the middle, perhaps by the expanding stomach whose blade continues on to embrace the stomach at its lower curvature. That portion of the large bowel between the lower end of the kidney and the upper end of the rectum has a peculiarly elongated mesentery known as the mesosigmoid. It suspends in its fold the sigmoid loop, the S-romanum or the pelvic loop. As the sigmoid loop with its mesentery is of growing interest to the abdominal surgeon, I carefully investigated some two hundred subjects of all ages from a four weeks' old fetus to subjects of 80 years of age. In animals, as the carnivora, there is no sigmoid as one can easily observe in the dog and cat. In the solipeds as the horse, one can see an enormous sigmoid loop with an astonishingly long mesosigmoid, with beautifully ordered nerves, lymph and blood vessels coursing through it. The mesosigmoid then belongs only to animals of certain classes which originally required a long digestive canal to retain the food a considerable time during its passage for absorptive purposes. Yet, after all, the sigmoid loop and mesosigmoid is a result of a mode of development especially due to the peculiar late use and growth of the kidney.

I shall include in the mesosigmoid all that part of

the mesocolon which lies between the lower end of the descending colon and the lower end of the mesorectum. In short, the mesorectum and the mesosigmoid will be considered as one peritoneal support and called the mesosigmoid. As Treves remarks, the sigmoid flexure and rectum said to possess a mesentery, can not be separated. All the large bowel which lies below the lower end of the descending colon and possesses a mesentery we shall designate as the sigmoid flexure, and the peritoneal support the mesosigmoid. Pittard suggested fifty years ago that we should not separate the mesorectum and mesosigmoid. In all the anatomies in command it is plain to observe how the description of the sigmoid flexure or the S-romanum has been handed down from book to book and from generation to generation—one writer copying his predecessor without a shadow of variation.

Fig. 621.

Fig. 47 (after R. J. Goodlee, 1882, in Quain) represents an instructive cross section of the abdominal cavity on a level with the foramen of Winslow. L. 1, first lumbar vertebra. The peritoneum is shown by a Ps—psoas muscle; d, diaphragm; A o, aorta; V c, vena cava; S A, splenic artery; S V, splenic vein; C A, coronary artery; S, splenic vessels cut as they enter the spleen; H A, hepatic artery; P V, portal vein; B. D., common bile duct; L, liver; St, stomach; K, kidney; F W, Winslow's foramen; S S, bursa omentalis; P, pancreas; Sp, spleen; S O, small foramen; L T, ligamentum teres; G S O, gastro-splenic omentum; L S, great omental cavity. The peritoneum can be traced from the middle line anteriorly, where it is seen covering the round ligament of the liver and forming the beginning of the suspensory ligament of the liver, along the right side of the abdominal wall, over the front of the right kidney to the inferior vena cava, where it forms the posterior boundary of Winslow's hiatus. From Winslow's foramen the bursa omentalis extends over the pancreas and left kidney as far as the spleen, whence it is reflected backward along the posterior wall of the small omentum to the anterior of the foramen where it merges into the large sac. The peritoneum turns around the hepatic vessels and forms the anterior of the gastro-hepatic omentum which covers the anterior surface of the stomach and forms the gastro-splenic ligament as it reflects itself on the spleen. The spleen is nearly all enveloped by peritoneum and from its posterior border the peritoneum is reflected on the diaphragm on to the posterior dorsal wall to the middle line.

It is an anatomic literary legacy anciently started by some cloistered monk of Esculapius. It is not always the most wise to introduce new terms, but some seven years ago I began to investigate the sigmoid loop and mesosigmoid and after the examination of over two hundred cases I am convinced that the old division of the mesentery into mesosigmoid and mesorectum is artificial, confusing and unnatural. Beside one can not find any distinct anatomic division or landmark between the mesosigmoid and mesorectum, nor between the loop and rectum. The description given by some of the best English works in anatomy in regard to the sigmoid and its mesentery is to say the least meager and indefinite. "Quain," ninth edition, occupied, according to the British mind the proud position of being the best English anatomy extant. The following is the description which this

anatomy offers on the sigmoid flexure (page 616, vol. II.): "The sigmoid flexure of the colon, situated in the left iliac fossa, consists of a double bending of the intestines upon itself in the form of the letter S, immediately before it becomes continuous with the rectum at the margin of the pelvis opposite to the left sacro-iliac articulation. It is attached by a distinct mesocolon to the left fossa and is very movable, falling into the pelvis when the bladder is empty. It is placed immediately behind the anterior wall of the abdomen or is concealed only by a few turns of the small intestine. The sigmoid flexure is the narrowest part of the colon. The description from a prominent anatomy is not only meager, but absolutely misleading. In the first place my examinations show it is seldom situated in the left iliac fossa; and, 2, that its mesentery does not attach it to the left iliac fossa; and 3, it does not assume an S-shape. So that

toward the left—the line of least resistance and forces the colon leftward with its mesentery. But the leftward moving of the descending mesocolon only takes place as far downward as the lower pole of the kidney; that portion of the mesocolon extending from the lower pole of the kidney to the rectum does not, at first, move to the left, but constitutes what we include in the mesosigmoid. Now the position of the mesosigmoid varies much as regards its position in early life. I have examined a child eighteen months old with the mesosigmoid inserted directly in the mid-dorsal line as high as the second lumbar vertebra—even higher than the lower pole of the left kidney. In others the whole mesosigmoid may move to the left, earlier. Occasionally, in adults, it was found that the mesosigmoid had moved but slightly out of its original mid-dorsal insertion. However, generally by the sixth month of gestation the mesosigmoid has begun to move definitely toward the left, *i.e.*, its mid-dorsal insertion has begun to shift its line downward and outward toward the left iliac fossa. The left blade of the mesosigmoid in my opinion, becomes displaced, drawn out with the advancing leftward mesosigmoid insertion followed by the right blade covering up the old line. The various forces at work shoving the mesosigmoid line of insertion leftward

Fig. 48. This figure 1 sketched to illustrate the mesosigmoid, the sigmoid loop, the psoas muscle and the intersigmoid fossa. 1, psoas muscle; 2, line of insertion of mesosigmoid; 3 points to the intersigmoid fossa; 4 is placed on the iliac muscle at the junction of the lower end of the colon and upper end of the sigmoid loop; 5 is near the hook which suspends the S-iliac.

Fig. 49 1 sketched from a post mortem examination of a 6-months-old child in which Dr. Waite and I performed the autopsy. We found an enormously long S-iliac, as shown in the figure, reaching into the right iliac fossa and existing in the state of a volvulus; a and b represent the mesenteric axis around which the loop c has rotated. The volvulus at the autopsy did not seem twisted tight enough to cause obstruction. The figure illustrates the notable long S-iliac found in the newborn.

are: (a), the rapidly increasing packet of small intestines; (b), the large left lobe of the liver; (c), the rapidly increasing left kidney; and (d), the increased lateral abdominal space.

It is thus noted that the mesosigmoid moves from its mid-dorsal insertion to its left iliac insertion gradually. I have actually observed in fetuses and children that it will require two years after birth in some subjects for the mesosigmoid to assume its oblique adult insertion. In one adult it could be said that it had only partially moved from its original insertion. In other adults it could be observed that the mesosigmoid had its insertion excessively to the left. Also, it was frequently noted that the line of the mesosigmoid insertion varies very much. The upper end may advance much more than the lower end or *vice versa*. The line of the insertion of the mesosigmoid in adults begins at the lower end of the ascending colon and ends at the point where the rectum leaves its mesentery. The lower end of the ascending colon is at a point where the bowel begins to pass transversely across the psoas muscle at its outer border. The lower end of the mesosigmoid is

investigations in general, do not agree with Quain in situation, attachment or shape. Also I can assert that the junction of the mesosigmoid and mesorectum (or the bowels) at the left sacro-iliac joint is not what nature generally presents. No one can see a division between the sigmoid bowel and the rectum.

The first and most significant matter to investigate is the origin, cause and final location of the mesosigmoid. This is naturally determined by examining fetuses of all ages, the newborn children and the adult. In the fetus the descending mesocolon is inserted directly in the middle line of the body from the second lumbar vertebra to the end of the sacrum. At the end of the third month of gestation, one finds that the kidney is beginning to increase rapidly, insinuating itself between the blades of the descending mesocolon. As the kidney increases in size it grows

at a point where the mesorectum ceases, or at the third sacral vertebra. The course of the line of insertion of the mesosigmoid in the adult may be described as follows: the line begins just below the lower pole of the left kidney and passes generally in a curve or transversely over the psoas muscle. Sometimes the line of the mesosigmoid insertion and the ureter converge to a point at the ureter at the right side of the psoas muscle. The line then runs irregularly midway between the right edge of the psoas muscle and the mid-dorsal line, downward into the pelvis on the anterior surface of the sacrum, varying in its point from the right to the left border of the sacral anterior surface. In fetal life the line of insertion of the mesosigmoid may pass in its middle point up to the second lumbar vertebra, or even to the lower end of the duodenum where the spermatic vessels emerge which aid in forming the conical intersigmoid fossa. The base or dorsal line of the sigmoid varies very much in its length. It may be four or twelve inches but will probably average six. This line in many adults extends directly from the lower pole of the left kidney to the point of disappearance of the mesosigmoid at the third sacral vertebra. The basal insertion of the mesosigmoid is nearer the median line than distal or periphery, *i. e.*, the S-romanum. The length of the distal line of the mesosigmoid I measured in fifty adult subjects and its average was sixteen and three-fourths inches. With a base line of six inches and a distal bowel line of sixteen inches it gives the mesosigmoid a fan or truncated cone-shape very similar to the shape of the mesenterium. The shortest adult base mesosigmoid line was eight inches, while the longest distal was twenty-eight inches in fifty subjects. The length of the mesosigmoid from the dorsal line of insertion to the bowel is an average of two and one-half inches. In fifty subjects the longest was five inches and the shortest an inch and a half.

(To be continued.)

SOCIETY PROCEEDINGS.

Chicago Pathological Society.

Regular Meeting, June 10, 1895.

WELLER VAN HOOK, M.D., President, in the chair.

DR. E. FRIEND read a paper on

A CASE OF LICHEN RUBER PLANUS.

I take the liberty of presenting before you this evening a patient, affected with not an altogether common, yet at the same time to my mind, rather interesting example of generalized lichen ruber planus, or as is more commonly known here in America, lichen planus. The patient was kindly referred to me at the United Hebrew Charity Dispensary, by Dr. Fischkin. Her history sheet read as follows: Mrs. Anna O., nationality American, age 40 years, occupation nurse, family history negative. Patient is of a dark complexion, dark eyes and hair, height five feet five inches. Weight 105 pounds, which is 30 pounds less than she weighed last Christmas. Previous history: during childhood, patient had measles, typhoid fever, mumps, since which time the patient has been quite well, to the time of the birth of her third child, which was twelve years ago; since this time patient has been troubled with a supposed bladder affection, which manifested itself by a frequent desire to urinate, and a burning and smarting pain while urinating. The urine remaining clear at all times. This has persisted more or less up to the present time, when patient urinates about every hour, and sometimes a "spasm" as she terms it preventing her urine passing freely. *Status Præsens:* her present disease began in January last, with a severe chill which lasted three hours, followed by fever and a tired, drowsy, sleepy feeling. The patient stated she was entertaining friends at the time

and had to desist, one of her lady friends remarking that she had never before seen Mrs. O. in an intoxicated condition. Following these symptoms, she had a severe headache, and two days afterward she noticed an eruption in the right pectoral region of the chest characterized by separate and discrete millet seed to split pea sized shining, polygonal, and round, bluish or pinkish papules, with a central depression, (so well likened by Kaposi to a piece of wax, upon which an impression had been made with point of a pin), hard and firm to the touch. The color disappearing somewhat on pressure.

The post-cervical lymphatics became and are still enlarged. This eruption spread along the right side of the chest, thence to the neck, opposite side of the chest, back, flexor surfaces of the arms, but better marked on the fore-arms, abdomen and inner and outer aspect of the thighs and legs. On the abdomen the eruption is more marked, at the waist band line, and here especially these papules undergoing involution leave a characteristic, sepia brown pigmentation and the appearance of an atrophy of the skin. The itching which was very slight during the entire course of the disease was present here to greater extent than in any other portion of the body. The inguinal lymphatics are enlarged, especially in the right inguinal region to the size of a pigeon's egg, separate, distinct and tender to the touch. In a number of places on the back, the papules are arranged in chains, or like beads on a string and correspond to Kaposi's lichen ruber moniliformis.

The physical examination reveals the mouth entirely free from any affection. Heart and lungs normal, abdominal viscera normal, with exception of the spleen, which although apparently not enlarged is quite tender, both on percussion and palpation. Vaginal examination reveals nothing abnormal with the exception of a cervix laceration, which the patient is unaware of and does not trouble her in the least. The urethra for some distance is the seat of a number of small hyperemic polypoid growths, these having been removed from time to time by a number of different physicians. Appetite is ravenous. Bowels are regular. Menstruation regular and painless. Urinary analysis negative. The patient's treatment has been the Asiatic pills one after each meal, and locally Unna's salve composed of carbolic acid, 20, corros. sublimate 1 part in benzoated oxid of zinc basis 500; she has made quite an improvement in about one week's treatment. The patient kindly allowed me to excise a section of skin of her back containing a number of typical lichen papules, for histologic examination, which I am sorry I can not present to you this evening owing to the lack of time required in preparing them.

Appendix. The histologic examination of a section of the skin involved in the bead-like formation, which was fixed in picric acid and bichlorid of mercury, hardened in alcohol, and stained in alum carmine, revealed the following pathologic changes: over each papule, the epidermis was much flattened, especially the lining layers beneath which the papillæ were literally packed, with a round cell infiltration and in those papillæ not the seat of such a dense infiltration, the capillaries were very much distended. This infiltration of round cells also followed along the hair follicles and sebaceous ducts, but seldom deep in the corium. There was to some extent a hypertrophy of the rete malphigii. A bacteriologic examination was made with negative results.

This case seems of particular interest in that a number of subjective and objective symptoms point toward an infectious nature of the disease, as Lassar believes, and who has found a bacillus supposed to be responsible for this disease:

1. The suddenness of its onset.
2. Beginning with a chill and followed by a marked fever, and general malaise.
3. Enlargement of the lymphatics.
4. Rapid loss in weight.
5. Marked tenderness of the spleen.

DR. C. D. WESCOTT reported a case of

FIBROSIS OF BOTH OPTIC NERVES, FOLLOWING FRACTURE OF THE BASE OF THE SKULL.

By the courtesy of my friend, Dr. Hektoen, professor of pathologic anatomy at Rush Medical College, I am privileged to report the following rare case. I know of no case in my own experience or in my reading which is parallel:

A young, vigorous man, 23 years old, died from acute, general, serofibrinous, leptomeningitis after an illness of two days, characterized by coma, opisthotonos and other grave symptoms. The following history was obtained: one year previous he fell from a United States mail car while the train

was running at the rate of about forty miles an hour, and sustained a compound fracture of the frontal bone, on which account he was confined to his bed for seven weeks. Some bone was removed. During the first few days after the accident he is reported to have had convulsions, but since his recovery he has attended to his duties as railway mail clerk. Shortly before the fatal illness he noticed that his eyesight was rapidly failing and as near as it can be learned it was the left eye in particular that appeared to give out. At the post-mortem examination there was found a cicatrix in the left frontal region beginning about one inch above the left supra-orbital notch, and describing a semicircle toward the left, ending in the median line three inches above the point of commencement. In the forehead, corresponding to the lower portion of this scar, was a depression in the bone one inch long transversely, and half an inch wide vertically; this depression was due to a loss of substance in the bone, the entire thickness of which was replaced by firm, white, fibrous membrane adherent to the scalp and to the dura mater. The dura was also firmly adherent to the floor of the skull in the left anterior fossa and manifestly thickened in the adherent parts. There were no old fibrous adhesions between the pia and the dura. In the pia was a marked sero-fibrinous inflammation with turbid fluid in the ventricles and at the base. There were no abscesses in the brain. There was considerable deformity in the bone forming the body of the sphenoid and the cribriform plate of the ethmoid, but there was no dead bone and there was no suppuration in the pericranial cavities such as the ethmoid sinuses, the ears, etc. There seemed to be much firm fibrous tissue about the optic nerves in front of the commissure and extending through the optic foramina and sphenoidal fissures into the orbit for a little distance. As the optic nerves passed through the foramina they were imbedded in this firm scar-like tissue and appeared compressed, the left more so than the right. The commissure and optic tracts did not show any changes to the naked eye. The other organs in the body were free from any chronic disease. The sections of the nerves removed have been submitted to Dr. E. R. LeCount, for microscopic examination and the following is his report:

The right nerve (cross section) shows very slight thickening of the perineural connective tissue. The nerve bundles are completely degenerated throughout the whole diameter of the nerve, and in place of cross sections of nerve fibers are seen, instead, a granular debris and the nuclei of endoneural connective tissue. Here and there, but seen only seldom, are cells which resemble neurilemma nuclei. The left nerve also on cross section shows a great increase in the perineural or interfascicular connective tissue. It is thickened, more fibrous, hyalin looking and homogeneous-like cicatrix tissue and the spaces formerly occupied by nerve bundles in place of being circular in shape are angular, compressed, of various shapes and very irregular. There is an excess of cells and nuclei in these spaces—none of these, however, resemble leucocytes. There is complete disappearance of nerve elements proper.

DR. A. E. HALSTEAD read an abstract of a paper on

FLOATING BODIES IN JOINTS.

Floating bodies in joints, or joint mice, are bodies usually composed of bone, cartilage, masses of fibrin or fat, or fibrous tissue, either loose in the joint or attached to some part of the joint surface by pedicles. A majority of these bodies are found in the knee joint, some in the elbow, and rarely in the ankle and wrist. The reason for the frequent occurrence in the knee is that its surface is large and, by its position, it is greatly exposed to traumatism.

Etiology—Classifications—1. Those found in otherwise healthy joints, the disease, if any, occasioned by the presence of the bodies.

2. Those found in diseased joints.

In healthy joints. (a), of purely traumatic origin. Very rare cases reported by Volker, Fischer and Feuerer. (b), composed of separated pieces of cartilage or of bone that were not broken off at the time of injury, but became detached later. The osteochondritis dessicans of König and quiet necrosis of Paget. Cause unknown. (c), those originating from hemorrhage into a sound joint, as result of traumatism. Exceedingly rare. Cases reported by Gurlt, Fischer, Shattock and Bowlby. (d), those caused by drawing into the joint foreign bodies embedded in the capsule, such as bullets, needle points, etc. Case reported by Shaw.

In diseased joints. 1, So-called corpora oryzoidea in tubercular hydrops articuli and hydrops fibrinosis of Volkmann and Ranke. Originate (a), as pure concretions. (b),

desquamated epithelium forming nuclei for deposit of fibrin; (c), detached villi. (d), those originating from cartilaginous metamorphosis of synovial membrane or fibrous layer of capsule drawn into the joint. Cases reported by Klein, Fischer, Delgarde and Schmidt. (e), those resulting from pathologic changes occurring in normal joint villi, with subsequent detachment of villi. (f), those which occur in arthritis deformans. Case reported by Recklinghausen.

Growth of body. Body is observed to increase in size in one of my own cases, and others reported, probably: (a), by deposition of successive layers of fibrin; (b), proliferation of cartilage or bone cells nourished by synovia.

Symptoms. (a), sudden locking of joint, usually in position of extension, any attempt at movement causing severe pain; (b), acute synovitis from one to four weeks; symptoms recurring usually three or four times a year; (c), crepitation and lengthening of femur usually present. Increased length of femur in one of my own cases of fully 3 centimeters.

Diagnosis. 1, sudden pain in otherwise healthy joint; 2, acute synovitis, with no other apparent cause, make probable diagnosis, and 3, locating floating body makes it positive.

Treatment—(pre-antiseptic)—1. Palliative: (a), fixation of loose body by compression; (b), by passing needles through the capsule; (c), by subcutaneous ligature.

2. Radical: (a), removal through direct incision; (b), incising skin and capsule at different levels; (c), subcutaneous operation performed at two sittings. Mortality was very high and complete recovery rare.

Antiseptic. By direct incision, preferably under local anesthesia, (Schleich's method .02 per cent. cocain), capsule sutured with catgut, skin with silkworm gut; no drainage or irrigation. Patient should walk in one week.

Three cases reported, two of so-called osteochondritis dessicans.

Conclusions—1, so-called osteochondritis dessicans explains most cases in normal joints; 2, few, if any, result from direct violence; 3, chief symptoms, sudden pain and locking of joint in nearly extended position, followed by acute inflammation; 4, lengthened femur may occur from irritation caused by pressure of these bodies; 5, direct incision, as soon as diagnosis is made, preferably under cocain anesthesia, is the only treatment.

THE PRESIDENT.—Some recent investigations in reference to the physiology of joints may have an important bearing upon the production of joint bodies, or, at least, upon their growth after they have once gotten loose.¹ It seems that the serous membranes of the joints do not stand in open communication with the lymphatic vessels of the extremities, as has been thought; which means that fluids effused into the joints are not readily resorbed. This result derived from experimental study is in harmony with the fact, well-known for years, that fluid effused into a joint is much more readily gotten rid of if there is a rent in the capsule than if resorption has to take place solely from the surface of the serous membrane itself. The practical bearing of this fact upon the formation of joint bodies is this, that resorption of small masses of tissue once loosened is slow, and that resorp-

tion of fluid produced by the irritation of the synovial membrane is also slow, so that quantities of fibrin can be deposited upon the surfaces of loose bodies, and a large quantity of nutriment is supplied for the growth of these masses, thus enabling them to reach a considerable size.

DR. S. L. WEBER—There is one point in the etiology of foreign bodies in the knee joint that I wish to speak of, and I do not know that I have seen it referred to. As to the kind of bodies, the essayist has described them well. They are not of traumatic origin; that is, they are not due to blood clot. A large majority of these bodies are apparently attached to the intra-articular ligaments, very close to the villi of the joint, and they sometimes start from there. What can be the cause of that? Why does such a formation of cartilage occur within the joint? Why does it not occur in other joints as well as the knee joint? My point is this: We know the knee joint originally was a double joint, and that the ligaments running from the patella to the inner surface of the condyles are the remains of a former wall between the joints. Just the nature of the wall I do not know, but it must have been cartilaginous, possibly bony, and that in the evolution of the knee joint this cartilaginous wall has gradually been done away with, and we have now one joint instead of two. I think the formation of this cartilage in these intra-articular ligaments is a relapse to the former evolutionary type, not a degeneration. I think that point, which I have never seen made, will explain the formation of these cartilaginous bodies, or a large percentage of them as found in the knee joint, and why they occur in the knee joint and not elsewhere.

DR. HALSTEAD (closing)—The reason why these bodies occur more frequently in the knee joint than in any other is because this joint, on account of its position, is more generally exposed to trauma, and in the second place because of the large surface over which the trauma may be distributed. It is said that some of these joint bodies are due to a so-called osteochondritis dessicans. I do not think we have usually degeneration of the villi of joints, but sometimes we may have. Klein, in his histology, has shown by cuts and the text that the synovial membranes of the joints, especially the knee joint and also the villi, contain cartilage cells. I said in my paper that in most cases where villi formed loose bodies in the joint, in 95 per cent. of them there would be some inflammatory condition of the joint previous to the appearance or existence of the bodies. Cartilage cells are normally present in every joint, and we need not go back to the evolutionary period for their existence. Take any normal joint and we will find in it cartilage cells, and we know that inflammation will stimulate their growth, so that later they may become detached.

(To be continued.)

Mississippi Valley Medical Association.

Abstract of the Proceedings of the Twenty-first Annual Meeting, held in Detroit, Sept. 3, 4, 5 and 6, 1895.

(Concluded from p. 462.)

DR. C. B. BURR, of Flint, Mich., read a paper on

THE PARANOIAC—A MENACE TO SOCIETY.

He made brief and pointed reference to the numerous recent murders of prominent persons by so-called "cranks." What to do with these persons is one of the problems confronting our modern civilization, and is one demanding an answer from students of the subject. We have room enough in our asylums. The trouble is, harmless lunatics are kept in confinement, while dangerous paranoiacs are allowed their liberty. These murders disturb the public but a day, and do not scare us into further provision for a safeguard. The public do not sincerely seek advice from professional sources in the matter. No one who has been threatened by a paranoiac would be willing to have his commitment settled by a jury without medical testimony as to the danger involved in granting freedom to such an individual. The paranoiac is a menace to society and should be sequestered. But doubtless the public will continue to view with indifference or approval, now and then, the execution of a criminally insane person, as "sane enough to hang," and vainly hope for a deterrent effect of this example upon other deluded minds.

DR. I. N. LOVE, of St. Louis, remarked that doubtless all of us would hesitate to offer criticism on so valuable and thorough a paper from such an authority as Dr. Burr. He then related a case in St. Louis where a man had murdered

his wife and child, having become a paranoiac through excesses and debauchery. The entire profession of St. Louis agreed that it was the work of a paranoiac, yet a country jury declared he was sane enough to hang. He emphasized the fact that often these people are stimulated to crime by the notoriety the newspapers give them, and consequently the papers should be encouraged to suppress such items.

DR. HUGH T. PATRICK, of Chicago, called attention to the fact that the fixed illusions began as early in life as 5 and 8 years, and then in such cases measures of restraint should be instituted. These illusions are not always discovered, even by the family physician.

The next paper was by DR. A. E. STERNE, of Indianapolis, entitled "Toxicity in Hysteria, Epilepsy and Neurasthenia," which will appear in full in the JOURNAL.

DR. HUGH T. PATRICK, of Chicago, followed with a paper on SOME OF THE MORE RECENT METHODS OF STAINING NERVE TISSUE.

The article was elegantly illustrated with water color drawings of each of the stains used in nerve tissue, and a most thorough and practical resumé of the subject, with its application and technique was given. He considered the method of Nissl to be the method *par excellence* for nerve cells. With it, minute changes in the cell structure could be detected which would elude any other method. The method of Bevan Lewis, while marking an advance in technique, was thought to be less perfect than claimed for it by the originator. It is, however, excellent for hypertrophied neuroglia cells. The beautiful results obtained by the Golgi method, as modified by Ramon y Cajal, were illustrated and the importance of the discoveries due to it were emphasized. Rosin's stain which is practically the Ehrlich-Biondi blood stain, gives in some cases almost ideal results. The method of Flatner—chlorid of iron and dinero-resorcin—was illustrated as applied to normal and degenerated nerve fibers, and the Doctor thought the method was to have an important future. The method of Marchi was said to excel any other for degeneration of from three weeks' to three months' duration. Allusion was also made to the developmental method of Flechsig, and to an unusual but valuable result of the Weigert-Pal stain and illustrated drawings shown.

DR. STERNE said that the carmine stain has a particular adaptability for double staining. In bringing out the anatomic details it is practically a necessity. The Nissl stain is the most exact, and for giving an idea of the ganglionic structure can not be excelled. For all purposes the Marchi method is perhaps the most reliable.

DR. PATRICK said he had simply pointed out the advantages of each method. We want for each case that which will give us the best results.

Then followed a paper by DR. A. P. BUCHMAN, of Fort Wayne, Ind., entitled

PSYCHOLOGY IN MEDICINE.

The author discussed the subjective and objective relations of mind and pathologic conditions. The unit force acting properly is health; abnormal action of this unit is disease. The structure of man is governed by a connected train of associated movements called ether, of the existence of which we can have no anatomic proof; but to which the growth of the body must bear definite relation. Fear, grief, anger or joy modify the functions of the vital centers. The sympathetic nervous system is the center of the emotions, and the cerebro-spinal system of that of abstraction. Thus we come to psycho-physiology and bio-chemistry. Thence we step to the subject of hypnotism. The different methods used in producing hypnotism were minutely described; then the possible uses and dangers of hypnotism in medicine were discussed, showing that while good might be done, there was also much danger in its use.

DR. STERNE said it was giving the hypnotizer a dangerous power. Any one can hypnotize, as only a certain mental concentration is necessary. The interest in the subject is not so much a medical as scientific one. There is frequently, if not always, an element of fraud in hypnotism. There is a chance of murderers claiming they were hypnotized.

DR. PATRICK emphasized the fact that the hypnotist has no hypnotic power. It seems almost a farce to discourage this idea, as it was exploded a century ago. It is purely a subjective influence.

DR. BURR remarked that the insane could not frequently be hypnotized. They could, if the hypnotizer had any power in reality. It is possible in epilepsy to do much with it; also in hypochondria and melancholia it might be valuable.

DR. BUCHMAN claimed the French Academy had in the past ten years positively demonstrated the existence of hypnotic power.

DR. PATRICK said, in rebuttal, he did not claim that there was no such thing as hypnotism, but that the hypnotizer had no direct power in himself over the subject hypnotized.

DR. C. J. HELM, of Peru, Ind., then presented a paper on "The Nervous System as a Factor in Disease." The paper was an excellent resumé of a great subject, and to make a notice of the points made without free excerpts is impossible. Slight functional disturbances, if constant and continued, may produce actual organic lesions. Change is the great remedy for these troubles, not necessarily of surroundings but of the waste places in the nervous system; give the forces some new direction. Study your patients in every phase. Get them out of the ruts they have gotten into, and you will have then cured your patients before you know it.

DR. ROBERT H. BABCOCK, of Chicago, presented "Some Considerations with Regard to the Senile Heart." The condition is not always due to age or necessarily found in the aged. Importance should always be given to the myocardial changes. Dyspnea is a most frequent symptom of senile heart, although it occurs in other conditions as well. It finally becomes the almost surely fatal symptom—Cheyne-Stokes respiration. Various remedies were advised, and among them the hypodermic use of morphia in a single dose.

DR. FÜTTERER, of Chicago, said we sometimes find in these cases a more or less intermittent pulse.

DR. J. B. HERRICK, of Chicago, added his testimony with regard to arhythmia, which he considers a frequent and most important symptom.

DR. BABCOCK said that the intermittence is not necessarily a dangerous symptom, but at the same time any such senile heart is liable to stop during one of these diastolic irregularities coming on suddenly. In Cheyne-Stokes respiration morphia seemed to act best with small doses of atropin.

DR. FRANK BILLINGS, of Chicago, presented a paper on "Intercostal Neuralgia." The disease is always secondary and consequently, in reality, only a symptom. It may be due to toxic forms of functional nerve disturbance, or to pressure by tumors. The functional form is most common and usually due to a defective excretion or mal-assimilation. Indigestion is a most frequent factor, whether due to the character of food ingested or to nervous conditions. Insufficient food and lack of outdoor exercise are frequent causes. Intercostal neuralgia occurs oftener in females, usually on the left side. Palpitation is usually present. Gas in the stomach with eructation is always present. In diagnosis we must always search for the cause. It may be confounded with pleurisy or muscular cardiac rheumatism. In treatment, remove the cause and give any simple restorative tonic.

DR. W. H. PORTER, of New York, read a very exhaustive paper entitled "New Light on the Rôle which Iron Plays in the Physiologic Economy—How and where does the Hemoglobin come from?" It is not the product of synthesis. It is difficult to formulate a nucleo-albumin. The iron is not excreted by the salivary, gastric or sweat glands. The hair uses up some, the urine a slight amount. The bile uses most, but the total in both hair and bile is only one-tenth grain daily. Some writers say that the iron is stored up in the liver, but this is not practical. The intake and output both being very small, we must conclude that iron in the body is very stable. There is then a question whether iron should be so frequently and indiscriminately used in anemia.

DR. JOHN NORTH, of Toledo, had almost given up the administration of iron in cases of anemia. In most cases we should correct the trouble in the alimentary canal, avoid the destruction of the nucleo-albumins, and no iron will be needed.

The paper of DR. JOHN AULDE, of Philadelphia, on "The Abortive Treatment of Typhoid Fever," was read by the Secretary of the Section. The author reviewed the advantages of guaiacol, carbolic acid, salol, betanaphthol and others, and finally gave his own and others' experience with arsenite of copper, stating that, in his opinion, the disease could be aborted at almost any stage by the use of copper arsenite with appropriate constitutional remedies. As a rule 1-100th gr. should be given every four or six hours. The remedy may be given hypodermically if the disease be advanced to the second or third week.

DR. GUSTAV BLECH, of Detroit, read a paper on "Medicinal Treatment of Typhoid Fever." The author opened his paper with: "There is no specific treatment for typhoid fever." Hydrozone, 1-32, is a most valuable intestinal antiseptic. Irrigation of bowels with cold water is a necessary adjuvant in all cases.

The two preceding papers with that of DR. J. E. WOODBRIDGE, of Youngstown, Ohio, on "Typhoid Fever and its Abortive Treatment," were read in succession and discussed jointly.

DR. LOVE said the treatment suggested by Dr. Woodbridge was not original; that all physicians had used the same for years. He protested against the use of the term, abort, as he thought it could not be done. Rest is an important factor in the treatment. Typhoid fever is a matter of diagnosis. He questioned the diagnosis of typhoid in some of the cases reported by Dr. Woodbridge.

DR. NORTH would change the word abort, to miscarriage. The germs do not enter the circulation. If we can discover something which will eliminate the germs, we can thus cut short the attack. The constant study of the one disease is the only way to progress. He does not think one can become too enthusiastic, but conclusions can be drawn too hastily.

DR. PORTER said "abort" is an unfortunate and misleading word. We can decrease the intensity and cut shorter the duration of an attack with such remedy. It can not be abortion in any germ disease.

DR. J. B. HERRICK said in an experience with over one thousand cases of typhoid fever, he is inclined to think that there is no specific for the condition. For the febrile condition, he does not consider anything equal to the cold bath. Even Woodbridge's treatment is an expectant one.

DR. WOODBRIDGE, in closing, made reference to former discussions and papers by himself and others. Even if we could exclude the diagnosis of genuine typhoid in these cases, what better treatment can we find for the condition? When, however, the rose spots appear along with the usual symptoms, we must admit it is typhoid fever, and these cases can all be aborted in a few days.

DR. E. L. SHURLY, of Detroit, presented a paper on "Treatment of Pulmonary Consumption in Hospitals." For many reasons the treatment in general hospitals is not practicable. Other patients and dangers of contagion, whether real or imaginary, are important factors. Home-sickness and poverty are also against it. Foreign hospitals for tuberculosis are successful, but the conditions are different in this country. The Harper Hospital of Detroit has been the nearest a success of any American institution. Americans are too restless and have not patience enough to test the system. The hospital must not only be thoroughly equipped, but located in an equable climate.

DR. GUSTAV FÜTTERER, of Chicago, at the same time presented his paper on "The Direct Cause of Tuberculosis," which will appear in full in the JOURNAL.

DR. E. B. DENCH, of New York, read the paper on
THE TREATMENT OF ACUTE INFLAMMATIONS OF THE MIDDLE EAR
AND MASTOID PROCESS.

For convenience, the author anatomically divided the middle ear into two parts, by a line drawn through the styloid process. Inflammations in the middle ear produce the ordinary results of the same process elsewhere within a cavity lined by a mucous producing membrane, but because of transfusion the tissue necrosis is not so extensive; yet there is enough retained to cause an outward bulging of the tympanic membrane. If seen early, free blood letting should be practiced and a single dose of an opiate given. Do not give but one dose of the opiate under any circumstances. Also apply dry heat locally. Do not use wet heat. If not seen until later, free opening is the only thing to be advised. The technique of the operation was minutely and carefully described. The more acute and severe the case, the more prompt should be the measures for relief.

An incision should be made often, even when it is known the cavity contains no fluid. The incision does not end the danger; the entire cavity must be thoroughly washed out and made antiseptic by irrigation.

"Sequelæ of la Grippe." This paper was read by DR. F. C. HEATH, of Indianapolis. Several cases of eye results were given and the more common condition of ear complications noticed, with treatment considered.

In the discussion, DR. STRAIGHT thought the stomach was the most frequently affected of all organs.

DR. NORTH said quinin given for la grippe had done more damage than any other one thing.

DR. WHEELLOCK saw two distinct kinds of reaction following in-ear cases with periostitis or middle ear abscess.

DR. J. M. BALL, of St. Louis, read a paper entitled "Artificial Ripening of Cataract." A complete history of the operations was given, and the various methods were explained. Before doing any of them, the surgeon should be sure the zonula is intact, the tension normal, and the pupil dilatable. Division of the anterior capsule in these cases is always more or less dangerous and may be serious. Bettman's operation or direct massage or trituration is of all the most desirable. It is the least dangerous, most certain, and speedy. It has

stood the vital test of experience, and is worthy of confidence. If prolapse of the iris occurs, snip it off at once, contrary to most authority, but he had found it satisfactory and beyond expectations.

DR. J. O. STILLSON, of Indianapolis, read a paper entitled, "Complications in Cataract, Arising from Diabetes, Albuminuria," etc. The diabetic cataract is as yet a puzzle. A serous retinitis is often a symptom of Bright's disease. Albuminuria is a frequent complement of cataract. It is not only desirable but necessary to treat these conditions if they exist, before operating for the senile cataract.

DR. K. K. WHEELOCK, of Fort Wayne, Ind., read a paper entitled "Rheumatism and Gout in its Relation to the Eye." The paper was a thoroughly practical one and presented this somewhat old but nevertheless important subject in an interesting manner. The paper elicited a warm discussion.

DR. G. W. McCASKEY, of Fort Wayne, Ind., followed with a contribution on

BIO-CHEMISTRY IN ITS RELATION TO NERVOUS DISEASES.

In this paper the somewhat peculiar and certainly novel attempt was made to establish the general theory of the causation of nervous diseases by chemic poisons, circulating in the blood and acting by a process of selective affinity upon different parts of the nervous system. The author referred to these poisons under the following groups, the classification being entirely tentative, and based upon their source of origin instead of their ultimate chemic analysis or physiologic action: 1, bacteriologic products—ptomaines; 2, products of perverted tissue metabolism; 3, defective elimination of excretion; 4, perverted secretion of glandular organs; 5, products of imperfect digestion; 6, chemic compounds probably present in independent blood states, and of unknown origin.

Many conditions, heretofore unknown as to their etiology, will be found to be due to one of the above conditions existing in the system.

One of the most practical papers of the Section was that read by DR. J. H. TAYLOR, of Indianapolis, entitled "How Shall We Rear Our Babies?" The suggestions and directions were for both physician and mother, and put in so pointed a manner that the paper ought to have a wide circulation.

The next paper was by DR. FENTON B. TURCK, of Chicago, which was entitled

DISEASES OF THE MOUTH, NOSE AND THROAT, AS ETIOLOGIC FACTORS IN CHRONIC GLANDULAR GASTRITIS, WITH BACTERIOLOGIC STUDIES OF THE PHARYNGEAL VAULT.

Bacteriologic study has developed the fact that upon the mucous membrane of the mouth, nose and pharynx, groups of microorganisms may form, which may also be found growing on the mucous membrane of the stomach, and certain germs that are found in the inflamed mouth may also be found growing on the walls of the stomach in gastritis. Under normal conditions the mucous membrane of the stomach does not favor colonization upon its walls; but let some etiologic factor come into play and microorganisms will develop. The mouth, nose and throat, when in a diseased state, become incubators ready to infect when the conditions of the stomach permit the development of growing microorganisms upon its walls. The author then referred to the bacteriologic studies of Miller, Wurtz and Lindet. Microorganisms of the mouth are carried by the food after mastication into the stomach; many of them are again recognized in the stomach, and in cases of gastritis are found in colonies growing upon the mucous walls. The author in his clinical and experimental work has presented similar groups of microorganisms taken from the gums and cavities in the teeth, as well as from the material removed by the gyromele (revolving sound) from the walls of the stomach. In cultures upon the prepared mucous membrane of the pig, he has been able to cultivate some of the microorganisms and find the same developing in the stomach that are found in the mouth. But in the control animal, he has not yet found microorganisms growing in colonies in the stomach.

After reporting several cases, Dr. Turck concluded that clinical observation indicates a marked relation between diseases of the mouth and post-nasal cavity and chronic inflammation in the stomach and intestines; that the invasion of the stomach from the infected mouth and pharynx is supported by the fact that many of the non-pathogenic microorganisms present the identical, biologic and physical forms in cases of gastritis the same as those found in diseases of the mouth and post-nasal cavities of the same patients. Dr. Turck exhibited a chart showing the predominating microorganisms found in eight cases that were studied bacteriologically.

DR. LARRABEE, of Louisville said, in the discussion, that the germ theory had been superseded by germ facts as presented.

DR. FRANK BILLINGS, of Chicago, complimented Dr. Turck on his excellent clinical and experimental work, saying that the Doctor stands at the head of his profession in the work he has accomplished. He had shown that when there is a lowered vitality of the mucous membrane of the stomach by errors of diet, a soil is produced favorable for the development of microorganisms.

DR. H. W. LOEB, of St. Louis, read a paper entitled
EXPERIENCES WITH PAQUIN'S ANTI-TUBERCLE SERUM IN THE TREATMENT OF LARYNGEAL TUBERCULOSIS,

in which he gave the history of nine cases of this disease, seven of which had been treated with the serum. The patients all improved greatly. One case particularly lost all dysphagia, pain in the larynx, cough and night sweats. Other patients showed a much greater improvement than under any other plan of treatment yet tried. The Doctor quoted the confirmatory evidence of Maragliano of Genoa, Cole, Semon, Wiggins and Paquin. He will continue his investigations and present further conclusions at a later date.

In the discussion, DR. PAUL PAQUIN, of St. Louis, explained in detail the treatment which he had instituted. He said it was just in its beginning. It will have to be improved as we go along, and it will take years to do so. The best results have been obtained in the acute forms of the disease, and not in the chronic. The law underlying serumtherapy is a natural one. It is trying to fight bacteria by using nature's remedy. He had had failures with serum, but he could mention forty or more cases of recovery. He thought that in some cases it would require other treatment beside serum. He had not had good results inside of two or three months, and it frequently required five or six months, or even longer. He had made over ten thousand injections with serum in tubercular cases, but did not recall one which was attended with fatal results. He counseled study of the climate, as well as the patient, before sending a patient away. Tuberculous patients could not live in Colorado or New Mexico. They will die quicker there than anywhere.

DR. VICTOR C. VAUGHAN, of Ann Arbor, Mich., presented an article on "Yeast Nuclein and its Therapeutic Uses." Physiologically, nucleins form the chief chemic constituents of the living parts of cells; that constituent of the cell by virtue of which this histologic unit grows, develops and reproduces. The nuclein of various cells differs, and is limited only by the variety of cells. Chemically, the nucleins contain a large amount of phosphorus. Some are combined with albumin, forming the so-called nucleo-albumin. The nuclein molecule has a remarkable power of recuperation after partial decomposition. Some nucleins have germicidal properties. Experiments were made with animals, apparently proving that previous treatment by the nuclein gave immunity to the pneumococcus. Some thirty experiments were detailed and results given which seemed quite promising.

DR. HUGH T. PATRICK, of Chicago, read a paper on
DIAGNOSIS OF HYSTERIA.

The writer dwelt particularly upon the peculiarities of hysterical anesthesia, hyperesthesia and paralyses. The principal peculiarities of the first are its distribution in the form of a glove, sleeve, or stocking, with sharply cut border and in disseminated and irregular patches. Dr. Patrick called attention to a distinguishing trait not yet described, namely, almost instantaneous shifting of the line of demarcation between the anesthetic and normal areas. This peculiar feature applies equally well to hyperesthesia. Among the hyperesthesias was described hysterical joint disease and hysterical angina pectoris, with the differential points of diagnosis between these affections and organic disease. The peculiarities of the hysterical gait were described at some length and their relation shown to the affection described by Blocq and called by him *astasia-abasia*. The writer protested against this affection being considered a nosologic entity, as it is simply an exaggeration of a common feature in hysterical paralyses. The peculiarities which distinguish an hysterical from an organic paralysis of the upper extremity were also described, and hysterical affections of the special senses were briefly alluded to.

DR. B. M. RICKETTS, of Cincinnati, read a paper entitled
HEMORRHOIDS—PROLAPSE RECTUM—A NEW OPERATION.

The object of this paper was to present means more simple than had heretofore been offered for the radical cure of a prolapsed rectum and the obliteration of hemorrhoids. After widely dilating the sphincter with the fingers under

surgical anesthesia, a large semicircular needle is passed subcutaneously from the muco-cutaneous line to the upper border of the pile-bearing area, and then returned to make its exit at the point of entrance. The needle is then removed and the silk ligature made tight about the venus plexus, and the ends left hanging. These ligatures may be from one-half to an inch apart, as the case may require. It is not necessary to tie all the varices in this way, as the atrophic changes will necessarily obliterate the remaining ones. No tissue is sacrificed; the mucous membrane remains intact; there is no hemorrhage, no infection, no pain of consequence, and the loss of time is practically *nil*. The sutures are allowed to come away of their own accord. The operations made in this way for this condition have resulted in an absolute cure, and the patients have experienced but little pain during the life of the ligature.

Prolapsed rectum is treated in the same manner, except a greater number of ligatures are required. If they are properly and evenly adjusted, the atrophy of the tissues is symmetrical and the pathologic condition is relieved without stenosis.

DR. WM. PEPPER, of Philadelphia, by request, delivered the Address on Medicine. He selected for his subject "Daniel Drake: or Then and Now," which appeared in full in the *Journal* September 14.

DR. J. HOMER COULTER, of Chicago, read this paper:

THE DEFLECTED SEPTUM AND ITS REPAIR.

The author first dwelt upon the etiology of the condition. In stenosis of any degree there is created in each inspiration, within the cavity, a more or less complete vacuum. Thus the atmospheric pressure is to that degree increased and is a constant force of no inconsiderable gravity. He holds further that such a force would be more efficient in producing structural changes in the cartilaginous septum than would a more violent force suddenly applied, because the natural cartilaginous resiliency would more easily recover and throw off the effect of the latter.

The author then gave the points in the operation, because in the observance of these lies the success of the operator. Where the deviation is well anterior, or involving merely the ale, it is very much simplified because of convenience in operating and after-treatment as well. Until recent years but little attention was paid to the preservation of the mucous membrane, when operating on a deflected septum. A new form of punch was suggested for removing the cartilage and leaving the membrane intact.

DR. W. F. BREAKLEY, of Ann Arbor, Mich., read a paper entitled "A Case of Comminuted Fracture of the Ilium with Specimen and Photographs." No reports show such an extensive fracture of the ilium as this case. It was literally shattered into pieces. The patient fell ten feet on a pile of stones, producing this fracture and also a Colles fracture with dislocation of the ulna. The patient never rallied from the shock of the accident.

DR. HAL C. WYMAN, of Detroit, presented an article on "The Treatment of Cancer." The cure of cancer is rare, and unless the treatment is begun early, the disease terminates in death. In the treatment of cancer there is still an open field. The cure by early removal, while the disease is local, is urged and practiced by all who have opportunity. But the opportunity will not occur with sufficient frequency to stamp out the disease until the people are educated as to the facts.

DR. LEWIS C. CLINE, of Indianapolis, Ind., read a paper on
LARYNGITIS FROM A RHINOLOGIC STANDPOINT.

The author adheres to Bosworth's classification of laryngitis, and applies the word *itis* only to inflammations of a purely catarrhal character, which excludes at once syphilis, tuberculosis and other constitutional diseases, as they are more properly called syphilis or tuberculosis of the larynx.

The cases that are least amenable to treatment are the atrophic, but much can be done to comfort and palliate these cases by attention to dress, stimulant and lubricant applications. For stimulating and astringent, he finds nothing equal to nitrate of silver, from 10 to 40 grains to the ounce, according to the indications. For overwork cases, the first law is rest, with occasional mild, stimulating applications with an atomizer. The great majority of cases that had come under his observation had had atrophic or hypertrophic rhinitis to a greater or less degree. Spurs and deflected septum are often associated with these conditions. The lesions most frequently observed are hypertrophies of the posterior ends of the inferior turbinate body, and a thickened, lumpy condition of the posterior end of the septum

The drill, saw, snare and galvano-cautery are aids in removing these conditions in the more aggravated forms, while the application of silver and various astringents with sprays have served the author in the mild form.

DR. J. A. WESSINGER, of Ann Arbor, Mich., contributed a paper on "The Therapeutics of Oleo-Creosote and Creosote Carbonate." He summed up his experience with these remedies in the following conclusions: 1, the dosage is practically unlimited as far as toxicity is concerned, but it is preferable to begin with a small dosage, two to three drops after eating, and increase until the desired result is obtained; 2, to be of value in tuberculosis, a clinical diagnosis must be made early; 3, while these agents are distinctly germicidal, they also serve as tissue builders; 4, creosote, carbonate and oleate have the power of increasing the number of red blood corpuscles, and they also increase the percentage of hemoglobin in the blood.

DR. I. N. LOVE, of St. Louis, read a paper entitled:

THE BICYCLE FROM A MEDICAL STANDPOINT.

Bicyclists should understand the importance of going reasonably slow. The wheel brings into play all the muscles, and the maintaining of equipose has beneficial results. The matter of position is important. The rider should maintain an erect posture and not assume an unsightly stoop, in imitation of the hoop snake, which takes its tail in its mouth and sails through the country. A study of the question of the wheel for women had resulted in an opinion favorable to its moderate use in cases of acute diseases. Specialists had agreed to this. Numerous cases of long-standing pelvic diseases had been benefited by a judicious use of the bicycle. Women maintain a better position than men. An hour's wheeling three times a day is ample. The costume is important from the standpoints of health and art. He objected most emphatically to bloomers, which lessened the respect of mankind for womanhood and blemished the landscape. Leggings and accordeon-plaited skirts were about the thing. Corsets should be put aside. Skirt and shirt waist were favored, and even the sweater was approved.

The discussion was opened by DR. C. B. PARKER, of Cleveland, and continued by DR. W. N. WISHARD, of Indianapolis; DR. STERNE, of Indianapolis; DR. WALKER, of Evansville, Ind. They all advocated and advised a moderate use of the wheel for both men and women.

A paper was read by DR. T. O. SUMMERS, of St. Louis, entitled "The Physiologic Aspects of Leucocytosis," and one by DR. A. GOLDSPOHN, of Chicago, on "The Proper Indications for Repair of Pathologic Lacerations of the Cervix Uteri, and for the Relief of Pathologic Anteflexions and the Proper Operations to Meet Them."

The Nominating Committee reported as follows. The report was adopted:

President—Dr. H. O. Walker, Detroit.

First Vice-President—Dr. B. M. Ricketts, Cincinnati.

Second Vice-President—Dr. F. C. Woodburn, Indianapolis.

Secretary—Dr. H. W. Loeb, St. Louis.

Treasurer—Dr. H. N. Moyer, Chicago.

Judicial Council—Drs. W. N. Wishard, T. E. Holland, and A. P. Buchman.

The Nominating Committee also submitted the following resolutions:

Resolved, That it is the sense of this committee that the best interests of the Association will be subserved by the appointment of a permanent Executive Committee, composed of the titular officers of the Association and the ex-Presidents, and that this committee shall conduct all the business of the Association; be it further

Resolved, That we recommend the creation of the office of assistant secretary, to be appointed by the Chairman of the Committee of Arrangements, from the place in which the meeting is held.

On motion, the Association adjourned to meet in St. Paul, Minn., on the third Tuesday of October, 1896. Dr. C. A. Wheaton, of St. Paul, was selected Chairman of the Committee of Arrangements.

Tri-State Medical Association.—The semi-annual meeting of the Tri-State Medical Association was held at Cumberland, Md., September 5, with an attendance of thirty. The following officers were elected: President, C. S. Hoffman, Keyser, W. Va.; Vice-Presidents, J. M. Spear, of Cumberland; S. H. Gulp, of Bedford; Recording Secretary, Percival Lantz, of Alaska, W. Va.; Corresponding Secretary, F. W. Fochtman, of Cumberland; Treasurer, H. W. Hodgson, of Cumberland. The next meeting will be held in Cumberland some time during next December.

THE

Journal of the American Medical Association

PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

PER ANNUM, IN ADVANCE \$5.00

SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,

No. 86 FIFTH AVENUE, CHICAGO, ILLINOIS.

W. H. LOWDERMILK & CO., WASHINGTON AGENT.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 86 Fifth Avenue, Chicago.

SATURDAY, SEPTEMBER 21, 1895.

PATHOGENY OF ADDISON'S DISEASE.

Among the morbid entities whose pathogeny is still obscure, the disease first described by the English clinician ADDISON, in 1855, and since known by his name is not the least interesting. Characterized by marked emaciation, asthenia, toxemic symptoms, vomiting, diarrhea, bradycardia, etc.,—and, generally, by melanoderma or bronzing of the skin, its exact causation is still unknown, but the coöperation of physiologic chemistry and clinical and experimental pathology has furnished clues which lead us to believe that the solution of the problem is near at hand.

The theories to account for the origin of the disease may be divided into three groups—the capsular, nervous and toxic. The capsular theory, which was advanced by ADDISON, accounts for the disease by the degenerative changes in the suprarenal capsules. Shortly after the appearance of ADDISON'S work, BROWN-SÉQUARD undertook a series of experimental researches which may be summed up as follows:¹ 1, the suprarenal capsules are indispensable to life, their complete ablation is rapidly followed by death, which occurs far more rapidly than from suppression of urine; 2, these organs modify and destroy a substance which can be transformed into pigment; after destruction of the capsules this substance accumulates in the blood; 3, after destruction of both capsules, the blood becomes toxic and when injected into other animals of the same species often causes death.

BROWN-SÉQUARD'S results have been confirmed by GRATIOLLET, ABELOUS and LANGLOIS and denied by

HARLEY, SCHIFF, TIZZONI, SENMOLA and others. The failures of the latter investigators are probably due to lapse of sufficient time for death to occur and to faulty technique. It may take over a month for the fatal issue and, again, in animals usually selected for experiment, and especially guinea pigs, capsulectomy is very difficult. The inferior cava is in such close relation to the capsules that in order to avoid death from hemorrhage small pieces of the organ are often left *in situ*, which of course spoils the whole experiment.

The nervous theory is upheld by a number of distinguished investigators, among them ALEZIAS and ARNAUD, KAHLDEN, LANCEREAUX, BRAULT and PER-RUCHET. According to this theory, the disease is due to changes in the abdominal sympathetic, and the adrenals are either not affected at all or only indirectly. ALEZIAS and ARNAUD assert that the pericapsular nerves are at fault. These are intimately connected with the capsule and it seems reasonable to suppose that any changes in them have extended from the capsule itself. As a result of their researches, they assert that whenever the cortex of the capsule, the nervous filaments or the ganglia in this part are affected, bronzing of the skin occurs. In cases where toxemic symptoms beside are found, then we have also changes in the medulla of the organ. The nerves and ganglia to which these changes are attributed are the pericapsular ganglia, the solar plexus, the right semilunar ganglion, different branches of the abdominal sympathetic and, according to KALINDERO and BOBES, even the spinal cord itself. In forty-nine cases where changes in the sympathetic are looked for, the nerves and ganglia were found perfectly normal in twelve.

The theory which accords best with the present state of our knowledge in other directions is the toxic theory. According to this view, a toxic substance is elaborated by the capsules and when they are destroyed this collects in the system and auto-intoxication and death follow. Among the adherents of this theory we find CHARRIN, McMUNN, NOTHNAGEL, SCHAFFER and OLIVER, FOA and PELLECARRI, MARINO-ZUCCO and others. As a result of experiments we know that double capsulectomy invariably results in death. In a winter frog this occurs in twelve or thirteen days; in summer frogs, when metabolism is more active, in forty-eight hours or more. If only one capsule is destroyed, or if any large portion of the other is left, the animal lives; but after extirpation of both capsules, life can only be prolonged for some days by inserting a fragment of capsule in the dorsal lymph sac of the frog. Blood taken from the decapsulated frog, paralyzed and dying, is toxic for other frogs recently operated on and rapidly produces paralysis and death.

PROFESSOR SCHAFFER, in his recent masterly address

on "Internal Secretions," before the British Medical Association² points out that animals differ greatly in their reaction to subcutaneous injections of suprarenal capsules. The guinea pig, he states, will stand a large dose subcutaneously without showing any symptoms save, possibly, a slightly accelerated pulse. This seems to hold good for the dog and cat also, unless very large doses are used. The rabbit, on the contrary, is extremely susceptible; a large dose will kill in half an hour. SCHAFFER found that intravenous injection of capsular extracts produced even more marked results. "Experiments show conclusively that the medulla of the suprarenal capsule contains a dialyzable organic principle, soluble in water and not destroyed by boiling for a short time, and which exerts a powerful physiologic action upon the muscular system in general, but especially upon the skeletal muscles, the muscular walls of the blood vessels and the muscular wall of the heart. A certain amount of action is also manifested upon some of the nerve centers in the bulb, especially the cardio-inhibitory center and, to a small extent, upon the respiratory center."

Its action on muscle is compared to different alkaloids by various writers; by OLIVER and SCHAFFER to veratrin, the contraction after excitation being greatly prolonged; the blood pressure is much greater also, and the cardiac pulsations are increased. These effects pass off in a few minutes and, as this author remarks, the question is, What becomes of this active principle? The effect passes off, he states, just as quickly if the renal arteries are clamped, showing that it is not eliminated through these organs. If the aorta and cava are tied, so no blood at all circulates in the abdominal organs, it passes off almost as quickly. What, then, becomes of it? SCHAFFER decides that the most probable explanation is that this active principle is stored away and gradually rendered innocuous in certain organs—a view which is corroborated by the fact that the effects on skeletal muscles are manifested for a long time after those on the heart and vessels have ceased.

A very small amount of the extract will suffice to produce marked results. Thus .0055 gr. of dried suprarenal will produce a maximum effect upon a dog of 10 kilos. Moreover, this active principle is contained only in the capsular medulla and not in the cortex. PROFESSOR SCHAFFER considers it probable that this substance is continually being secreted into the blood by the capsules and though in very minute quantities may have beneficial effects on the muscular functions and especially on those of the vascular system. It appears, then, that the toxic theory offers at present the best solution of the problem and, if it prove to be the correct one, it does not seem too much to expect that serumtherapy or its

allies may furnish a means of combating this insidious disease which, though perhaps not so prevalent as some others of "man's foes," has thus far remained invulnerable to the resources of our therapeutic armamentarium.

THE CHOLERA.

The dispatches for the week indicate the continued progress of cholera in China, Japan and the Sandwich Islands. Cholera has appeared on the U. S. steamship *Bennington* while at Honolulu. The authorities on the Pacific coast are now fully aware of the necessity for vigilance, and no danger need be feared. The action of the Government is seen in the circular published in our "Public Service" column. The application of the same general practice of disinfection of fomites, or "suspicious" baggage, that has obtained on the Atlantic coast for the past five years will be followed by the same success that obtained there.

There seems no reason to doubt the character of the fatal cases at Grimsby in England, August 30 and September 3. The first case was that of a man who had been engaged in cleaning out the cholera ship used in 1893. Beyond a mere passing notice and some criticism of the Town Council for declaring against the notification of diarrhea, the deaths have attracted little or no attention. The fact is that England has been taught enough about cholera and its cause—thanks to the persistent pounding of MR. ERNEST HART and his colleagues—not to get hysterical at its mere mention. The disease is no longer a bugbear, but a blessing in disguise, enforcing the lesson of an uncontaminated water supply and general cleanliness. The latest contribution to this lesson is furnished from Bombay. Prior to 1892 whenever a high death rate from general causes prevailed, an outbreak of cholera accompanied or followed. Since 1892, however, although the general death rate has been very high, there have been few cases of cholera. This is ascribed to the pure and plentiful water supply introduced in the year mentioned and to the general measures of cleanliness and sanitation since enforced. Moral, *re cholera Asiatica*: Don't defile the water you drink, nor the air you breathe, nor the soil you live on; so shall the Indian pestilence pass you by unharmed.

We observe with some surprise that persons who should know better, have been vigorously denouncing "quarantines" in the columns of the daily press. It would be unfortunate for the country if such views should prevail. "Quarantine" as understood and practiced in the civilized world to-day means simply *inspection and disinfection, hospitals for the sick, and cleanliness for the ship*. It is simply quarreling with an obsolete method, long since extinct, to oppose quarantines. The day of detention quarantines *per*

² British Medical Journal, Aug. 10, 1895.

se passed in this country, when the Government took command of the quarantine service as a permanent charge in 1888, on the recommendation of SURGEON-GENERAL HAMILTON and these quarantines have since been perfected on the lines then laid down, and for which a half a million was appropriated by the act of Aug. 1, 1888. Subsequent acts, establishing supervision over the ship from its point of departure, and a more rigid inspection of immigration, have greatly improved the situation.

An amusing statement is attributed to a leading hygienist, that if all the cholera germs in the world were dumped into Lake Michigan, Chicago would be in no danger. This must be erroneous for the whole world knows cholera to be waterborne. The Indian "tanks," the wells and the water supply have been the chief sources of propagation, from time immemorial. *The bacillus lives in water, and dies when it is thoroughly dried.*—That is the lesson taught by bacteriology, and a study of epidemiology.

There is no longer any use to appeal to local self-glorification by making statements directly contrary to the known truths of science. No American public should dread or fear the truth. It is concealment that is misleading and disastrous.

We doubt not that the medical officers of the Navy will be able to arrest the spread of the disease on the *Bennington*, so that when it returns to the Mare Island Navy Yard the disastrous history of the French troop ship, at Toulon, from Tonquin, may not be repeated. And we have equal faith that the Marine-Hospital Service will stamp out the disease now at Angel Island Quarantine, if the local authorities do not obstruct matters by foolish interference. It is not San Francisco but the whole country that is interested in this matter.

The only question now is the sanitary condition of "Chinatown," and that question is being settled by a house-to-house inspection of that celestial spot, by the health authorities of San Francisco. In the meantime, there is every reason, on many accounts, why all the interior cities should put themselves in good sanitary condition.

VACCINATION OF SCHOOL CHILDREN.

One by one, the courts of the different States are settling the question of the legality of compulsory vaccination of school children. Feb. 11, 1895, the general term of the Supreme Court of New York, affirmed, in *re Smith*, a decision holding constitutional, Section 200 of the Public Health Law of that State which provides that no child or person not vaccinated shall be admitted or received into any of the public schools of the State. And only recently has been made accessible, the decision of the Supreme Court of Errors of Connecticut in the case of *Bissell*

v. Davison, rendered Dec. 1, 1894, of much the same purport. In the latter case, the court holds that a statute providing that the board of school visitors of any town may require that every child shall be vaccinated before being permitted to attend the public schools, is valid, and there is no reason for implying that the power is only to be exercised when an epidemic of smallpox is reasonably to be apprehended. It does not deprive a child of his rights, without due process of law, or deny to him the equal protection of the laws, guaranteed by the Federal and State constitutions. The duty of providing for the education of the children within its limits, through the support and maintenance of public schools, is to be considered in the light of a governmental duty resting upon the sovereign State. In the performance of this duty, the State maintains and supports, at great expense, and with an ever-watchful solicitude, public schools, and secures to its youth the privilege of attendance therein. This is a privilege, rather than a right, in the technical sense of the term. This privilege is granted, and is to be enjoyed, upon such terms and under such reasonable conditions and restrictions as the law-making power, within constitutional limits, may see fit to impose; and, within those limits, the question what terms, conditions, and restrictions will best subserve the end sought in the establishment and maintenance of the schools is a question solely for the Legislature, and not for the courts. Such a statute as that under consideration is essentially a police regulation,—as much so as would be one giving the power to exclude, temporarily, scholars afflicted with infectious or contagious diseases, or coming from homes or districts where such diseases are prevalent. It is a reasonable exercise of the power to require vaccination, if such requirement can ever in the nature of things, be a reasonable one. Support for these propositions is also found in precedents established in California and Pennsylvania.

THE IMMEDIATE EFFECTS OF INJURIES OF THE BRAIN.

An interesting medico-legal point brought out in a recent murder trial, in regard to which there seems to be a lack of definite and positive statement in the text-books, is the question as to the immediate results on consciousness and motility, of gunshot wounds of the brain. A woman was shot with a pistol while in bed, and it is said she rose, spoke to her husband, and made her way to a rear porch. The prosecution claimed, and brought medical testimony to support its claim, that with such a wound she could not have walked or talked as she was said to have done. The details in the newspaper accounts as to the wound are not very exact, but it seems to have been high up in the brain; at first it was stated in the notes as one-half inch above the *crus cerebri*,

but this was corrected to corpus collosum. The ball passed through both hemispheres from right to left; the woman was unconscious when found and remained so until her death, sixteen hours later.

These rather vague particulars taken from the daily press furnish no sufficient data on which to decide this particular case, but they suggest very strongly the question whether any one can say just what will be the immediate effect of a small projectile wound of any portion of the brain above the medulla. Destruction of the pyramidal fibers could follow a wound as high as the internal capsule, but above that, many of them would undoubtedly escape, and there are numerous instances of gunshot and other wounds apparently in a situation to involve parts of the motor region that have not been directly followed by any general or even extensive paralysis. When it comes to the question of consciousness there are still more difficulties, and it is hard to say what injuries inevitably destroy it completely and at once. All we know is that the tolerance of injury by the brain is very great, that its limits have not been defined with even any approximate accuracy, and that therefore any positive statements as to just what will or will not occur are hardly justifiable in the present state of our knowledge. The most one can safely say is what is possible, hardly what is probable, and it would be well if our text-books on medical jurisprudence which are generally looked upon as authorities in this matter, stated more definitely than some of them do, the fact of the limitations of our knowledge in regard to this particular point.

THE RADICAL CURE OF HERNIA.

The operation for the radical cure of hernia has received the official approval of the War Department. From twenty to thirty men are discharged every year from our Army on account of rupture. These men become valueless as soldiers and under present laws are each entitled to a pension of \$8 per month and to a suitable truss renewed every three years. As most of the ruptured soldiers are young men with a long expectancy of life, the disability is a costly one to the Government. It remains to be seen whether the radical operation will save the injured soldiers for further military service and by so doing reduce the list of ruptured pensioners; and also whether the victims of rupture will take advantage of the opportunity afforded them of being treated for a radical cure. According to a recent circular from the office of the ADJUTANT GENERAL of the Army, cases of hernia suitable for an operation should receive surgical treatment, which, by the most approved modern methods, is successful in a large proportion of the cases operated on, and in skillful hands is attended with little risk. Operations for the radical cure of hernia will be performed, with the consent of the

soldier, by medical officers specially designated by the SURGEON GENERAL of the Army.

Medical officers will report cases of hernia considered favorable for operation to the SURGEON GENERAL. If the case is considered unsuitable for operation, or if an operation is declined by the soldier, the fact will be noted on the certificate of disability.

LESS THAN A CENT A VISIT.

Some of the cheapest styles of medical practice that can be found anywhere in the world, can be found on the "east side" of New York city. But that which cheapens the business to its minimum is a new kind of coöperative scheme of medication, on the plan of an insurance association. A writer to the New York *Herald* calls attention to some of the features of this scheme. He says:

"Nearly every head of a family, in this eastern section of the city, belongs to a secret benefit society of some sort. Until lately these societies confined their activity to life insurance, funeral benefits and sick benefits, but lately the feature of medical insurance has been added to several of them.

"The plan is to engage some young physician who for a fee of 75 cents per quarter from each member of the society undertakes to attend the member or his family in case of sickness. At first sight it seems as if this might be a profitable arrangement in the case of a society with one thousand or more members but in practice it is not so. Every member of the society has several children, one or more of whom are almost constantly ailing, and the slightest ailment furnishes an excuse to call the doctor when his visit costs nothing extra.

"One young physician who rashly entered into contracts with three of these societies, having an aggregate membership of 1,500, told me that he estimated that he got three-quarters of a cent for each call he made.

"'I can find no time for private practice,' he said. 'To-day I have had forty-two calls from my society patients, and I have an average of thirty a day. I am all worn, out with the work, and when my quarter runs out nothing will induce me to renew the contract.

"'Why, if a child scratches its finger I have to go and dress it, and I have even found cases where the society members called on me to visit their neighbors, passing them off as members of their own family and charging them a small fee for the accommodation.'"

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

The program for the eighth annual meeting of the American Association of Obstetricians and Gynecologists has just been issued. The daily sessions will be held in the south parlor of the Auditorium Hotel, Chicago, Tuesday, Wednesday and Thursday, September 24, 25 and 26. The President is DR. J. HENRY CARSTENS, of Detroit; the Secretary, DR. WM. WARREN POTTER, of Buffalo.

The work of this Association has attracted a great

deal of attention, its papers and discussions being universally quoted. It enjoys the reputation of being one of the most scientific and active organizations in this country. The papers represent advanced thought in both gynecology and obstetrics. At its meetings the results of original research are reported. The discussions are free and spirited, as might be expected, when they are participated in by such men as JOSEPH PRICE, JOSEPH EASTMAN, L. S. McMURTRY, C. A. L. REED, A. VANDER VEER, W. E. B. DAVIS, ROBERT T. MORRIS, JAMES F. W. ROSS, H. W. LONGYEAR, J. D. GRIFFITH, and others equally prominent.

The Association is called to order promptly on time at every session; the members are not restricted to time in debate, and there is a notable absence of the "mutual admiration" element in the discussions.

The profession are cordially invited to attend the meeting by the Chairman of the Committee of Arrangements, DR. J. B. MURPHY.

THE AMERICAN PUBLIC HEALTH ASSOCIATION.

This Association which now includes in its membership representatives from the whole of North America, will this year meet in Denver, Colo., October 1, 2, 3 and 4. The Local Committee of Arrangements, of which DR. HENRY SEWALL is chairman, and fifty-three other doctors, two United States Senators, the Mayor, the Governor, the Chief Justice of the State, six Judges, four ex-Governors, a member of Congress, forty-four other prominent citizens and the Ladies' Reception Committee, are the other members, have prepared a very handsome program. The illuminated cover and well executed illustrations are works of art. One can scarcely glance at this elaborate setting forth of the beauties of Colorado, without a desire to attend the meeting, participate in its exercises and see the glorious scenery for which Colorado is famous.

The usual reduction of railway fares has been promised.

CORRESPONDENCE.

Is the Journal Too Good?

MARIENVILLE, PA., July 29, 1895.

To the Editor:—The more one sees of THE JOURNAL (big capitals in *The*, please,) the more satisfaction there is in seeing it all, from title page to finis, of the highest order. The profession ought to be proud of it. Personally, I am willing to add 50 per cent. to the annual dues, if necessary, to keep it up to the highest point in medical journalism.

* * * * *

There is a point, however, worth noting. In a conversation with Trustee Dr. E. E. Montgomery, at the Philadelphia meeting, I said the only criticism I heard now about the JOURNAL was that "it was too good." There is more than "something" in that. The JOURNAL wants a big circulation. It can't reach all classes—and there are classes and classes in the profession—by a series of articles that are so good as to be exclusive to all but well posted M.D.'s. The editor, of course, desires to be a lift and help to all that come within

range. In this view, it is worth while considering if a column or two could not be set aside for notes, queries and brief articles on treatment exclusively. This or some other way that will bring the JOURNAL in touch with all classes, or as one might put it, the mass of the profession. However, as things are going now, the man who has a bound volume of the JOURNAL at the end of this year, will have a fund of information that he can't get in any \$7 to \$10 "Practice" on the market, to say nothing of surgery, etc. "Here's to you!"

"Palman qui meruit ferat."

Very truly yours,
S. S. TOWLER, M.D.

A Way to Increase the Membership.

HUNTINGDON, PA., Sept. 16, 1895.

To the Editor:—Will you please send to my address about twenty-five blank applications for membership in the AMERICAN MEDICAL ASSOCIATION?

It seems to me, if some member, treasurer or secretary of each county medical society would distribute to each member of their society a blank application for membership in the AMERICAN MEDICAL ASSOCIATION, telling them also that in connection with their certificate of membership they would receive a weekly journal of medicine which is second to none in the United States, that there would be a larger ingathering of membership to the ASSOCIATION. It is for this purpose that I desire the blanks, and if you have any surplus copies of the JOURNAL I think I could use them to good advantage. Yours respectfully, G. G. HARMAN, M.D.

We have printed the foregoing letter, although it was not intended for publication, as it contains a valuable suggestion for secretaries of societies who desire to help enroll American physicians in the membership of the Great ASSOCIATION.

Not In the Chromo Business.

SPRINGFIELD, ILL., Sept. 9, 1895.

To the Editor:—I am in receipt of an offer, from a New York firm of medical publishers, which seems to me a stroke of enterprise that you might emulate. They will send me their journal (a weekly like our own) four months free, together with a copy of a standard medical work, price \$5, and will give unlimited credit if I become a subscriber to the aforesaid journal.

Now, will you tell me what earthly show *our* JOURNAL stands in competition with this kind of push?

As one of the stockholders of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION I feel that I have a right to protest against your old-fogy methods. You are too conservative and dignified. Haven't you got a chromo concealed somewhere about the premises that you might offer for a new subscriber? Or why not give a bicycle and the JOURNAL free for a year to any one who will take it out of the postoffice?

Possibly you think the JOURNAL worth its subscription price, and undoubtedly it is. But if we are to give it a circulation commensurate with its value we, the present subscribers who are its owners, must do something to counteract these efforts of the medical book publishers to monopolize the periodical field.

If you will send me one or two sample copies each week for a month or so, I will see what I can do among the profession here. And if each of us will do the same, I think we can offset the gift enterprise business pretty effectually.

Yours for our own JOURNAL, F. W. R.

BOOK NOTICES.

Examination of Water for Sanitary and Technic Purposes. By HENRY LEFFMANN, A.M., M.D., Ph.D. Philadelphia: P. Blakiston, Son & Company. Third Edition. 1895.

Dr. Beam, who was associated with Dr. Leffmann in the publication of the earlier editions, is now permanently residing in

a distant land and has severed his connection with the work and turned over his copyright privileges to his former associate. The new edition contains little that is not in the second edition. The spelling of certain words has been changed, so that we now have chlorin, chlorid, technic, analytic, etc. From the table of contents we would infer that there was a considerable alteration in the text, but on examination we find merely a rearrangement of the matter. A few paragraphs have been added under the heading of Biologic Examinations and their Interpretation. For instance, citation is made of Vaughan's culture of the bacteria of water at 38 degrees C., to exclude all growths except those that flourish at the body temperature. The Franklands are cited on the differentiation of the typhoid bacillus, and several methods are briefly stated from the works of various experimenters for the detection of the spirillum of cholera. The sand filters at Lawrence, Mass., are described. The author, however, is not accurate in all of his statements, as, for instance, on page 103, where he appears to consider that the object of the convention of bacteriologists lately held in New York city was merely to secure a consensus of opinion among bacteriologists as to the most satisfactory method of microbe counting. However, the book has its uses, and with exceptions noted is of considerable value.

The Diseases of Personality. By TH. RIBOT, Professor of Comparative and Experimental Psychology in the College of France. Authorized translation, second revised edition. Pp. 163. Chicago: The Open Court Publishing Company. Price, cloth, 75c; paper, 25c. 1895.

This book is one of a series of psychologic phantasies which have been published from time by the Open Court Company. Professor Ribot first published his studies of the diseases of personality in Paris, 1884. The fact that the book passed through four editions gives ample proof of its value to psychologists.

The work is divided into four chapters devoted to Organic Disorders, Affective Disorders, Disorders of the Intellect, Dissolution of Personality, respectively.

The author gives a number of observations of cases of spontaneous alterations of the "Ego," which he thinks to be a more rational basis for the study of the morbid manifestations of personality. His deductions from a psychologic standpoint are clear, logical and concise, and will be read with profit by those interested in this branch of science, and familiar with its peculiar phraseology.

NEW INSTRUMENTS.

A NEW NEEDLE HOLDER.

The above drawing illustrates a needle holder which I have found more convenient than any other which I have heretofore used. The handle is of such size and shape that it can be firmly grasped by the hand. The two rings on the lower half of the handle are for the tips of the middle and third fingers, and the instrument is easily opened by grasping the upper half of the handle between the bases of the thumb and index finger and simply opening the hand. Two pieces of copper are set between the jaws, insuring the needle against slipping.

In getting rid of the spring and lock, we are rid of parts which often annoy by getting out of order and retard our work. The grooved steel jaw is also often troublesome by breaking needles or tilting them in the wrong direction when they are firmly grasped. I believe that much more rapid work can be done with this instrument than with any other with which I am acquainted.

The figure is one-half the exact size of the holder, and was made for me by Sharp & Smith of Chicago.

JNO. MADDEN, M.D.

63 and 64 Sentinel Building, Milwaukee, Wis.

PUBLIC HEALTH.

In Honor of Jenner.—In order to fitly commemorate the centenary of vaccination, which will occur in May, 1896, the National Health Society of Russia is organizing an ambitious program. It proposes to offer four prizes for the best works on vaccination; to collect and furnish materials for a history of the practice in Russia and Western Europe; to publish a Russian translation of Jenner's works, with his biography and portrait; to give an exhibition of objects connected with vaccination and to hold a commemorative meeting on the day of the centenary, May 12. Dr. Vladimir Hubert will edit the history of the great discovery.

Oleomargarine and Natural Butter.—In order to determine the relative digestibility of oleomargarine and natural butter, Dr. Adolph Jolles (*Sitzbericht: Kaiserl. Academie in Wien*, 6th Marz, 1894) has carried out a long series of observations on dogs fed during four consecutive periods with natural butter and with margarine. All other things being equal, it was found that from 97 to 98 per cent. of the fatty matter was uniformly digested, whether it was butter or margarine which was used. During the first and third period, while butter was given, 98.4 and 97.1 per cent; during the second and fourth, while margarine was used, 97.9 and 97.3 per cent of the fatty matter given was digested. It thus appeared in this experiment, where proper care was taken to have all the conditions similar, that natural butter and manufactured margarine had practically identical coefficients of digestibility and nutritive value.¹

Lofly Stature versus Long Life.—A writer in the *National Popular Review* has been investigating the age period at death of those abnormally tall individuals who are classed as "giants," and believes he has found that all who measure over six and one-half feet have been short in their life's span. He is of opinion that there is sure to be some failing link in the physiologic chain of these abnormal beings; and this, too, independently of any of those moral inadequacies which too often exist and help to precipitate an early downfall or breakdown. He further says:

"As a rule, giants are not long lived. They have too many gauntlets to run. Being giants—that being anything over six feet six—they naturally drift into the show business and are thenceforth incarcerated in vans, close rooms and in the dingy and effluvia-laden air of the exhibition room. Their not over-resisting lungs here inhale the combined effluvia and aroma that arises from the lungs, skin and not over-clean or over-well aired clothes of their many admirers, all of which is not conducive in either health or to long life. It would seem reasonable to believe that a giant—be he seven or ten feet tall—who is well formed, and who has every organ in a just proportion to his bulk, should live as long as a small man or as long as his heredity might otherwise permit. Reasoning theoretically, this would seem probable, but when we come to analyze the subject and compare the actual facts we find that something or other always goes wrong, and, owing to many an "if," we find that our giant dies early, as a rule. Some one organ goes wrong, and the great machine comes to a stop, or some organ does not keep pace with the rest of the increase in bulk, and he goes

¹ Boston Medical and Surgical Journal, Sept. 12, 1895.

halting and squeaky, or either an overwork or an underwork here or there, and a physiologic inadequacy, of some sort is the result, with a general deterioration of the whole structure and a finally premature death."

Medicine and Hygiene at Bordeaux.—Marcel Baudouin is not at all enthusiastic over the medical exhibit in the Exposition at Bordeaux. He says in *Le Progres Medical*, he finds there only odd bits touching upon the science of medicine and hygiene and complains that the exhibit is not complete and has no definite lodging place. There are indeed, says he, under those pavilions, in the midst of the endless rows of chairs and flower beds, in those elegant palaces, striking copies, by the way, of the colossal buildings at Chicago, many surgical instruments, sanitary appliances, mountains of bottles of mineral waters, etc. And, here and there, one comes upon some show cases that interest the physician, some pictures or instruments which attract the eye of the hygienist. He refers to two reminders of the Chicago Exposition: the optometer of Dr. Clark and the Leblanc stoves, and that the exhibit of cold storage rooms for the preservation of meats, milk and other foods, is an interesting feature to scientists. The one exhibit which aroused the writer's real enthusiasm is the emergency hospital station installed in the Exposition by the Society of Ambulances of Bordeaux. Alongside of this hospital is the pavilion in which the society exhibits its apparatus and the plans of its principal stations. There is also the two-wheeled litter exhibited by this same Bordeaux society, very well built, and extremely light." This is the first wheel litter ever seen in France with pneumatic tires.

Medical Climatology of Brazil.—Rio Janeiro, the capital of Brazil, with 600,000 inhabitants, is bathed by the sea on the southeast, east and north. It is in a valley between spurs of the coast range, of which Corcovado, 800 meters, is the highest point, and the city extends upward on these slopes to a height of 750 meters. The subsoil is humid and saturated with organic matters. Dr. Fives, of Almeida, believes this has a great deal to do with the prevalence of yellow fever and all the zymotic diseases. Yellow fever is endemic in many Brazilian cities and Rio Janeiro pays a yearly tribute. This disease frequently assumes an epidemic character, when its proportions are alarming. Nevertheless, the mortality figures for 1893 are lower than those of the years immediately preceding. Next to el vomito, beri-beri and tuberculosis are potent factors in the death rate, as also all pulmonary affections, on account of the constant humidity of the soil. The following table gives an idea of the climatic conditions of the city:

	Mean Barometer.	Thermometer in the shade.	Difference bet. Maxima and Minima Thermometers.
January	754 mm. 72	26.1°	14.0°
April	758 " 21	23.0°	9.4°
July	762 " 82	19.2°	29.5°
October	756 " 71	21.2°	18.8°

A sample of the number of rainy days and quantity of rain is afforded by the following:

1886	149 rainy days	12 mm. .87 of rain.
1887	154 rainy days	13 mm. .35 of rain.
1888	169 rainy days	13 mm. .99 of rain.

In July, 1892, Drs. Francisco de Doncher, Luis Laureys and Guimaraez Bouzeau made a report to the National Congress, in which they stated the causes of the insalubrity of Rio were due to: 1, corruption of the soil; 2, insufficient water; 3, defective system of the "City Improvement Company"; 4, existence of the Manque canal in communication with the two large lagoons, which constantly communicate with the sea; 5, defective hygiene in certain private establishments. They recommended thorough drainage of the subsoil as the first step to be taken. Porto Alegre has 50,000 inhabitants, 8,000 to 10,000 of whom are foreigners. Morbidity and mortality are very high in this city; also tuberculosis, typhoid fever and gastro-enteritis. Paludism is as common as in Rio Bahia. This town is noted for the large number of aneurysms. During the twenty years from 1870 to 1890, out of 53,188 patients, 90 had aortic aneurysms, and 36, aneurysms of other arteries. Dr. Britto attributes this prevalence to mountain climbing and too elaborate diet.¹

Systematic Inspection of Canned Food Supplies.—The *Sanitary Record*, for July 26, devotes a leading article to the imperfections of legislation in Great Britain in the matter of a thoroughly organized system of inspection of food. It makes no scruple in saying that the existing laws fall ridiculously short of the requirements of the case, and that the officers responsible for the detection and prevention of adulteration are greatly hampered. The laws, it avers, seem to have been so drawn up as to protect the adulterator, and even to shield those who must know that they are engaged in the sale of foods that are unfit for human consumption. In the following paragraph, allusion is made to the defective supervision had over canned goods, a portion of which, at least, is derived from this country:

"There is positively little safeguard as regards the sale of meat and fish in tins. Yet probably the greater number of cases of poisoning from the eating of unwholesome viands are due to tinned foods. Unfortunately, there exist a number of firms in the United States and in South America who pack enormous quantities of meat and fish without taking the necessary precautions. Often the cattle or fish are in a diseased state, the cleaning and cooking is carried out in a careless way and the packing in tins is scamped. The consequence is that air sometimes gets into the tins, decomposition sets in, and the persons who consume the contents run serious risks of alkaloidal poisoning. Even tinned milk of inferior brands is frequently found to be in shockingly unwholesome condition. Of the adulteration of tinned and bottled comestibles with borax and other 'preservatives,' and of coppers and other coloring matters, we need not write on this occasion. But it is evident enough that the law as regards inspection of foods, the control of preparation and sale of viands, requires revision and strengthening, and, above all, of simplification. The practical sanitarian always feels angry when he reads that a coroner's jury has returned a verdict of accidental death, when some one has fallen a victim to the eating of unwholesome food, for he knows well enough that such deaths would become almost impossible were proper and thorough inspection feasible."

The writer of the article looks forward to the time when this subject will be adequately dealt with, and this will be when the legislators of the United Kingdom devote their energies to "really useful work."

Health Reports.—The following health reports have been received at the office of the Supervising Surgeon-General Marine-Hospital Service:

SMALLPOX—UNITED STATES.

Illinois: Chicago, August 1 to 31, 7 deaths.
Louisiana: New Orleans, September 1 to 7, 8 cases.
Michigan: Battle Creek, Bedford Twp., Charleston Twp., Detroit, smallpox reported present September 1 to 7.
Ohio: Dayton, September 13, 1 case.
Texas: Eagle Pass, September 9 to 15, 1 case.
West Virginia: Wheeling, September 13, 20 cases.

SMALLPOX—FOREIGN.

Batoum: August 20 to 27, 1 case.
Cairo: August 6, to 12, 2 deaths.
Constantinople: June 1 to 30, 39 deaths.
Dublin: August 24 to 31, 3 cases.
Havana: August 29 to September 5, 2 deaths.
London, Eng., August 24 to 31, 4 deaths.
Prague: August 17 to 24, 1 case.
St. Petersburg; August 10 to 24, 3 cases.
Trieste: August 17 to 24, 2 cases.
Tuxpan: August 24 to 31, 7 deaths.
Rio de Janeiro: August 10 to 17, 67 deaths.

CHOLERA—FOREIGN.

Hawaiian Islands: Honolulu, September 5, 39 cases, 32 deaths.
Japan: Osaka, July 19 to August 1, 1076 cases, 717 deaths; Hiogo, July 19 to August 1, 246 cases, 193 deaths; August 10 to 17, 287 cases, 237 deaths.
France: Paris, August 11 to 17, 8 cases.
India: Madras, August 3 to 9, 4 deaths; Calcutta, July 27 to August 3, 11 deaths; Bombay, August 6 to 13, 4 deaths; Singapore, June 1 to 30, 80 deaths; July 22 to 29, 38 cases, 31 deaths.
Morocco: Tangier, September 11, cholera reported.

¹ Journal d'Hygiene, 1895, No. 982.

Russia; Volhynia, July 21 to August 3, 688 cases, 238 deaths.

Turkey: Constantinople, August 8, 1 case, 1 death.

Turkey in Asia: Aleppo, July 28 to August 12, 264 cases, 93 deaths; Konia, (vilayet) July 21 to August 12, 32 cases, 16 deaths; Adana, (vilayet) July 23 to August 10, 105 cases, 49 deaths; Aleppo, (vilayet) July 24 to August 12, 98 cases, 57 deaths; Diabekir, August 5 to 12, 83 cases, 66 deaths; Hisnei-Mansur, July 28 to August 10, 87 cases, 69 deaths; Homs, August 9, 1 case, 1 death; Hudavendkjar, (vilayet) July 29 to August 12, 24 cases, 22 deaths.

YELLOW FEVER—FOREIGN.

Brazil: Rio de Janeiro, August 10 to 17, 8 deaths.

Mexico: Vera Cruz, August 22 to September 5, 2 deaths.

Puerto Rico: San Juan, August 24 to 31, 1 case, 2 deaths.

Cuba: Cienfuegos, September 1 to 8, 4 cases, 2 deaths; Havana, August 29 to September 5, 80 cases, 26 deaths.

NECROLOGY.

VAN BUREN HUBBARD, M.D., surgeon and major, U. S. A., is reported by telegram, dated September 9, to have died at Fort McPherson, Ga., at which post he has been serving as post surgeon. The cause of his death is reported in the telegraphic notice as an illness of several weeks from an old trouble. The regulation military funeral was held September 8, and the body, under the escort of his brother, Dr. George C. Hubbard, was taken to Staten Island for burial. Major Hubbard was appointed to the Army from civil life and was brevetted during the war for meritorious services. He was from Ohio.

FELIX WEIDMAN, M.D., of Albany, N. Y., September 10, aged 70. He was graduated from the Albany Medical College in 1847.—F. B. Haller, M.D., of Vandalia, Ill., September 14, aged 69. He was an honored member of the Illinois State Medical Society.—J. T. Strong, M.D., of Plainfield, Ind., September 10, aged 55. He was graduated from the University of Michigan and served with credit during the war.—Newton Herrick Ballou, M.D., of Lansingburg, N. Y., September 9. He was born in Sheldon, Vt., in 1816, was graduated from the Jefferson Medical College of Philadelphia in 1839. He served through the war as surgeon of the 2d Regiment, Vermont Volunteers. He had practiced medicine nearly fifty years, having spent twenty-five years in St. Albans, twenty years in Burlington, and a few years in Lansingburgh.—James Ash, M.D., of Philadelphia, September 2, aged 67. He was descended from a family which lived in this country before the Revolution, and was graduated from the Medical School of the University of Pennsylvania about fifty years ago. He practiced medicine in Germantown, Pa., until the beginning of the Civil War, when he entered the service of his country as surgeon of the 1st Excelsior Brigade of New York, retaining that position until the end of the war. He was a member of the Philadelphia County Medical Society, the Sons of the Revolution, etc.—Edward S. Donaldson, M.D., of Waupaca, Wis., September 2, aged 51.—W. P. Burts, M.D., of Ft. Worth, Texas, September 5, aged 68.—Willard Wright, M.D., of Atlantic City, N. J., September 8, aged 63. He was born in New York, and was graduated from the University of Pennsylvania. He went to Atlantic City in 1872 and took an active part in the Greeley campaign. He was elected mayor of Atlantic City five times and was appointed postmaster by President Cleveland during the latter's first term.—Charles S. Beck, M.D., of West Superior, Wis., September 4, aged 35.—V. C. McClure, M.D., of Chicago, September 16, aged 80.—George Spees, M.D., of Milwaukee, Wis., September 13, aged 62.

MISCELLANY.

Denver, Colo., Medical College.—The opening exercises of this college were held September 11.

Petroleum in Military Hospital Laundries.—According to *Public Health*, August, in one of the military hospitals of Germany, petroleum is used in washing the linen, as commonly employed in certain districts of Russia. One gram is added to

each litre of soapy water. The cleansing is said to be more easily effected, and the linen is less spoiled and becomes whiter, while the expense is less, owing to a saving in soap. The method is to be tried in other German military hospitals.

A Case to go to the Jury.—The general term of the Supreme Court of New York decided June 21, 1895, in the case of Comstock v. Green, that there was evidence to go to the jury. This was an action brought to recover for the professional services of the plaintiff, as a physician, rendered to the wife of the defendant, which were necessary for her health and comfort. The evidence in question tended to prove: 1, that the defendant's negligence and ill treatment of his wife while she was ill was such as to justify her in going away with her daughter, where she could be cared for and protected; 2, that she did go away, with the consent and approval of the defendant; 3, that she needed the medical attendance and services of the plaintiff for which the bill was rendered. Further than this, the court indicates no opinion; but, in holding as it does, it reverses the Allegheny county court.

Medical Women in America.—Commenting on the interesting address of Dr. Frances Emily White, professor of physiology in the Woman's Medical College of Pennsylvania on "The American Medical Woman," Dr. Malcolm Morris, editor of the *Practitioner*, is moved to remark that, of the leading women in the medical profession whose portraits and biographical sketches are being published in the *Woman's Medical Journal*, "there is not one whose name has," so far as he is aware, "crossed the Atlantic." This omission bids fair to be remedied before Dr. Forbes Winslow's return to Albion. Judging from the newspaper accounts the English alienist has succeeded in arousing the medical woman in America to a volubility and vehemence sufficient to carry her name across two Atlantics.

A Question of Heredity.—A writer in the *New York World* calls attention to the fact that family reunions—save those possibly of the Smith family—have few delegates bearing the true family name. His explanation of the circumstance may be judged from the following paragraph:

"A recent reunion of the Stone family held at Milford, Conn., was remarkable for its resemblance to all other family reunions in one important respect. This was that the majority of the representatives of the honored ancestor bore some other name. In other words, there were more descendants through female lines than through an exclusive male line. This of course is a mathematical certainty. In ten generations a single female descendant changes the name permanently, whereas it requires an uninterrupted succession of ten generations of male descendants to maintain the name unchanged. But this is not the main point. The main point is this: if the female ancestry as well as the male ancestry is recognized, which is only common sense, then a family reunion ought to recognize not merely all the descendants but all the ancestors as well. This country is going into the business of ancestor worship now on a scale not exceeded by China. When we get to worshipping ancestors it is just as well to bear in mind how many ancestors we have. They are many."

Photography in Colors.—At the recent Springfield, Mass., meeting of the American Association for the Advancement of Science, reference was made by Prof. W. L. Stevens to the progress that is being made in color-photographs. He expressed the opinion that the best method had been devised by F. E. Ives, of Philadelphia, who had made a camera which took three negatives at once, each sensitive to one of the three primary colors which, combined make our sensations of color. Prints on glass from these three negatives could be looked at in a special box in such a way as to reproduce in a wonderfully faithful manner all the original colors of an object or group of objects. Within a few months, however,

Mr. Ives, by means of three suitably dyed gelatine prints placed one over the other between plates of glass, has been able to produce a photograph which gives to the eye the natural colors of an object or landscape when hung as a transparency in the window or before a light without any special apparatus.

Physicians Alone to Report Births and Deaths.—Section 2609 of Vol. 1 of Hill's Annotated Statutes and Codes of the State of Washington, requiring physicians, accoucheurs and midwives to register their names and post-office address with the county auditor of the county where they reside, and requiring them to report, under penalty of \$10, to the county auditor all births and deaths which may come under their supervision, with a certificate of the cause of death and such correlative facts as the board of health may require, has been amended so as to omit all reference to accoucheurs and midwives; requiring the reports to be made on or before the 15th of every month, instead of within thirty days from date of their occurrence; and making the penalty recoverable at the suit of any member of any State or local board of health, instead of at the suit of the county auditor.

Diabetes as a Complication in Surgery.—Leon Legendre, in his inaugural thesis—*These de Paris, 1895*—rehearses the gravity of operations undertaken with diabetic patients. All suppuration in these subjects tends to assume a gangrenous form. Systematic abstention from operating seems to constitute as great a fault as too frequent surgical intervention; the just course seems to lie between these two extremes. Before performing any operation it is necessary to learn what form of diabetes is present. The "lean" form—cachectic, pancreatic—does not seem capable of disassociation; with "fat" diabetics, on the contrary, it is probable that three divisions may be established: nervous persons, who have become diabetic by reason of a moral or physical shock, and who manifest all the classical signs of a pancreatic lesion. Next, the cases in which the glycosuria is not strongly marked and is discovered by accident, so to speak; these maintain a good nutrition for a long time—their symptoms are obscure—their personal and family histories are characteristic of arthritism. Lastly, the atheromatous form of Reynier, characterized by small amount of sugar, the condition in general remaining good for a long time, with an anatomic basis consisting of atheromatous lesions in the bulbar arteries. Hence, when a diabetic patient is to be operated on it is of the greatest importance—1, to seek the origin of the diabetes; 2, to analyze the urine; 3, to ascertain the state of the reflexes. Bouchard has shown the relation between the gravity of the diabetes and the disappearance of the patellar reflexes. As regards surgical interference in diabetic patients, the following conclusions are formulated: 1, no operation of expediency should ever be performed; 2, necessity alone should force the surgeon to operative measures; 3, asepsis is more essential than antiseptics in these cases, since antiseptic agents are, as a rule, badly borne by them.

Results of Operations for Cancer of the Breast.—Messrs. Jones and Platt, surgeon and resident surgical officer respectively, publish the results of all the cases of carcinoma of the breast, 55 in number, operated on by Mr. Jones in the Manchester Royal Infirmary during the ten years 1883–1892 inclusive. The ultimate results so far as learned were—deaths soon after operation 2; patients who died without recurrence 2; patients who died from recurrence 34; now living with recurrence 8; now living and free from recurrence 6; no further information obtainable 3; total 55. From a careful consideration of the facts presented the following conclusions are drawn: 1. Cancer of the breast, although a formidable disease, is amenable to treatment by operation, and the proportion of cures so obtained may confidently be put down at 12 per cent. 2. Non-success after operation is very frequently due to the extensive character of the disease when it first comes under observation; probably if relief were sought earlier a much larger proportion of cures would

be obtained. 3. Moderate enlargement of the axillary glands is no bar to successful operation or to a successful issue, provided they are systematically and carefully removed and the axillary space carefully cleared. 4. It is wellnigh impossible to discover trifling enlargement of the axillary glands by an examination through the unbroken skin. 5. No operation for removal of cancer of the breast can be considered complete, unless the axilla be examined through the wound—the additional risk of such a procedure being very slight. 6. The large number of cases in which recurrence occurs locally, points to the necessity for very free removal of tissue; all doubtful skin must be taken away and great care must be exercised not to leave any outlying portions of breast tissue. 7. Operation is contra-indicated when the whole of the growth can not be removed or when the supraclavicular glands are enlarged. The only condition which might render an operation justifiable under such circumstances would be the presence of a foul cancerous ulcer, the removal of which is desirable on account of the great inconvenience which it occasions.¹

Estimation of Duties on Medicines.—The collector of customs at Key West, Fla., recently wrote to the Treasury Department, stating that it has been the practice at that port, in estimating the duties on cases of medicines which arrive from Havana for immediate transportation without appraisement, to estimate the duty on each article, and that as the invoices cover a great many items which are expressed in Spanish, Latin, and botanical names, and generally indistinctly written, considerable delay occurs in the completion of the transportation papers, and inquiring whether such invoices may not be properly taken up in the entry as one case of medicines and the duty estimated on the aggregate value. The reply, made July 24, 1895, by Assistant Secretary Hamlin, is that if the merchandise is all of the same general character, and subject to the same rate of duty, it should be included in a single item in the entry and the duty estimated on the aggregate value as suggested, and that all items of the same general character and embraced in the same tariff designation should be included in a single item in the entry.

Certain Important Summer Charities of New York.—Among the summer charities of New York city, much good work is done by the Bartholdi Crèche and the Sick Children's Mission. The Bartholdi Crèche is on Randall's Island, opposite 120th Street. The distinguishing feature of this charity is to meet the needs of poor mothers and children who can not leave their homes to go all day to any of the more distant fresh air resorts. A mother can take her sick babe at a moment's notice and in a few moments reach shady groves and bracing air. Last summer 4,366 mothers and children took advantage of this outing. This year, so far, the average is 700 to 800 a week. Trained nurses and helpers are in constant attendance. Tea and pure milk are provided. The crèche is one of the very many instrumentalities working for the prevention of sickness and death among the tenement-house, children, by taking them away from the disease-breeding influences of those parts of the city where they live, and administering to them the tonic of pure fresh air. The summer work of the Children's Aid Society is the maintenance of the Children's Summer home with the Haxtun Cottage for Crippled Children, at Bath Beach, L. I., the Health Home for mothers with sick infants at Coney Island, and the Sick Children's Mission, 287 East Broadway. At the Summer Home there were in 1894 over 5,000 children, 3,775 remaining a week. At the Health Home there were more than 7,000 mothers and infants who also received medical care, 2,000 of these were kept a week, and in some instances the time was prolonged, that a permanent cure might be effected. The Sick Children's Mission employed fifteen physicians to visit the tenement houses. Nearly 4,000 children were treated, 5,200 medical and food prescriptions were filled, and 32,000 tenement houses visited. My attention was called specially to the Crippled Children's Cottage, as the unique feature of the summer work of the society. Here little cripples, mostly

¹ The Lancet, Aug. 31, 1895.

girls are treated, and in many instances cured. The summer work of the society requires \$20,000 for its support, and depends entirely upon individual gifts.

Amicrobic Suppuration.—At a recent meeting of the Paris Surgical Society, MM. Roger and Bonnet stated that it seems actually demonstrated that pus becomes sterile when inclosed in any old focus which does not communicate with the air. Microbes, virulent at first, become attenuated, then succumb, and, finally, are completely dissolved. Nevertheless, trouble may still be caused, as is shown by the following instance: a man entered the service of the authors, for pains at the upper part of the left hypochondrium, with febrile accesses returning every evening and accompanying the three classical stages of intermittent fever. A large tumor was found in the left flank, which was taken for a hypertrophied spleen and paludism was diagnosed. Quinin had no effect and the diagnosis was in doubt, when, three weeks after his admission, the patient passed a great quantity of pus in the urine. M. Tuffier, being consulted, deemed surgical intervention necessary, and made an incision in the lumbar region, which gave issue to two quarts of thick, reddish, fetid pus; the apparently normal kidney was discerned at the bottom of the wound. A diagnosis was now made of perinephric phlegmon, opening into the renal pelvis. Following the operation the patient had no more febrile exacerbations and rapidly recovered. Microscopic examination of the pus revealed no microbes—cultures were negative—inoculation on animals produced no effect. We have here, say the authors, to deal with an amicrobic suppuration—that is to say, a pus formation in which the microbes have been destroyed; nevertheless, this foyer continued to increase in area and tended to an opening into the neighboring organs; it caused violent pains and provoked an intermittent fever absolutely like that from fertile suppurations. It is absolutely impossible to ascertain whether the pyogenic agents are still living or have been destroyed. From a theoretic point of view this is another instance of the pyretogenous rôle of microbial products, and shows that they may produce symptomatic intermittent fever, which is sometimes considered as due to the passage of bacteria into the blood. M. Rendu remarked that the most curious fact in the case was that the patient had febrile attacks daily; in the perinephric phlegmons which he had seen, the fever was manifested only in the last days.¹

The "Bicycle Face."—In the midst of the ceaseless péans of praise to the bicycle as one of the most health-giving institutions a faint voice of warning sometimes is heard. Thus a recent medical writer in the *St. James' Budget*, while not denying the undoubted virtues of bicycle exercise, points out that not all riders present that healthful appearance one might look for, and in fact there is seen among their number a type, ashen-hued and haggard, already recognized as the "bicycle face." Not so with tricycle riders—and here is where he looks for an explanation. The distinguishing feature of the bicycle, and especially of the safety, this observer claims, is the difficulty of maintaining the equilibrium. "Learning" to ride, means mastering the art of keeping the machine upright. It has a tendency to fall to one side or the other all the time, which has to be counteracted by a special effort. The learner knows it very well to his cost; but once learned, he forgets about it, and does his balancing more or less automatically. Nevertheless, the effort is still there, and puts a constant, though unconscious, effort upon his brain and nervous system. The reason why the bicycle has to be "learned" at all, is that the center of equilibrium in the brain requires to be taught the business of doing its duty under novel circumstances. The falling bicycle is maintained upright by a constant series of small muscular movements, which unconsciously adjust the weight in the proper position and are themselves controlled by a special brain-center, situated at the back of the head. The strain upon this center is incessant, though unmarked; and some people can not stand it for more than a short time. This it is that causes the headache and the nervous exhaustion. Probably it does not affect those who begin very young, and possibly

it affects those with either very tough or very dull nerves but little. Most of us, however, are obliged to live in such a way that our nervous systems become very susceptible to any unaccustomed strain, and those who are most likely to use the bicycle belong to the most susceptible classes. The nervous effort entailed by balancing the machine is too much for them. The explanation may strike some people as fantastic, but it is sound physiology, and it squares with the facts. Experienced cyclists often say that the tricycle, and even the old high bicycle—which requires less effort to balance—are less fatiguing for prolonged work, such as a tour, than the safety; yet the latter is lighter, quicker, and superior in nearly every respect, save that of stability. It is a question of balance. "Wheeling" is not a pursuit that will suit everybody.—*Western Druggist*.

Abandonment of Fort Buford, N. D.—This post, recently ordered by the Secretary of War to be discontinued, is situated on the north bank of the Missouri River, two miles below the mouth of the Yellowstone, one mile from the telegraph office and railway station on the Great Northern road and 660 miles from St. Paul, Minn. In 1866 when the post was established, it received a mail from the East once in two weeks in favorable weather, but in winter it was often cut off from communication with the outside world for six or more weeks at a time. The quarters first built were miserable adobe huts, protected from Indian assault by a stockade twelve feet high, on a plain which extended from the flood bank of the river northward to the hills, about four miles distant. Beyond the buttes or hills on the north is a rolling, barren prairie country. South of the post is the river, usually about half a mile wide, with bottom lands on either side subject to overflow and overgrown with cottonwood and willows. The site is dry with good surface drainage toward the river and toward shallow ravines on the east and the west. Water was found at a depth of fifty-two feet from the surface, underlying a thick bed of blue clay. In 1872 a permanent post was built, with the barracks of the men and the quarters of the officers facing each other on each side of a small rectangular parade ground. The former consisted of two double and three single frame buildings, each with wings for the kitchen, dining-room and store rooms. Ventilation was aided by inlets opening under the stoves and by exits in the ridge. The latter were small frame buildings of five rooms each, insufficiently heated in winter by stoves burning bituminous coal. The hospital was a two-story wooden structure consisting of an administration building and two twelve-bed wards, with kitchen and dining-room in an extension in the rear. Waste water was carried away by the natural inclination of the ground and by surface ditches. The earth closet system was used in the removal of excreta, which with all garbage, ashes and other refuse matters, were carted away daily to a dumping ground a mile distant from the post. As the well water proved to be quite hard, a systematic supply was taken from the river. This had the disadvantage of being often turbid, but when cleared of its suspended matters it was regarded as an excellent water. It was pumped from a depth of eighteen feet into a large storage tank of 56,000 gallons and distributed from an elevation of 100 feet. There was no visible source of contamination except the natural drainage of the country above the post, and no disease was ever attributed to the use of the water. Ice was cut from the river for use in summer. Gardens were cultivated in the bottom lands, producing lettuce, radishes, potatoes, cabbage, peas, turnips and beets in quantity sufficient to furnish a fair supply to the garrison during the season. The climate of this post was very trying as being one of great extremes. The mean temperature from November to February inclusive is below freezing and in February, the coldest month, the minimum may reach or exceed 40 degrees below zero, while in July and August the maximum is 100 degrees Fah. Changes of temperature are sudden, frequent and of great range, while violent winds and heavy snow storms are of common occurrence. The diseases of the post were rheumatic, catarrhal and pulmonary affections occurring mostly during the long winters, when the ordinary occupation of the troops in garrison was shoveling snow to keep the communications open for various purposes, but particularly for the delivery of fuel wherewith to keep themselves warm.

¹ *Gaz. Med. de Paris*, No. 82, 1895.

Society Notes.

TOLEDO MEDICAL ASSOCIATION.—A regular meeting of the Toledo Medical Association was held in that city September 12.—At a recent meeting of the Brown County, Wis., Medical Society, at Green Bay, the following officers were elected for the ensuing year: President, B. C. Brett; Vice-President, F. L. Lewis; Secretary, H. M. Beck. This society was organized in 1868, but since the formation of the Fox River Valley Medical Society there have been no meetings of this society until this one.—The meeting of the Cuyahoga County, Ohio, Medical Society was held September 5.—A regular meeting of the Washington County Medical Society was held in Hillsboro, Wash., September 3.

Washington Notes.

HEALTH OF THE DISTRICT.—The report of the Health Officer for the week ended September 7, follows: number of deaths (still-births not included): white, 51; colored, 44; total, 95. Death rate per 1,000 per annum, white, 14.13; colored, 26.03; total, 17.93. Death rate per 1,000 per annum for corresponding week last year, 15.51. Reports to the Health Department for the past week show a continued improvement in the health of the city. The deaths in the week before last were 111, and during last week they numbered 95. The death rate fell from 21.41 to 17.93, and the decrease in mortality amounted to over 14 per cent. The absence of contagious diseases in virulent form, which has prevailed during the summer months, was still manifest, there having been but one death from diphtheria and two from whooping cough reported.

HIGHEST TEMPERATURE IN SEPTEMBER FOR TWENTY-FOUR YEARS.—On the twelfth day of the present month the Weather Bureau reported the maximum temperature in Washington to be 96.2 degrees. Not since 1871 has the record for a maximum temperature been broken for the second ten days of September, and in that year on the 12th of the month, the same date of the present break of the record, the thermometer registered 94. The warm wave spread over almost the entire country, and broke records in ten cities, while in four other localities the thermometer reached the highest mark it had ever attained. At Atlantic City the thermometer was 92 degrees, 6 degrees higher than ever before, and in Baltimore it was 94, or 4 degrees in excess of previous records. A list of cities where the record of previous years was broken on the 12th inst. and the increase over previous records being given, follows: Block Island, R. I., 78-2; New York, 92-3; Harrisburg, Pa., 92-4; Philadelphia, 94-3; San Antonio, Texas, 98-2; Columbus, Ohio, 94-1; Parkersburg, W. Va., 94-2.

MEAT INSPECTION POSTPONED.—Secretary Morton has modified the order issued on August 18, concerning the inspection of meat exported, changing the date when it is to go into effect, from September 16 to October 16. It has been represented, satisfactorily, that the enforcement of the order at the time moved would cause great loss to shippers and a postponement would not be detrimental. Consequently he has extended the time.

THE WOMAN'S CLINIC.—The regular quarterly meeting of the Board of Directors of the Woman's Clinic was held on the 7th inst. The report of the various committees showed increased work and usefulness of the hospital during the past three months.

CENTRAL DISPENSARY AND EMERGENCY HOSPITAL.—The regular monthly meeting of the Board of Directors of the Hospital was held on the 13th inst. Many improvements have been made to the building during the summer months, such as painting, changes in the heating plant, electric elevator replacing steam, and new fire escapes. The work of the hospital has steadily increased. Resolutions of regret at the loss by death of Mr. J. G. Judd, one of the directors, were passed and ordered printed.

PUBLIC WELLS.—The report of the inspector shows that during the year 194 wells were inspected, 96 were found to

be good, 41 suspicious and 57 condemned. The most interesting part of the report deals with the investigation of the action of the Potomac water on lead pipe, to determine if enough lead is dissolved by the water to be injurious to public health.

TO INCREASE THE WATER SUPPLY.—The Commissioners of the District have ordered advertisements to be made for furnishing the city with a pumping engine of 8,000,000 gallons power.

Foreign Requirements for the Practice of Medicine.

GREAT BRITAIN.

Foreign practitioners can practice medicine in Great Britain without restriction, but unless registered can not recover their fees by legal process nor give medical evidence in courts of law, nor hold public medical offices. Under the Medical Act of 1886 the General Medical Council may recognize equivalent qualifications granted in countries which treat this country with reciprocity; after certain formalities such qualifications would be registrable. At present, however, no foreign countries have arranged to treat this country with reciprocity, and, as a rule, British practitioners are required in European countries to pass an examination of greater or less severity. The following list contains particulars as to the regulations of the British Colonies as well as of foreign countries:

BRITISH COLONIES AND DEPENDENCIES—(AUSTRALASIA)

Australia.—The applicant must be registered by the Medical Board of the colony in which he proposes to practice. He may be required to prove the genuineness and authenticity of his diplomas.

New Zealand.—Certain legal formalities must be gone through, but there is no examination.

Tasmania.—A diploma must be verified by the Medical Examining Board.

DOMINION OF CANADA.

Except in British Columbia and Ontario it is necessary only to register British diplomas, but evidence of authenticity and genuineness may be required. For this registration a fee is charged, and in some cases there is also an annual tax. In British Columbia the Medical Council of the colony holds an examination, and there is a fee of \$100; in Ontario an examination is held by the College of Physicians and Surgeons of Toronto.

SOUTH AFRICA.

There is a Colonial Medical Council both in the Cape of Good Hope and Natal. British diplomas are registrable after inspection and verification.

By a resolution of the Executive Council, ratified by the Volksraad, every medical practitioner, dentist, and apothecary must be registered and licensed before he can be permitted to practice within the limits of the South African Republic. The section of the Act which applies is stringent, and runs as follows: "It shall not be allowed to any person in this Republic to have himself advertised as medical practitioner, surgeon, dentist, apothecary, chemist, or druggist unless his name appears in the Register of the Medical Board and his admission fee has been paid. Contravention of this rule will be punished with a fine of from £10 to £100, or in case of non-payment with imprisonment with or without hard labor for a period of from one to six months." Also, "Any admitted medical doctor, surgeon or dentist, apothecary, chemist or druggist shall pay the following license during the time they carry on their profession within the Republic: doctors, for a year, £25, for nine months £20, for six months £15, and for three months, £10; apothecaries, for a year, £10, for nine months £8, for six months £6, and for three months £5."

WEST INDIES.

British qualifications are everywhere recognized. In some instances registration is necessary, for which a small fee is charged.

EUROPE.

Austria.—It is necessary to pass the State examination, or obtain a University Degree in Medicine, and to become an Austrian subject. Exemptions may be granted under very special circumstances.

Belgium.—Upon the advice of a jury which has a right to grant the diploma of Doctor, the Government can give permission to practice medicine to a foreign subject who possesses a diploma in medicine, surgery, and midwifery.

Denmark.—Foreigners are required to pass the State examination.

France.—Under the new law the degree of M.D. obtained by examination before a French faculty, is indispensable. This law has recently been extended to Algiers. The examinations are precisely the same as those which have to be passed by French students, but holders of British diplomas may obtain exemption from portions of the curriculum and examination at the discretion of the Minister of Public Instruction. In no case, however, shall the exemption extend to more than three of the prescribed examinations. The examinations may be passed before any one of the following Medical Faculties: Paris, Montpellier, Nancy, Bordeaux, Lyons, Lille, or Toulouse. Before he is admitted to examination the candidate must submit his qualifications, and whatever other degrees or qualifications he may possess, to the Minister of Public Instruction, stating the Faculty before which he wishes to present himself. The examinations are conducted in the French language. Fees to the amount of £64 must be paid.

Holland.—Foreigners are required to pass the State examination.

Germany.—Any person may practice medicine, but if he has not passed the State examination he does so at his own peril, and is liable to fine and imprisonment if convicted of a mistake. A student who intends to enter the profession of medicine must attend a gymnasium (upper school), and pass an examination in general knowledge—Latin, Greek, German, French, divinity, mathematics, physics, history and geography. After passing this examination the student may be accepted as an ordinary full student of a university. At the end of the fourth semester (second year) he can pass his first State examination (*Tentamen Physicum*), which embraces anatomy, physiology and physics, chemistry, botany and zoology. In the tenth semester he may pass the final State examination. In some universities the degree of M.D. can be obtained at the end of the eighth semester (fourth year)—that is, before the *Staats-Examen* can be passed. The degree of M.D. does not in itself confer a license to practice in the German Empire. We believe that the Universities of Leipzig, Göttingen, Heidelberg and some others do not grant the degree of M.D. except to persons who have passed the State examina-

tion. The fee for the *Tentamen Physicum* is £116s.; for the final State examination £10 6s. The fee to the university for the M.D. degree varies between £15 and £25.

Greece.—A State examination must be passed, but graduates of foreign schools may take their examination in French or English.

Italy.—A foreigner must (a) obtain an authorization (*abilitazione*) from one of the Royal Universities of Italy; or (b) if he desires to practice only among foreigners he is at liberty to do so.

Monaco.—The following British qualifications are, for the purposes of medical practice in the Principality of Monaco, considered equivalent to the French diploma of Doctor of Medicine: the degree of Doctor of Medicine, of the universities of "the United Kingdom of Great Britain," and the diplomas of Fellow of the Royal Colleges of Surgeons and Physicians of London, Edinburgh, Dublin, and of the Faculty of Physicians and Surgeons of Glasgow. Every application for leave to practice must be accompanied by the diplomas of the applicant or by copies of those documents, certified as correct either by a consul of the Principality or by the Mayor of Monaco. The applicants must enter into an undertaking to live in the Principality and to practice their profession during the whole or part of the months of May, June, July, August, September and October, agreeably to Article 1 of the Ordinance of May 29, 1894. Only those who send in their applications in time will be included in the official list, which is to be drawn up and distributed at the beginning of each month to all the hotels and boarding houses, where it will be posted up in a conspicuous place. This list will contain the name and nationality of the practitioners and the nature and source of their qualifications.

Portugal.—The State examination must be passed.

Roumania.—A State examination must be passed (*viva voce*.)

Russia.—The State examination must be passed, but if the applicant possesses the degree of M.D. from a university of high repute, the Minister of Education may give an authorization after requiring the candidate to compose and defend a dissertation.

Norway.—The State examination must be passed.

Spain.—The State examination must be passed, but exemptions are sometimes granted on application through the British Ambassador. A license costing from £1 to £24 must be taken out. This regulation applies to Spanish colonies, (Canary Islands, etc.)

Switzerland.—A qualified English practitioner desiring to practice in Switzerland, even if he desires to practice only among his own countrymen, is required to pass the Federal examination in that country. The degree of Doctor of Medicine does not give the right to practice. The Federal examination may be passed at Basle, Zürich or Berne in German, and at Geneva or Lausanne in French. The applicant is advised to obtain from one of his teachers in this country an introduction to a professor at the university at which he proposes to pass the examination. His proper course would be to call upon the Rector of the university. We are informed that every information would be afforded, and that no difficulties are placed in the way of candidates. At the University of Zürich, the three examinations which it is necessary to pass are held as a rule at the following periods of the year. First examination: end of January and mid-September; second examination: end of January and mid-September; third examination: beginning of January, end of May and beginning of October. At Basle the next examinations are in October. At Geneva the examinations are held in the third week of October, and in the second week of July, at the opening and conclusion respectively of the winter and summer session. At Lausanne the examinations take place as follows: first and second examinations: April and October; final examination: February and March, and June and July.

Turkey.—An examination must be passed (fee, £4 10s.) at Constantinople.

SOUTH AMERICA.

Argentine Republic.—The applicant's diplomas must be verified by the Argentine Consul in this country (fee £1 4s). This should be done before leaving this country. On arriving at Buenos Ayres the indorsement of the Argentine Consul in this country must be verified by the Argentine Foreign Office. Three examinations must be passed in the University of Buenos Ayres or Cordova. First examination: anatomy with dissections, physiology, pathology, ophthalmology, and gynecology. Second examination: clinical and operative surgery, histology, materia medica, and mental diseases. Third examination: clinical medicine, pathology, midwifery, and toxicology. The fee for examination is \$300, half of which is retained in case of rejection. The examinations can be passed consecutively at a few short intervals or separately; a rejected candidate is not re-admitted to examination until after the lapse of six months. The examination is conducted *viva voce* in Spanish. Temporary authorizations to practice for six months may be obtained from the Governor of a province, and the applicant may utilize this time to improve his knowledge of Spanish. The regulations for graduates of Spanish universities are less onerous.

Brazil.—A State examination must be passed which is conducted in Portuguese or French.

Chili.—The regulations resemble those in the Argentine Republic; examination by the University of Santiago.

Peru.—An examination must be passed before the University of Lima; it is conducted in Spanish.

Uruguay.—The conditions are similar to those in the Argentine Republic; examination by the University of Montevideo.—*BAITISI MEDICAL JOURNAL.*

THE PUBLIC SERVICES.

Circular—Disinfection of baggage arriving from Oriental ports, at ports on the Pacific Coast.

TREASURY DEPARTMENT, OFFICE OF THE SECRETARY,

WASHINGTON, D. C., Sept. 7, 1895.

To medical officers of the Marine-Hospital Service, consular officers, collectors of customs, State and local quarantine officers, steamship companies and others concerned:

On account of the officially reported prevalence of cholera in Hongkong and Yokohama, and other Chinese and Japanese ports, and in Honolulu, attention is called to article 5 of the Quarantine Regulations, Treasury Department, to be observed at foreign ports, issued April 26, 1894.

No special provisions having been reported from these ports for proper disinfection of suspected baggage, it is hereby ordered on recommendation of the Surgeon-General of the Marine-Hospital Service, that all unlabelled baggage of steerage passengers, including hand baggage, and all labelled baggage of said passengers, which in the opinion of the quarantine officer should be disinfected or re-disinfected, arriving from Oriental ports, including ports of Hawaii, at any port in the

States of Oregon, Washington, or California, shall be disinfected as provided in article 6 of the Quarantine Regulations for domestic ports, before being landed.

This regulation will also apply to any other baggage which the quarantine officer may suspect of being infected.

CHARLES S. HAMLIN,
Acting Secretary.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from September 7, 1895, to September 13, 1895.

Capt. Charles Richard, Asst. Surgeon, so much of S. O. 112, A. G. O., May 13, 1895, as directs him to take station at St. Louis, Mo., for duty as attending surgeon and examiner of recruits, in that city, is revoked, and upon the expiration of his present leave of absence, he is ordered to Ft. Brady, Mich., for duty, relieving Capt. William B. Davis, Asst. Surgeon. Capt. Davis, on being thus relieved, will proceed to and take station in New York city, for duty as attending surgeon and examiner of recruits, relieving Capt. William H. Corbuser, Asst. Surgeon. Capt. Corbuser, on being thus relieved, is ordered to Ft. Monroe, Va., for duty at that post.

Capt. William W. Gray, Asst. Surgeon, upon the expiration of his present leave of absence, will be relieved from duty at Ft. Schuyler, N. Y., and ordered to Philadelphia, Pa., for duty as attending surgeon and examiner of recruits in that city, relieving Capt. Samuel Q. Robinson, Asst. Surgeon. Capt. Robinson, on being thus relieved, is ordered to Ft. Reno, Oklahoma, for duty, relieving Major William H. Gardner, Surgeon. Major Gardner, on being thus relieved, is ordered to Ft. Thomas, Ky., for duty, relieving Major James C. Worthington, Surgeon.

Major James C. Worthington, Surgeon, on being relieved from duty at Ft. Thomas, Ky., is ordered to Vancouver Bks., Washington, for duty, relieving Capt. William Stephenson, Asst. Surgeon. Capt. Stephenson, on being thus relieved, is ordered to the Presidio of San Francisco, Cal., for duty at that post.

The following named officers will report in person, on Monday, Sept. 23, 1895, to Col. Charles H. Alden, Asst. Surgeon-General, President of the examining board appointed to meet in Washington, D. C., for examination as to their fitness for promotion: Capt. Louis S. Tesson, Asst. Surgeon; Capt. William H. Corbuser, Asst. Surgeon; Capt. Daniel M. Appel, Asst. Surgeon; Capt. Samuel Q. Robinson, Asst. Surgeon.

First Lieut. Charles E. B. Flagg, Asst. Surgeon, so much of S. O. 202, A. G. O., Aug. 29, 1895, as relieves him from duty at Angel Island, Cal., and assigns him to duty at Ft. Hancock, Texas, is revoked.

Capt. Edward C. Carter, Asst. Surgeon, upon the abandonment of Ft. Buford, N. D., will report for duty at Ft. Harrison, Mont.

First Lieut. Charles F. Kieffer, Asst. Surgeon, when his services are no longer needed at Ft. Buford, will be relieved from duty at that post, and will report for duty at Ft. Omaha, Neb.

First Lieut. Francis A. Winter, Asst. Surgeon, so much of the order as directs him, on being relieved from duty at Ft. Hancock, Texas, by Lieut. Flagg, to report for duty at Ft. Grant, Ariz., is amended to direct him to so report upon the abandonment of Ft. Hancock.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending September 14, 1895.

Surgeon J. L. Neilson, detached from the U. S. R. S. "Wabash," and to the U. S. S. "Maine."

P. A. Surgeon V. C. B. Means, from Naval Hospital, New York, and to the U. S. S. "Maine."

Asst. Surgeon T. W. Richards, from the U. S. R. S. "Minnesota," and to the U. S. S. "Maine."

Surgeon D. O. Lewis, from the U. S. S. "Mohican," and to the U. S. S. "Marion."

P. A. Surgeon J. E. Page, from the U. S. S. "Philadelphia," and to the Mare Island Hospital.

Asst. Surgeon R. K. Smith, from the U. S. R. S. "Vermont," and to the U. S. S. "Philadelphia."

Medical Director A. L. Gihon, detached from the Naval Hospital, Washington, D. C., and placed on retired list September 28.

Medical Inspector Geo. A. Bright, detached from the Navy Yard, New York, and to Naval Hospital, Washington, D. C.

Medical Inspector A. F. Price, detached from Torpedo Station, and to the New York Navy Yard.

Surgeon B. F. Stephenson, detached from the Marine Rendezvous, Boston, and to the U. S. R. S. "Wabash."

P. A. Surgeon J. F. Uric, ordered to the Marine Rendezvous, Boston, Mass.

Surgeon J. M. Steele, detached from Marine Rendezvous, New York, and to the Torpedo Station, Newport.

Surgeon L. G. Heneberger, ordered to Marine Rendezvous, New York, in addition to present duties.

Asst. Surgeon J. H. Moore, detached from the U. S. S. "Atlanta," and ordered to the U. S. T. S. "Constellation."

P. A. Surgeon Philip Leach, ordered to the Naval Hospital, New York.

ORIGINAL ARTICLES.

ALCOHOLIC INTOLERANCE AND PREDISPOSITIONS.

Read in the Section on State Medicine at the Forty-sixth Annual Meeting of the American Medical Association at Baltimore, Md., May 7-10, 1895.

BY T. D. CROTHERS, M.D.
SUPERINTENDENT WALNUT LODGE HOSPITAL,
HARTFORD, CONN.

The fact that many persons use spirits to excess at intervals, or in moderation for a life time, and from superficial observation are apparently no worse, is both misleading and dangerous. In one case it conveys the impression that spirits are harmless in small quantities, and occasional excesses are of little injury from which restoration quickly follows. In the second case the danger of repeated pathologic disturbances are masked until organic changes take place, and most serious results follow, that are not apparent except in other departures from health.

The so-called moderate user of spirits when examined critically appears differently from what he himself or friends suppose. His fancied vigor and mental health is an illusion. His freedom from pain or discomfort is the work of narcotism and diminished nerve sensibilities. Constant dulling of the senses by the steady use of small doses of alcohol removes all warnings of danger, and increases the delusions of power and capacity to determine the relation of surroundings, and proper adjustment to them. This goes on slowly or rapidly, and the effects accumulate, always marked and along unusual lines not recognized. By and by, alterations in character and conduct appear, changes of the emotions and higher brain power, are manifest in irritability, suspicion, credulity and instability. Then neuritis, rheumatism, indigestion and various complex neurotic disturbances appear. Finally, death follows some acute inflammation or fatty degeneration of the liver or heart, or lungs. Bright's disease, heart failure or the very comprehensive term neurasthenia, are used to express states of degeneration, specifically due to alcohol and its accumulative effects on the cell and nerve organization.

Recently Dr. Pierret, of Lyons, and Dr. Lanceriaux, of Paris, have presented elaborate studies of the effects of moderate drinking of wine, beer and the stronger alcohols, confirming the conclusions of other physicians in a very marked way, showing that spirits in small quantities and taken at intervals, as at meals, or at stated times, is always injurious. This injury is poisoning, cell starvation and exhaustion which may not be prominent in some cases or appear to materially disturb the normal relations of life and living, but its accumulative degenerations after a time break out in the next generation with great certainty: This tolerance of spirits always

produces predisposition in the next or succeeding generations.

The capacity to use spirits in small quantities at intervals, becomes incapacity in the next generation. The intolerance of spirits extends from indifference up to positive repugnance and acute poisoning. Many persons manifest indifference to the taste and effects of spirits. Like tobacco, at first it is repugnant, later they are not unpleasantly affected by it in small doses. The increased action of the heart and circulation of the blood to the brain is pleasing within certain limits; beyond this, pain and suffering forbid its further use. This is a common form of intolerance. Spirits are usually taken in company, from contagion or surroundings. After a certain quantity is used, the system repels it, and headache, vertigo and distress follow.

This intolerance is overcome in some cases, and paroxysmal periodicity is the form of the inebriety that follows. In some cases a marked taste and repugnance is common. Spirits are often drunk impulsively and in large quantities, with condiments to conceal the flavor. In these cases there has been a natural intolerance formerly which has been overcome by repeated effort. In other cases, this intolerance after being held in abeyance for a time, asserts itself in an emphatic change to rigid abstinence and bitter denunciations of persons who use spirits. Many of the most dogmatic reformers who have used spirits at first, then suddenly stopped, have had naturally a constitutional intolerance of spirits. This has been overcome by circumstance, principally surroundings, ill health and want of training. Finally, from some unknown causes, this repelling diathesis has attained power to assert itself over the acquired taste and forced physiologic abstinence. To the man, it is simply an effort of the will which he thinks all persons can use, but literally it is the operation of physiologic laws, not his will.

Many very interesting cases of marked changes of living and character are made examples of theories of the will, of moral force and of faith, that are untrue and misleading.

This form of intolerance may appear after the first toxic use of spirits. The intoxication has created a profound impression of antagonism to any farther use of spirits. This is both physical and mental, the pain and suffering from the action of spirits is recalled by the memory and mind so vividly, as to repel any use of spirits again. Some persons will suffer from nausea and intense depression from the odor of spirits, and even the sight of an intoxicated man is painful. Another class, after the first intoxication, are never able to retain spirits without causing most intense irritation and nausea. I have met with cases who have used beer and wine freely for varying periods before 20, then suddenly developed an intense intolerance, and ever after suf-

ferred from severe headache when any form of spirits was taken. I have seen two cases, both direct descendants from inebriate parents, who could not bear any form of spirits. They suffered from functional paralysis of the stomach, ending in acute vomiting and cardiac feebleness. Both of these men enjoyed the odor of spirits, but could not use it in any form.

Many of these cases of intolerance for spirits are the direct descendants of inebriates. Others are from some allied neurotic families, in which unusual drug sensitiveness prevails. Functional peculiarities are always more noted among neurotics and tolerances or intolerances of various drugs. In the normal man not weighed down by abnormal heredity, spirits would be naturally more or less intolerant. This would follow from the complex physiologic action of alcohol, viz., the sudden rise of the heart's action, disturbance of sensation and perversion of nutrition that always follow from its use. In a neurotic this will be concealed or exaggerated. Concealed in the moderate drinker, and exaggerated in the violent opposition mentally and physically to its use. The *predisposition* to the use of spirits is a direct or indirect heredity, and a neurosis from some allied condition of degeneration. In other cases it is a defect due to some abnormal condition of the brain centers.

The largest number of persons in which this condition exists, experience very pleasant effects from the use of spirits. A sense of exhilaration and apparent physical and mental vigor, together with a certain nerve rest, and power of adaptability and enjoyment of the surroundings comes from its use. The ordinary depressions and reactions from the action of alcohol on the heart and nerve centers are not prominent or noticeable, and are not regarded as due to spirits. This pleasing physiologic state continues and fosters egotism and delusions of strength and power of control. The constant dulling of the senses removes all consciousness of danger and capacity to judge of their actual condition. Later, a variety of complex disorders appear, with changes of character and irregularity of conduct. If the man lives in an automatic circle these changes are unnoticed, and he may continue a long time, only increasing the spirits for its effects. If he lives in a circle of much strain and change he will become an inebriate and show marked symptoms of degeneration and disease. Acute inflammations of the liver, stomach, lungs, and heart failure are common. Rheumatism and neurotic disorders of very complex forms appear. Inebriety appears as a rule in all of these cases. Drug taking of all kinds follows naturally. The delusions which begins early in the case continue with increasing intensity. This is manifest in the warm defense of the moderate use of alcohol, and the delusion that spirits have some real virtue and power to help on toward an ideal physical and mental health.

I have seen cases in which the mind was wrecked and imbecile in all other lines, yet clear and emphatic in defense of the moderate use of spirits. This delusion clings to the mind tenaciously. When the case has recovered, and a long period of abstinence has supervened, it will appear in the efforts to use spirits again moderately. The physiologic impression coming from heredity, and fastened in the mind by the early exhilaration from the use of spirits, is seldom effaced. The brain is permanently impaired, the predisposition for alcohol, or any narcotic drugs,

has become a dominant idea that may be concealed for a time but is never broken up.

A certain number of persons realize early the physiologic defect of organization, and by the most heroic efforts, avoid wreck in total abstinence. In such cases certain physical conditions, and environment, are the real exacting causes. If these can be obviated or provided against, they can overcome this tendency—the value of institutional treatment is to teach these physical causes and the way to avoid them; to point out the danger, not from spirits and drugs alone, but the conditions which call for the seductive effects of such drugs. This is vaguely outlined in the confused literature of moralists, who speak of the battles with the demon appetite; of the sinful tendency to be overcome by prayer; of the influence of the lower nature to attain supremacy; of the natural tendency of man to go down, to become an animal, to give free reign to his lower instincts. In reality this, when seen from a higher point of view, is physical degeneration, with consciousness of its presence and tendency, and expectation of being able to control it. In a certain number of cases all consciousness of the real condition is absent. Paralysis exists from the beginning; in others only a partial palsy is present. In the former, delusional efforts for restoration, and delusional confidence in recovery, with continuous failures, are common symptoms. In the latter, successful and continued efforts along natural lines of cause and effect, are followed by both temporary and permanent restoration.

Many men in active life, are profoundly conscious of the danger of a single glass of spirits. They recognize the degenerative predisposition that is present urging them to take spirits, but overcome this tendency. Such cases often appeal to me for counsel to acquire new strength for this struggle. Suicide is the frequent ending of such cases; finding this craze for relief increasing and being overcome by it, give way to melancholy. This predisposition and central nerve degeneration not unfrequently dies out in middle or later life. Some unknown physiologic change takes place in the nerve centers and all desire or taste for spirits disappears. Conditions of ill health, surroundings and other causes are inoperative. He never drinks again. The taste of spirits is repelling and seem to have no effect. Such men often explain this as a mere effort of the will, or the power of some supernatural force, or the effect of some drug, or remedial appliance.

This predisposition in other cases never dies out, but always remains slumbering and ready to be fanned into a mild flame at any moment. In certain states of living and surroundings it never appears; in others, it is dominant beyond the power of control. Mental contagion, strain, irregularity of life and living, bring it into prominence. Again this degeneration breaks out at distinct periods of life then dies out, only to appear in some other form. The period of adolescence is often marked by alcoholic excess, which subsides in manhood, or appears in the senile stage again.

There are undoubtedly certain periods of life which are favorable for the development of these predispositions to seek relief from spirits or drugs. One of these periods is the menopause in women, and the senile stage in man. A vast region of unexplored facts stretch out in all directions from this point. Alcoholic intolerance and alcoholic predispositions

are physiologic and psychologic facts within the observation of any one. They are also unknown pathologic conditions, of both defective growth, and exhaustion and poisoning. The normal or approximately healthy man is not predisposed to use alcohol or narcotic drugs. While alcohol is not pleasing alone, when mixed in water and flavoring substances it may be tolerated, but when its effects are realized a natural intolerance begins. Unlike any other drug it conceals the conditions which it provokes, until such a time when they become fixed, then repugnance begins. This persistent concealment breaks out in the next generation as a physiologic bias and tendency to use the same drugs, to conceal the degeneration produced by the same causes. This persistent poisoning incapacitates and limits the vigor of the next life, giving it certain impulses to exhaustion; and breaking up its power of adaptability, causes pain and suffering which seeks relief in the same way. These subtle forces of heredity and morbid impulses, whose causes are only faintly comprehended, are expressed in these terms, intolerance and predisposition. Along this line we need new studies.

ALCOHOL IN THE GRIPPE.

Read in the Section on State Medicine at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY CHARLES H. SHEPARD, M.D.

BROOKLYN, N. Y.

The present form of the grippe is an infectious disease finding its way through the respiratory mucous membrane, and the resulting toxins, by their migrations, tend to induce a lasting lassitude and depression that are characteristic symptoms in many of the cases. The primary cause of this disease is the susceptibility of the system. This is shown by the fact that some persons enjoy entire freedom, while others succumb to its influence every time it appears.

There are many conditions that favor it. What is called a poor circulation is accompanied by an inability to throw off morbid influences, and persons in that condition are likely to suffer from every epidemic. The same applies to indigestion, for when the body is not well nourished there is but feeble reactive force. Those having a torpid liver find the grippe an added burden to the discomfort of life, and those with an inactive skin are still more likely to suffer from its baneful influence, but among the more prominent causes of susceptibility may be classed the almost universal habit of drug taking, from the mild tonics, to patent medicines. Whenever one is out of order in any way, the first thing seems to be to swallow something, instead of trying to find out the cause of the trouble and seeking to obviate it by regulating the habits of life. This custom tends continually to lower the tone of the system, and the more it is indulged in the more evident becomes the apparent necessity of continuing the down-hill course. A large share of the deterioration of our people is due to the use of alcoholic tonics, or stimulants, as they are sometimes called. The majority do not look beyond the fact that they seem to feel better after their use, but this feeling comes from the benumbing action of the alcohol itself, and never from any building up action of the drug, because it has no such action. What is supposed by some to be that action is only an irritation resulting from the efforts of the

system to get rid of the drug. It only exhausts the vitality so much quicker, and therefore alcohol should always be considered a poison to the human system, and is already so considered by some of the highest medical authorities. The cells of the brain lie buried in a nutrient plasma, and their vigor depends upon the quality of this plasma. Should this become impregnated with alcohol in even a small degree, the action would necessarily be, so far, an abnormal one. These cells become exhausted from their natural activity and are then shrunken, depending for renewal on rest and the nutrient plasma by which they are surrounded: This has been demonstrated by experiments on dogs and pigeons. Out of a number, some were killed, and on examination the brain cells were found well nourished and full, while their companions, after exercise and fatigue, showed shrunken brain cells.

Irritability always follows exhaustion in a nerve cell, by whatever cause excited, and there is every reason to believe that insomnia, neurasthenia, and acute insanity are due to fatigue of the nerve cells through failure of the nutrient plasma to furnish the necessary nutriment for restoration. There is a collapse that frequently comes after the use of so-called tonics and stimulants. Outraged nature cries aloud for help. This it is that causes so many to return to their cups. The condition may be called brain and nerve exhaustion. It is found most difficult to treat by ordinary methods, because these nearly all depend upon rousing up the vitality by recourse to some new irritant or drug.

The strain upon the nervous energy of the individual in the pressure of modern civilization is so great that many, not knowing or realizing the inevitable result, and feeling that there is no time for rest and recuperation, seek in alcohol or some narcotic a surcease for their jaded feelings. This, with some more quickly than with others, is sure to bring about a condition of neurasthenia, so aptly termed by Dr. Beard a chronic functional disease of the nervous system, the basis of which is impoverishment of the nervous tissue in excess of repair, which may exist without any evidence of profound organic complication. We have daily before our eyes a profusion of examples of the various forms of nervous prostration. Experts can readily recognize in their patients underlying symptoms of nerve exhaustion, which their personal record showed had long antedated the expression of any distinct climax of disease.

It is difficult for the ordinary mind to see the end from the beginning, for while some individuals, probably from inheritance from a sound ancestry, are enabled to ignore the laws of health for a long time, the superficial observer can point to them with pride and say: "They do no harm, in moderation." Even the Royal Commission of England reports that the temperate use of opium in India should be viewed in the same light as the temperate use of alcohol in England, which according to their measure is harmful or harmless according to the amount and discretion with which it is used. This is altogether too much of a commercial report. It needs a commission from America, France, or possibly Germany, to get a perfectly unbiased opinion. The question of the toleration of narcotics is not settled and never will be until it is settled right. The consensus of medical opinion is coming more and more to the conclusion that alcohol is only and always a poison, and

therefore has no place in the human economy. Such authority as Dr. Forel, the famous specialist of the University of Zurich, says: "Alcohol, even when diluted as in wine, beer and cider, is a poison which changes pathologically the tissues of the body and leads to fatty degeneration. I am one who assigns but a very subordinate position to alcohol as a medicine."

For these reasons we contend that alcohol has no place in the treatment of grippe; on the contrary, it is because of the too frequent use of this and other narcotics that epidemics, particularly the grippe, make such fearful headway in our land, and such must inevitably be the rule until our people study the laws of health and obey them.

The injurious and deteriorating effect of the use of any narcotic, tobacco not excepted, is daily demonstrated to those who have eyes to see. Too frequently there is to be found in the daily papers an account of the physical wreck of some young man from the excessive use of the drug. As the future of our nation depends upon the young, too much can not be done to save them from physical degeneracy. Tea and coffee also belong in the same category of irritant drugs, which by rousing the vital forces to get rid of the poison, provoke the action which is mistakenly supposed to be an added force, whereas that action is only one of self-preservation. It will readily be seen how much supporting or building-up of the system there is in such substances by trying to live on them to the exclusion of other things. The result would quickly prove the absurdity of the idea.

Having demonstrated that alcohol is in no sense a relief or remedy for the grippe, it may be well to consider briefly what remedies are offered for this disease, and the reasons why they are used, and also, what is more desirable, present a sure method of prevention and help. For instance, quinin is ranked as a powerful germ destroyer, and its use is considered by many as of paramount importance. Quinin is essentially a nerve poison and capable of producing a profound disturbance of the nervous centers. Practicing physicians are familiar with instances that are rightly accused by patients as having permanently damaged one or another of the nerve functions. A drug of such potency for evil ought to be employed with the greatest care, and never when a milder agency will equally well or better secure the result. Its tolerance by a patient is simply a test of the power of resistance of his nervous system. The increased nervousness of some portions of our population is undoubtedly due to a previous saturating of the system with this recognized anti-periodic. Exceedingly pernicious is the practice that has obtained in some sections of dosing children with this drug. It is sure to lay the foundation of a miserable neurasthenic condition in after life. Attention to the digestive tract by following hygienic and dietetic treatment is the all-important and all-sufficient course to pursue in such cases. Strychnin has been used to some extent. The drug antipyrin is also used, and whenever there is a fever that remedy tends to reduce it, and thus seems to have a good effect, but its action may be more dangerous than the grippe itself. The value of such supposed remedies depends entirely upon the vital reaction of the patient. Again, it is recommended as a *sine qua non* that the patient should be confined to the house or bed, with absolute rest, according to the severity of the attack. Certainly,

the isolation of cases tends to restrict the spread of the disease, but when the best conditions are secured such a course is unnecessary.

The value of rest and passive exercise is receiving universal recognition as a means of forestalling the cause of disease and building up physiologic barriers against its invasion. Brain workers should secure at least one month's vacation out of the twelve. There is no new order of sleep, of rest, or of nutrition. Chemistry can never supply this need, and as all nerve derangement is indicative of innutrition, the first step toward recovery is rest of mind and body.

The remedy that does not draw upon the vitality, but rather conserves its force, and relieves the tortured body by simple elimination, is the most desirable, and this we find fulfilled in the Turkish bath. Its first effect is to quicken the circulation and render the skin active. By this means the reactive power of the system is brought up to its highest vigor, and the action of every function is made more acute. The heat of the bath is a perfect germ destroyer, and during the sweating stage there is a continuous elimination of all poisons, and the process needs only to be persevered in and repeated until the body is freed and regains its normal tone.

Those who have had the privilege of using the hot air treatment in such cases find that it conserves all the vital powers and restores normal action by encouraging a return of the circulation to its natural condition, both in frequency and fullness, and thus gradually and surely secures the desired result. Thus the action of the Turkish bath will not only cure, but what is more important, its frequent use will prevent such diseased conditions. When a person recovers under the use of drugs he is weakened by the drain upon his vitality; on the contrary, by the Turkish bath treatment, his whole system is invigorated, and he is better able to resist all disease.

Those who are in a position where they can not take advantage of the Turkish bath, should bear in mind its vital principle, which is sweating produced by heat. A simple but effectual manner of securing this sweating is by means of the hot sitz bath, hot foot bath, or drinking hot water and going to bed and covering the body with extra clothing. After a profuse sweating, carefully bathe the body in tepid water, gradually cooling it to a normal temperature and avoiding unnecessary exposure. Many cases have been relieved by this simple treatment persevered in. By all means should the patient sleep in pure air and eat as little as possible, and that only when hungry. It is also expedient to secure an abundance of rest after the bath.

An interesting statement in this connection was published in the *London Standard*, Jan. 2, 1890, written by a late surgeon of the Gold Coast of Africa, in which he says: "From what I have witnessed on the continent and in London, the present epidemic which is causing so much consternation, does not appear to be true influenza. Some of the worst cases remind me of a disease I saw some years ago among the natives of the swamps of the Niger, which in them often develops into fatal inflammation of the lungs. Irrespective of disinfectants and inhalations there is a simple, effective and ready remedy, the juice of oranges in large quantities, not of two or three, but of dozens. The first unpleasant symptoms disappear, and the acid citrate of potash of the juice, by a sim-

ple chemic action, decreases the amount of fibrin in the blood to an extent which prevents the development of pneumonia."

In our opinion, therefore, the wise man is he who, with a cheerful spirit, a well-nourished and properly clothed body, uniformly seeks the purifying and invigorating influence of the Turkish bath, and when any such epidemic appears he needs only a little more fervency in his devotions to the religion of cleanliness. It is an important work for us to educate the people to see and understand the far-reaching effectiveness of the Turkish bath, and when large public Turkish baths are demanded by the community, and built by the city, and the people shall have learned to live more in accordance with the laws of health, our land will be freed, not only from the grippe, but from all other forms of pestilence.

Experience proves that the effect of alcohol on the tissues of the body is in every way deteriorating, while experience also proves in the most convincing manner, that the action of the Turkish bath continually tends to renew and build up every tissue. We know also that alcohol interferes with the nutritive processes and hinders elimination, while the Turkish bath promotes the natural action of the nutritive powers, and by throwing off the *débris*, or used-up tissue, from the system, creates a demand and leaves room for a new supply. Again, it is a fact that alcohol benumbs the nerves and interferes with the coördinating powers of the brain itself, the more alcohol the more disturbance is produced, while the action of the Turkish bath soothes irritated nerves and gives clearer and more powerful mental vision, because it renders more pure the blood that furnishes nutriment to the brain.

It would seem evident to the average intelligence that the Turkish bath is a far more rational remedy for the grippe than drugs or alcohol.

81 Columbia Heights.

FATALITY OF SURGICAL OPERATIONS IN ALCOHOLISM.

Read in the Section on State Medicine, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY I. N. QUIMBY, M.D.

JERSEY CITY, N. J.

I thought it might be of some interest to call the attention of this Section of our Association to a form of rheumatism which has frequently come under my observation during the last twenty years, and which has not been fully, I think, recognized as a distinctive form of that disease by the profession. I have had some twenty cases of this form of rheumatism during the above mentioned period.

Not to take up the time of the Section, I will only describe two or three typical cases to illustrate the few remarks I have to make. This form of rheumatism apparently arises wholly from the moderate but continuous use of fermented and distilled liquors and has been aptly termed alcoholic rheumatism.

I think too many of us in our daily rounds in the treatment of the more common forms of diseases, are too apt, for want of time or patient investigation, to fall in the habit of a sort of routine way of diagnosis and treatment, the result of which is often unfortunate to patient and physician. The first case I will describe is somewhat unique.

In the fall of 1875, I was called to see Mr. M., a builder by profession, aged 48, who gave me the following history:

He had always been healthy and apparently well, but had been for the previous fifteen years a moderate but continuous user of fermented and distilled liquors, when he was taken with what was described as an acute attack of rheumatism in his left shoulder and elbow joint, with some hoarseness. After several weeks of treatment with colchicum, iodid of potassium, etc., he recovered from the attack of rheumatism, but the hoarseness, which was considerable, still continued to a greater or less degree. He remained in apparent good health for about six or seven months when he was again similarly attacked with rheumatism but with increased amount of hoarseness, articulating with difficulty. The patient was treated again in about the same way by the same physician, but was relieved less promptly and was left with increased amount of hoarseness. On the third attack, which occurred three or four months after the second attack, I was called to the case, not so much on account of the rheumatism, but on account of the severe attack of aphonia.

No doubt but what there are cases of laryngeal rheumatism occasionally occurring, owing to its complex anatomic structure, and its location between the pharynx and the bronchi, both of which are susceptible of inflammation, separately or in connection with an attack of articular rheumatism, from which he had been suffering for over a year, not being able to speak above a whisper. The laryngeal trouble apparently was the most prominent feature of the present attack.

The patient had been treated by a competent and experienced physician using the most approved remedies for rheumatism and its concomitants at that time.

I felt that there was some complication in the disease or deficiency in treatment, which caused a frequent return of the rheumatism, and this continuous and persistent aphonia; therefore, after a thorough examination of the case and analysis of the urine, and satisfying myself that there was no tumor pressing on the trachea or larynx, and finding that he had continued his moderate yet continuous methods of drinking alcoholic liquors, I arrived at the conclusion that it was this imbibation of alcoholic narcotic irritants which was producing some pathogenic microorganisms in the various tissues of the body, which had much to do, perhaps, with keeping up the rheumatic disturbances and the serious and persistent aphonia from which he has been suffering for over a year, not being able to speak above a whisper, and which was the most prominent feature of the present attack.

I, therefore, began a reconstructive course of treatment, not by giving the general rheumatic remedies, but those of a general tendency to restore the system to its normal condition. I directed that all alcoholic liquors of whatever nature should be immediately discontinued. This was somewhat reluctantly, but immediately complied with. Then I gave the patient 5 gr. calomel, 10 gr. bis. sub. carb. $\frac{1}{2}$ gr. ipecac, followed in a few hours by a saline solution of Rochelle salts. He was also given a saline bath, temperature 90, for ten minutes, after which he was put upon the following treatment:

Bismuth sub. carb.	2 drams.	8
Tinc. nux. vom.	2 drams.	8
Belladonna	1 gr.	06
Aqua. mint. pip.	3 oz.	95
Syr. P. V.	1 oz.	32

One teaspoonful every two hours.

A diet of a bland nature was ordered, soups, toast, milk, canned corn, a limited amount of fruits, stewed prunes and oranges, etc.

This treatment with some variation, was kept up for two or three weeks, which was followed by marked improvement, the rheumatism disappearing in the joints and the aphonia markedly relieved.

At this time the character of treatment was somewhat modified. I continued the bismuth in combination with strychnin, baths, and occasionally, say twice a week, a 5 gr. blue pill followed by the saline solution.

At the end of three more weeks of this somewhat modified treatment, the aphonia almost entirely disappeared. At the end of six months he was apparently a well man, his voice was entirely restored. This patient remained practically a well man for over five years, when he again resumed his moderate drinking, which he kept up for about two years, when his rheumatism and hoarseness reappeared, although the attack was not so persistent nor severe as formerly.

Recognizing that alcohol was the main basis of the disease, I directed him again to desist from the use of all fermented or alcoholic beverages. After acting upon the bowels pretty freely by 5 gr. calomel, bismuth and ipecac, followed by the saline solution and warm baths, I then kept him for twenty-four hours on 20 gr. doses of salicylate of soda, every two hours, which relieved the rheumatism. After which I put him upon the same general treatment as formerly, and in the course of three or four weeks he was again an apparently well man.

I treated the patient for three attacks, covering a period of about fifteen years, for practically the same disease, with the same treatment and the same result.

As he removed from our city, I lost sight of the case.

The second case I will describe is a German grocer, aged 55, who had nearly all his life been a moderate drinker of the alcoholics, mostly beer, and who has had repeated attacks for the past twelve years of articular rheumatism in both ankles with more or less edema of the feet. These attacks were frequently accompanied with severe lumbago. He had been treated by a number of physicians, and, as he said, by all kinds of medicines, including electricity and Turkish baths, etc., but without permanent relief. During all these years of suffering he had continued his moderate use of the alcoholics; none of his physicians, some four or five, had apparently realized or taken into consideration his drinking habit as a factor in the causation of his rheumatism. His last attack was in the fall of 1888, when he was taken with acute rheumatic pericarditis, at which time I was called to see the case and found the patient with anxious look and suffering a good deal of pain around the region of the heart. The action of the heart was irregular and somewhat tumultuous, and the sound lacked clearness; the pulse was 130, with strong, quick beats, his skin dry and hot and temperature 103; coated tongue, offensive breath, etc. As the pain from the pericarditis was so acute, I was obliged to resort to venesection, which gave great and

prompt relief, after which I gave an active mercurial purgative. I then put him upon bromid of amo. 10 gr., extract belladonna one-tenth gr., with nauseating doses of ipecac every two hours. The patient was kept upon this treatment until the active symptoms had subsided, when I put him upon about the same reconstructive treatment as in the former patient, previously described, interdicting all fermented and alcoholic liquors. I kept the patient upon about the same treatment, and following my advice he abstained absolutely from all alcoholic liquors, when at the end of two or three months he seemed to have entirely recovered and had not been so well, as he expressed it, in ten years.

He kept in good health and abstained from liquor from 1888 to 1892, then thought, as he said, that he was so well that he could return with impunity to his former imbibation of beer. But after indulging in his old habits for a little over a year, he was attacked again with an acute attack of rheumatism in the right knee and ankle (with slight amount of albumin in the urine) which laid him up for two or three weeks. I put him on about the same general reconstructive treatment except venesection, as previously given. This treatment was continued for a month, when he apparently had recovered again, and has remained well up to the present time, although he has been compelled to become a total abstainer, as he has found by sad but valuable experience, that when he returns to his cups his rheumatism returns, therefore one of the most valuable remedial agents for this form of rheumatism is abstinence from alcoholics.

I have described the above cases somewhat minutely as typifying some twenty other cases mentioned in this paper, and also to call the attention of the profession sharply to the fact that fermented and distilled liquor, although taken in moderation, was the principal factor in producing a microorganism, which so altered the blood and cell growth as to produce this species of alcoholic rheumatism. Alcohol has a tendency to encourage urea and uric acid in the blood and tissues, and cause a precipitation of the uric acid in the joints in acute alcoholic rheumatism. If this then is a fact, and I do not think that it can be disputed by any close observer, it would not take very much observation to recognize the fact that users of alcohol, even in a moderate way, are often very seriously affected thereby; just what form or kind of microorganism this is, or upon what organ it is deposited, or its method of generating disease, is yet far from positive solution.

We are just at the dawn of a new era and in a great field of investigation. A glimmer of light is being observed and some facts have already been brought forth by such patient investigators as Drs. Richardson, Norman Kerr, Davis, Kellogg, Crothers, Magnan and many others, who have demonstrated that alcohol in its most imperceptible action upon the tissues and cells is a great moving factor in the production of some of the most serious and complicated diseases.

What physician would be so bold or hazardous at this time as to assert that the use of alcohol even in a moderate way did not have a tendency to produce various affections, such as congestion, ulceration and thickening of the gastric mucous membrane of the stomach, which did not in its turn produce indigestion, mal-nutrition and mal-assimilation, the result of

which would have a tendency to produce disease of the kidneys, pernicious anemia, cirrhosis of the liver, fatty degeneration of the heart, tubercular disease of the lungs, cerebral spinal irritation, with softening and lessening of the resisting power of the red corpuscles of the blood, producing various affections of the respiratory, digestive and nervous systems.

It is stated by Dr. Nordau, the famous writer and philosopher, who combines scientific knowledge with literary powers and originality of thought, that there is going on a general degeneration of the race. And who is bold enough at this period of the world's history to successfully deny or refute it?

The symptoms of degeneracy are physical and mental; the physical characteristic as exhibited in the multiple and stunted growth in the first line of asymmetry, the peculiar and unequal development of the two halves of the face and cranium, the frequent imperfection in the development of the external ear which may be conspicuous for its enormous size, either clinging close to the head or protruding from it like a handle, and the lobe of which is either lacking or too largely developed and the helix of which is not properly involuted; moreover, we have the innumerable cases of strabismus, irregular angle and unequal apertures, defective and imperfect vision, hair lip, irregularity in position and form of the teeth, deficiency in the hard and soft palates, webbed and supernumerary fingers and toes. The numerous forms of neuroses, the diminished birth rate, the congenital weaknesses, which I think are becoming more general among the working classes who use alcohol, whose diseased and deformed children crowd our hospitals and charitable institutions. The increasing number of cases of apoplexy, idiocy and other mental disorders showing the rapid increase of the defective classes, are the fearful annual tribute paid to alcohol. Who can successfully estimate the affect that alcohol has had and is having, directly and indirectly upon the tissues, in producing these unequal mental and physical developments?

While there is a great difference of opinion among medical men in reference to the direct and remote effects of alcohol upon the human organism, there can be no question but that its destructive power is very great and that it is too recklessly and perniciously prescribed.

And there can be no question but that it has been fairly demonstrated that alcohol neither aids digestion, prevents disease, nor prolongs life; that it causes an unnatural flow and precipitation of the pepsin of the gastric juice of the stomach, interfering with the metabolic processes, and coagulates and hardens all the albuminoids of food, thus retarding their solvency and assimilation. That it produces temporary interstitial paralysis of the vasomotor nerves of the digestive organs, which by reflex action, prevents and perverts the proper action of the ferments of the stomach, thus interfering with the digestive and assimilative processes.

Alcohol has a great affinity for water, and when introduced into the system interferes with the normal action of the red corpuscles and robs the blood of its due proportion of oxygen; it has no normal reconstructive power; it also prevents the proper elimination of the carbonaceous and other effete matter from the blood and tissues of the body, thereby encouraging the formation of ptomaines and other deadly microorganisms yet, notwithstanding all this there

is no drug in the whole range of the Pharmacopœia that has been used with such reckless inconsistency.

If the above facts are correct, is it not about time that the whole medical profession changes its base of action and opinion in reference to the *modus operandi* of alcohol?

Chassaignac, the great French surgeon, once said that: "America at this moment wields the surgical scepter of the world." If that is so, let us endeavor to so investigate as to arrive at the exact facts, so that we may be able to disseminate the truth in reference to the destructive effect of alcohol among the people.

Let us develop a national literature which shall lead the world in this momentous question; let the medical profession of this country free itself from the old superstitions which have so long controlled it. Let the facts which recent investigations have so clearly demonstrated in reference to alcohol and its painful effects, be known. Let us promulgate these, and carefully guard the altar of scientific truth, that the world may see its light and be guided thereby.

SOME FACTORS IN THE SOLUTION OF THE ALCOHOLIC PROBLEM.

Read in the Section on State Medicine at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY J. W. GROSVENOR, M.D.

BUFFALO, N. Y.

An alcoholic problem confronts the people of these United States. Multitudes—perhaps the majority—of our population do not believe this statement. Especially is this true of our foreign-born residents. The vast majority of them have drawn alcohol from the maternal breast and have been educated to believe that alcoholic drinks are the healthiest that exist; they see no alcoholic problem.

The brewer, the distiller, the saloonist can find no alcoholic problem which will restrict their business. The ordinary merchant fails to recognize any alcoholic problem which forbids a reciprocity of business between himself and the vendor of alcoholics. The professional man searches in vain for an alcoholic problem which will offend the consciences of his clients.

The eyes of myriads of our people in looking for this problem are blinded that they see not, and their ears in listening for its goings are stopped that they hear not. If, perchance, a representative of these classes meets the alcoholic problem he is very apt to ignore it, and, like the Pharisee, passes by on the other side.

In spite of the fact that an alcoholic problem is unseen and unacknowledged to a large extent in our country, it *has* an existence and calls loudly for solution. Its existence is recognized by many philanthropists, some political economists, and hosts of our people who have at heart the welfare of our homes and nation. Its recognition as an established fact is growing into larger prominence every year.

This problem will not be rightly solved until its presence is openly acknowledged by a greater number of our framers of national thought, by our foremost scientific minds, by our leading spirits in moral and economic reforms, and by a majority of the middle class of our republic. For the solution of the alcoholic problem a vast amount of teaching must be done in order to establish the mere fact of its exist-

ence. Unless our souls are thoroughly impregnated with a belief in the need of a reform, the voices and hands which we raise in its behalf will be weak and crippled.

What is the alcoholic problem? Succinctly stated it is the *right* use of alcohol—its best use for all classes and conditions of people. For the individual it is the use which will give the greatest aid in the development of the soundest physical organism, the keenest and broadest intellect, the purest morality, which will enable a man to make the most and best of himself; in respect to home life it is the use which will produce the sweetest courtesies and the most self-denying love; in regard to society it is the use which will insure strictest fidelity to assumed trusts and the most honorable dealings between man and man; concerning citizenship it is the use from which will emanate the noblest patriotism. This is the problem presented for our solution—one of the largest and most difficult problems before the American people to-day.

The Nature of Alcohol.—Whoever undertakes to solve the alcoholic problem should know and appreciate alcohol's characteristics. In a contest at war he is most likely to win who—*ceteris paribus*—best knows the resources of the enemy. No class of scientists are more fully qualified to tell us what alcohol is and what it does, than the chemists and physiologists. Over and over again, chemists who have studied it in the laboratory and physiologists who have observed its action upon the living being have declared that *alcohol is a poison*. Scarcely an intelligent person can be found who is not ready to acknowledge that opium is a poison. He who will experiment with both opium and alcohol on his own system will discover that in many respects the action of the latter is not very unlike that of the former. Nearly every physician of a few years' practice has seen or known well-authenticated cases of sudden death caused by the ingestion of some form of alcohol. Indeed, the evidence that alcohol is a poison is overwhelming; and yet not infrequently, both in word and in print, this statement is stoutly contradicted by professional men of intelligence. To counteract any belief in a non-poisonous quality of alcohol it should be handled and treated as are other poisonous substances. Every receptacle which contains it should be distinctly lettered *poison*, and pictured with the ominous skull and cross-bones.

Alcohol is an Anesthetic.—Used on the external surface of the body, the part to which it is applied becomes less sensitive to impressions; used internally in large quantities the whole system yields to profound narcosis; the body may then be bruised and pricked with sharp instruments without expressing any signs of sensation.

Alcohol is a Paralyzant.—Under the influence of moderate quantities the senses are appreciably affected; as proved by actual experiment, vision is less acute, hearing is blunted, touch is less sensitive, taste and smell are impaired, muscular power is weakened.

Under the influence of large quantities of alcohol, the taker lies as in a deep sleep, or as almost dead.

The question whether *alcohol is a stimulant or depressant* has been energetically discussed for the last hundred years. A unanimous opinion has not been reached. Probably a diversity of opinion is largely due to a difference of meaning attached to the term

stimulant. If a stimulant is that which excites mental processes and increases muscular activity, alcohol without doubt may be called a stimulant. It is not difficult to observe that a person immediately after taking alcohol shows a quickening of thought and of muscular action. The vasomotor nerves have become partially paralyzed, the brain and muscular fibers are supplied with a greater than a normal quantity of blood, and thus activity is increased. Soon, however, the blood becoming impure, ceases properly to nourish the various organs, and brain and muscles perform their functions with abnormal slowness.

The increased activity, as well as the abnormal slowness of movement, has been caused by the paralyzing property of alcohol. In producing stimulation, alcohol acts as a sedative, and thus it should be called. Stimulation is the product of sedation.

Notwithstanding experiment has shown the reasonableness of the view here presented, it is probable that the vast majority of physicians believe the strongest quality of alcohol to be its stimulating power. So long as alcohol is called a stimulant by chemists, physiologists and physicians this will be regarded by the laity as its leading characteristic; it will be used as a *sine qua non* for the promotion of strength. The nature of alcohol as a poison, an anesthetic, a paralyzer, a sedative has a large place as a factor in the solution of the alcoholic problem.

Taken internally, Alcohol has no Usefulness for the Healthy Human Organism.—It furnishes neither material for addition to its tissues nor heat for warming it; it is neither a tissue-forming nor a heat-producing food; it has no power to build up and sustain the physical system. Subjected to arctic cold or tropical heat, to the severest physical strain of the athlete, to the highest mental tension, to hardships on land and sea, man finds in alcohol no genuine aid. This is the teaching of reason, experiment and experience.

The internal Use of Alcohol works a Positive Injury to the Healthy Human Organism.—It vitiates all the solids and fluids of the body. The numerous diseases which are the product of its moderate and excessive ingestion, forcibly testify to the truth of this statement. The nervous, circulatory, digestive, osseous and glandular systems profoundly feel its deleterious influence.

Alcohol as a Medicine.—Since its discovery, alcohol has had a prominent place among remedial agents for the sick. In this rôle it has had its ebb and flow of popularity. Notwithstanding a large majority of physicians recommend it as a valuable medicine, it is my belief that confidence in its remedial virtues is on the wane. The London Temperance Hospital is a positive witness to the fact that all diseases can be as successfully treated and all surgical operations as successfully performed without the use of alcohol as with it. The American Temperance Hospital in Chicago forcibly teaches the same lesson. The long and successful experience of some of our most eminent medical practitioners, both in this country and Great Britain, bears unequivocal testimony to the same truth. With almost the certainty of a mathematical demonstration it has been shown that alcohol has slight, if any, utility as a necessary article of the *materia medica*. I predict that ere many decades shall have passed it will have gone the innocuous way of the physician's lancet.

The factors thus far mentioned as connected with

the solution of the alcoholic problem relate to the individual. They should awaken and foster a special interest in the practicing physician. As he goes his daily and nightly rounds he comes in contact with individual life, and this alcoholic problem in some form is apt to meet him at every turn. On him, to a large extent, depends its solution. If he believes that it exists and demands serious consideration, so will believe the families that place confidence in him; if he understands the alcoholic problem he can make his patrons understand it; if he has thoroughly studied the nature of alcohol he has the power to inspire in others an interest in its study; if he has no faith in alcohol as a constructor and sustainer of the healthy human organism, his position as a student of physiology gives him abundant opportunity to lead the indifferent and uninstructed into the same faith; if, by research and the test of experience, he has become convinced that alcohol has little or no utility as a medicine, his views will be likely to find expression in the chamber of sickness, in the medical society, in the columns of the medical journal and in every place where they are likely to produce good results; if by a life of total abstention from alcoholic beverages he shows his disbelief in their power to do good to either mind or body, his example will have marked influence on the lives of his associates. The physician who does not hold these attitudes can do no better service for himself and his clients than to study the alcoholic problem anew, stand ready to accept new light on this all-important subject and use his enlarged knowledge for the benefit of his kind.

The physician holds an important relation not only to individuals but also to communities and the nation. He is a citizen as well as a physician and as such has a responsibility to do his share in the solution of the alcoholic problem that meets him in all the walks of life.

Alcohol is an Enemy to the Home.—The American home is the bulwark against anarchy, communism, socialism and all those isms that tend to undermine a respect for law, true liberty and morality. No more potent home-breakers exist than the alcoholized father and mother.

Alcohol is Inimical to the good Order of Society.—It is the forerunner of poverty, crime and immorality. The social cup, the treating glass lead on to social discord and vicious conduct. Alcoholized society is society undermined, disorganized, ruined.

The wide-spread Use of Alcoholic Beverages in a Nation is a Menace to its Integrity and Life.—To a large extent a nation must depend for its stability upon the physical soundness of its citizens. Alcohol has been aptly termed, "the genius of degeneration." Its degenerating influence on the national body may be slow but it is sure. Several generations may pass before its work produces an effect which is glaringly visible. At length, however, the national mind will be invaded; mental processes become weakened and disordered; judgment beclouded and unbalanced; cowardice is substituted for courage; the baser faculties win control; the vision and vagaries of the national intellect, partially alienated, are transmuted into legislative enactments; the execution of law becomes feeble and erratic; the nation is hurried far along on the highroad to ruin; it stands tottering on the brink of despair and ready to plunge into the depths of disaster or destruction.

The Relation of Heredity to Alcoholism.—From the earliest historical periods, heredity has been recognized as a cause of alcoholism. Aristotle declared that a "drunken woman brings forth children like unto herself," and Plutarch declared that "drunkards beget drunkards." All along the historical road may be found abundant testimony to substantiate this truth. The evidence in favor of it is as clear and strong in respect to alcoholism as in respect to insanity. Although many of the students of the alcoholic question may not believe in the direct hereditary transmission of this disease, they acknowledge that a constitutional tendency to it may be hereditarily transmitted. Alcoholized ancestors may transmit to their descendants, not only an irresistible craving for alcohol, but also many defective conditions of mind and body. Through these defective conditions, alcoholic habits may be acquired which have their outcome in seriously degenerated descendants. Thus it is seen that from the view-point of heredity the solution of the alcoholic problem has a large place in its relation to the physical and mental soundness of the race. The alcoholic problem is a racial problem.

Permit me to call your attention to one more factor which relates to a solution of this question. *I refer to the use of alcohol in our public charitable institutions, especially in general and insane hospitals.* The annual bills for alcohol in its varied forms in many of these institutions is so large that they suggest great extravagance and ill-directed use. A large per cent. of insanity is the result of alcoholic drinking. Very many of the inmates of general hospitals are the victims, directly or indirectly, of alcoholic excesses. I fail to see the reasonableness of treating such cases with alcohol. Perhaps it is done on the principle of curing the bite with the hair of the same dog. The superintendent of the London County Asylum, Banstead, Eng., a hospital for the insane, has made this statement: "Since the withdrawal of beer from the dietary the rate of recovery has gone up. During the past year (1893) for example, the recoveries reached 46.97 per cent. . . . These inmates take their food better without the liquor."

If alcohol has little or no genuine usefulness in the treatment of disease, I can see no valid excuse for spending annually in any one of our largest hospitals several thousands of dollars for alcoholic liquors. Such expenditure for the whole country must amount to an immense sum for a single year and for a series of years doubtless mounts up into the millions. To my mind, this is a vast waste for which the taxpayer has good reason to complain.

The factors presented in this paper, as related to the solution of the alcoholic problem, are only a few of the vast number that exist and meet us at every turn of life. They have been massed here without any attempt at special discussion or detail, in order to exhibit the magnitude of this problem which reaches out into almost all avenues of individual and national life.

If science and experience teach that the internal use of alcohol is unnecessary for the healthy human organism, has scarcely any or no utility as a medicine, is a producer or instigator of scores of diseases, lays the foundation for crime and immorality, strikes with a destroying hand the home and the virtues of well-ordered society, threatens the peace, prosperity and permanency of our republic, we, as physicians

and citizens, are called to consider and intelligently act upon the questions whether it shall not be suppressed from our list of medical remedies, banished from our persons and home life as a beverage, and whether by the responsible positions we occupy we are not bound to teach by the wayside and in public the destructive nature of alcohol, and to enforce our views upon the public mind with all the energy at our command.

If, on the other hand, we have some slight belief in the efficacy of alcohol as a tissue-builder or blood warmer, we should advocate its restriction to the narrowest possible limits.

I am confident that we shall not make great advance in the solution of the alcoholic problem until, as a profession, we have earnestly declared to the people again and again, the lessons which during the last few decades have been taught by investigation in the laboratories of the chemist and physiologist and by observation at the bedside of the sick.

A new era will fully dawn upon our nation when alcohol in minimum amount is used as a remedial agent for victims of disease, and as a beverage for the healthy human organism shall cease to exist.

PRACTICAL LIFE INSURANCE EXAMINATIONS.

Read in the Section on State Medicine at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY JOHN L. DAVIS, M.D.

MEDICAL DIRECTOR UNION CENTRAL LIFE INSURANCE COMPANY, CINCINNATI, OHIO.

My justification for asking your attention to a subject that may appear trite and perfectly familiar to you is the fact that while physicians are receiving as fees from insurance companies and coöperative associations about \$2,500,000 per annum, they are not in every instance giving a *quid pro quo*. I understand fully and we all agree that members of the AMERICAN MEDICAL ASSOCIATION always give a *quid* much bigger than the *quo*; but it is the doctors who are not of us that I shall describe. My remarks will not apply to the strictly technical part of the examination, for I feel that after fifteen years' work in examining applicants' lungs and hearts and kidneys I have too much yet to learn to warrant my giving you instructions in physical diagnosis. Hence for the sake of avoiding argument I will assume that every man who has a diploma is *ipse facto*, a good diagnostician. I will admit this, though the medical director of every company is chagrined, perhaps daily, to find what manner of report is submitted to his office by doctors who hold diplomas as good as his own; but in the aggregate we may say that examiners do remarkably well and no complaint as a rule is called for. So we will let that pass. That is the part of the subject not to be touched by this paper. But some suggestions will not be out of place as to the practical element in the examination, as to those features which disclose the examiner's business acumen, social tact, "horse sense" and understanding of human nature. As far as my experience goes, it is here that the doctor is possibly more often at fault than in diagnosis. The ideal examiner for an insurance company must not only be competent and skilled in diagnosis, but he must be tactful and approachable, willing to display a sympathetic camaraderie, putting the applicant at his ease and by his manner relieving him of restraint

which is inimical to a satisfactory examination; and at the same time he must sincerely appreciate the agent's position; he must do his work skillfully, but at the same time promptly and in a business-like way and by his manner, if not by word, commend the applicant's motive in taking insurance, incidentally, perhaps, speaking well of the company and a good word for the agent. And all this must be honestly done; hypocrisy will not pass; the fraud will be detected. The examiner must honestly and earnestly believe in insurance and in his company, and must fully sympathize with the agent in his difficult task. He can do all of this without sacrificing his dignity as a physician; nay, such sympathetic genuine interest in his fellow-man adds a dignity to the profession which nothing else can do.

I recently attended an underwriters' meeting and one subject under discussion was "The Fool Doctor." I can not understand why I should have been invited, when a fool doctor was discussed, but I was there. And the agents painted a picture of the doings of the fool doctor until I blushed for my profession. What does the fool doctor look like? Well, like any of us most; but it is what he does and says. He stands on the corner and tells people he is going to examine Mr. Cræsus next week for the Jumbo Tontine. Somebody gives a pointer to the agent of the Bonanza Life Company and he quietly has Mr. Cræsus examined this week, and, as insurance men say, the Jumbo Tontine holds the bag and the fool doctor wonders how it happened. But sometimes the fool doctor reaches the applicant before the other company gets him and then the conversation opens up like this: "Ah, Mr. Cræsus, I want to examine you for the Jumbo Tontine, don't ye know. I always feel a little afraid of those big companies and carry my own insurance in the Picayune Promiser which is going to do first-rate some day, and is much cheaper than the Jumbo." And so forth. Mr. Cræsus hesitates, not having been fully and soundly converted and tells the fool that he is pretty busy this morning and will call at the doctor's to-morrow; and to-morrow, you know, never comes; nor does Mr. Cræsus. In many little ways the fool doctor shows his right to the title. He forgets his pen or his bottle or his examination blank even. I have actually known an examiner to forget the examination blank. And he must call again to complete his report. And the interim between the calls! Oh, how it is fraught with dangers from within and without! Mr. Cræsus' wife may get his ear (for conversational purposes I mean); I have noticed the combination of Cræsus and the fool doctor is often completed by that kind of a wife. At all events, through some internal or external cause, Cræsus will change his mind and the other company, or I may say the goblins, "will get him if you don't watch out." All companies aim to secure as examiners, men not only of professional skill and integrity, but of sound judgment and insight into human nature; for these extra professional attainments constitute a most important safeguard for the company. Very different indeed are the relations between the examiner and applicant on the one hand, and the physician and patient on the other. The patient is anxious to fully disclose his symptoms and diseases, present and past, his habits and family tendencies; he will communicate every unfavorable element which his case involves. But when the same man is an applicant for insurance, often the most

minute and searching inquiries are needed to reveal what in the other case would have been eagerly disclosed. This reticence is in most cases explained by failure to appreciate the importance of information sought in the insurance examination. But sometimes, unfortunately, facts are withheld or misstated with the deliberate purpose of deceiving the examiner. There is need, therefore, of the greatest tact and skill in drawing out and properly weighing every feature required for a perfect report. Skill in physical examinations, integrity, good judgment and tact in dealing with men are the qualifications of a first-class examiner. Every appointee should aim to possess these requisites, realizing that a single fact improperly or incompletely set forth in the examination may involve the company in an unwarranted loss of many thousand dollars, or may, on the other hand, cause the rejection of a desirable risk who is rightfully entitled to insurance.

The examiner should at all times be mindful how fully the home office is dependent upon his individual examinations for final decision. And he should feel that in the responsible work of selecting safe risks for the company, the examiner is the direct representative of the medical department; he should realize fully that the duties of examiner and medical director are complimentary and coöperative; and, hence, our mutual relations should always be most cordial and confidential.

The examination should always be made in private. When alone with the examiner the applicant will answer more freely than otherwise on matters unfavorable to himself. Explanations of a private or personal nature should always be treated as confidential, which is impossible when a third person is present. Another reason for this requirement is that it relieves the examiner from the annoyance of outside dictation and interference with the applicant's statements. The examination is a matter strictly between the applicant and the medical representative of the company, and no third person must be permitted to interfere.

In meeting the applicant, the first essential is his identity; if not personally acquainted with him, the examiner must assure himself beyond a doubt that the man he examines is the party whose signature appears on the application. The attempt is sometimes made to substitute a healthy man for the examination which the applicant himself could not pass, owing to bad health. Hence, the need of identification.

A great deal may be learned about the applicant before the physician reaches the strictly physical examination. The examiner should note in the first place his gait, attitude, expression, manner, etc. He will observe whether the eye is bright or dull; the complexion clear and healthy or showing signs of dissipation, disease or premature decay. All of these points will be noted at a single glance by the experienced physician.

The applicant may be unduly nervous, especially if not used to being in a doctor's office. The examiner's manner should be reassuring and calculated to inspire confidence and frankness. The applicant must be at his ease during the examination, so that the pulse and respiration may be tranquil and the answers freely given without embarrassment of any kind.

As preliminary to the detailed examination it is a

good plan to question the applicant as to his residence and occupation, and learn whether the surroundings are sanitary or otherwise, whether the employment is healthful or hazardous, etc. Facts may be incidentally obtained in the party's business or domestic arrangements, suggesting the question of so-called "moral hazard." Particulars can be learned as to drinking habits and other vices tending to shorten life. Often specific questions will not elicit information nearly so well as will a frank conversation casually covering the points at issue.

There is perhaps no need of reminding physicians of the disastrous results of excessive drinking. But the practical effects of alcoholism come with such striking force in the death losses of insurance companies that a few words to the examiner on this matter will not be amiss. There is no other topic of inquiry in the examination which calls for as great skill on the examiner's part as does this question. Applicants often are apparently unaware of the amount of alcohol they are ingesting; the most detailed and careful inquiry is therefore needed to get the facts. A person who drinks and inherits the taste for liquor is not safely insurable.

A difficult question is, to what extent can a man drink without shortening his life? It is an undisputable fact, as has been proved by the experience especially of foreign companies, that total abstainers, other things equal, are the most desirable risks. It must be remembered, however, that abstainers who have formerly been hard drinkers and are "reformed" are not first-class risks; with them there remains the damage done the organs by alcohol as well as the possibility of a return to the old habit.

It has been shown by Anstie that when an ounce and a half of alcohol or less is taken in twenty-four hours it is not found in the excretions. If, however, more than this amount is taken, the excess is eliminated as alcohol, showing that whatever may be the effect of an ounce and a half, more than this amount is excessive and can not be appropriated by the tissues. Even a less amount may be dangerous, if occupation or surroundings favor a stronger habit. The form in which alcohol is ingested is an important consideration. The stronger drinks, as whisky and brandy, are usually the more dangerous; this is certainly the case when taken on an empty stomach. Furthermore, the regular drinking of a moderate amount is often not as serious as the occasional ingestion of a greater amount with a period of abstinence following, to be again followed in a few days by another round of free drinking. Examiners should, therefore, clearly state the manner of drinking, whether regular or occasional, as well as the approximate amount and kind of drink used.

Free drinking leads directly to disease of the liver, kidneys and heart inflammation, hypertrophy, fatty degeneration, etc. All organs and tissues are weakened and the free drinker is less able to resist any intercurrent disease which he contracts. He is more liable to accident, to suicide, or other violent death, and in every way is an undesirable risk. These are the dangers beyond the limit indicated. But, undoubtedly, for many men the danger line is below the figures given by Anstie.

The importance of searching inquiry into this habit is evident. No company wants heavy drinkers, whether the habit is regular or only occasional and, as a rule, the less a man drinks the more favorably

is he regarded by insurance companies. Examiners are, therefore, urged to investigate this question most thoroughly in every applicant examined, remembering that among drinkers we will accept only the most moderate, and even these are regarded with disfavor.

A few words on the family history with its bearing upon the risk is next in order; for the character of the risk is affected more or less by the mortality and morbidity of the family history. In some cases the applicant in feature and physique bears a striking resemblance to father or mother, sometimes to a more remote relative. Often, however, the resemblance is not clear or appears to be blended. Where there is close physical resemblance we may assume a corresponding similarity in internal organs and tissues, and the inference is reasonable that diseases and tissue changes will affect such persons approximately in the same way. In this assumption we have the basis for the important part which heredity plays in life insurance. Many diseases are recognized as hereditary, though when transmitted they may appear in a form or manifestation different from that experienced by the ancestor. For instance, many authentic cases are recorded illustrating the interchangeability of consumption, cancer and scrofula. In other words, hereditary transmission is not always characterized by the specific germ of the disease, but rather by a tissue weakness or susceptibility manifested by some allied pathologic condition. Diseases recognized as hereditary in the sense described are consumption, cancer, scrofula, syphilis, insanity, alcoholism, epilepsy, gout, rheumatism, diabetes and Bright's disease.

Some of these diseases are so commonly recognized as hereditary that occasionally applicants are on their guard when there is a family taint and will make every effort to conceal such instances in their report, knowing how seriously the true facts would impair the risk. Often, therefore, such innocent terms as "malaria," "typhoid fever," or even "old age" (perhaps suspiciously premature) are reported as causes of death, where the actual cause was consumption or cancer. Great pains are usually taken by the applicant to show that every case of consumption in his family is acquired—not hereditary. Sometimes an assumed ignorance will report "Don't know" as a cause of death, where the facts positively indicate transmissible disease. Experienced examiners are familiar with all such subterfuges, and know that these evasions or indefinite terms are unfortunate for the applicant and are regarded with suspicion by the company. The examiner should, therefore, use every effort to get at the facts in such cases, basing his answer upon a full inquiry into symptoms, clinical history, etc. The same care should be exercised when a member of the family is stated to be in "poor" or "moderate health"; the cause must be clearly indicated. Sometimes an evident effort is made to offset unfavorable features in the family history by attributing marvelous longevity to grandparents and other far-off ancestors.

It may not be necessary to caution examiners against relying too implicitly upon statements made about remote ancestors, unless a reliable family record is at hand. Many persons of middle age can not give trustworthy information about their grandparents.

The points suggested represent the common expe-

rience of insurance companies. The examiner should, therefore, first satisfy himself that the history reported is as full and accurate as can be had; then he should state his answers clearly and positively. If the examiner is capable and alert he will not report a death from congestion after a six weeks illness, nor a death from "pneumonia" without cough as a symptom. Though these are ostensibly statements of the applicant, it is the examiner's place to supervise them and not permit statements to be made that are obviously improbable and conflicting.

Before forwarding his report, the examiner should see that every question upon the form is answered. He should remember that this written examination is all the information the medical directors have upon which to base their action. The examiner will understand how difficult this decision sometimes is, if, having dismissed the applicant, he will put himself in the medical director's place, and with only the written examination before him try to decide the case. He will, under the circumstances, often see the need of further particulars to clear up some point at issue. Such supplemental statements are of great value, and are appreciated at the home office.

Apart from the detailed examination, anything in the applicant's appearance or manner or surroundings which impresses the examiner unfavorably should be noted. The amount of insurance desired may be far beyond the limit justified by the man's circumstances or station in life; or the examiner may feel that the party is urged to insure for speculative purposes by designing relatives or persons having no legitimate interest in his insurance. All such matters come within the scope of the report and should be fully stated. A confidential letter may be sent to the department by the examiner at any time and will be duly appreciated.

In rating a risk the examiner should bear in mind that the final decision rests with the home office. His action should be based on the applicant's personal appearance and examination together with his habits, occupation and surroundings. The bearing of his past record and family history should perhaps be left largely to the medical directors, who sum up all the items in the case. The most satisfactory classification is such as is indicated by phrases like these: "Superior, personally;" "Average, except bad surroundings;" "First-class, except for rheumatism;" "Good, aside from drinking habits."

In conclusion, attention may be called to the fact that sometimes the decision in a case made by the home office differs from that anticipated by the local examiner. It should be understood by the examiner that such differences by no means necessarily reflect upon his judgment and character as an examiner. His view is limited to the single case, or at most to a few similar cases; while the judgment of the medical directors at the home office is based upon a large aggregation of cases identical with that submitted. As a diagnostician, the examiner may be perfectly correct, but as a rule the home office with its collated evidence and statistics is in a better position than he, to judge as to how much a man's expectancy may be affected by past or present personal conditions in connection with a given family history. In other words, the examiner deals with the individual; the medical director with the class, making indeed such exceptions as large experience has seemed to warrant.

THE DEPOPULATION OF CIVILIZED NATIONS.

Read by title in the Section on State Medicine, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY H. B. MCKLVEEN, M.D.

CHARITON, IOWA.

You see the title I have given to this paper is the depopulation of civilized nations. Probably it would be more proper to put it, the cessation of increase of population; for it is not so much the causes that depopulate, that I wish to speak of, as the causes which hinder the increase of the population,

It seems that the people of all civilized nations have in matters relating to the perpetuation of the species become subject to some influence, which as the nation becomes cultured prevents its increase. They seem to be approaching the same finale that characterizes a certain variety of butterfly which attains the perfect state and then dies.

In this country the subject does not receive the attention it merits, in fact it only attracts the notice of medical men, and then not as a condition which may confront them, but rather as a curiosity.

In France a great deal of attention has been paid to this matter. In 1891 one-fourth of the papers submitted to the Academy of Sciences were upon this subject. The result has been that active efforts have been made by legislation to increase the number of births and to protect the lives of those that may be born.

In most European countries reliable statistics exist by which we can determine the ratio between births and deaths, but in the United States we have no very exact figures with which to compare ourselves with other countries.

France in 1890 had over 100,000 more deaths than births.

England, though not so bad, showed a greater mortality than natality.

Germany makes a better showing than any nation of Europe, except Austria. In Germany the births slightly exceed the deaths.

In Austria the natality is 65 per 1,000 of the population and the mortality 49 per 1,000.

In 1880 in the United States there were born 37 per 1,000 of the population, while in 1890 the rate had fallen to 29½ per 1,000.

This condition existing as it does in times of peace, when there is neither famine nor plague to increase the mortality and with every effort made by science to lengthen life, becomes really alarming.

With compulsory vaccination to prevent smallpox, better hygienic conditions in our cities, a greater knowledge of sanitary laws and the advancement of medicine and surgery, the mortality has decreased in all countries. In France, alone, the deaths have in twenty-five years decreased over 100,000 annually.

What is the cause of this falling off in the number of births? We should expect an increase, since science has done so much to rob child-bearing of its horrors.

Demographers differ as to the cause. Among those mentioned are the late age at which the young people are now married. This decreases the fertile period; the obstacles in the way of legal formalities; the financial embarrassment of large families; the exactions of military service; the unequal emigration of adult celibates; the tendency of people to go to the cities to reside; unhygienic modes of living; the common practice of abortion.

In our own country not all of these mentioned causes can be held accountable; for instance, there are very few legal formalities connected with marriage.

Compulsory military service is unknown in our country, but in continental Europe every young man has to serve a certain part of his best days, and it is a decided hindrance to his marrying as soon as he otherwise might.

At the present time, marriages are consummated at a much later age than formerly. This is due to several reasons: the lengthened educational course is one; the young men and women of to-day are just finishing their education at an age at which their parents became father and mother.

Of course education is a good thing for the individual, but our present systems of education seem to be playing sad havoc with the birth rate and this will be more noticeable in the future, because of the fact that education is becoming more general. Another cause might be mentioned: the young men feel the necessity of having something ahead in a pecuniary way, in order that they might begin their married career in a manner commensurate to their former method of living.

We are living in an age of luxury, and things that were considered luxuries in the past are necessities at present.

Bunyan, the author of the immortal "Pilgrim's Progress," said that when he and his wife were married they had neither pot nor spoon betwixt them. How many couples at the present day would marry under such conditions, which up to fifty years ago were common enough?

At the present time, with few avenues to wealth open before him, the young man is very much older by the time he has sufficient laid by on which to marry than were his ancestors.

One of the most potent causes of the decrease in births is the tendency of people to flock to the cities. Children which are an actual source of wealth to the man in the rural districts, become a source of expense to the urban resident. This causes them from necessity to limit their families. I might mention the desire of parents to give their children exceptional educational advantages. This causes them, when only of moderate means, to wish that they have but few children, especially if they are to distribute their favors equitably.

The wealthy are best able to properly raise large families but, as a rule, they are the ones who have the fewest children. The social pleasures which the rich women can enjoy cause them to abhor maternity, because it interferes with their imagined happiness. Among the poor in the cities, children are particularly a great burden, for it is often necessary in order to live, that the wife shall leave home to labor, and this she can not do and raise a family.

1. I might here state that only one-fifth of the women are able to nurse their offspring as nature intended. No wonder that 26 per cent. of the children die in their first year, for no food man can compound is equal to that nature provides. Why this inability to nurse children? In the first place, the waists and breasts of our women are compressed by tight lacing, tight clothing, corsets, stays and all that is necessary to make a fashionable figure. This causes chronic induration of the breasts, and has a tendency to prevent secretion and in many cases abscesses form.

2. The lungs are so compressed as to prevent proper oxygenizing of the blood.

3. The abdominal and pelvic organs are so displaced that digestion is impaired and the pelvic viscera are in a state of passive congestion with all the attendant evils, rendering the woman unable to furnish the proper nourishment for her child.

Women have until very recent years been taught that they should do nothing which compelled them to come in contact with the public. Now all is changed, and we find women engaged in nearly every vocation. What is the result? They take the place formerly occupied by men, at a much reduced salary. The consequence is that thousands of men who did earn good salaries are now filling the ranks of the army of the unemployed. Five thousand clerks, bookkeepers and stenographers were fed daily at the soup kitchens in Chicago during the winter of 1893-94, whose places are now filled by women. Had these men kept their positions they would have married, perhaps had a family of two or three children. The women who engage in these vocations do so at the expense of their domestic education.

I will now mention another cause of reduced natality—a cause that, did it not exist, we should have much less reason to look with alarm upon decreasing natality. I have reference to the common crime of abortion. So prevalent is this practice that I doubt if an audience of laymen of any size can come before a speaker, but that he faces some one who is guilty of this crime.

Charpentier relates an incident of a doctor in France who was indicted for this crime and confessed to having produced over five thousand abortions. Suppose that one-half of these had attained adult life. There would be enough to make a city of 2,500 inhabitants. Again, suppose that some catastrophe should happen that would kill every one of these people. What an appalling disaster this would be! The whole world would hear of it. Pages in the newspapers would be devoted to it. Every one would mourn the loss. But when one man slaughters 5,000 of the innocents, we only know of it as an incident of medical importance.

In France the practice is much more common in proportion to the population than in our own country, due perhaps to the lower moral status of the people. It is estimated that in France alone half a million abortions are annually produced. I have never seen statistics relative to the number in our own country.

Upon what the demographer based his calculations I can not say. The figures may or may not be too great, but we do know that were there no criminal abortions produced, there would be little probability of the race becoming extinct.

I have asked a number of physicians how often they are approached by persons desirous of having them produce abortions. The average was twice a month. Were this true the country over, this would mean that the physicians of the United States were asked 3,120,000 times a year to produce abortions. The same individual may ask twenty different doctors before finding one who will do the work. Millions and millions the world over are annually produced and we hear but very little of it.

I have now spoken of the principal causes of the decrease in the number of births. I might say I have diagnosed the case. Now, what treatment should

be employed? For one thing, this crime should be denounced by the clergy. How often have those of you who attend church heard scathing denunciations from the pulpit upon such minor crimes as the use of liquor, tobacco, etc., *ad infinitum*. Did any of you ever hear the crime of abortion mentioned, and yet I doubt if any minister can look down on his congregation when two-thirds of the pews are filled, but that there is some one within hearing of his voice who is guilty of this crime. A clergyman asked a doctor I know why he did not attend church. He replied he was in better company when with the loafers on the street. "How so, doctor?" said the clergyman. "Well," answered the doctor, "when in church I see so many who are guilty of having committed abortion, which is a form of murder, who seem to take such an active part in church work that it seems like a travesty on religion, and so I stay away. When I am with the loafers I am with immoral men, but not murderers."

The doctor may have been too hard on them or else he possessed an intimate knowledge of the community, but such is often the case; those whom you least suspect are most guilty.

It should be a part of the religious and moral training of every young man and woman to be made aware of the heinousness of this crime. Every mother who calls herself a Christian should teach her sons and daughters that it is murder and nothing else. Murder in its worst form, for it is unprovoked and premeditated. Better a thousand times had she who thinks of doing this crime let nature take its course and let her bury herself in obscurity, be she single, until she can again mingle with the world. France has many public maternities where these unfortunate women can go, and they use them too, for one of every eight children born in that country are illegitimate.

A true physician should consider it an insult to be approached by any one desirous of having him produce an abortion. Some doctors in refusing seem to apologize for so doing. It is within the power of the physician to do much toward stopping this practice of abortion, by showing up the criminal phase and the physical dangers.

The newspapers, the great educators of the people, should refuse to advertise for these abortionists who by carefully worded personal notices inform the unfortunate where they can get relief. In one issue of the Chicago papers, I found over a score such notices. Although it is against all law, yet no convictions take place worth mentioning and when they do it nearly always savors of blackmail.

The educational methods should be changed, so that the student may receive physical training and hygienic knowledge. You can not have a sound mind in an unsound body. A lack of domestic education leaves the woman unfitted to make a home what a home should be, and much discomfort and unhappiness may result from such ignorance. Girls should be taught that woman's sphere is, first of all, a domestic one; her first duty is to her family and her home. What man would desire a woman who knew nothing of domestic duties?

The tendency of people to flock to the cities is one of the things that work to decrease population and one of the hardest to remedy. Farm life is gradually becoming more attractive and we may hope that the future may change this migration. Thousands in

the cities are merely existing, who have strength and ability to prosper in the country if they would be willing to sacrifice their love for the city's hustle and bustle.

In France every method has been tried to increase the birth rate. A premium paid for each child born; taxes regulated so that the man with a large family would have less to pay; maternities established, but all in vain. Despairing of attaining an increase in birth, they now seek to preserve the lives of those that are born. Laws to preserve the little ones have been passed. It is a misdemeanor punishable by very heavy fines to give a child less than a year old any solid food, save by physician's orders. I doubt if legislation will ever do much to remedy these conditions. We can at best only hope that an evolution may take place, but for the present and immediate future, I think that the theories of Darwin and Herbert Spencer will hold good.

The increase of natality is in inverse proportion to the efforts of the individual to climb the social scale, and the development of a nation in numbers is in inverse proportion to the refinement and social ambition of the individual.

ENTERIC FEVER IN INFANCY.

Read in the Section on Diseases of Children at the Forty-sixth Annual Meeting of the American Medical Association at Baltimore, Md., May 7-10, 1895.

BY WM. B. NOYES, M.D.

NEW YORK.

The subject of typhoid fever in infancy is one which has been much discussed, recently and in former years, but it is brought up again for new study because of the great uncertainty which still exists in the minds of many in regard to its occurrence, the indefiniteness of most of the literature on the subject, and the very great importance which the exact knowledge of typhoid fever must always have in all its different phases.

In medical literature, recent and old, some authorities of high repute speak of having seen scores of cases in early infancy and childhood and consider the disease not uncommon. The other extreme is represented by Northrup, of New York, who is exceedingly skeptical of its occurrence in infancy. His belief is based on his experience in the last twelve years at the New York Foundling Asylum where 1,800 children constantly under observation living inside and outside of the hospital, liable to every possible exposure which New York city can furnish, have never at any time developed a single case in children under 3 years of age.

Dr. O'Dwyer, with twenty years' experience in the same institution, has seen nothing of it. The physicians of the New York Infant Asylum, a smaller but active children's service, have never observed it. The Nursery and Child's Hospital does not record it. The Children's Hospital of Philadelphia, the largest service in the United States, according to the statement of the resident physician, Dr. Page, has never had a case of typhoid fever in early infancy.

With these statements and the negative records of most institutions in this country in regard to the occurrence of typhoid fever at this age, you will realize that it is necessary to study very carefully the following statistics which I have collected from the entire medical literature on the subject, after which a careful discussion may enable us to reach more positive conclusions than have hitherto been possible:

I.—TYPHOID FEVER IN ENGLISH EPIDEMICS.

1. In London epidemics, according to the *British Medical Journal*, 1882, there occurred in 1870-71, 126 deaths under 5 years of age, or 18 per cent. of all cases. In 1880 there occurred fifty-eight deaths under 5 years, or 13 per cent. of all cases. In 1881, eighty-three deaths under 5 years, or 8 per cent. of all cases.

2. In an epidemic in Stockport, England, 1890, there occurred 218 cases, 8 of which were under 5 years of age.

3. In Southend, Essex, from January to October, 1890, out of 152 cases, 65 per cent. occurred under 15 years, 13 per cent. under 5 years, including a male infant under 1, nine boys under 5.

4. Murchison reports in 5,911 cases of typhoid fever in the London Fever Hospital fifty-eight cases, thirty-four females, twenty-four males, under 5 years of age.

5. St. Thomas Hospital Reports record from 1878 to 1880, 3 cases under 5 years, out of 124 cases of typhoid fever.

6. St. Bartholomew Hospital Records from 1875-80 report out of 113 cases of typhoid fever 9 under 5, with 1 death.

7. Homerton Fever Hospital Records show an average of 2.4 per cent. of their cases of typhoid fever from birth to 4 years, 11.24 per cent. from 5 to 9 years.

8. The Metropolitan Asylums Board, of London, representing nine fever hospitals record from 1871-93, 266 cases of typhoid fever under 5 years, with 33 deaths.

Of cases older they report: From 5 to 10 years, 1,143 cases, mortality 102, or 8.9 per cent.; 10 to 15 years, 2,019 cases, mortality 265, or 13.1 per cent.; 15 to 20 years, 1,955 cases, mortality 346, or 17 per cent.; over 40 years, 338 cases, mortality 96, or 29.3 per cent.

The Northwestern Hospital alone, from 1889 to 1893, had 101 cases of typhoid under 5, with 9 deaths.

II.—EPIDEMICS OF TYPHOID FEVER ON THE CONTINENT.

1. Gassicourt, out of eighty-five cases of typhoid in Hospital Trousseau, Paris, records three cases from 1 to 2 years, eight from 2 to 5 years, thirty-four from 5 to 10, of which fifty-five were mild, twenty-two moderate, eight severe, and four fatal, or 4.6 per cent. (*Rev. des Maladies de L'Enfance*, 1890.)

2. In Berlin, 1878. 623 deaths from typhoid were reported, of which 98 were under 5, 39 from 5 to 10, (Keating, *Arch. Pediatrics*.)

3. In Heidelberg, from 1861 to 1879, Roth in the *Arch. für Kinderheilkunde*, 1881, reports eighty-two cases in the Luisenanstalt and Polyclinic under 15, five under 5 (one in the first year, three in the second) thirty cases from 5 to 10. These are epidemic cases.

4. In Gerhardt's *Kinderkrankheiten*, vol. 1, page 50, Wolff states that in an epidemic at Erfurt, 23.6 per cent. of all fatal cases occurred in children. From birth to 1 year, 7.5 per cent; 1 to 2 years, 12.7 per cent; 3 to 5, 42 per cent; 6 to 10, 28.2 per cent.

5. In Basel, out of 2,213 fatal cases of typhoid fever, between 1824 and 1873, from birth to 5 years occurred 108 cases; from 6 to 10 years, 85 cases. (Same authority.)

6. Barthez and Rilliet (*Maladies des Enfants*) studied 1,113 cases of typhoid which passed under their observation; of these 90 cases occurred from 2 to 4 years, mortality 25 per cent.; 176 occurred from 5

to 7 years, mortality 26; 349 cases occurred from 8 to 11, mortality 37 deaths; 498 cases occurred from 12 to 15, 68 deaths.

7. Archambault (*Gaz. Med. de Paris*, 1880) out of 165 cases under 14, reports two cases at twenty-one months, nine from 2 to 4 years, seventeen from 4 to 6.

8. Griesinger out of 510 cases in Zurich, between 1850 and 1863, reports 3.3 per cent. between 1 and 9; 20.1 per cent between 10 and 20.

III.—AMERICAN STATISTICS OF TYPHOID EPIDEMICS.

1. Report of Board of Health, Michigan, 1884, records an epidemic of thirty-one cases, all but six under 9.

2. Pennsylvania Board of Health, in 1885, reported an epidemic of 1,071 cases, 220 cases under 10 years, including: 4 infants 1 year old; 14 infants 2 years old; 10 infants 3 years old; 24 infants 4 years old; 27 infants 5 years old; 31 infants 6 years old; 33 infants 7 years old; 42 infants 8 years old; 404 cases from 10 to 20 years, 260 from 20 to 30.

3. In Providence, R. I., in an epidemic in 1883, reported in the *Boston Medical and Surgical Journal*, 1883, out of 200 cases, 15 occurred between the ages of 1 and 5 years; 32 between 6 to 10.

4. In the Windsor, Vt., epidemic reported in the *Medical Record*, 1894, out of 130 cases, 24 occurred from 3 to 10 years; three cases under 3 years.

5. In the Montclair epidemic, 1894, to which I shall again refer, 115 cases, 8 being infants under 3 years of age.

6. In *Boston Medical and Surgical Journal*, 1888, Holyoke reports an outbreak of typhoid in the Home of the Boston Children's Friend Society of fifty children above 6 years, thirty-five were sick with typhoid; of fourteen children from 4 to 6 years, six were attacked; of ten under 4, one was attacked.

These statistics, selected with care from a mass of less reliable reports, absolutely prove that during epidemics, typhoid fever is very common in childhood, and that in the first five years of life it occurs in a regular proportion of cases quite as frequently as one would expect from the special diet and care infants receive. If we have been free to a certain extent from these epidemic cases in America, it simply indicates that we have guarded the children better than they have abroad.

IV.—DOES TYPHOID FEVER OCCUR IN INFANCY EXCEPT IN EPIDEMICS?

In the *Medical Record*, March, 1895, Stowell published an elaborate table of eighty-five cases under 3 years, representing all the available sporadic cases, of which the diagnosis is strictly reliable. Gerhardt gives a series of twenty cases, Hensch thirty-five; Earl, Christopher and all who have written on this subject have reported cases. Some are entirely trustworthy, others not. It is not of very vital importance for our discussion to give a detailed account of these isolated cases. The question is not whether cases of this disease have at rare intervals been observed, but whether in cases always passing before us, especially in the class of intestinal troubles with a continued fever, that appear so frequently in clinics and general practice in the summer, there are not quite often genuine cases of typhoid fever in infants overlooked.

The diagnosis wrongly applied may be malaria, gastro-enteritis, broncho-pneumonia, tuberculosis or

meningitis. For this reason a very careful consideration of the symptoms is necessary.

V.—PATHOLOGIC LESIONS.

A study of the ordinary lesions of typhoid fever as it appears in adult life need not detain us. In infancy, all the abdominal viscera will be found more or less congested. The spleen is enlarged and swollen to far beyond its usual size. The entire mucous membrane of the intestine is congested, especially in the Peyer's patches and in the solitary follicles, which increase in size through proliferation of the lymphoid cells, forming what Hensch and Reilliet called "plaques molles." This hyperplasia may be followed by fatty degeneration of the new formed cells, terminating in resolution; or it may develop into what they call "plaques dur," which indicate that an infiltration of the entire follicle and the tissues beneath has taken place. This stage may be followed by exfoliation of superficial epithelial cells, necrosis, ultimate formation of ulcers. This swelling of Peyer's patches occurs earlier in children than in adults and is sufficient to make the patches protrude beyond the mucous membrane in projections which are frequently the seat of little excoriations, which may later develop ulcers and sloughs, as occurred in twenty-nine out of forty-four of Gerhardt's post-mortem examinations. But in infants this simple hyperplasia generally clears up without ulcerations, which Vogel, Friedleben and other authorities claimed never to have seen under 5 years. Hensch found ulcers thirteen times in 23 autopsies out of 239 cases of typhoid fever in young children, and noticed that they were generally small, shallow, occupying a part instead of the entire Peyer's patch. All this process inevitably causes the mesenteric nodes to swell as in lymphatic infections in other parts of the body. The swelling is not a condition peculiar to typhoid fever. But it is more marked than in almost any other intestinal trouble.

The pathologic changes in the infantile cases, while distinct, are much less severe than in adults. It is a very interesting fact that in a series of animal inoculations with typhoid bacilli by Santerelli (*Annals de L'Institute Pasteur*, 1892-1894) the changes in the intestine and other viscera were almost identical with those we have just described in children. These experiments consisted of a series of inoculations of rabbits, guinea pigs, white mice and monkeys with pure cultures of the Eberth bacillus, and were followed by a second series of experiments of inoculations with sterilized filtered products of the Eberth bacillus. The results were similar in the two cases. Swollen hyperemic spleen, congested intestine, diarrheal intestinal contents, infiltrated and congested Peyer's patches, red and hypertrophied solitary follicles. Hardened microscopic sections of the intestine showed a change in the epithelial lining, especially, and detachment of masses of epithelial cells together, such as occurs in a poisoning by arsenic or other corrosive drugs. Enormous infiltration of Peyer's patches occurred, abundant accumulation of lymphoid cells in and around the follicles and invading the submucous spaces. This change was not a simple hypertrophy of lymphatic plaques, but a condition just short of a beginning purulent infiltration. No typhoid bacilli could be found in these Peyer's patches in the animal, but enormous numbers were seen in the adjacent lymphatic glands and in the

connective tissue of the mesentery. From these experiments, Santerelli comes to the conclusion that typhoid fever produced in animals is by preference an infection of the lymphatic system, and the toxin produced by the Eberth bacillus causes the anatomic lesions. These changes occur in all mucous surfaces and we should expect to find in both animals and in man, lesions in the mucous membrane of the mouth, larynx, bronchi and stomach with resulting symptoms, which occurs very frequently. Typhoid fever can no more truly be called a disease of the intestine than smallpox of the skin, though both have their characteristic lesions in those places.

V.—DIAGNOSTIC SYMPTOMS.

The symptoms in adult life are familiar. The following symptoms may be regarded as characteristic of the cases in infancy:

1. Any long-continued fever that will not yield to appropriate doses of quinin should suggest typhoid, especially if of gradual onset, high in the evening, and when no existing condition of the throat, lungs or bowels offers an explanation. It is more suggestive if remaining continuously high for several days, increasing a little each day for three or four days, yielding after several days of observation some resemblance to a typhoid chart. And if the continuous high fever is well borne by the child, as Jacobi first noticed, with so little prostration perhaps that the child will play around, it is still more suggestive of typhoid fever.

2. The second symptom is gastro-intestinal disorder, especially when a decided tendency to constipation is present; putrid stools, of an especially offensive character and odor, if there is diarrhea. These, when only seen on the diaper, may not look very different from the green spinach stools that occur in other diarrheas, because the fluid is soaked up on the napkin. If seen in a vessel, the thin, semi-fluid character, greenish-yellow particles, and all the characteristics of a typical peasoup stool are present. If there is trouble with insufficient digestion of milk, the lumps of undigested casein or other food will somewhat change the appearance. The lack of acute symptoms of an intestinal nature is more characteristic of typhoid than are violent symptoms.

Henoch noted normal movements in 26 out of 233 cases, absolute constipation in 23, and in 184 cases, first, constipation, succeeded by diarrhea about the end of the first week. Vomiting may or may not occur. Loss of appetite is present from the beginning. A tongue coated with yellowish or brownish-white, or red at the tip and sides, sometimes moist, generally dry, will be noticed. It may be so heavily coated and the entire mouth so affected that a condition resembling aphthous stomatitis may be present, which in one case in the Montclair epidemic first led the family to call in a physician.

But the condition of *sordes* is far less frequent in infants than in adults. The tongue may vary from day to day, the excessive dryness of the tongue, with foul odor, the coating of the lips and gums, and rhagades is a later condition, keeping pace with the advance of somnolence and severe nervous symptoms.

3. In addition to the fever and intestinal symptoms, an examination of the skin may yield the lenticular rose spots familiar in ordinary typhoid. These may come early or late, or in two or three crops, and

are to be expected in most cases in children. Stowell found them in 66 per cent. of his cases. Cadet De Gassicourt in the same proportion. Earl in all his cases but three. Henoch in nearly all. Ashby in thirty-nine cases out of fifty, or 78 per cent. Roth in thirty-seven cases found them present, in forty-three absent.

4. Symptoms of headache frequently occur, which a baby will indicate by rubbing or picking at its head, nose or ears, or burrowing its head back in the pillows, but not by active cerebral symptoms, which would characterize meningitis. As the disease goes on, these head symptoms will frequently increase.

5. Enlarged spleen is very important when found, but not always to be accurately demonstrated in a young child, especially if tympanitis is present. A painful spleen is a more important point. The spleen ought to be felt below the border of the ribs to be pronounced enlarged, percussion not being a satisfactory test. According to Eustace Smith, it begins to enlarge by the sixth or seventh day and is soft and tender, the change being simply hyperemia, not a production of new tissue.

6. Tympanitis is sometimes excessive, but in most recorded cases moderate. This swelling is due to the accumulation of gas through decomposition of food and inability of the bowels to expel the gaseous contents in consequence of loss of nerve power or local injury from ulceration. The more ulceration the more distension.

7. Bronchitis seems to be as regular a symptom as in measles, agreeing with the pathologic changes, redness and swelling of the bronchial tubes generally found, but the breathing is, later, too superficial to make râles. It has been demonstrated that the bronchial mucous membrane excretes the Eberth bacilli and its products, or is at least irritated by it. The younger and sicker the children, the less the cough, as the sensibility of the mucous membrane is so blunted that mucus accumulates in the posterior and lower parts of the lung, diminishing resonance but causing no new real pneumonic dullness. Pneumonia in these cases is rare; Roth in eighty-four cases having four; Henoch very few.

8. The author has seen angina twice, and finds that Henoch, Eustace Smith and Parrot mention its occurrence in infants. In 6,500 cases of typhoid fever in St. Petersburg, Ouskow notes that in 5 per cent. of the cases there was marked redness or ulceration of tonsils. Gassicourt states that in the Paris epidemics, 1865 and 1882, sore throat was very common, but in other epidemics, 1876 for instance, it was rare. In the cases in children the occurrence of sore throat when found will generally confuse rather than help the diagnosis.

9. Epistaxis, according to Keating and others, is as rare in children as it is common in adults. I find it occasionally reported. Hemorrhage from the bowels seems to be rare in childhood and infancy.

10. Neither in children nor adults can the Eberth bacillus be demonstrated in the stools until the tenth to the twentieth day (Chantemesse, Santerelli;) it is doubtful whether reliable bacteriologists have as yet succeeded in demonstrating this in the stools in infants. A number of excellent authorities have never been able to do this even in adults. Though it has been claimed both in infants and adults, more recent methods make it doubtful whether older observers may not have at times con-

fused the bacillus coli communis with Eberth's bacillus. The stools will, from the outset, be swarming with all sorts of bacteria, especially the bacillus coli communis. It seems to be true that as the typhoid fever progresses, these ordinarily innocuous bacilli assume a more virulent character and multiply enormously, but if the Eberth bacilli can not be found in the stools in children, they frequently can be demonstrated in the lymphatic tissues and spleen. In the same way, in the animal inoculation experiments of Santerelli, the stools never seem to contain the Eberth bacillus, while the spleen and the lymphatic system have numbers.

11. The study of the blood in typhoid fever may yield some results of value. It will certainly exclude malaria. I note results reported by Loisan, Simonin and Arnaud, of examination of blood from the finger in 241 cultures made from 65 adult typhoid patients. In a few cases the Eberth bacillus was found alone or associated with staphylococci. In forty-five cases, staphylococci alone were found. (*Rev. de Med.*, April, 1893.) But the Eberth bacillus is not a regular blood parasite, being in all cases found much more abundantly in other parts of the body. These authors have also pursued similar investigations in fresh urine and in the buccal secretions, finding Eberth bacilli in a few cases.

12. There are not commonly marked kidney symptoms, though transient albuminuria in the second week or after the end of the fever may occur.

13. Relapses are infrequent, but at times occur.

14. Ehrlich's test, which is yielded only by typhoid miliary tuberculosis, septicemia and cancerous cachexia may assist in the diagnosis.

COURSE.

The disease seems to appear in three forms; an abortive type of short duration, a type resembling ordinary adult typhoid lasting about three weeks, and a malignant or prolonged form. These bear to one another about the same relation as varioloid, ordinary variola and malignant variola in its more fatal form. The cause of these variations may be the anatomic difference in the extent of the lesions, *i. e.*, whether there is simple congestion, or some considerable infiltration of new cells, or ulcerations varying in size, depth or number. But going further than these gross changes, the occurrence of the Eberth bacillus alone, or its occurrence together with other pathogenic microbes and their ptomaine products, may be the more important condition which determines in which of these three forms the disease may appear. In other words, not how extensive is the change in the coats of the intestines, but how much actual poisoning is taking place? And if the lymphatic theory of the disease is true, the intestinal changes are merely the result of the severity of the disease, not the cause.

The convalescence in children is, as a rule, quicker and less complicated. It is evident from the different series of cases of typhoid in childhood that autopsies are not very abundant. Stowell in his list of eighty-five reliable cases records but twenty-four autopsies. Hoelscher reporting 2,000 typhoid autopsies in the *Munchner Med. Wochenschrift*, January, 1891, reports but eight under 10 years, two being babies of two and nine months respectively. Even in epidemics affecting many children, very few deaths occur. This seems to me to indicate that, as a rule,

typhoid is a much milder disease in childhood than in adult life, as many infants may pass through it with less severe and distinct symptoms than adults present.

Out of 265 cases of typhoid fever treated in the Manchester Hospital for sick children, Ashby noted a frequent tendency to an abortive or two weeks' course. While from 2 to 12, the mortality was 10 per cent., he found as a rule, that the children were rarely acutely ill. Though indicating their disease with rose spots, remittent temperature, rounded abdomen and other symptoms, they would frequently be playing around the room and show little prostration.

Jurgëson, in the Transactions of the Sydenham Society, makes a study of eighty-seven cases of abortive typhoid, sixteen terminating from fourth to seventh day, nineteen from eighth to tenth, twenty-four from eleventh to thirteenth, twenty-eight from fourteenth to sixteenth. He holds that if the pyrexial state lasts longer than the twenty-sixth day it is probably due to a progressive ulcerative enteritis. Henoeh, out of 190 cases in which he could calculate from the beginning with some degree of certainty, found 11 cases that lasted from seven to nine days, 11 cases ten days, 17 cases eleven days, 8 cases twelve days, 45 cases thirteen to fifteen days, 15 cases sixteen to seventeen days, 25 cases eighteen to nineteen days, 39 cases twenty to twenty-three days, 14 cases twenty-four to thirty days, 1 case thirty-five days.

Gerhardt regards it absolutely demonstrated that these abortive cases are frequent, indicating a light and incomplete working of the typhoid fever on the infant organism. He holds that it is characterized by some degree of suddenness in the onset, at times beginning even with a chill. And this, with the rapid increase of the temperature, seems to portend something of a dangerous nature. The spleen swells early, roseola comes early, and the abdomen is usually protruded and sensitive. The fever may drop rapidly and the child soon become convalescent.

Reilliet and Barthez in *Maladies des Enfants*, in 837 of their cases of typhoid in young children which recovered, find a longer duration; 47 lasting from eleven to fourteen days, 298 lasting from fifteen to twenty-one days, 317 lasting from twenty-two to thirty-one days, 133 lasting from thirty-two to forty-five days.

In the 143 fatal cases which they report, 4 lasted five days, 6 lasted two days, 33 lasted eight to fourteen days, 40 lasted from twenty-two to thirty-two days, 18 lasted from thirty-two to forty-five days, 12 longer.

Yet the diagnosis of these abortive cases must inevitably and at all times be difficult, from the insidious onset and irregular character of all the symptoms, and for awhile, at least, if there is diarrhea, a diagnosis of gastro-enteritis will adequately explain all symptoms; if there be constipation, or merely occasional movements of altered or putrid stools, a diagnosis of ptomaine poisoning from some undigested fermenting substance in the intestines will also account for all the symptoms. And this is not really a false diagnosis. It merely does not state what is the bacterial agent that causes this ptomaine poisoning.

To illustrate this, I will give a history of a case of my own already published. (*Medical Record*, July, 1894):

An infant aged eleven months was brought to me (had been staying for a ten days' visit in Montclair, N. J., where he had been weaned and fed on unsterilized cow's milk diluted with barley water. On his return to New York he was fretful, restless and had a slight temperature of 102 degrees, attributed by his mother to cutting teeth, but had nothing else characteristic in his condition. Slight bowel trouble with colic. For two days he seemed to improve a little, though still with a slight fever; on the third day the temperature was 102.6 degrees, A.M.; 103.8 degrees, P.M., and for the first time he appeared very sick. Moderate diarrhea with colicky pains, coated tongue, occasional vomiting, negative chest signs. Diagnosis; gastro-enteritis. On the fifth and sixth days the temperature was 102.6 A.M., and 104 P.M. Frequent stools of foul odor, tongue coated white, with red tip and sides. Lungs gave only physical signs of bronchitis. Great fretfulness. Hands brought frequently to head, as if suffering great pain. There were no other definite symptoms.

After another day of slight improvement the child was taken back from the city to Montclair. During the two weeks which had elapsed since he had left Montclair, about fifty cases of typhoid fever had developed, and this time it was publicly recognized that the origin of every one of these cases was due to one cause alone; the polluted milk served to the families in all cases by one dairyman, who had himself had two cases of typhoid in his family one month before, and had infected his well and washed the cans and bottles, if not watered his milk, with the infected water. The baby had fed for ten days on this milk. The combination of symptoms which the child had developed, of high and continued fever during the past week, the tongue with clean margin, the character of the stools, the absence of other symptoms, all suggested a diagnosis of typhoid fever. On the eighth day temperature was 104, pulse 160, respiration 25, stools four. Rose spots appeared on the abdomen very distinct, disappearing on pressure.

A second case of typhoid, the nurse of the baby, was detected at this time. She had used the same infected milk. A third case of an aunt of the baby appeared a day after, and other cases in the neighborhood and milk route to the number of 150 occurred.

From this time the case followed a fairly typical course, with exceptionally severe nervous symptoms. Death in fourth week from exhaustion.

I failed to make a diagnosis of this case, until confirmed by the epidemic, and yet it seemed to me that this history of the early symptoms has something characteristic in it which will help in making diagnoses, in an abortive case that goes no further than the first or second week.

The later history in this case followed a course which I find not at all uncommon in recorded cases of typhoid in infancy, characterized by certain symptoms which simulate meningitis. At the beginning of the third week, following a little gastric irritation, vomiting and general irritability increased, the temperature rose 4 degrees. There developed a stiffness of the neck and back which reached, after a time, a condition of opisthotonos. Incoördination and continued movement of the eyeballs, great hypersensitiveness to sound, light and touch especially in the head. Irregular and at times convulsive movements especially marked in the left arm and leg. Continued twitching of the fingers, a peculiar cry, a rapid, feeble and irregular pulse, 160 to 180, rapid respiration. This seemed almost certainly an acute meningitis. Careful examination of the case, and consultation with one of the most reliable authorities on children's diseases in New York, made it seem probable that this was not an acute meningitis: 1, fontanelle was not elevated; 2, the child was bright enough to take notice of its surroundings; 3, no tache-cerebral; 4, no boat-shaped abdomen; 5, no expulsive vomiting; 5, photophobia, hypersensitiveness to sound, were not sufficient. The entire condition, acute as it seemed, was judged to indicate a passive congestion of the brain caused by the weak heart, and an attempt was

made to remedy this condition by heart stimulation which proved successful after a few hours, there being no return of those cerebral symptoms during the remaining days of the case.

This history suggests cases of Henoch with tremor, and stiffness of the extremities with frequent jerking or twitching, which showed no brain lesion at the autopsy. Also one where there was contracture of both legs and right arm and continued grinding of teeth. Autopsy with only slight changes in the brain; also one of a little girl who showed distinct stiffness of the neck, later, actual opisthotonos and marked contracture of the neck, but on autopsy showed no brain lesion. Another case in the Montclair epidemic of Brown, which I reported with other cases in the *Medical Record*, 1894, showed marked nervous symptoms, great restlessness, tossing of head from side to side, rigidity of muscles of neck, opisthotonos, almost complete blindness for five days, strabismus at times, hydrocephalic cry, complete recovery after twenty-eight days.

In Gerhardt's *Kinderkrankheiten*, Soltmann speaks of this condition. After intestinal symptoms have almost entirely disappeared, symptoms indicating motor irritation, such as twitching, contractures, light convulsive symptoms, later genuine convulsions, succeeded by stupor as death approaches; even aphasia and paralysis have been noted. Autopsy in these cases excludes meningitis, as well as encephalitis or neuritis. The observers agree in considering the actual cause to be anemia or a diseased condition of the blood, or else excessive weakness in its circulation.

Simon (*Gaz. des Hopitaux*, 1886,) thinks that the congestion always present in spleen, lungs and other organs in these cases of typhoid is always more or less present in the brain, cord and meninges, and he thinks that edema of the brain is the chief cause.

Reilliet and Barthez (*Maladies des Enfants*) refer to a case at fourteen months, with convulsions, preceded by general irritability, agitation, strabismus, contracture of the neck and limbs, a condition which lasted three days. Autopsy indicated sero-bloody effusion in and under the arachnoid. Of their 143 fatal cases, 5 showed thick serous exudate, adherence of membranes, softened brain substance, or, in other words, were genuine meningitis. In nearly all cases of this nature on record, however, simple hyperemia is all that the autopsies develop. These cases all belong to the third or malignant type. The condition is more than a simple change in the circulation or in the character of the blood. It means a more or less absolute overwhelming of the nerve centers by a poison, whether this be the product of the Eberth bacillus or other bacteria.

There are a large number of cases of typhoid in infancy reported from time to time, with inconclusive clinical histories, which are very definite on the subject of the changes in the intestine found on autopsy, which are called "undoubted typhoid lesions," because they yield swollen and ulcerated Peyer's patches, enlarged mesentery, lymph nodes and other similar changes. Are these lesions always peculiar to typhoid fever, or do they occur in other intestinal diseases? Northrup exhibited to the New York Academy of Medicine, an intestine showing all these changes coming from a child sick for only a few hours with some acute trouble, positively not typhoid fever. He asserts that he has frequently met with this condi-

tion in autopsies. Dr. Seibert agrees with him. He explains, and I think justly, many of the so-called typhoid lesions in this way. It is desirable that a very careful consideration of pseudo-typhoid intestinal lesions be made, for it brings up a condition which is not recognized by our existing classifications of intestinal diseases. It is not impossible that the name, enteric fever, if it does not include more than one distinct disease, may possibly be a disease of more than one cause. That is to say, beside the cases undoubtedly caused by the Eberth bacillus, there may be other elements at work, whether bacillus coli communis, or the bacteria connected with milk infection which produce an analogous condition. Whether it will, at a later day, become possible to clearly distinguish these divisions is impossible to say.

The later stages of typhoid fever after the formation of ulcers when they exist, are essentially a septicemic condition from the poisoning by various bacteria and their ptomaine products, but more especially by streptococci. It is certain that, as the disease progresses, the Eberth bacillus becomes less numerous and the streptococci and staphylococci more numerous. The picture of the disease, then, is indistinguishable from the condition so common in severe, long-continued gastro-enteritis, or milk infections which we observe in summer.

Vincent, in the *Annales de l'Institut Pasteur*, 1893, studies this later and secondary condition of infection by a combination of Eberth bacilli and streptococci. In the bacteriologic examinations from the spleen and other organs, in thirty-one autopsies of typhoid cases he found six times streptococci associated with typhoid bacilli. He regards the typhoid patients peculiarly exposed to streptococci infection, since the system in a great measure has lost its resisting power, and only an angina, parotitis, otitis, or some other source of pus is needed to start this double infection. Even the saliva contains numerous streptococci, and ulcers in the intestine may permit absorption. Furunculosis is common.

He examined forty-one abscesses occurring in typhoid cases, and in thirty-two he found staphylococci, pyogenes aureus or albus, and found that these cases happened to recover. In eight cases he found the Eberth bacilli also, five of which cases died. He claims from his test that typhoid bacilli and streptococci, combined, cause a more virulent poisoning and thus a special danger to the patient. In a fatal case of typhoid fever with rose spots and clear history, on autopsy he found very slight lesions in Peyer's patches and intestinal follicles, spleen not much swollen, and in the different organs typhoid bacilli and streptococci.

In a series of animal inoculations he found that injection of the Eberth bacilli cultures, alone, was followed by an active phagocytosis, but injection of Eberth bacilli and streptococci together was followed by no phagocytosis, the animal eventually succumbing to this double infection. This, though only a limited work, opens up a new field of investigation in typhoid fever, and a possible explanation of its characteristic course and exceptional features.

Our present state of knowledge will perhaps enable us to decide that these aborted and short cases, with their early symptoms as described, are more purely the result of simple infection by the Eberth bacillus, while the later course, in common with the condition occurring after gastro-enteritis or milk infection, may

become a simple streptococci infection or a septicemic condition.

This conclusion is simply analogous to conditions present in other diseases.

The severity of an attack of diphtheria varies largely in proportion to the extent the infection by the Löffler bacilli is complicated by streptococci.

In scarlet fever the same is true, and in tuberculosis of the lung, as Prudden has so forcibly demonstrated, the lesions and symptoms vary according to the complication of tubercle bacilli with streptococci.

In conclusion, we would once more emphasize that typhoid fever in early infancy in a typical form is rare in this country, though not uncommon abroad. It is in a mild or abortive form that we must look for it here, if we wish to separate it from other intestinal or meningeal diseases that may appear.

And, lastly, when we have a case which is severe and prolonged, we may see in it not the result of the simple infection by the typhoid fever bacilli, but a complication by other pathogenic bacteria.

162 W. 73d Street.

TYPHOID FEVER IN CHILDREN.

Read in the Section on Diseases of Children, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY JOHN ELIOT WOODBRIDGE, M.D.

YOUNGSTOWN, OHIO.

Typhoid fever is the same disease, is produced by the same causes and is governed by the same laws, at whatever time of life it may occur, from earliest infancy to the frailest anility; modified as it may be, by age, by organic development, by concurrent affections, or by extrinsic causes, and probably by the quantity of poison ingested. In the child as in the adult, it is caused by the same morbid influence, which can be neutralized by the same antidotes. In either instance the patient should be regarded and treated simply as the container of the specific poison.

It follows, that notwithstanding the minor modifications which the character of the disease may undergo, on account of age or other causes, that it is amenable to practically the same curative treatment in infancy as in adult life.

I must, therefore, make the same declaration here that I have made in every medical society before which I have discussed typhoid fever since 1880, viz., that every case can be aborted and that death is a wholly unnecessary consequence of the disease; and farther, that these results are attainable by a treatment so mild and gentle that, should the newborn babe be given the dose intended for a robust manhood, no harm would result; or should the child, overfond of its medicine, take at once the portion intended for fifty doses, it need cause no anxiety.

Yet, symptomatically treated, typhoid fever is one of the most serious affections of infancy and early child-life; and in the most alarming forms of the disease, in which the fever rises rapidly to an excessive height and the nervous symptoms point to some grave cerebral lesion, the true character of the ailment is rarely recognized in time to benefit the patient. Indeed, in a very large majority of these cases a correct diagnosis is never made. Therefore, while treating of typhoid fever in the adult, my pleading has always been for an early diagnosis. In discussing typhoid fever in children, the burden of my plea must be for a correct diagnosis; since the disease in babyhood is so frequently overlooked.

While Murchison and other eminent authorities have recognized and acknowledged the possibility of the occurrence of typhoid fever in earliest infancy, and even during utero-gestation, yet neither the best text-books, the teachers in the medical colleges, nor the general practitioner have realized how frequently the disease occurs in desperate forms during early childhood.

Reynolds' "System of Medicine" devotes more than seventy-five pages to typhoid fever and does not mention the disease in children in the whole article. Pepper's "System of Medicine," in five large volumes, justly praised wherever the English language is spoken, yields less than two dozen lines out of more than one hundred pages on typhoid fever to the disease in children. Professor Osler, whose "Principles and Practice of Medicine," is perhaps more largely quoted than any other work on the subject, disposes of typhoid fever in children in less than one dozen lines, and this is the author who said: "Cases (of typhoid fever) coming on with severe headache, photophobia, delirium, twitching of the muscles and retraction of the head are almost invariably regarded as cerebro-spinal meningitis." And again: "I have thrice performed autopsies on cases of this kind, in which no suspicion of typhoid fever had been present; the intense cerebro-spinal manifestations having dominated the scene. . . . Cerebro-spinal meningitis is, however, a rare disease; typhoid fever a very common one, and the onset with severe nervous symptoms, is by no means infrequent. Fully one half of the cases of the so-called brain fever belong to this category."

But while medical literature has recognized the possible predominance of the nervous symptoms of typhoid fever in the adult, it has failed to give due warning of the frequency with which these symptoms occur as the most prominent manifestations of the disease in early childhood, an omission which has been responsible for many errors in diagnosis and treatment.

In the first number of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION for this year, a distinguished professor of the diseases of children, says that: "It has been my good or ill fortune to see during the past ten years, a number of cases in children under the age of 2 years, which presented mild intestinal disturbance, no marked tenderness over the bowels, a very high temperature, and where the apparent cerebral complications, delirium and stupor being prominent symptoms, were the apparent cause of death. In these cases, in the death certificate, the cause of death was usually given as congestive fever or meningitis. Two of these cases occurring within the past year, in both of which the post-mortem examinations revealed a pronounced error of diagnosis, has emphasized in my mind the thought that typhoid fever exists more frequently in early child-life and in a serious form than is generally suspected. I present the following case:

"A little girl of eighteen months, the child of a very prominent physician, was taken sick early in May, with marked intestinal disturbances; the evacuations from the bowels were frequent and copious, accompanied by mucus and blood. The temperature ranged from 102 to 104, and on one occasion reached 105 degrees. There seemed to be a history of acute indigestion. The usual treatment was applied in this direction, and the temperature was controlled by

cooling baths. Flushing of the colon with medicated warm water was applied, followed by starch water injections containing a few drops of laudanum, for the purpose of calming and reducing the frequency of the operations which interfered with sleep. During the early part of the attack, the child, though having frequent operations, was noticed to be calm and gave no evidence of pain. Not until the fourth day, however, was marked obtundity observed and the staring appearance of the eyes, together with the indifference to surroundings, impressed me with the fact that there was a cerebral complication. The course of the treatment was continued and the supposed cerebral complication became more pronounced. Inability to distinguish light or sound, and a crossing of the eyes, apparently justifying a diagnosis of meningitis. The child died about the tenth day. Post-mortem examination developed the absence of meningeal inflammation and the presence of ulcerations of the glands of Peyer, showing us, the physicians in attendance, how little we knew of the cause of death."

The author adds: "The indications for treatment were the same. A recognition of the disease in advance would probably have made no difference."

I have quoted thus largely from this paper because it is really a valuable contribution to medical literature, and I honor the learned author for giving less enlightened members of the profession the benefit of the many sad experiences which have finally opened his eyes to the fact that he has been stupidly floundering in his differentiation of diseases, albeit he has yet to learn of his greater deficiency and gross culpability in the treatment of typhoid fever. I forego all criticism on the long years and the number of pronounced errors of diagnosis which were required to implant in his mind a just conception of the vast number of children who must die annually of typhoid fever, after having been treated by the average practitioner for acute indigestion and later for meningitis, and finally are buried under a false death certificate. If this article, by one of the world's most distinguished professors and medical editors, truly represents the practice of the class to which he belongs, it paints a sad picture of the little victims of typhoid fever who were so unfortunate as to have come under their skillful care. It presents to our view what costly mistakes these illustrious gentlemen make, and yet the author eliminates but one or two of the diseases with which, in infancy and early childhood, typhoid fever is so often confounded.

With our present knowledge of the causes which produce typhoid fever, and the susceptibility of young children to their influence, taken in connection with the exceedingly limited number of cases of the disease, which are reported to the various health departments in our cities, where the disease prevails, it must be evident that the eminent writer of the paper quoted is not the only physician who should have had the fact emphasized in his mind "that typhoid fever exists more frequently in early child-life and in a serious form than is generally suspected."

I have, in consultation, seen typhoid fever in young children mistaken for malarial fever, pneumonia, cholera-infantum, teething and even for worms, in addition to meningitis and acute indigestion.

The diagnosis of typhoid fever in children as in adults, should be made by reasoning by exclusion, and if thus the disease can not be eliminated from

the patient's possible ailments, the case should be treated as typhoid fever; because no other disease is so insidious in its character; because no other disease is so amenable to treatment in its earlier stages and so intractable after its anatomic lesions have reached a certain stage; because it is so often impossible to make a positive diagnosis in time to save the patient's life; and, finally, because the best treatment we yet know for typhoid fever not only fulfills both of the requirements of Hippocrates—it is curative, it is harmless in health or in any pathologic condition at all resembling the disease for which it is instituted.

I learned the importance of making a correct diagnosis in typhoid fever many years ago, and in 1881 I was taught a lesson on the management of the disease in children which I shall never forget.

Little Gracie Wick, aged three years and ten months, was taken sick on December 14. Her temperature on my first visit was 105 degrees. In fourteen days she died of typhoid fever. A few weeks later her younger

Annie W., age 3 years; date of admission, Feb. 7, 1895.

sister Emily, aged two years and ten months, was attacked by the disease, which ran a parallel course and ended in death, again on the fourteenth day. Both children presented abdominal symptoms. In both, the nervous symptoms predominated. Both had opisthotonos, and both died the victims of almost criminal stupidity on my part. They were my last two fatal cases of typhoid fever and to-day should I be called as promptly as I was then, they would have been in no danger of dying.

Looking back to those gloomy days, I can not realize why I let those children die, for I know well enough how to treat typhoid fever in adults even then. I made a very inadequate effort to assuage the pangs of conscience, by calling two of the oldest and ablest physicians of the city in consultation, after the time had passed when counsel could have been of any avail.

As a marked contrast to the sad picture portrayed by the death of these little ones, my last two fatal

cases, I wish to present the clinical charts of a few of the cases of typhoid fever I have treated during the intervening years and relate the annals that have been kept of them, and as an addendum give the records of a few cases treated by other physicians, by that which, for want of a better name, I have designated antiseptic medicine, for it is antiseptic medicine, and it is also something more.

Case 105.—Annie W., aged 3 years. (Cousin of Case 78, John J.) I was called to see this patient on February 7, and given the following history: she had been sick eight days, had been treated by an irregular physician, under a diagnosis of malarial fever until the parents, alarmed by the severe symptoms, continued high fever and the enormous tympanitic distension, questioned him closely as to the nature of the disease, finally eliciting from him on admission that it might be typhoid fever; when he was promptly discharged. I found the temperature 105.5 degrees, pulse 140, on the evening of my first visit and the same the next morning, the parents having about given up hope, as the child was thought to be dying twice during the night preceding my first visit. There was marked impairment of vision, deafness, and well-marked retraction of the head. When asked if I entertained any hope for the life of the child, I gave my usual favorable prognosis saying: "I think the child will recover and she certainly will if she survive the next forty-eight hours." She had intestinal

Sarah J., age 13 years; date of admission, Feb. 17, 1895.

hemorrhage, which in my experience is rare in young children. She also lost all power of speech, her lower limbs were paralyzed, she had just recovered from whooping cough, which returned to plague us during this attack of typhoid fever, in spite of which she made a good recovery. Her temperature, as you will see, touched normal on the tenth day of treatment, but went up slightly again on the eleventh day. On the thirteenth day the temperature and pulse were normal and the patient was discharged, and ten days later was in more robust health than before her illness.

Case 111.—Sarah J., aged 13 years. (Cousin of Case 105, Annie W.) When I first saw this case her temperature was 103 degrees, pulse 130. The next evening it was 103.8 degrees with a pulse of 136. I gave my usual prognosis—ten or twelve days of illness—no danger. Her temperature touched normal on the tenth day of treatment. This case was an exception to the almost invariable rule commented on by so many observers, that after this so-called antiseptic treatment of typhoid fever, almost as soon as the temperature touches normal, the patient is in better health than before the illness. This patient had had some stomach trouble before her illness, and although she recovered quickly from the fever and her appetite was better than usual, for a week or two, she has since been to my office several times for treatment of her old trouble.

Case 112.—Florence J., aged 11 years. (Sister of Case 111.) On February 27, the temperature of this patient was 102.5, pulse 130. Three days later it was 103 degrees, from which time it declined to normal on the thirteenth day of treatment, the patient being in good condition and having an excellent appetite.

Case 113.—Blanche J., aged 5 years. (Sister of Case 112.) This patient had temperature of 101.5 on March 2, with a pulse of 128. On the third day of treatment it was 104 degrees, from which point it declined to normal on the eleventh day.

I am not infrequently called to see young children, especially in consultation, in the late stages of typhoid fever, when no suspicion of the character of the disease had been aroused, but in which the symptoms are so distinctive that no trouble should have been experienced in making an accurate diagnosis. One case of this sort which had been, however, under the care of an irregular practitioner was

Case 98.—Margeret O., aged 2 years. I found the child lying in a cradle, in the corner of the kitchen, between the wall and the cooking range. She was moaning pitifully and sometimes screaming violently; her head was retracted and turning rapidly from side to side. A diagnosis of brain fever had been made. The temperature was 106 degrees; the bowels very tympanitic and the stools very frequent. Taking the necessary steps in the order of their importance, I first

done me the honor to write me several letters of inquiry (he is altogether the best questioner with whom I have ever corresponded) in regard to my method of treating typhoid fever. He has favored me with the reports of several cases treated since our correspondence began.

Case marked—"Dr. McWilliams No.—Helen McC., aged six years and three months. She was taken sick, as you will observe, while away from home at a summer resort. A diagnosis of typhoid fever was made by a local physician, and on the tenth day she was sent home to be under the care of the family physician, Dr. McWilliams. Her temperature was 106 degrees the first day that the Doctor saw her and on the tenth day she was sitting up, dressed, enjoying 'Judge,' 'Puck,' etc."

Dr. Cunningham, of Youngstown, reports the following:

Case marked "Dr. Cunningham No.—Ella G., aged seven months. She was under the care of three different physicians, before I saw her in consultation.

Florence J., age 11 years; date of admission, February 27.

Blanche J., age 5 years; date of admission, March 2, 1895.

dropped a little powder (to be described hereafter) on the child's tongue; I then ordered the cradle to be moved as far as possible from the fire, and had the child sponged and ordered that the powder be given every fifteen minutes. Later in the night I visited the child but found little change in its condition. The next day I visited her three times and that evening the temperature fell to 105 degrees. The following day the symptoms began to improve rapidly, and she made a quick recovery, being well in ten days.

While visiting this child on the second day, I saw a younger child sitting in a suspicious position and when it moved a bloody stool remained. Glancing around the floor I saw two or three others, which though small were quite apparent. I asked the mother to explain and her answer was brief and to the point: "I declare to goodness he's been doing that all day!" Upon examination I found the child with a very rapid pulse and a high temperature. The recovery of this child was somewhat tedious, owing to the advanced stage of the disease when I was able to begin treatment.

One of the most prominent physicians in Chicago, (a gentleman who was long at the head of Cook County Hospital, and was for many years one of the most highly esteemed professors in the foremost medical college in that city so noted for its clever and accomplished preceptors, and whose name is cut in the corner-stone of the college, as one of its founders) has

The first physician (according to the statements of the family) made a diagnosis of whooping cough; the second physician said it was meningitis." The child growing worse, Dr. Cunningham was called and made a diagnosis of typhoid fever. When the temperature went to 105 degrees he called me in consultation. The chart indicates the rapidity with which the child recovered. The correctness of the diagnosis was corroborated a few weeks later, when the mother of the child (see chart marked Dr. Cunningham No.—Mrs. G.) had an attack of typhoid fever, from which she recovered; and the uncle (see chart marked Dr. Cunningham No.—James K.) died of shock, resulting from an intussusception, occurring after he was almost well from an attack of typhoid fever.

Dr. C. N. Udell of Iowa, kindly sent me a report of twelve cases of typhoid fever, and one of cholera-infantum treated by my method, with excellent results from which I extract the following record of cases of typhoid fever in children:

Case 8.—S. B., male, aged 9 years. Was taken with chills

fever, headache, vomiting and some abdominal pains. Treated by the family for ague. I was called after the boy had been sick eight days. Found the temperature 104.6 degrees, skin dry, tongue very dry and red, dirty gray fur in center; very nervous; hyperesthesia, delirium, a papular rash, secretions locked. Gave to this boy Nos. 1 and 2 for two days; repeated it at short intervals. Then No. 1 for three days; No. 3 for four days. Discharged patient on ninth day. In this case, as in all others, I insisted on frequent sponging of the body, frequent change of linen, good ventilation of the sick room, same food given at regular intervals, etc.

Case 10.—N. S., male, aged 8 years. Had an intermittent fever. Prescribed c. cath. pills and quinin without seeing patient. Continued sick and weak; no improvement. Visited the boy and found temperature 104 degrees, skin dry, suppression of urine; very weak, headache, and general aching; some delirium, very foul breath, heavy gray fur on tongue with edges red, sordes on teeth, a good deal of tympanitis, some eruption, and sudamina. Diagnosis: septic fever, or paludal typhoid.

Ella G., age 8 months; date of admission, March 12, 1895.

Gave R. No. 1 and No. 2. After three days gave R. No. 3. On the seventh day gave Nos. 1 and 2 again. Then No. 3 for about one week at longer intervals. Patient discharged well.

Case 11.—D. H., male, aged 2 years. Was sick with diarrhea, high fever, very restless, abdomen puffed, vomiting, and furred tongue with foul breath. Gave baptisia tinct. R. No. 3 in minute doses. Recovery in five days.

Case 12.—E. P., aged eighteen months. Hygienic surroundings very bad. Child had cholera infantum with very offensive stools. Gave R. No. 1 in very minute doses every half hour. Had the child kept as clean as possible, and that was not very clean. The child recovered speedily in spite of bad nursing.

These cases illustrate the admirable results which may be invariably obtained and even confidently predicted, when proper treatment has been instituted at a sufficiently early stage of the disease and intelligently and energetically prosecuted; and they by

contrast, serve as a warning against the danger of mistaking the nature of the most common, the most dangerous and by far the most frequently overlooked cases of typhoid fever in children, viz., those cases in which the nervous manifestations are in the ascendant; those cases which are diagnosed as brain fever, meningitis, or cerebro-spinal meningitis. These are the cases in which an inaccurate diagnosis is most liable to occur and which is so often followed by such disastrous results.

As long as the best treatment for typhoid fever, known to the medical profession, aimed only to ameliorate the most perilous symptoms as they presented themselves, it did not, perhaps, greatly signify when an exact diagnosis was made, or indeed, whether or not it was ever correctly made, but we are approach-

Helen McC., age 6 years and 3 months; date of admission, Aug. 22, 1894.

ing a more enlightened era. In reality, the day has even now dawned upon us in which the treatment to a fatal end, of a case of typhoid fever with a temperature of 105 degrees, as a case of indigestion, with inefficient antiseptic medicine, starch and laudanum injections, and cooling baths, is no longer admissible.

The physician who respects the Hippocratic oath and does the utmost in his power for his patient, must acquire skill in differentiating betwixt those diseases which can and which can not be benefited by the abortive treatment of typhoid fever.

Without entering into the field of speculative controversy, it may be generally stated, that any of the so-called microbic diseases, such, for instance, as diphtheria, malarial fever, measles, scarlatina, cholera infantum, etc., would lose much of their fatality if treated on the same general principles which I

have so often advanced for the treatment of typhoid fever.

In the treatment of typhoid fever in children, the first and most important step is to thoroughly asepticize the alimentary canal, and to eliminate as much as possible of the specific poison, by free catharsis and diuresis.

This can be effectually done in older children, with the tablets and soft capsules described in a previous paper, published in the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*. In younger children, my method of procedure is to begin the treatment with the following powder:

R. No 1—Podophyllin resin . . .	grains 1.	06
Mercurous chlorid, mild . . .	drachms 1.	4
Guaiacol carbonate	drachms ii.	8
Menthol	grains x.	60
Eucalyptol.	q. s.	qs.

Of this powder I give to a child 1 year old, $\frac{1}{2}$ to 1 grain every hour or oftener, if the case present very severe symptoms. I order each dose of medicine to be washed down with large draughts of distilled water, urging the child to drink as much as possible between the doses of medicine. These doses of the powder should produce free catharsis during the second period of twenty-four hours. Should diarrhea be present before treatment is begun, the indication for the antiseptic medicine is all the more urgent and nothing should be exhibited that could in any way interfere with its action or its administration. As soon as the free movements of the bowels change in color, or the absence of odor shows that the physiologic effect of the antiseptic has been secured, the remedy may be given in smaller doses and less frequently. If the carbonate of guaiacol in the powder is insufficient to produce the desired condition, it may be given separately or combined with eucalyptol in olive oil or any other suitable diluent. If the temperature continue long at 105 degrees, guaiacol and eucalyptol may be used externally, or an occasional sponge bath may be given.

DISCUSSION ON PAPERS OF DRs. NOYES AND WOODBRIDGE.

DR. WILLIAM OSLER, of Baltimore—In typhoid fever I think we are agreed that young children are really not so susceptible as adults. Take an epidemic like that Plymouth, where many young children are exposed, and yet we find the percentage of susceptibility among them not so great as in adults. There is, therefore, less susceptibility on the part of very young persons. In a large number of cases in children, the disease pursues a milder course. There are many practitioners who have observed numerous cases without a death, and nearly all of us may have had a series of thirty or forty cases without losing one. I have treated a series of fifty-three cases without a loss; again, in another series of cases there would be considerable mortality.

An important point referred to by Dr. Noyes and others, is in reference to the simulation of typhoid fever by other diseases. That is to say, the frequency with which typhoid fever begins in children with head symptoms. This fact requires constant emphasis. The disease may set in with severe headache, or crampy attacks, or general twitching of the muscles. Another point that has been referred to is the anatomic diagnosis of typhoid fever. It is not a new observation that there are many cases in which the Peyerian glands are enlarged, and where there are those febrile influences at work. There are other cases where we meet the typhoid bacilli not so much in the lymphatics, as in the spleen and other parts of the body. There are two or three recorded observations in which the disease was shown definitely to be typhoid fever by bacteriologic examination, where the Peyerian glands were little or not at all affected. Typhoid septicemia may be due to general invasion of the blood or organs by typhoid bacilli. Several such instances have been placed on record.

Now we come to the treatment of typhoid fever, which of course, is the burning question. It is difficult really to

know what to say about the treatment, and in relation to the statement which Dr. Woodbridge makes, it is a question whether it is not better to say nothing at all. When a man comes forward with such emphatic statements as Dr. Woodbridge makes, it startles us. We are not accustomed to them in the medical profession. It is an innovation to meet with such an emphatic statement as the Doctor makes, namely, that there need be no case of typhoid fever resulting fatally. He must know his disease well to say that, and you have to know that which he does not appear to know—that typhoid fever is not a disease in which the bacilli live on the surface of the bowel, but that typhoid bacilli live in the tissues themselves, and what can you do to disinfect the intestine with such a mixture as Dr. Woodbridge describes?

It is astonishing what a degree of credulity we have in the medical profession. We all have it in a measure, and it is painful that it is so. I am not one of those who cry out: "Can any good come out of Nazareth?" There is just as good work done in Youngstown and similar places, as in Baltimore or Philadelphia; but I do say that such emphatic statements should not be made, except when based upon a long list of cases, and upon cases studied more rigidly and thoroughly than Dr. Woodbridge seems to have studied his, particularly with reference to the question of diagnosis.

I was extremely grieved to hear the jokingly ungallant remark of my friend, Dr. Adams. The character of his resident physician must be very exceptional. I do not think I ever had to deal with a resident physician into whose hands I would intrust the giving of a typhoid fever bath. I think it should be given by an intelligent nurse. (Laughter.) Doctors have not the patience, moreover, their skins are too sensitive; it is well known that the skin of the hands and arms of the female is much less sensitive than that of the male, and woman alone can give the thorough frictions of rubbing which form such an essential feature in the treatment. I am sure the Doctor's list of mortality would be very greatly reduced if he were to instruct his nurse in the matter of giving the bath, and not trust so much to his resident physician. (Laughter.) I am a warm advocate of the Brandt method, have used it with the usual success that attends that method in the hospitals, and have reduced the mortality by from 6 to 7 per cent., varying with the severity of the cases. There can be no question that in the hospitals throughout the country the mortality may be reduced by that percentage if the Brandt method is introduced, and the bath is trusted to the nurse. (Laughter and applause.)

DR. PEPPER, of Philadelphia—We have not said the last word as to the diagnosis of typhoid fever, nor as to any particular method of diagnosis. We have assumed at times that we knew all the affections. There are many that await discovery, and these display themselves in adults and children in such manner that at times they resemble affections with which we are more familiar. We must apply ourselves to an immense series of typhoid fever cases as occurring at all ages, and in different localities, because age and locality modify typhoid fever preëminently, and we must apply a more defined diagnosis than not only is applied to-day, but perhaps more defined than our knowledge of physiology will at this time permit, before we can attempt to dogmatize in reference to this disease.

I would urge, then, the greatest caution in regard to this question of diagnosis and great reservation in drawing conclusions. How often have the conclusions of one generation been repudiated by the diagnosis of the succeeding generation, and it is not only to-day that we have the means of that refined diagnosis on which all these statistics of the future as to anatomic lesion will ultimately be fixed. I have been treating children for thirty years, and have been trying to diagnose typhoid fever in children for over thirty years, and I feel great modesty in regard to the matter, because I find myself making as great blunders to-day as I made many years ago, due, perhaps, to giving too much attention to the later methods. This is so in regard to every test, except that of pure bacterial culture, and upon that, I think, is going to rest the diagnosis that shall stand the test of time.

I have treated a long series of typhoid fever cases without a death, and have also treated a long list of typhoid fever coming from the same communities, with the same care and same remedies, and have had disastrous results in a certain proportion of cases. I have used the Brandt treatment rigidly, and have had patients to die after it had been used with the utmost care. When we come to the question of treatment, I would unhesitatingly give my acquiescence

to Dr. Adams' position. It seems to me that with the evidence before the world to-day, drawn from every country in the world, in hospitals, and in private practice, that the medical practitioner who does not use the cold bath treatment in infectious diseases is derelict. It appears to me that he must be prepared to use it when certain conditions arise. I think, also, that the man who depends absolutely upon it, and applies it in a strictly routine way, without reference to the qualifications of particular cases has not yet learned the resources of his art.

I think the Brandt treatment as liable to abuses as any other treatment that has been brought forward, or that ever will be brought forward, but that in dealing with continued high fever infections—continued fever—it is the best method of treatment, is evidenced by the most convincing proof. It is perfectly compatible with other elements of treatment. I am less of a skeptic than my friend Osler, as regards medication. I believe myself that in a disease like typhoid fever, where we have a large anatomic lesion, as a rule, he is perfectly right in saying that we should remember that it is not a question simply of intestinal lesion. Some symptoms are so virulent that the system becomes saturated with the poison to such a degree that no treatment will save that subject. But in the ordinary cases, in the majority of instances, we have those intestinal lesions as a source of abiding danger, as a source of many symptoms.

I believe that upon the diet largely depends the extent to which this intestinal lesion may develop. I believe this in consequence of a very long and extensive observation of the disease, continued after the introduction of the Brandt method, and I believe in the use, at the earliest moment suspicion enters the mind of the practitioner that there may be an infection and symptoms similar to typhoid fever, of some remedy, because of its harmlessness, which shall exert its influence upon the intestinal lesion—antiseptic, if you please, or a sedative. We should apply some remedy to affect the intestinal walls. I do not attempt to dogmatize as to what that remedy shall be. We are not going to do any harm if we follow that up by the Brandt treatment. Some of the formulas I see published, I should not consent to take into my own stomach if I had typhoid fever, and I do not think they ought to be administered to patients. It is well to apply those remedies that are harmless, and I believe that before the Brandt treatment comes in there is an opportunity for direct local treatment of the mucous membrane by rigid diet, and by such medication as may, to some degree, influence the extent to which the disease may progress and limit the subsequent course of the case. Once let the case reach the end of the second week, and I do not think anything in the world will affect remedially the intestinal lesion. That is the time when the Brandt treatment is our sheet anchor, as it were, but I would not pin my faith to any one specific treatment. I think it is dreadful to say the treatment of typhoid fever must be confined to the antiseptic treatment or the Brandt treatment. I should not like to say that the successful treatment of typhoid fever depends upon any particular treatment. I plead for less dogmatism. (Applause.)

DR. J. A. WORK, Elkhart, Ind.—I am not prepared to accept any one course of treatment, without medicine or with medicine. I am very much pleased with what was said by the gentleman just preceding me, in reference to his liberality in treating typhoid fever. I believe that we made a mistake in former years in the treatment by not beginning in the very earliest stages to eliminate it, as I believe that the early effort at elimination is the keynote of treatment in typhoid fever, or in the treatment of any zymotic disease. I advocated this at Milwaukee two years ago. I had experience before I advocated that treatment, and have had experience since. It is a fact that we are too often called too late in the disease, and consequently too late to apply effective eliminating remedies. Eliminate first, and then neutralize at the same time by antiseptic remedies, reduce the fever by sponge bath or by the Brandt treatment. We must realize that we have a human being to treat, and not a disease alone.

DR. GEO. N. ACKER, of Washington—I think the true diagnosis in these cases is often made when the case is over. In Washington we have a great many cases of typhoid fever in the Children's Hospital. Dr. Adams and myself have had a number; he lost one and I lost two under treatment by different methods. One of my cases was complicated by pneumonia and died, and the other suffered from perforating ulcer. The Doctor and myself are connected with the same hospital, and treat about the same class of cases. He sees a better class of cases than I do, because he has more patients

than I have. I give more medicine than Dr. Adams, and always have done so. If I see a case early enough, I give calomel in small doses and then I give sulphuric or muriatic acid in small doses. I always apply the sponge treatment, when the temperature goes over 103, but I rarely ever resort to the Brandt method of treatment, for the reason that I have found that it depresses the heart action; I have had poor success with it, and I have charts to show it. I maintain that this great change in temperature is more injurious than beneficial. Dr. Adams proves by his charts that the temperature has fallen from 105 to 97 degrees. I do not believe that is good. Dr. Adams says he always wants the resident physician present. So do I, because I would not trust any nurse with a case where the change in temperature is so great. The Brandt method does not shorten the course of the disease, and I have discontinued it.

In regard to Dr. Woodbridge's paper, I do not understand his cases of typhoid fever. We do not have such cases in Washington, where every patient gets well. I have had in my hospital practice forty cases, without a death, but then I have had deaths after that, and I think that, in the long run, the Doctor will find that he will have the same experience.

DR. ATKINSON, of Baltimore—The discussion seems to hinge upon two points—the question of diagnosis and the question of treatment. A great deal of the confusion which exists in regard to the diagnosis of typhoid fever in children grows out of the expectation so often held that typhoid fever runs a typical course in children, when it does not. In most cases of typhoid fever in children they are typical. It has been agreed generally here that typhoid fever nearly always runs a typical course—a favorable course. My experience is that typhoid fever in children runs a favorable course; but I think our results will be more satisfactory if we disabuse our minds of the idea that certain characteristics invariably must be present. As soon as we are able to exclude the tangible affections that we can attribute to other causes, to spinal meningitis, for instance; as soon as we are able to definitely exclude those agents that are capable of recognition, and have a fever that is continuous, day in and day out for ten days or two weeks, that we are unable to control by the ordinary remedies; we are then almost certain that we have a case of typhoid fever to treat. In adults, errors of diagnosis of this kind often result disastrously, but in a child it is not so disastrous if we are not too zealous in the activity of our treatment. Most cases of typhoid fever recover and the question of treatment, I think, becomes quite a small one. Mild cases of typhoid fever are best treated if left alone.

In my experience, constipation is the rule in typhoid fever in children, and not diarrhea. If we supply nourishment and treat the symptoms by the usual efficacious methods, we find that mild typhoid fever will terminate in the usual time. When the temperature rises, I have no hesitation in giving my testimony in support of the statements of Dr. Adams and others, to the effect that the Brandt treatment is the proper treatment. As for the injury inflicted by it, as referred to by Dr. Acker, I think that is for the most part imaginary. After the bath is administered, the temperature will soon rise to the same degree as prior to the bath, and even when we give forty or fifty or sixty or seventy baths, we find that within a few hours the temperature has again reached the point at which it was prior to each of these baths. Nevertheless, the benefits arising from the bath are apparent. Previous to the bath we find the tongue hard and dry; after the bath it has a soft coating. When the child protrudes the tongue, it comes out readily and goes back with a jerk, showing the activity with which the child responds to the order. The use of the bath when administered in an unprejudiced way, will give us the best management of typhoid fever, whether in adults or children. I think the administration of medicine to be carried along the intestinal canal is commendable. The administration of an agent that will lessen the offensiveness of the stools is desirable, but as for conduction to the recovery of the patient, I think it is not worthy of consideration.

DR. PARKER, of Massachusetts—Typhoid fever in children is like typhoid fever anywhere else. It is a serious disease and demands our most careful consideration. In the hospitals of Vienna and Munich I found that very great concern was given to every detail, and more particularly to the details of the hygiene of the bed. There is one point here which has not been touched, and that is the stimulation of the patient. To use brandy or whisky, or the various preparations which we have administered for that purpose, I think is a mistake. I believe strong stimulants act injuri-

ously, are not easily controlled, and are not advisable. Therefore, it seems to me that the Munich treatment of red wine is altogether the safest and best stimulant in typhoid fever. In regard to the intestinal antiseptic, I think this of great importance. I have seen patients show great improvement when attention was given to the administration of intestinal antiseptics.

Dr. BURNS—If one attends the local society, then the county medical society, then the convention of the State society, and finally attends the convention of the National society, with a view to acquiring some practical knowledge of the etiology or diagnosis of yellow fever, or of cerebro-spinal meningitis, he finds himself sadly disappointed. I live in a malarious country, and am constantly beset with the difficulties that appeal to all medical men who live in similar countries. I am convinced that in cerebro-spinal meningitis, its relation to typhoid fever and some other diseases is such that the more one studies either typhoid fever or cerebro-spinal meningitis, the more he is confused by the similarity that exists between these diseases. As has been said here to-day, in different ages it was thought that the solution of the problem had been made, but time proved the fallacy of the hope, and now the solution of the problem of diagnosis seems to be as far off as ever. The bacteriologists have deluded themselves as others have in the past. We find the different masses constantly opposing each other, and thereby impeding progress.

Dr. LARRABEE, of Louisville—We find all sorts of opinions on the subject of typhoid fever. Sanitary conditions have much to do with typhoid fever. Typhoid fever will prevail anywhere that the child gets the poison, whether it be one year or any number of years old. The point of greatest advancement in regard to the diagnosis of typhoid fever has been the elimination from practice of the several diseases that were supposed to conflict. That is the elimination of so-called remittent fever. This remittent fever has been determined in most instances, if not in all, to be the fever under consideration, and then the withdrawal by the famous author himself of another disease renders it still easier to diagnose typhoid fever. So that the disease in childhood is made plainer by the elimination of these other diseases. I agree perfectly with the first gentleman, who said that these cases are to be diagnosed by exclusion. We are dealing with a fever that is interrupted by quinin, and particularly when there is the symptom which has not been alluded to, but which I think makes a bedside diagnosis as soon as any other, and that is the thing from which it takes its name—the typhoid, the smoky hue.

The gentleman spoke of a child protruding and pulling back the tongue quickly. But there is more in the condition that originally named the disease. Unless that condition be present, I should suspect something else. The next question was the headache manifested in the child. It does not continue to be a symptom after the second or third day, and the continuation of the fever is a good symptom of typhoid fever. As to the duration of infantile cases, it is usually observed that in the common cases there is a cut-off. That is the time we have the most decided symptoms of poison. When we reach the limit of 14 or 15 years, I think there is no distinction in the two cases. There is a crisis about the fourteenth day.

Another point is that we do not shoot any worse by having a mark to shoot at; that is, having a definite object in view. The claim is made that in the Brandt method, if it be very carefully guarded, as Dr. Adams says, and giving a drink of whisky and a little opiate, the mortality is greatly reduced. The Doctor says it also makes a patient comfortable. Is that the only object we have in view in typhoid fever? We have a chart here, presented by the Doctor, which, stretched across the room like a Chinese scroll, gives the temperature covering a period of six or seven weeks. This patient recovered. Now the question is, whether that treatment was better than if an attempt had been made to thwart the disease, as spoken of by Dr. Woodbridge. Whether it is better navigation for the sailor to pay attention to only one course, and cast the lead to see where the safety lies, or whether it is better to take a certain observation and ascertain the true position. In other words, whether the thermometer is the only thing to go by, or whether it would be better to take into consideration other symptoms; whether it is curing a case to suppress the temperature for a given length of time, admitting that it again returns to the point it had previously attained. Is not the patient under that treatment more liable to be worn out than under the other treatment? I am not prepared to indorse one method any more than another. It does seem to me that having a chart

and knowing where we are going, is a great deal better than throwing the lead to see where you are, at one time, as compared with another. The only comment I have to make, is that we are about where the sailor was when he tried the lead over on Nantucket. We have not progressed as much as we thought we had.

Dr. BURR, of Chicago—I make two pleas: a plea for the earlier employment of hydropathy in typhoid fever, and a plea for the treatment of the temperature in the disease. If there is anything in any plan for the cure or control of any disease, it should have its physiologic basis. I have not heard a word said to-day for any of those remedies, except the so-called intestinal antiseptic remedies. If it is worth while, as Dr. Pepper has said, to institute your method of treatment six or eight or ten days after the disease has begun, when the temperature has reached 104 or 105, it is certainly worth while to have that treatment in the beginning of the disease, and if it is of any avail whatever in the control of it, it has the additional merit of being resorted to at once. Do not wait for the diagnosis. There is no treatment so harmless and so easy. I want to say that in my own experience, and from what I have read of the statistics of the most eminent practitioners, there is no method so appropriate and so safe. Until we get the all-powerful specific, we must use controlling methods.

I want to say one more thing in regard to temperature. It seems as though we have been fighting fever on the score of temperature. Temperature is a symptom, not a disease. It is not high temperature that ails your patient, it is poison, and if you have not the direct specific for the poison, or for the control of it, and if you can stimulate the nerve cells and stimulate the alimentary cell itself, whether it is in the muscle or nerve, or in the protoplasm of the blood itself, you are going to help your patient that much in weathering a severe disease. I will also say that in the carrying out of this hydropathic proceeding, it can be done without harshness by following plans which I hope to place before you to-morrow, in the use of the portable bath tub, and without disturbing the patient, by lifting out of bed to place in the tub. You can very soon educate the most delicate person to take the bath by this mode.

Dr. S. SOLIS-COHEN, Philadelphia—The great mistake that is made by those who criticise the Brandt method of treatment, and indeed by some of those who use it, is in reference to the reduction of temperature. A reduction of temperature is an incident in the treatment of typhoid fever. It is an index of the severity of the process that is going on in the organism. It is due, I believe, to poisoning by two things—by metabolic products and by poisons degenerating within the individual attacked by the typho bacillus, and not directly due to it.

The treatment by cold bathing instituted early in the course of the disease, carried out systematically and with judgment, by trained nurses, under the supervision of the physician, does two things: first, it soothes the excited nervous system of the individual. This excitement of the nervous system is one of the most serious features of the disease, and gives rise sometimes, as stated here, to the most puzzling symptoms. I remember very well an experience in my own house—fortunately the child recovered—in which the nervous symptoms predominated over everything else in the case, and were obscuring to the diagnosis, and prohibitive of the treatment by the cold bath, and led to the prolongation of the case. Cases are rare where the nervous dread of the bath prevents continuous application. In some cases I have seen a pronounced nervous excitement calmed and the delirium allayed by the use of the bath, and the instance cited by my friend, Dr. Larrabee, of the child quickly drawing back its tongue is an argument in favor of this method of treatment, because that is what it was due to.

The Brandt treatment is not an anti-thermic, but an antityphic treatment. It allays nervous excitement. Secondly, it stimulates metabolism, the kidneys and bowels are all set at work, and there is an increased throwing off of the poison to which typhoid fever is due. I indorse the words of Dr. Pepper, when he says that the physician who fails to give the patient the chance that is afforded by the cold bath is guilty of neglect. I do not advocate applying the bath indiscriminately. I believe there are cases which show in the beginning that they are going to run so mild a course that the bath treatment is unnecessary, but, on the other hand, I do not believe that it is doing any harm to steer a safe course and resort to the use of the Brandt treatment as the safest course. There are toxins produced in the intestines under the unhealthy condition, poisons independent of typhus bacillus. I believe that by the early use of some

antiseptic drug this might be prevented. What that shall be, I will not take the time to discuss.

Another point I wish to call attention to is this: it is absolutely necessary, in order that the Brandt treatment may be properly carried out, that the patient after the bath shall be put into a warm bed and dried, warm applications applied to the feet, and a little alcohol should be given, just as before the patient is put in the bath. They should not be allowed to remain in the bath until the temperature falls so much as 7 degrees. I think a fall of a degree or two is the safer course. I am satisfied that the use of the Brandt treatment, with proper safeguards, will materially reduce the mortality in typhoid fever cases.

DR. WOODBRIDGE, Youngstown, Ohio—I feel a little embarrassed. My peculiar theories have not been quite so severely criticised as I have been accustomed to have them criticised. Consequently I have not very much to answer. One criticism I revert to, made by the distinguished gentleman, Dr. Pepper. Does he mean that I would be derelict in failing to give my patient the benefit of the Brandt treatment, when after nineteen years of experience in treating hundreds of cases of typhoid fever, I have had no death for thirteen years, when my brother practitioners had as many deaths as in former years, not to follow the Brandt treatment? Would it be wise for me to abandon the method I have pursued with such success? I am just as certain as can be, that Dr. Pepper will within five years be a better advocate of what I have outlined than he is now of the Brandt treatment. A treatment that will take hundreds of cases of typhoid fever safely through an attack, with no delirium, with no headache after the first two or three days, with the tympanitis disappearing within forty-eight hours of beginning of treatment, with an average duration of disease of less than ten days, is better than the Brandt method.

It seems to me that the position of the medical profession, to say that in typhoid fever it is impossible for the medicine to abort the disease, while saying that nature can abort it, is an inconsistency.

DR. OSLER, of Baltimore—Tell us about the drainage of Youngstown.

DR. WOODBRIDGE—We empty our sewers into the river and let the lower portion of the city have the benefit. (Laughter.) Seriously speaking, there is a large portion of our town above the waterworks, where there are no sewers and the drainage all washes into the river.

DR. ADAMS, of Washington—I believe I have been misunderstood here. Dr. Cohen has manifested a disposition to help me out. In speaking of the nurse administering the bath, I meant that it should be done under competent supervision. The doctors do not do anything so far as the handling of the patient is concerned, but help the nurse to put the child, if a large one, into the bath. Almost a mutiny, so to speak, occurred in the hospital a couple of years ago. The doctors said that they did not care about being disturbed at 2 o'clock in the morning for the purpose of supervising the bath, and I decided with the nurses that they had a right to supervise the baths. As Dr. Cohen says, there are cases of typhoid fever in which there need be no treatment of this kind. If the temperature does not rise, I do not see the necessity of employing the Brandt treatment. I have tried the intestinal antiseptic, but have not seen any especially beneficial results from it. I have not tried the remedy advocated by Dr. Woodbridge.

HEMORRHAGIC PLEURISY.

BY FRED. W. D. EVELYN, (EDIN. UNIV.)
PRESIDENT SAN FRANCISCO POLYCLINIC.

A. B., age 45; miner: family and personal history good; no specific disease; moderately alcoholic; general nutrition good. Stated that two weeks ago he had felt a sharp pain in right side; did not last long; experienced no unpleasant sensations, no fever, he thought, although face was flushed. Saw a doctor, but was not examined. Just before presenting himself for examination at the clinic had been a little short of wind but no other trouble. Slight cough; no spit; appetite poor; bowels constipated; urine scanty and high colored. On admission face was flushed, slightly anxious; no dyspnea; tongue moist; white fur; lips, slight cyanosis at angles;

temperature 100 degrees, respiration 32, pulse 80. Tension marked, regular. Physical examination: chest regular and uniform in outline; apex beat normal in position; no abnormal pulsations on chest wall; veins not varicose; movement free on left; retarded on right inframammary and lower axillary region; no vocal or friction fremitus; percussion: left side normal; right, area of inaction referred to above gave a dull toneless note accompanied by sense of resistance; other areas, note somewhat tympanitic. Auscultation; left side, harsh breathing over all; right, dull area; general absence of normal breath sounds, but in certain areas large bubbling râles, simulating redux crepitations could be heard. Voice sounds absent, except at points where they seemed to be conducted to chest wall. Effusion into pleura was concluded to be present and probably of a non-homogenous nature. Notwithstanding the relatively high level reached (fifth rib) there were no signs of visceral displacement or positive intrathoracic pressure. Aspiration gave a fluid of a dark pink color, containing a large proportion of blood.

Patient complaining of great pain and distress. The aspiration was stopped, only five ounces being removed; patient was seen daily. Bowels and kidneys were kept somewhat active. No rise in temperature, no symptoms, save slight pain and very slight shortness of breath were complained of. In the absence of all indications of urgency, I did not aspirate for one week, then drew off eighteen ounces of a similar fluid; later on abstracted twenty ounces; no symptoms whatever supervened; the temperature became normal; the lung gradually filled out to its normal extent, but at the end of five weeks physical examination failed to detect any indications of fluid and the auscultatory phenomena were perfectly normal. Three months later, lung was perfectly resilient and the patient in good health. No heart or other lesions were present.

Some points of interest in this case may be suggested. The most complete and perfect return of the lung to its normal condition; the extensive effusion and the almost negative constitutional and mechanical symptoms; the sudden onset sufficiently pronounced to admit of it being considered acute.

Stasis: a mechanical congestion resulting from pulmonary congestion, pneumonia, etc; the absence of secondary causes of hemorrhage, cancer, miliary tuberculosis, renal, hepatic or splenic lesions must not be overlooked. Their absence would almost exclude the possibility of the case being one of hemorrhagic pleurisy following hemothorax. The effusion was not simply a solution of hematin crystals but contained blood discs and admitted the conclusion that the case was one of rapidly forming effusion; friction and accordingly pain, being of a correspondingly short duration; active congestion and either an excessive diapedesis of the red corpuscles through the vessels, or the rupture of a vessel with a free hemorrhage into the cavity.

The New England Climate. From the *Boston Globe*:—"Change of climate is what you need," said the high-priced physician, after he had listened to all the details of the patient's case. "Change of climate!" exclaimed the patient in surprise; "Why, man alive, I've never had anything else. I've lived right here in New England all my life."

SOCIETY PROCEEDINGS.

American Orthopedic Association.

Abstract of the Proceedings of the Ninth Annual Meeting, held in Chicago, Sept. 17, 18 and 19, 1895.

The society met in the Columbus Memorial Building, 103 State Street, and was called to order by the President, Dr. JOHN RIDLON, of Chicago.

After the transaction of some routine business, the President delivered his Address. He selected for his subject

THE GROWTH AND PROSPERITY OF THE AMERICAN ORTHOPEDIC ASSOCIATION.

He said if one thing more than another had been instrumental in bringing about the present healthful organization, it was a wisely framed constitution and by-laws and a strict adherence to their requirements. To become a member the candidate must be personally known by at least two members of the Association who voluntarily nominate him for membership, and he must have a creditable record of orthopedic work either as a writer, a teacher, or a clinician.

The generous expenditure of practically the entire income of the Association in the annual publication of its volume of Transactions had played no unimportant part in the development of the society. In this regard, President Ridlon urged upon the members the serious consideration of the publication of a monthly or, at least, bi-monthly journal, which shall contain all the papers read and discussions before the Association and abstracts of all other worthy publications upon orthopedic subjects, whether first appearing here or abroad. Such a journal could be issued at little, if any, increase upon the cost of the present Transactions, and in the hands of an enterprising editor could within a year or two be made almost self-supporting.

Dr. Ridlon closed his address by paying a tribute to the memory of Drs. Little and Detmold. Wm. John Little was born in London on August 17, 1810, and died July 7, 1894, being nearly 84 years old. Wm. Detmold was born in Hanover on Dec. 27, 1808, and died in New York Dec. 27, 1894. In reviewing the record of the long and active lives, and of the work accomplished by Dr. Little and Dr. Detmold, one feels that truly there were intellectual giants in those days.

Drs. R. W. LOVETT and JOHN DANE, of Boston, contributed a joint paper entitled

FLAT FOOT.

They submitted the following conclusions: 1, that the feet of the infant at birth are not flat; that the tracing at that time resembles the adult normal foot; 2, that a body of fat develops under the arch which gives the appearance of flat foot for some years, and that at the age of 4 or 5 years this is absorbed; 3, that the smoke tracing is not a perfect method of studying abnormalities of the arch of the foot, because it fails to detect the slighter cases or to record pronation; 4, that the element of pronation is more constant than breaking down of the arch of the foot and may be entirely separated from it; 5, that the condition of pronated foot without breaking down of the arch of the foot should be recognized and not confused with flat foot; 6, that the treatment of pronated and flat foot is the same, and consists in the use of proper boots, the application of a pad or plate, the stretching of the gastrocnemius muscle where it is shortened, and in the routine use of massage if obtainable, and always of exercises to develop the muscles which hold up the arch.

Dr. S. L. McCURDY, of Pittsburg, read a paper on

CONGENITAL ABSENCE OF RADII WITH OPERATION.

The patient was five months old, birth at full term. Presentation normal. Complete absence of the radii, with abnormal relationship existing in the blood vessels and soft structures of the forearm, otherwise child perfectly developed. Operative interference was not advised, for the reason that no successful method had been invented. In the worst cases, where there is much bony deficiency, the choice lies between amputation and doing nothing. Professor Bardenheuer two years ago presented a new method for the operative treatment of these deformities. His operation in the forearm consisted in replacing the defect at its lower part with bone, and thereby permanently correcting the deformed position of the hand.

The operation is performed by a longitudinal incision, the distal end of the ulna and the carpus are exposed, and the first isolated from its attachments. The ulna is then split through its middle into a radial and an ulnar section. These

are separated by allowing the carpal bones to come up between them. By means of a nail through each side, the ends are fixed to the carpus. A plaster bandage is applied, and left on for four or five weeks. This operation is easily carried out. It has been done by Bardenheuer three times, and the results in all three cases were good, both from a functional and cosmetic point of view. In all cases the deformity was permanently corrected. The same principles may be adopted in the treatment of other defects. In cases of congenital defects of the tibia or fibula the same operation has been done once in each. The best result was obtained in the fibular defect.

March 1, 1895, operation was done, the desire being to adhere to the method described as near as possible. It was not possible, however, to follow the method. The soft structures, tendons, etc., were so much shortened that to attempt to shift the end of the ulna across to the center of the carpus would have been impossible except by a virtual amputation of the arm. To have split the ulna and wire the carpal bones between these ends would have been impossible. The only method was to sever the ulna at a point where the free end of the upper fragment could be brought to the semilunar. The semilunar was curetted and drilled, and after drilling the ulna these bones were adjusted with silkworm gut. It was necessary to tenotomize the tendons upon the radial side of the forearm before the hand could be straightened. A number of arteries were severed and required ligation. The cut through the soft tissues was made obliquely across the forearm, beginning upon the dorsum of the wrist, upward and around under the forearm, the object being to allow the structures to slide upon each other, and then sutured in the corrected position, thus avoiding the gap that could otherwise be left after a cross section. After dressings were applied, the hand was put up in plaster-of-Paris. Primary healing. The operation was done on the left hand, and a second operation was planned for the right arm, but the patient died with pulmonary tuberculosis five months afterward.

The author reported a case of congenital deformity with a decided history of natural impression. Mrs. S., whose husband was a railroad conductor, when about six weeks pregnant, was startled by the appearance of a crowd of men with a man on a stretcher, thinking it was her husband. She has a habit (when startled or in grief) of grasping the fingers on the left hand including the thumb, just below the knuckles, by the right hand. While the injured man was not her husband, the impression was imparted to her unborn child.

Dr. A. M. PHELPS, of New York, reported a case of congenital dislocation of the shoulder joint, and described an operation for its relief.

REMOVAL OF THE ASTRAGALUS FOR TALIPES VALGUS.

Dr. JAMES E. MOORE, of Minneapolis, read a paper on this subject, in which he said that the modern non-operative treatment of talipes valgus was so satisfactory that it is rarely necessary to consider operative measures. In acquired flat foot, several operations have been tried in extreme cases, and among them Ogston's operation, which had probably been performed more frequently than any other, but at present it did not seem to have any very enthusiastic advocates. The scaphoid had been removed, but had not been followed by flattering results. The writer had studied this subject carefully about two years ago when the following case fell into his hands. The patient was a woman, 20 years of age, who had cut the internal lateral ligament of the ankle when she was a child by stepping on a piece of glass. An examination showed that the uninjured foot showed a natural tendency toward flat foot, and the injured foot showed extreme flat foot, with the inner side of the great toe turned almost directly downward. She had grown gradually worse for some years, so that when she came to him she had been obliged to give up her employment as a domestic on account of the severe pain produced by standing or walking. On June 26, 1894, chloroform was administered with the hope of forcibly correcting the deformity, but owing to the extreme rigidity of the foot, failure was feared, so the patient's consent was gained to resort to a cutting operation if it was found necessary. It was found impossible to overcome the deformity by manual force, and an operation was decided upon. The displaced astragalus formed the bulk of the deformity and was the keynote to the trouble. This, the author decided to remove, which he did through a longitudinal incision in the inner side of the foot. The foot could be immediately placed in a very satisfactory position. The usual surgical dressing was applied and the foot held in proper position by a plaster-of-Paris

bandage. The healing was prompt and satisfactory, and in about two months the patient began to walk. There is a marked improvement in the position of the foot. A photograph was shown, taken about one year after the patient began to walk, showing that the ankle, which was atrophied, had developed considerably. The result of the operation was more satisfactory from a practical than from an esthetic point of view. The patient still complains of some pain. When she stands much or walks more than usual, the foot is somewhat swollen in the evening, but she is now at work. While she is in every way better than before the operation, the result is not perfect, but the writer hopes that eventually she will be quite well.

DR. JOEL E. GOLDTHWAIT, of Boston, read a paper entitled

TENDON TRANSPLANTATION IN THE TREATMENT OF DEFORMITIES RESULTING FROM INFANTILE PARALYSIS.

The purpose of this paper was to call attention to the possibility of furnishing better mechanical attachments for certain non-paralyzed, or only partially paralyzed, muscles, as a part of the treatment of infantile paralysis. A certain number of cases were reported with results that were most gratifying, and from which it appears not unreasonable to class tendon transplantation with tenotomy and the other surgical procedures which have a place in the treatment of this condition. At the knee, undoubtedly, tendon transplantation could be employed to advantage in a certain limited number of cases, and possibly at some of the other articulations, although the best results are to be looked for in those portions of the body where the tendons are well formed and lie superficially. The operation is not to be attempted upon the tendons of muscles which are wholly paralyzed, except possibly in rare instances for the purpose of furnishing an additional support of a purely tendinous character. It is conceivable that in the foot, for instance, if the tendons on the inner side are more atrophied and offer less resistance than those on the outer side, these tendons might be attached to the inner side and thus increase the lateral support. This is merely a suggestion, however, it not having been tried practically, and the benefit to be derived therefrom would undoubtedly be slight. There is also a question as to whether or not, two atrophied tendons would unite firmly, although from watching the other cases, the author doubts if there would be any trouble on this account. The best results from tendon transplantation are to be obtained in those cases in which one group of muscles has been destroyed, leaving the antagonizing or accessory muscles very little, if any, impaired. This results in a definite deformity which becomes more marked as the age increases. The best illustration of this is to be found in the condition so commonly seen in the foot where the gastrocnemius and the muscles at the inner side of the foot have been destroyed, the peroneal muscles retaining their normal contractility. The result is a valgus which constantly increases, both from the muscular contraction and from the faulty mechanical position in which the weight of the body must be received upon the foot in walking or in standing. This is also seen in connection with the anterior muscles of the foot; the anterior tibial and the extensor pollicis so often being destroyed leaves the peroneus tertius and the extensor communis digitorum, the only muscles to be used in flexing the foot at the ankle. This also results in a valgus which steadily increases. To correct these mechanical conditions and to use the non-paralyzed muscles to the best advantage, the author had operated upon four cases and given the tendons of the muscles new attachments.

Case 1.—A young woman, 19 years of age, who came to the Carney Hospital, October last, complaining of trouble in the left foot. When nine months old she became paralyzed, which partially cleared up, leaving the foot very weak, so that walking has always been difficult. This has been growing worse of late and there has been considerable pain, referred to the inner side of the foot under the inner malleolus. The left leg was one inch shorter than the right. There was marked atrophy of the left calf and the foot was in the position of extreme calcaneo-valgus. In walking, the weight was borne upon the inner edge of the heel, the anterior portion of the foot being turned outward fully 40 degrees with the normal axis of the ankle joint. The posterior muscles were all paralyzed, with the exception of the peroneus longus and brevis, and the tendons of these muscles, instead of lying in the groove behind the external malleolus had been drawn forward so that they rested on the outer surface of the malleolus near its anterior edge. With the tendons in this position the action of the muscles caused extreme valgus and slight flexion at the ankle, instead of extension

as should be the case. The anterior muscles were practically normal and, having no posterior muscles to antagonize them, their contraction caused such extreme flexion that the dorsum of the foot rested against the anterior surface of the leg. A short time after this, the patient entered the hospital and the following operation was performed: an oblique incision four inches long was made, so that it crosses the tendo-Achilles about one inch above its insertion into the os calcis. Through this wound the peroneal edges are exposed and divided at about the lower edge of the malleolus. The tendo-Achilles is then freed and the tendon of the peroneus brevis passed under this and attached to the tendon of the flexor longus pollicis. The tendon of the peroneus longus was then attached to the tendo-Achilles, after which the wound was closed, and a plaster-of-Paris bandage applied, holding the foot extended in order to relieve the strain as much as possible from the sutured tendons. One month later, a valgus plate was applied, and this has been worn since.

The method of attaching the tendons to each other is of great importance, and unless they are firmly joined the benefit of the operation is lost. The tendon to which the attachment is to be made is split and the end of the severed tendon, after it has been scored, is drawn through this slit, and securely held by two quilted sutures which are so placed that when tightened the outer tendon is spread out, furnishing a broad surface for union. The result was best shown by the photograph which was exhibited. The valgus has largely been corrected, and what remains is controlled by the plate, so that the tread of the foot in walking is quite normal. As a fair test of the result, during the last five months the patient has been doing general housework and has suffered no inconvenience from the foot.

DR. ROYAL WHITMAN, of New York, read a paper entitled A STUDY OF THE WEAK FOOT WITH REFERENCE TO ITS CAUSES, ITS DIAONOSIS AND ITS CURE; WITH AN ANALYSIS OF ONE THOUSAND CASES OF SO-CALLED FLAT FOOT.

The reader emphasized the importance of looking on the foot as a mechanism, and on the flat foot not as a deformity only, but rather as a weak or disabled machine. Attention was called to the function of the normal foot. That it was not only a support, but also a lever. If this activity or leverage was diseased or lost, the foot was subjected to great mechanical disadvantage. He laid particular stress upon the component elements which made up the weak or flat foot. These were: 1, the improper distribution of the weight upon the foot because of the pronation or valgus; 2, the displacement of the line of strain by the abduction of the foot; and 3, the secondary lowering of the arch.

The various predisposing and exciting causes of weakness were enumerated. The importance of the early recognition of the weakness and of the training of children in order that future disability might be avoided; the importance of the proper shoe, both in childhood and in adult life, and the treatment for the various grades of weakness and deformity were then discussed and illustrated by diagrams and casts.

In conclusion, the writer emphasized the following points: flat foot, in its surgical sense, is a compound deformity, of which the elements of valgus and abduction, the improper distribution of the weight and strain, are of vastly greater importance than the depth of the arch. The weak and flat foot can be cured, but only by the application of the simple principles that any mechanic would apply to a disabled machine whose structure and use were known to him; in other words, there can be no permanent cure of weakness and deformity unless normal function is regained, nor effective treatment unless it has this end in view. The term weak foot has at least this advantage, that it implies nothing that the student must unlearn; it is because of the misapplication and misapprehension of flat foot, and because of the associations which have so long obscured the rational treatment of the deformity, that the term has been discarded from the title of this paper.

DR. L. A. WEIGEL, of Rochester, N. Y., contributed a paper on "Metatarsalgia."

ON THE DEFORMITIES AND MALFORMATIONS RESULTING FROM ACUTE INFECTIONS IN BONE.

DR. ROSWELL PARK, of Buffalo, N. Y., read this paper, in which he said that clinically, there are three locations in which bone infections are most commonly met with—beneath the periosteum, in the epiphyses, and in the diaphyses. From the pathologic side, infections are of four main varieties: 1, the tubercular; 2, the staphylococcus; 3, the streptococcus; 4, the pneumococcus. To these may be added rare instances in which other organisms are primarily or second

arily present. Of these, certainly the more common is the tubercular form, whose manifestations are usually not acute. The other three may be grouped in a general way as pyogenic forms of invasion in which pus is practically invariably produced, providing only that sufficient time has elapsed. The author alluded to the acute miliary tuberculosis of bone which corresponds in most essentials with similar invasions of the lungs, and of which he had seen occasional examples. It is not quite so rapid as the pyogenic forms, and it may take two or three weeks to produce such destruction of bone as to necessitate operation. It stands, therefore, in intermediate position between the acute infections and the slower (usually the tubercular) lesions. Nevertheless, it is sufficiently acute to demand prompt recognition, and when recognized may often be relieved by prompt operative interference. The course of a bone disease will depend first upon the location of the lesion, and secondly upon its character. As showing the relative frequency of parts involved, of thirty cases observed by Kocher the disease occurred thirteen times in the tibia and eleven in the femur. Of ninety-eight cases collected by Leucke and Volkman, the femur was involved thirty-six times, the tibia thirty-four and the humerus eleven. Disease in the immediate neighborhood of the hip joint is about five times as common as in that of the knee. Comparing epiphyses with diaphyses, and accepting Schede's sixty-seven cases, we find that of twenty-eight cases in which the femur was involved, half of them were in the shaft and half in the diaphysis. In the tibia, of twenty-seven cases only nine concerned the epiphysis; and of seven cases of the humerus, two involved the epiphysis. With regard to necrosis, it concerned orthopedists mainly in this, that it produces in many instances a weakening of the bone which may lead either to fracture, deformity or curvature. Spontaneous fractures of necrotic bone had occurred under the writer's observation, and he remembers one case of necrotic femur which broke as he was lifting the patient upon the operating table. Incidentally, there is danger of cancer in some of these cases, for Volkman collected thirty-two cases in which old and fistulous passages became the site of epitheliomatous changes, and in which cancer was the final result.

DR. JAMES KERR, of Washington, D. C., followed with a paper entitled "Joint Disability Following Fractures."

DR. R. W. LOVETT, of Boston, read a paper entitled

AMBULATORY TREATMENT OF POTT'S DISEASE.

He considered this disease a very grave one, which ought to be treated largely by recumbency during the active stage, for the reason that we recognize that our apparatus is intrinsically imperfect on account of the nature of the problem. If we use apparatus, it seems to him that the proper use would be in a small way to vary the monotony of recumbency. Used in any way, we should remember that the position of the superincumbent weight is a most important matter, and that the chest and head should be thrown as far back as possible. Indeed, we see nature trying to throw the chin into this position continually. We should also remember that the higher up the body or backward pull is made, the less is required, and that when this limitation in the use of apparatus is accepted, its field will be more limited than it is now. The use of traction during recumbency seems to the author an advantage, inasmuch as it adds but little to the discomfort of the child and it manifestly increases the length, which it can only do by diminishing the curvature in the vertebral column.

DR. A. E. HOADLEY, of Chicago, exhibited and described a new

SPINE BRACE.

It was designed and adopted by him for the mechanical support of the middle region of the spine. The range of its greatest utility is the support which it affords to the spinal column between the middle of the lumbar and the middle of the dorsal regions, although its usefulness is not strictly confined to these limits. Inasmuch as the greater number of diseases of the spinal column requiring mechanical fixation occur within this region, its usefulness will be comparatively very great, if found to be efficient. In its simplest form the brace consists of a steel frame, a rigid chest pad and two aprons. The chest pad is adjusted in contour to fit the upper anterior portion of the chest. The pad in length is about three times its width and adjusted transversely, resting immediately below the sterno-clavicular articulations. Its real length, transversely, should be as long as practical without being interfered with by the action of the pectoralis major muscles in the movement of the shoulder. It should be made of sheet metal, hammered to give shape and rigid-

ity, covered and lightly padded. The author then described in detail the component parts of this brace, which he divided into four portions—an upper, a lower and two lateral portions. This brace will be found useful to orthopedic surgeons.

REPORT OF FOUR CASES OF SPONDYLITIS OF THE SECOND CERVICAL VERTEBRA.

A paper was read on this subject by DR. REGINALD H. SAYRE, of New York. Three years ago he brought before the Association some cases of spondylitis of the second cervical vertebra, as it happened that within a few months' time four cases came under his observation which presented almost identical lesions, accompanied by very similar deformities. These cases had now been without apparatus to support the head for a number of months. In all of them there was noted a small swelling at the back of the neck, at the level of the first or second cervical vertebra, which in each instance happened to be on the right side of the neck. In each case the chin was directed toward the right side of the body, the right sterno-cleido-mastoid muscle was rigid, the face looked downward, while the left ear was brought much nearer the corresponding shoulder than its fellow. In one instance, the face was deflected so far from the perpendicular as to be almost parallel with the floor, and pressed so closely against the clavicle as to cause an excoriation. The position of the head was in marked contrast to that assumed by patients with torticollis, due to contraction of the right sterno-cleido-mastoid muscle. Motions of the head in any direction were excessively painful, and the patients supported their heads with their hands almost incessantly. In turning to view any object the entire body moved as a solid mass without any rotation of the head. The jaw was opened with great difficulty in all cases. At the present time, all but one case can open their mouths freely, and this case has much more control of the mouth than formerly, and is enabled to swallow with much more ease. In all the cases the chin was so much depressed as to make swallowing difficult. These cases were treated by means of a support which consisted of a pelvis belt with two upright back bars passing upward over the shoulders, and held in position by shoulder straps and an apron. From this an extension rod passed from between the shoulders to the base of the skull, where it joined a rolled metal band passing around the head and secured in position by a forehead strap and a strap passing under the jaw from ear to ear. Universal joints at the back of the neck and between the shoulder blades allowed the adjustment of this apparatus to any position of the head, while the distance between the head and body pieces was regulated by a ratchet and key extension. Three cases at the present time seem practically well, and since the removal of the support, the range of motion of the neck has increased in all directions, and there has been no return of pain.

DR. S. L. MCCURDY, of Pittsburg, described and exhibited a combination traction and immobilization hip joint brace. He said that protection is afforded a diseased joint by either confining the patient in bed, or in some portable appliance or brace that serves the same purpose. Immobilization is afforded by the use of plaster-of-Paris; cuirass of Bauer; portable bed of Phelps, or Bradford and Lovett, or a Thomas hip splint. Traction is of the utmost importance during the early stage to overcome muscular spasm and interarticular pressure, and ultimately to relieve pain, and during the stage of dissolution of bone to prevent shortening and angular deformity. In order, then, to apply traction, as well as immobilization, to the hip joint in disease, the author had devised a combination of the long traction hip splint and the Thomas splint.

DR. JOHN D. SKEER, of Chicago, (by invitation) exhibited

A NEW SURGICAL SAW,

and made some remarks relative to its use. He said that where there is non-union of the bones after excision of the knee joint, we have conditions that may give rise to any degree of deformity. Any procedure that will prevent the rotation and backward displacement of the tibia, without the interposition of any foreign body between the cut surfaces of the bones, will contribute to the success of the operation. If the tibia were cut off slightly concave and the femur correspondingly convex, the bones would lock together in such a way as to prevent rotation and the backward displacement of the tibia. This method of joining the bones together was first practiced by Dr. Fenwick, of Montreal, in 1868, and published in the *International Encyclopedia of Surgery*. The Doctor used a fretwork saw adapted to a butcher's frame, and states that the "bones should be accurately adjusted, and if they do not fit nicely, saw off a thin slice from either or both

of the bones, and, if necessary, remove thin slices with the cartilage knife."

Objection has been urged against Fenwick's operation, for the reason that pockets have been found between the ends of the bones in which matter accumulated and prevented union. Dr. Skeer apprehends that the pockets and irregular open spaces were made with the narrow saw and the cartilage knife at the time of the operation. He proposes to improve the technique of this operation by making the sections with a concavo-convex saw which he had devised for that purpose, and which cuts a true circle, so that when the cut surfaces of the bones are brought together they will coaptate with mathematical accuracy. The saw blade is nine inches long and two inches broad, curved on the flat with a concavity of one-fourth of an inch.

Dr. W. O. PLYMPTON, of New York, read a paper entitled
EXCISION OF THE KNEE AS AN ORTHOPEDIC PROCEDURE.

The success of the operation is no longer an experiment, when performed under right conditions and by a skillful operator, and should not only save limbs but lives. Too much can not be said in favor of early treatment by mechanical and fixation methods in disease of the knee joint. If the profession at large recognized disease of this joint in its incipency and employed extension and fixation methods of treatment, comparatively few cases would advance so far as to necessitate excision. It is the duty of the orthopedic surgeon who teaches, to lay special stress upon the early recognition, as well as early mechanical treatment, of these diseases. When the fixation and extension plan of treatment has been conscientiously tried and has not arrested the disease which is manifestly on the increase, the surgeon should explore the joint and do whatever the conditions demand, whether to wash out or to excise. When the articular surfaces are destroyed, the bone and the soft parts extensively involved, the joints should be excised. In the series of excisions which the author reported, there were several examples of great destruction from osteomyelitis and tubercular disease where amputation was avoided and several inches saved to the length of the limb by allowing the cavity to fill and the clot to organize. In one case of osteomyelitis seven inches of bone were reproduced. In determining what operation for excision of the knee best subserves the requirements, it may be said that that method which allows of the most complete removal of all diseased tissue and affords perfect drainage, retains the parts in best apposition and fixes the bones without the use of pins or wire and last, but not least, the one that can be done with the greatest ease and rapidity is to be preferred. Fenwick's operation fulfills all requirements with a few exceptions. Where the head of the femur is destroyed, precluding the section according to Fenwick, Phelps had devised a method to meet this condition by sawing a wedge-shape at the end of the femur and a V in the tibia for its reception. The length of time taken for excision of the knee is an important element with regard to the mortality of the operation, as the shock of the operation in excision of the knee must of necessity be profound. The author said that Dr. Phelps, on an average, did not consume more than fourteen and one-half minutes in excisions of the knee, except in exceptionally bad cases. He had seen him do an excision in ten minutes from the time the first incision was made until the last plaster bandage was in place.

Dr. A. J. STEELE, of St. Louis, exhibited an apparatus for the treatment of club foot, and two contrivances to be used in head traction and in hip traction.

Dr. LOUIS A. WEIGEL, of Rochester, N. Y., read a paper entitled

MECHANICAL SUPPORT IN THE TREATMENT OF SCOLIOSIS.

The author first dwelt upon the various theories as to the etiology and pathology of the affection, the various objections to supports, etc. When a bony distortion has taken place of slight degree, we can easily understand that the superincumbent weight falling upon an inclined plane must of necessity increase the deformity, and any plan of treatment which will endeavor to relieve the spine of this adverse factor is certainly a rational one. The author believes (and says he is in a position to prove) that mechanical support may be worn for an indefinite length of time without producing atrophy, and that in spite of an appliance, exceedingly good muscular development may be secured. If this can be shown, the principal objections against appliances will be done away with. The author believes that a mechanical appliance can be used with as much benefit and be made to do its work and be worn as comfortably on the back as on the legs.

The following officers were elected:

President—Dr. Royal Whitman, of New York.
First Vice-President—Dr. George W. Ryan, of Cincinnati.
Second Vice-President—Dr. Joel E. Goldthwait, of Boston.
Secretary—Dr. John Ridlon, of Chicago.
Treasurer—Dr. E. G. Brackett, of Boston.
Place of meeting, Buffalo; time, third week in May, 1896.

ASSOCIATION NEWS.

Rush Monument.—The following circular has been issued, but through some inadvertence has not been printed in the JOURNAL. There is still time for remittances, according to Dr. Rohé:

AMERICAN MEDICAL ASSOCIATION, RUSH MONUMENT
COMMITTEE.

BALTIMORE, MD., July 1, 1895.

Dear Doctor:—I beg leave to remind you that at the recent meeting of the AMERICAN MEDICAL ASSOCIATION in this city the following resolution, offered by Dr. J. W. Hoff, of Ohio, was unanimously adopted:

Resolved, That each delegate to this ASSOCIATION be appointed a committee to collect funds for the Rush Monument from fellow-practitioners, and transfer the amounts to the Treasurer of the Committee on Rush Monument at as early a day as practicable.

In virtue of this action of the ASSOCIATION, you are constituted a member of this committee. I am sure I need not urge upon you the necessity of energetic action. If the hearty interest manifested at the Baltimore meeting can only be sustained a little while, the object for which the committee has so earnestly labored during the past ten years will be attained.

It is hoped that at the next annual meeting of the ASSOCIATION the committee may be able to report that the amount needed to erect the proposed monument to Benjamin Rush is in hand. Will you not do all in your power toward the accomplishment of this object?

Remittances may be made by check or money order, to the undersigned. Very truly yours,

ALBERT L. GIBON, Chairman.

GEORGE H. ROHE,

Secretary Rush Monument Committee.

Catonsville, Md.

THE RUSH MONUMENT FUND.

BALTIMORE, Sept. 23, 1895.

To the Editor:—The sum total of the Rush Monument Fund to date amounts to \$3,357.39. Among the recent contributions are the following:

Prof. Nicholas Senn, Chicago	\$100.00
Dr. Geo. M. Gould, Philadelphia	5.00
Dr. Franklin B. Ferguson, Deer Island, Me	2.00
Dr. Andrew Annan, Emmitsburg, Md	50.00
Dr. Jacob L. Williams, Boston	1.00
Medical Society Wayne Co., New York (through Dr. D. S. Colvin)	10.00
Dr. J. R. Buist, Nashville, Tenn	5.00
Dr. John B. Hamilton, Chicago, (3d contribution)	1.00
Dr. Geo. N. Acker, Washington, D. C.	1.00
Surgeon-General Geo. M. Sternberg, U. S. A.	10.00
Eastern Ohio Medical Association (through Dr. J. C. M. Floyd)	10.00
Dr. W. H. Marsh, Solomons, Md	1.00

Further contributions will be acknowledged in these columns. Very truly yours,

GEORGE H. ROHE,
Secretary and Treasurer Rush Monument Committee.

To Raise Bread and Diphtheria in the Same Bed.—The city physician of Rochester, Dr. Seitz, while visiting a house on Caswell Court, an over-populated street, recently, discovered that a pan of dough had been placed to rise in the bed of a boy, ill of diphtheria. A quilt was thrown over the patient and the dough. There are four other children in the family.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 86 FIFTH AVENUE, CHICAGO, ILLINOIS.
W. H. LOWDERMILK & CO., WASHINGTON AGENT.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 86 Fifth Avenue, Chicago.

SATURDAY, SEPTEMBER 28, 1895.

THE PATHOLOGY OF THE PARTIAL NEURASTHENIAS.

The discoveries in the finer structure of the nervous system, the resulting modifications in our views as regards its physiology, the recognition of the fact that nerve action is in the centers effected, not by continuity of the nerve cell and fiber, but by their contiguity, have revolutionized our ideas as to the pathology of a large number of disorders of which the anatomic lesions have so far evaded us. Adding to this, the hardly less important discovery by our countryman HODGE, of the effects of fatigue upon the nerve cell itself, we have a rational pathology suggested for nearly all the so-called functional disorders of the nerve centers, neurasthenia and insanity included. This fact is largely recognized by the authors of the most recent general work on nervous diseases, which in this respect is in advance of all its predecessors.

While to a large extent this pathology is, and must be only theoretical, it is a decided gain over our former agnostic condition in this regard. It is an advance to have a rational theory, and the possibilities in this direction are hereby infinitely increased. Taken in connection with the researches now being made upon the effects of various toxic agencies upon the neuron, these discoveries enable one to give a reasonable and possible explanation for almost or quite every general "functional" disorder of the nervous system.

With the theory of cortical localization carried a little beyond our actual acquisition of facts, we have also an explanation, by these discoveries, of the partial neurasthenias, the special dyskinesias, etc., which has been hitherto lacking. Writer's cramp, for ex-

ample, and the other occupation neuroses, together with much of the special disorder sometimes attributed to eye strain may, perhaps, be better accounted for by assuming a fatigue and derangement of the nerves of special functional centers, sometimes even without any extensive implication or participation of other nerve elements. The more complex and specialized the function disordered, the more rational can this explanation be made to appear. For example, BIANCHI has recently described a new type of partial neurasthenia (agnosiasthenia) in which distress is experienced from every attempt at reading, while general health, intellection and the use of the eyes for other purposes may be altogether uninterfered with.

This condition may reach absolute disability as far as reading is concerned, without any impairment of efficiency in other directions. The cerebral mechanisms involved in the act of reading are infinitely more complex than the peripheral, and it is as easy to suppose that their fatigue or insufficient reparative power may induce neuralgic discomforts in this case as in writer's cramp, where a peripheral pathology has never been extensively accepted, and in which we must therefore attribute a purely central origin to the pain.

Other professional neuroses than writer's cramp readily fall under the same law, and as much can probably be said of the other partial neurasthenias, the disabilities for mental or physical exertion which may exist separately, and many others that are possible and undoubtedly sometimes occur. They all find their best explanation in the fatigue and more or less permanent exhaustion of the neuron, of which the associated anatomic condition has now become known to us.

MEDICAL TEMPERANCE.

It has been apparent for some time that medical men can not ignore and stand aloof from the great revolution in public sentiment concerning alcohol used indiscriminately as a medicine and as a beverage. During the past year, not only in this country, but in Europe, the center of wine drinking, most startling innovations and changes have been proposed. In this country only two societies of medical men have taken up this topic. One, the Association for the Study and Cure of Inebriety, organized in 1870, for the exclusive purpose of studying the causes, conditions and means of treatment of inebriates; and the other, organized in 1891, called the Medical Temperance Association, whose special object is to promote investigation as to the action of alcohol in health and disease. Both of these societies discuss the medical side of the topic, and are in no way identified with any popular movements of the day. In England there are two societies studying along the same lines. In France, Italy, Switzerland, Ger-

many, Holland, Norway and Belgium, there are societies of medical men who discuss all phases of the alcoholic topic. In 1878 these societies joined with philanthropists and reformers in holding international conventions. From that time, at intervals of two or more years, meetings have been held in which leading physicians have not only presided, but taken a prominent part in the papers and discussions. The last of these congresses has just closed at Basle, Switzerland. Some idea of the medical interest of this meeting may be had from the fact that seventy-eight medical men were registered as members and delegates. Twenty-one were superintendents of asylums, sixteen were teachers of mental diseases, and twenty-nine were professors in medical colleges, and on health boards.

The papers read by these men were on the effects of alcohol on the body. Two of them related to some very striking experiments made in the Heidelberg University laboratory, on the physiologic action of small doses of alcohol upon mental processes. All the papers read were scientific and did not touch the moral or ethical side of the subject.

In France, all the leading medical societies have taken up the alcoholic question with unusual interest and spirit, and many very important and original studies have been made. The French government has appointed a commission to investigate the causes of the fatality from the use of spirits. The French Medical Temperance Society has been engaged in studying the different effects of alcohol on the body for some time.

In England, the Society for the Study of Inebriety, has for years been urging legal measures of restraint, with unusual success. The disease of inebriety has been recognized and parliament has passed laws for the organization of asylums and the control of these cases. The Medical Temperance Society has investigated alcohol in various ways, and brought out many new facts of great practical value. They have been largely instrumental in showing the folly of the beer ration in almshouses and asylums, and calling in question the indorsement of alcohol in medicine and as a beverage.

Leading medical men of worldwide reputation, both on the continent and in the British Isles, have taken up this subject fearlessly, and identified themselves as students and investigators, irrespective of public opinion, while in this country there is a strange shrinking from investigation or expression of personal convictions that are antagonistic to current opinions.

The two societies in this country who are working along this line have attracted very little attention medically, although the literature published in the *Journal of Inebriety*, by the Association for the Study and Cure of Inebriety, has attracted a great deal of

interest in Europe, and many of its articles have appeared in all the leading journals. The other society, the Medical Temperance Association, has presented some original work already, and is closely following along the most advanced lines of research concerning alcohol.

In Europe, the philanthropists and reformers are turning to the medical men for help and aid. In this country physicians stand aloof in an attitude of indifference and criticism. This should not be. Every medical man should recognize that the so-called temperance problem, which includes a knowledge of the nature and action of alcohol on the system, and the question of the causes and remedies of inebriety is a medical question to be settled by physicians.

The noise and roar of agitation rarely brings out facts as to the solution of great problems. It is the still small voice of science that must come from physicians, that will point out the means of relief from this evil. Physicians in this country, with few exceptions, are far behind medical men abroad in the interest and study of the alcoholic problem. This is remarkable, in view of the intense mental activity of American physicians and the freedom from entailments of custom that surround them.

The two societies, the Association for the Study and Cure of Inebriety, and the Medical Temperance Association, should be the most popular special medical associations in the country. They should be centers for the scientific study of this question, that would not only lead but direct public opinion.

Last year a voluntary gathering of teachers, leading business and literary men, with a few physicians, joined to make a scientific study of this subject. The confused outline work which was projected, clearly revealed the impossibility of any practical results, except along medical lines, by hardworking physicians. The absurdity of laymen and emotional reformers, going round the country teaching the physiologic action of alcohol, and the assent of medical men by silence, is apparent everywhere. The popular literature on this subject scattered broadcast, and the contradictory theories repeated in medical text-books as if they were absolute facts, are simply deplorable. In no other topic of like interest has there been so little respect for facts, or so little effort to find the truth.

This alcoholic problem is vital in every community, and physicians are the true teachers and they should investigate it in the same way that germ diseases are studied. We have recently published a number of papers read before the Section on State Medicine on this subject, and we heartily commend it, as one of the great outlying fields of medicine that must be occupied by practical medical men before its solution can be reached.

STATE CARE FOR THE INSANE.

The progress of "State care" in New York will, on October 1, pass another mile-stone. The insane of Kings County will, on that date, cease to be under the charge of the old board of county commissioners, and will be transferred to the State Commission in Lunacy. Salaries of the medical corps have been raised, and the employment of a female physician has been provided for. Under the law authorizing this transfer it has been stipulated that the present staff of officers should continue to hold their positions during "good behavior," that is to say, they are removable only for cause.

When this transfer shall have been made, there will then remain only the insane of New York still outside of State care. That county would probably have already fallen into line with the rest of the counties of the State had it been possible to settle certain questions relative to tax appropriations. There is a strong probability that an act will be passed by the next Legislature that will make it easy for New York County to adopt the State care, under which the hospitals become such in fact as well as in name. The insane under this change of systems, are cared for honestly and there is little room for petty thievery in contracts. The eyes of the State officers as well as of the local managers, are directed alike to the interests of economy and to the welfare of the patients; whereas, under the older system the business of awarding contracts, that would appear straight while being crooked, was that in which the officers excelled.

NEW MASSACHUSETTS LAWS RELATIVE TO COMMITMENT OF THE INSANE.

Chapter 429 of the Acts of Massachusetts of 1895 provides that no person shall be committed to a lunatic hospital, asylum or other receptacle for the insane, unless, in addition to the oral testimony given, there has been filed with the judge hearing the complaint or other proceedings for the commitment of the person alleged to be insane, the certificate of two physicians certifying to such person's insanity, made in accordance with the provisions of Section 1 of Chapter 286 of the Acts of 1895. This latter provides that in any hearing in any proceeding for the commitment for proper treatment of any person alleged to be insane, to a lunatic hospital, asylum or other place provided by law, no one shall be qualified as a physician to make to a judge at such hearing a certificate of the insanity of a person unless he shall make oath that he is a graduate of a legally chartered school or college; that he has been in the actual practice of his profession in this Commonwealth as a physician for at least three years since his said graduation, and for the three years next preceding his making said oath; nor unless he is duly registered in compliance with the law of 1894,

and continues to be so registered; nor unless his standing, character and professional knowledge of insanity is satisfactory to such judge.

Each certificate bearing date more than ten days prior to any commitment of any person alleged to be insane shall be null and void, and no certificate shall be valid or received in evidence if signed by any physician holding any office or appointment in or connected with the hospital, asylum or other place for the insane to which the person in question may be committed by the order of the judge. Every physician certifying as herein provided must himself have examined the person alleged to be insane, within five days of his signing the certificate, and every such physician shall state in said certificate that in his opinion said person is insane and a proper subject for treatment in an insane hospital or asylum, and shall specify the facts on which his opinion is founded.

A copy of the certificate, attested by the judge, shall be delivered by the officer or other person making the commitment, to the superintendent of the hospital or other place to which the person shall be committed, and shall be filed and kept with the order of commitment. And a copy of each physician's certificate of insanity required under the provisions of this act shall be mailed to the State Board of Lunacy and Charity by the superintendent of each lunatic hospital and asylum, within forty-eight hours after the commitment of each person adjudged insane.

HYPNOTISM AS A MORAL FORCE.

Word comes to us from Utah that an attempt is there being seriously made, presumably under the local governmental auspices, to reform criminals by hypnotism. Evil is to be eradicated and moral tendencies instilled into the criminal by passes and suggestions; whether the criminal has a will to be moral or not, he is to be made so. On the other hand, there comes from Germany the proposition to cure sexual perverts by the same means, but the foreigner is either less hopeful or more immoral, in that he proposes to substitute a less repulsive style of immorality for the existing tendencies of the subjects. He is perhaps a little less extravagant, if he is also less respectable in his ideas than the Utah practitioner, but it is hard to see why they are not almost equally irrational.

Hypnotism ought to be understood by the people and by medical men in particular, if the amount of literature on the subject could enlighten them, but there still seems to be a widely spread superstition which a few in the profession seem to share, that there is an occult force in the hypnotizer which his victim can not resist. And hypnotism as a moral force, usurping the place of training and religion is comparatively a new extension of the superstition.

THE SOCIETY OF AMERICAN OBSTETRICIANS AND GYNECOLOGISTS.

This active and energetic society held its annual session in Chicago this week, under the Presidency of Dr. J. H. CARSTENS, of Detroit. The proceedings which were varied and interesting, will be published in our next issue.

The entertainments included an excursion on the Lake, given by PROFESSOR J. B. MURPHY, and the annual dinner of the Society at the Union League Club. The speeches at the dinner were by DR. POTTER, McMURTRY, McDONALD; ROSS of Toronto; TAYLOR, HAMILTON, LYDSTON, MARTIN and DUDLEY. MR. EVANS of New York, gave some character songs which were well received.

A telegram was sent the venerable ROBERT BATTEY, of Rome, Ga., expressive of the sympathy of the Society, the Chicago Gynecological Society, and the invited physicians there present, with him in his illness and their best wishes for his speedy recovery.

DR. JOSEPH PRICE, of Philadelphia, was elected President; A. H. CORDIER, of Kansas City, Vice-President, and W. W. POTTER, of Buffalo, Secretary.

Richmond, Va., was chosen as the next place of meeting on Tuesday, Sept. 2, 1896.

EXCELLENT APPOINTMENTS.

The Commissioners of Cook County, Ill., have at last yielded to the voice of the medical profession and the public, and appointed a competent board to supervise matters at the County Hospital for the Insane.

Let us trust that the Commissioners will have the good sense to follow this up, by the appointment of a medical man as resident superintendent. DR. RICHARD DEWEY, SANGER BROWN and ARCHIBALD CHURCH are named as the board, to have supervisory control over the medical affairs of the hospital. It has been stated that the absence of DR. DEWEY will probably prevent his acceptance, but there is no dearth of good timber in Chicago. There are to be two resident assistants selected under civil service rules. The order of the Commissioners is elsewhere printed.

ARMY MEDICAL BOARD.

A board for the examination of candidates for admission to the Medical Corps of the Army has been called by SURGEON-GENERAL STERNBERG, the text of which will be found in the Public Service column.

CORRESPONDENCE.

The Doctor In Politics.

Sept. 24, 1895.

To the Editor:—The opinion held by some physicians that the medical profession should take a more prominent part in political affairs has received a new impetus from the recent meeting of the County Central Committee of Cook County, Illinois. The story told of the sanguinary encoun-

ters between members of that committee has led to the suggestion that hereafter a surgeon should be appointed to attend all meetings of the "business" men who control the destinies of one of the great parties in the second city of our great Republic.

The story of how one MR. GOODMAN, of Evanston, had his nose broken by the HONORABLE "BUCK" McCARTHY, an alderman, and the heroic deeds of this doughty champion in producing bruises on the face of the HONORABLE "JO." LAMMERS, also an alderman, and enucleating the eye of that worthy by the effective and simple process technically known as "gouging," has also stimulated the surgical instrument trade to a considerable extent. It is understood that in the enucleation of the eye of the HONORABLE "JO." LAMMERS, the HONORABLE MR. McCARTHY did not use scissors or scalpel, but with due regard for the prevention of hemorrhage, tore through the conjunctival mucous membrane with his right index finger. It is also stated in the press dispatches that no regard was paid to the modern teachings of antiseptic surgery, and that although preparations for the operation on the aldermanic eye had lasted for some time with the doors of the operating room closed, even the trained nurses engaged by the committee were denied admission. Whatever credit, therefore, may attach to the operation *per se*, it is discreditable to the intelligence of a great city that such important surgical operations should be intrusted to an illiterate alderman from the stock yards district, such as we understand the HONORABLE "BUCK" McCARTHY to be.

There is no question but such aldermen accurately represent the refinement of their constituents, for this is a free city, and everybody may vote at the primaries and at the polls. A gum-chewer, with a fog-horn voice, we send to Congress, because he represents fully our ideas of polite elegance and oratory. A bruiser who keeps a saloon we elect to our city council, because we believe in physical culture, and in his ability to legislate for the general good of the public. A Council composed of such worthies we return every year, because we think "business" men should always be preferred to legislate on the public health, over any physician. It is clear, Mr. Editor, that such is the opinion of our physicians, and as well of the clergy, or else it would not happen. It is said that the downfall of the Roman Republic began with the indifference of the leading citizens in regard to its political affairs. We do not believe this, for our profession is as patriotic as any, and we, by our silence, give full consent to any thug who wishes election to receive it. We must, in fact, accept the fact as it stands, that as a profession we prefer a scoundrel in our legislative halls, otherwise we would try to prevent it. Let us not, Mr. Editor, try to delude ourselves, as you seem to be constantly trying to do, into the belief that we, as a profession, do not like to be represented by the persons we send to our City Halls, our Legislatures, and our Congress. SENEX.

Post-Nasal Hypertrophy.

MINNEAPOLIS, MINN., Sept. 20, 1895.

To the Editor:—I wish to acknowledge through the JOURNAL, my appreciation of the article entitled, "Post-Nasal Hypertrophy in Its Relation to Hay Fever and Other Diseases," by W. H. Weaver, M.D., of Chicago, Feb. 9, 1895.

In my estimation this article contains the most valuable contribution to the treatment of all those forms of nasal disease characterized or accompanied by intumescence, which has been given to the profession in the past ten years. Dr. Weaver recommends that the posterior, (nearly always enlarged) extremities of the lower turbinates be snared, or with a bent probe cauterized with chromic acid, in order to destroy the sensitive terminals of the nerve supply to "MacKenzie's sensitive area," including the posterior ends of the lower turbinates and the surface of the septum opposite.

Of course we have all snared the posterior growths when we could engage them in our loops, and failing, have deeply cauterized with galvano-cautery, and still our patients have complained that they were not cured.

Dr. Weaver's recommendation seemed so rational that I at once adopted it, and have been so well pleased with results that I now seldom use, or have need to use, my cautery. Since the date of publication of Dr. Weaver's paper, Feb. 9, 1895, I have done the operation (applying chromic acid to the posterior extremity of a lower turbinate) sixty-two times in thirty-eight private patients, whose records are readily accessible and who for the most part had had no previous galvano-cautery treatment. Beside these, I have treated in like manner perhaps an equal number, who after the regulation snarings and deep cauterizations have still returned for further relief. The results have been incomparably better than by the galvano-cautery. The pain and shock are much less, there is almost never any inflammatory reaction sufficient to cause occlusion of the naris, and the relief is immediate and as permanent as more destructive methods will give. Since using this method I find much less necessity for snaring posterior growths, and where I have snared large growths I have found the benefit more than doubled by a subsequent application of the chromic acid. I find, further, that the efficient application of this method obviates the old time necessity of "tacking down" the anterior and middle regions of the lower turbinates, certainly in a large majority of cases.

And now a final word as to the application of the method. Having the lower turbinate well cocaineized, the acid is fused upon one side only of a properly bent applicator, passed back through the naris, carefully applied to the whole posterior extremity of the lower turbinate, and withdrawn without touching innocent parts. The nares are then flushed thoroughly and as promptly as possible with a *pint or more of soda water*. Then a drying powder containing antipyrin, and an oil spray. The patient seldom sneezes, and after an hour the slight discomfort in the nose is usually gone. To use merely an *alkalin spray* after such an application of chromic acid is to be guilty of malpractice.

EDWARD J. BROWN, M.D.

Coca Cola Statistics.

631½ WHITEHALL ST., ATLANTA, GA., Sept. 21, 1895.

To the Editor:—Desiring to find to what extent coca cola habitues are developed by the use of coca cola as a drink, I address this card to the medical profession, hoping that it will receive a ready response by any physician who has treated such cases. In replying, please state age of patient, sex, and amount drank daily.

Hoping some good may result from such a collection of cases, I am,

Yours respectfully,

R. R. KIME, M.D.

BOOK NOTICES.

The Index Catalogue of the Library of the Surgeon-General's Office. Authors and Subjects. Volume xvi. W. ZITHUS. Washington, D. C. Government Printing Office. 1895.

This volume completes the alphabet, and is therefore the final volume of the first series of this incomparable work. We learn from a letter transmitted by Deputy Surgeon-General John S. Billings that "the manuscript of a second series, including all the titles of books and articles received too late for insertion in the first series, has been prepared, and will probably make some five printed volumes of the same size and style as those constituting the first series. An appropriation for printing volume i, of the second series, has been granted by Congress, and the work will therefore proceed without interruption, the manuscript for the first volume being now nearly ready for the press." The library of the Surgeon-General's office now contains 116,847 books, and 191,598 pamphlets. This volume contains a list of contributors to the library, government societies, corporations and individ-

uals who have given numerous contributions. There is also found *corrigenda* of the entire sixteen volumes.

In mentioning the completion of this book, we desire to congratulate Dr. Billings, Dr. Fletcher and their coadjutors, and to say that so far as we are able, we feel sure we voice the expression of the entire Association when we say that no aid to American medical literature has been so important as this, since the foundation of the country. The teacher and the writer, and scarcely less the general practitioner, must turn to this great catalogue when in search of the literary treasures of the past, bearing on whatever subject he is especially interested in, and no one more than the medical editor knows how extremely valuable this Index is for reference. We are obliged to consult this work nearly every issue of the JOURNAL, to verify spellings and dates. It is also with pleasure that we note the continuation of the Index and the practical completion of its first volume.

Practical Dietetics, WITH SPECIAL REFERENCE TO DIET IN DISEASE. By W. GILMAN THOMPSON, M.D. 8vo., with pp. 802. New York: D. Appleton & Co. 1895.

To the members of the medical profession connected with hospitals, and especially those in the Government service, it has long been a source of astonishment that the profession in general paid so little attention to dietetics in the treatment of disease, as in the hospital service the diet is prescribed with the same regularity as medicines or drugs. Nor has medical literature, generally, given the subject of diet as much attention as its importance warrants, and this book will therefore go to the profession as one conveying information on a nearly new subject. We can not too highly commend the study of dietetics. For that purpose the volume under consideration is perhaps one of the best of modern works on this subject. The contents of the volume are included in nine parts and an appendix. Part i, Foods and Food Preparations, which refers to the composition, classification, force-producing value, etc. It includes both vegetable and animal food and the detection of adulterations in classes of food mentioned. Part ii is given to the study of Stimulants, Beverages, and Condiments. Part iii, Cooking, Food Preparation and Preservation, and Quantity of Food required. Part iv, Foods Required for Special Conditions. Part v, Food Digestion and conditions which specially affect digestion. Part vi, General Relation of Food to Special Diseases which are caused by Dietaries. Part vii, Administration of the Food for the Sick. Part viii, Diet in Disease and Diet in Infectious Diseases; diet in diseases of the respiratory system; diet in diseases of the circulatory system and blood; diet in diseases of the alimentary canal and diseases of the intestine, disease of the liver, of the nervous system, skin diseases, and a discussion of the diseases especially influenced by diet. Diet in miscellaneous diseases; diet for surgical patients. Part ix, Rations, Dietaries, giving the Army and Navy rations, as well as the U. S. Prison ration, various hospital dietaries, etc.

In the appendix will be found recipes for invalid food and beverages suitable for fevers, convalescence from acute illness, beverages of all kinds, beef preparations, broths and soups, meat, milk and eggs, farinaceous and gelatin preparations. With this book one may manage very many affections without the use of drugs of any sort.

The chapter on Milk is one of the most valuable in the book.

In regard to the treatment of obesity, which the author describes in detail, he speaks of the different systems, but says: "Nearly all of these systems agree in two particulars: 1, to reduce the total quantity of food ingested as much as possible, without impairing the strength of the patient; 2, to diminish the amount of fluid drunk, by prescribing what is called a dry diet. The treatment, moreover, is usually combined with systematic exercise or bathing, and it is highly important to keep the bowels active. Lean meat should form the basis of all diet. A non-restricted flesh diet may give rise to dyspepsia, gastric and intestinal catarrh. Soups of all kinds should be forbidden, as well as alcoholic

beverages, and what little fluid is allowed should consist of plain or aerated water. Highly succulent fruit, such as watermelons; vegetables, like raw tomatoes, which consist largely of water, should not be eaten. Sugar should be absolutely forbidden, and fat must be used very sparingly, and only in the form of a little butter. The allowance of farinaceous food must also be cut down as much as possible." As near as we can understand, the author's general directions are to eat and drink as little as possible, which would seem to be a very practical way of diminishing corpulence.

Green's Pathology and Morbid Anatomy. PATHOLOGY AND MORBID ANATOMY. By T. HENRY GREEN, M.D., Lecturer on Pathology and Morbid Anatomy at Charing-Cross Hospital Medical School, London. Seventh American, from the eighth and revised English edition. Octavo volume of 595 pages, with 224 engravings, and a colored plate. Cloth, \$2.75. Philadelphia: Lea Brothers & Co., Publishers, 1895.

This well-known text-book comes to us in a new edition, enriched with sixty new engravings, and will be found more than ever worthy of the favor with which former editions have been received. The radical changes that have been made in the study of pathology by the discovery of bacteria have necessitated the rewriting of all the books on pathology in the last fifteen years; the newness of the field makes discovery an almost everyday matter, and in consequence a text-book to be kept up to date must be revised almost every year. We have examined with some care the present volume and find that Dr. Murray has incorporated the latest bacteriologic studies in this edition. It is to be regretted that the publishers do not use more colored illustrations in the illustration of specimens requiring staining, in order that the natural color as seen by the student may appear. It is this that makes the value of such publications as that of Woodhead and others, and its adoption in Green would add very much to its usefulness.

Clinical Lectures on Diseases of the Nervous System. Delivered at the National Hospital for the Paralyzed and Epileptic, London, by W. R. GOWERS, M.D., F. R. S. 8vo., pp. 279. Philadelphia: P. Blakiston, Son & Co. 1895. Chicago: E. H. Colegrove & Co. Price, \$2.

These lectures have been reprinted from various English medical journals with the exception of two, which were printed in the *International Medical Magazine*, of Philadelphia. There are twenty lectures in the series, as follows: Principles of Diagnosis of Diseases of the Nervous System; Mistaken Diagnosis; Argyria; Syphilitic Hemiplegia; Bulbar Paralysis; Facial Paralysis; Facial Contraction with Palsy; Acute Ascending Myelitis; Locomotor Ataxia $\frac{1}{2}$; the Foot Clonus and its Meaning; Syringomyelia; Treatment of Muscular Contraction; the Infantile Cause of Epilepsy $\frac{1}{2}$; Neuralgia, Lead Palsy, Saturnine Tabes; Optic Neuritis, $\frac{1}{2}$.

The authoritative position of Gowers and his international reputation make it a work of supererogation for the reviewer to commend anything to which his name is attached, but while we commend the lectures and pay due deference to the great master who has prepared them, we extremely regret that there is no index in the volume, which is otherwise admirably printed. The illustrations might have been more frequent, if it is intended to be placed in competition with the French books on the subject.

Indurative Mediastino-Pericarditis. By THOMAS HARRIS, M.D., London. Reprinted from the *Medical Chronicle*, 1894-95. Imperial 8vo., pp. 67. London: Smith, Elder & Co. 1895.

The popularity of this article was such that its republication was considered desirable, so as to place it in permanent form as a monograph on this subject. The author of the term, indurative mediastino-pericarditis, is Kussmaul, whose original article appeared in the *Berliner Klinische Wochenschrift*, for 1873. These cases are those in which great difficulty of diagnosis is presented clinically and "where at the autopsy there is found an adherent pericardium with an increase of fibrous tissue in the mediastinum. The increased mediastinal tissue is united to the external surface of the pericardium, and both it and the pericardium are united to the left and, may also be to the right lung." The author has appended an extended bibliography to the monograph and has made a collection of twenty-five cases.

Hayem and Hare's Physical and Natural Therapeutics. PHYSICAL AND NATURAL THERAPEUTICS. The Remedial Use of Heat, Electricity, Modifications of Atmospheric Pressure, Climates and Mineral Waters. By GEORGE HAYEM, M.D., Professor of Clinical Medicine in the Faculty of Medicine of Paris. Edited with the assent of the author, by HOBART AMORY HARE, M.D., Professor of Therapeutics in the Jefferson Medical College of Philadelphia. In one handsome octavo volume of 414 pages with 113 engravings. Cloth, \$3. Philadelphia: Lea Brothers & Co., Publishers. 1895.

Dr. Hayem, the author, is not only Professor of Clinical Medicine in the Faculty of Medicine of Paris, but is also the editor of the *Revue des Sciences Medicales* and, as such, he is well known on both sides of the Atlantic.

This book will be found very useful to practitioners, not only as a work of general information on the subject, but for reference in the treatment of cases in which the benefit of mineral waters or change of climate is desired. Dr. Hare, who has edited this book, has so clearly set forth its objects and aims in the preface that we quote it: "Every practicing physician constantly sees cases which should be sent to health resorts and thereby gain the benefits of mineral waters or of change of climate." He sets forth clearly remedial measures, such as the application of heat and cold baths, and says that "electricity will be of greater advantage to the patient than the administration of drugs. Information concerning such resorts and methods has been scattered in a fragmentary way, and as a result they have been too much ignored. The object of the book is to provide in a concise form just what the physician needs in this respect." "Written by one of the foremost therapeutists of the day in Europe, it embodies not only his own views but also those held by Benibard, Fleury, the brothers Delmas and Winternitz in the chapter on thermic agents; von Vivenot, Lombard, H. Weber and Lindsley in the chapter on air therapy, and climate, and by Durand, Fardell, Leichtenstern, Lebret and Rotureau on mineral springs. In the portion devoted to electricity, the views of standard writers are linked with those of the author. It has been the aim of the editor to render the text applicable to the needs of the American physician, particularly by the addition of article on American climates and mineral springs."

The contents of the volume are as follows: Atmospheric Pressure as a Therapeutic Agent; Climate; Thermic Agents; Hydrotherapeutic Measures; Mineral Acids; Electricity. Nearly one-half of the book is devoted to electro-therapeutics and is a very fair epitome of the subject, although very much inferior in scope to the larger books such as Bigelow and others. As a luminous and philosophical presentation of the matters treated in the work, we take pleasure in commending it.

A System of Surgery by Various Authors. Edited by FREDERICK TREVES, F.R.C.S. Vol. 1, with 2 colored plates and 463 illustrations. 8vo., pp. 1,152. Philadelphia: Lea Bros. & Company. 1895.

This is an English surgery, so far as surgery may now be said to belong to any particular country, for the writers are all Englishmen, and it is evidently intended to be a correct exposition of the national views and methods of treatment of this important branch of medical knowledge. The names of the authors are a sufficient guarantee of the authoritative character of the work. The contents comprise an article on surgical bacteriology, by German Sims Woodhead; inflammation, suppuration, ulceration, gangrene, syncope, shock, wounds and contusions, by Dr. Watson-Cheyne; erysipelas, pyemia, tetanus and tetany, by C. B. Lockwood; burns and scalds, by Lockwood; military surgery, by Surgeon-Major Andrew Duncan; anesthetics, by Frederick W. Hewitt; surgical diseases due to microbial infection and parasites, by George Henry Makins; and rickets, by the same author; syphilis, gonorrhoea, and diseases of the skin, by Jonathan Hutchinson Jr.; tumors, by J. Bland Sutton; injuries and diseases of blood vessels, including aneurysm, and diseases of the jaws, by A. Pearce Gould; injuries and diseases of the lymphatics, by John H. Morgan; injuries and diseases of nerves, by Anthony Bowlby; injuries of bones, by Stanley Boyd; diseases of bones, by H. H. Clutton; injuries of the

joints and dislocations, by A. Marmaduke Shied; diseases of the joints, by Arthur E. Barker. The following are by the editor, Frederick Treves: the influence of constitutional conditions upon injuries; tuberculosis; hemophilia, and hysteria in its surgical relations.

In the main, the illustrations are new. Some of them are on colored plates, mostly well executed, and in a great many instances are from drawings or photographs of specimens in the British Museum or original cases. The work is brought up to date and is a fitting companion to the large work of Mr. Treves on operative surgery, with which the American profession are already familiar. In this book the actual details involved in operative procedures are not especially dwelt upon, and some subjects have been excluded that have appeared in other surgeries. It is natural, we suppose, that a branch of medicine which has shown almost revolutionary changes in the last ten years, should have an unusually large crop of literature at this time, and among them the present work will occupy an honorable place.

PUBLIC HEALTH.

Isolation of Infectious Disease at Home.—In his always interesting section on "Public Health," Malcolm Morris in the September *Practitioner*, approves of the suggestion that in planning a house some regard should be had for the future needs of the occupants in time of sickness. The idea is that one room should be set apart in design as the sick room *par excellence*. It should be shut off as much as may be from the common atmosphere and common noises of the dwelling—or, rather, it should be so arranged that it can be shut off at any time—and there should be a bath room and water closet at hand. The walls and floors and other surfaces should be impervious, so as to harbor no impurities and to admit of ready cleansing, and the furniture and fittings should be simple, with the same object. If in addition, there be a second room available for the nurse's use, the essentials for the proper seclusion of infectious cases are provided as far as is possible in a private house. A miniature hospital is then ready to hand and at ordinary times it can serve as a spare room or even as a bedroom in regular use, differing only from any other room in its adaptability to the special purpose in question. Such a provision would be an efficient adjunct to the sanitary authority in fighting the spread of the contagious and infectious diseases.

Cremation in Paris.—From statistics furnished by the Prefect of Police, it appears that cremation is gradually growing in favor in Paris, as shown by the following table:

Year.	Demanded by Families.	Debris from Hospitals.
1889	49	483
1890	121	2,188
1891	134	2,369
1892	159	2,261
1893	189	2,389
1894	216	2,247
1895 (four months)	75	1,065

The first apparatus was installed in the cemetery of Pere-Lachaise in 1887 and was of the Gorini model, used in Milan. The bodies were burned in this in from one hour and three-quarters to two hours, being reduced to extremely white ashes without any mixture of carbonized material and without odor or smoke. This apparatus proved unsuited for Paris, first because the incineration took too much time; secondly, the price of wood in Paris brought the cost of each incineration up to 20 or 25 francs. The authorities adopted a new apparatus constructed by M. M. Toisoul and Tradet. The results from this were very satisfactory. Incineration lasted from one hour to one hour and a quarter and cost but 3 francs. In Paris the *débris* from dissecting rooms alone amounts to 2,000 to 2,500 bodies yearly, and a crematory can be kept in use constantly, which considerably lessens the cost to private families. On account of this constant use it was necessary to provide a second crematory in case of necessary repairs to the other. The administration instead of ordering the Toisoul model, again adopted another new model, that of M. Fichet. Like the first, this is composed of

a gas chamber furnishing carbonic oxid and of a recuperator furnishing hot air to the vaulted chamber in which combustion takes place. The difference is that the carbonic oxid only serves to heat the recuperator, and combustion is caused by the hot air alone, owing to the large size of the recuperator. A body by this method is consumed in 50 or 55 minutes, but the expense for fuel is slightly more—18 hectoliters of coke daily for the Fichet and 14 for the Toisoul-Tradet. The crematory monument of the city, the construction of which was begun in the Pere-Lachaise cemetery in 1886-87 is only partly built and occupies only about one-third of its ultimate extent.¹

Modified Milk.—The average family physician will be apt to sympathize with Dr. Worcester, of Waltham, Mass., in his satisfaction at having at last found a "perfect substitute for breast milk." The Doctor confesses, as many of us might do, to having pinned his faith in turn upon the "statements which sleek agents have left with their blotters and pencils and lovely paper weights," and to have starved many a baby with the samples so left in his hands. The "perfect substitute," which he now enthusiastically recommends, is that produced by the Dresden process, the details of which he gives at considerable length.² Briefly summarized, this consists of the addition of the white of one egg and 13 drachms of milk-sugar to one pint of cow's milk, of 9.5 per cent. richness in fat, and one and a half pints of water. The milk-sugar is slowly added and thoroughly mixed with the egg-white, taking care not to beat air in the mixture, for egg foam will not mix well with water. To the paste so made, a pint and a half of water is slowly added, stirring constantly. This emulsion is then strained through fine linen into the sterilized milk which has also previously been cooled down below 100 degrees F. Slight stirring or shaking will now complete the mixture when it may be poured into the required number of nursing bottles. These, stoppered with sterilized cotton, can then be kept cool and warmed as needed. If sufficient care is taken in preparation, the mixture will keep for days and even months.

Medical Climatology of Peru.—In the study of the medical climatology of Peru, especial attention should be directed to paludism, verruga, goitre and oroya fever, which are very frequent. Lima, the capital, situated six miles from the coast and 150 meters above the sea level, contains 120,000 inhabitants. It is in a valley surrounded by several chains of mountains which slope toward the ocean. The climate is warm; the sky, cloudy in winter, is clear in summer although at this season a thick fog prevails in the morning which is dissipated by the heat of the sun. This is a constant phenomenon on the Peruvian coast—where it is known as *camanchaca*. Extreme temperatures are in summer 30 degrees C., winter 13 degrees; annual mean 22 degrees. A noteworthy fact is that whereas in former times the seasons, especially the spring, were well defined, now they are but slightly marked and pass from one to the other without any great transition. Earthquakes, invariably preceded by great rains are very frequent particularly during the equinox. Paludism heads the list of common diseases, 50 per cent. of the total. The "carrion disease"—new name for verruga, which was endemic at the time of the Incas—is found in two forms, the acute, or fever of the oroya, with or without consecutive eruption; the other, the verruga audina o peruana, a simple eruption without fever. The disease is attributed to drinking the water from certain streams which the Indians never use, even for their horses and mules. In 1843, Tschudi wrote that the disease is manifested, first, by sore throat, pains in the bones, and many febrile symptoms; within a few days an eruption covers the whole body, the lesions are red in color and some are as large as an egg; hemorrhages occur with such abundance that the patient's strength is much reduced. After summing up recent researches and the experimental inoculations submitted to by a medical student, Ayendano concludes that verruga is to be considered as a zymotic disease belonging to the telluric group with malaria, cholera and yellow fever, and that we may suppose, from analogy, it is due, like them, to the existence of a specific microorganism; that it is inoculable, but

¹ Revue Scientifique.

² Boston Medical and Surgical Journal, Sept. 19, 1895.

that there is not sufficient evidence yet to prove that it is contagious. Goitre and cretinism are frequent in the valley of Villamayo. Uta, which is a species of lupus, is, according to Ugaz, endemic in certain valleys on both slopes of the Andes. The lesions are usually found on the uncovered parts of the body. In February, 1891, in Lima, and especially in Jesus Maria convent, there occurred many cases of a fever with infectious characteristics, to which many distinguished persons succumbed and which threatened to spread indiscriminately. The National Academy of Medicine attributed this outbreak to the bad condition of the sewers, intra-urban cemeteries, and burial in churches.¹

Health Reports.—The following health reports have been received at the office of the Supervising Surgeon-General, Marine-Hospital Service:

SMALLPOX—UNITED STATES.

Arkansas: Clay County, August 7 to September 18, 43 cases, 7 deaths.

Louisiana: New Orleans, September 7 to 14, 2 cases, 1 death.

Michigan: Battle Creek, September 7 to 14, 2 cases 1 death; Detroit, Marshall, Bedford Twp., smallpox reported present, September 7 to 14.

Texas: September 17 to 22, 1 death.

CHOLERA—FOREIGN.

India: Bombay, August 13 to 20, 2 deaths; Calcutta, August 3 to 10, 18 deaths; Madras, August 10 to 16, 1 death.

Turkey: Aleppo, August 14 to 21, 63 cases, 32 deaths.

Japan: Nagasaki, August 12 to 19, 71 cases, 55 deaths.

YELLOW FEVER—FOREIGN.

Cuba: Santiago, September 1 to 14, 27 deaths.

Mexico: Vera Cruz, September 5 to 12, 2 deaths.

SMALLPOX—FOREIGN.

Calcutta: August 3 to 17, 6 deaths.

Dublin: September 1 to 7, 4 cases.

London: September 1 to 7, 25 cases, 5 deaths.

Manchester: September 1 to 7, 5 cases, 1 death.

Montevideo: September 10 to 17, 1 case.

Odesa: August 24 to 31, 1 death.

Trieste: September 24 to 31, 2 cases.

Tuxpan: September 1 to 7, 3 deaths.

Southampton: September 24 to 31, 1 case.

Zurich: August 17 to 24, 1 case.

NECROLOGY.

JAMES MCCREARY SUDDUTH, M.D., formerly of Bloomington, Ill., at Colton, Cal., September 20, aged 68. He was graduated from Rush College in 1854 and built up an extensive practice in Central Illinois. He afterward gave up the practice of medicine and became a banker and stock raiser. He leaves a widow, one son, Dr. William Xavier Sudduth, of Chicago, and two daughters, Miss Alice Sudduth, National Superintendent of the W. C. T. U., and Miss Margaret Sudduth, Managing Editor of the *Union Signal*.

H. V. GREGG, M.D., of Connersville, Ind., September 12. He had practiced medicine in Connersville since 1858, served during the Civil War as Surgeon of the 124th Indiana Volunteers, and was mustered out of service with the rank of Major. He was an active member of the AMERICAN MEDICAL ASSOCIATION.

WM. S. LAYMAN, M.D., one of the best known physicians of Schoharie County, N. Y., died September 5, in Schoharie. He was 64 years old. He was a graduate of the Albany Medical College in the class of 1854. He was a member of the State Medical Society, and was prominent in various social organizations.

OGDEN M. RANDEL, M.D., of Oneida, N. Y., September 15, aged 68. He was graduated from the University of Michigan in 1854.—A. W. Thompson, M.D., of Circleville, Ohio, September 16, aged 81.—C. C. Brady, M.D., of Lincolnville, Ind., September 10, aged 40 years.—W. LeRoy Wilcox, M.D., of Irving Park, Ill., September 22, aged 35. He was thrown from his carriage and accidentally killed.—Nathaniel Allison, M.D., of Mexico, Mo., September 15. He was born in Orange County, N. Y., in 1818, and moved to Mexico in 1845, where he has since lived.—Howard Hopkins Winters, M.D., of Lancaster, Pa., September 15. He was graduated from the University of Pennsylvania and has practiced in Lancaster nearly twenty years.—W. O. Stauffer,

M.D., of Indianapolis, September 11.—J. W. Crowders, M.D., of Dallas, Texas, September 11.—R. A. Herwick, M.D., of Smithton, Pa., September 17.—Newell P. Warner, M.D., of Syracuse, N. Y., September 16.—J. B. Galer, M.D., September 11, aged 74. He was born in Pennsylvania and was graduated from Rush Medical College.

MISCELLANY.

Bequests to Massachusetts Charitable Institutions.—Under the will of the late Mrs. Elizabeth T. Eldredge, of Newton, Mass., the Massachusetts General Hospital receives a donation of \$10,000 for the establishment of free beds. She also bequeaths to the Home for Aged Men \$25,000; to the Home for South Boston Orphans, South Boston, \$2,000; to the Association for the Relief of Aged Indigent Females, \$25,000; to the Society for the Prevention of Cruelty to Animals, \$1,000.

Association of Women Dentists.—There is a dental association, composed of female practitioners from all parts of the United States, and numbering forty-two active members. The chief condition of membership in it, is the possession of a diploma from some dental college in good standing. There are not less than one hundred and fifty women dentists in the country, and every year brings a larger number of students to the classes. A three-year course of study is required in the best of the schools to which women have access.

Thyroid Treatment of Uterine Fibroids.—Jouin has given thyroid extract in tablets of 0.15 ctgm, 4 to 8 tablets daily, in cases of uterine fibroids. In three cases he noticed a diminution of the hemorrhages and in two a partial disappearance of the tumor. In one case it was unsuccessful; two others are too recent to arrive at any conclusion. He believes that experimental researches into this phase of its sphere of activity should be undertaken. Physiology as yet, he says, furnishes only very hypothetical views as to the action of the thyroid juice in the therapeutics of fibroid tumors.¹

Dr. Winslow on Female 'Cycling.'—Dr. Forbes Winslow states that he has been misrepresented regarding his opinions of the bad effect of the bicycle on women. In a recent letter to the *New York Herald* he remarks that an interviewer approached him with some general questions on the subject, and that "in reply to his question, I stated that I personally did not approve of lady bicyclists (an opinion universally indorsed by physicians in my part of the world), but really, I had no practical experience in the matter. I was then asked as to the moral effect, but on this matter I expressed no statement of any description, and I desire that the words which have been quoted as mine should be emphatically denied, as being purely invention and not in any way based on what I said on the subject. I believe that many young girls run the danger of serious bodily illness from excessive straining, but it is a subject which I have never studied sufficiently well to be quoted as an authority. I agree with your remarks on the subject, and trust to your sense of fairness to emphatically deny what has been given broadcast as my opinion in the matter."

Aural Complications in Typhoid Fever from Secondary Infection.

—It is not rare to see aural complications during the course of typhoid fever; these are generally, at least in the beginning, a simple catarrhal otitis. This otitis may continue catarrhal or it may become purulent. Suppuration of the middle ear is of considerable importance and generally ends in spontaneous perforation of the tympanic membrane, when there will be a purulent discharge from the meatus. In many cases the suppuration will invade the mastoid cells; then we will have chronic otitis and caries of the petrous portion. To prevent these serious results the ears of typhoid patients should be watched carefully. The treatment of otitis may be divided into two parts; first, we try to arrest its development and prevent suppuration; second, if suppuration follows or if pus is already formed it must be evacuated and its reformation prevented. For prevention, rigorous antisepsis

¹ Journal d' Hygiene, Aug. 1, 1895.

¹ Rev. Int. de Med. et Clin. Prac., 1895, No. 15.

of the external ear and pharynx must be established by irrigating the canal several times daily with a boric acid solution; then drying the canal carefully, after which a plug of borated cotton is inserted.¹

For Impostors in Massachusetts.—Section 10 of Chapter 458 of the Massachusetts Acts of 1894 has been amended so that it now reads as follows: "Whoever, not being registered as aforesaid, shall advertise or hold himself out to the public as a physician or surgeon in this Commonwealth, or appends to his name the letters, 'M.D.', or uses the title of doctor meaning thereby a doctor of medicine, shall be punished by a fine of not less than one hundred nor more than five hundred dollars for each offense, or by imprisonment in jail for three months, or both." Here the words "or appends," after the word "Commonwealth," have been substituted for the words "by appending," and the word "uses," following the letters "M.D.," has been substituted for the word "using," thereby materially broadening the scope of the statute.

Density of Population in New York City.—In the London *Lancet* for August 10, the American correspondent presents the following analysis of the figures obtained by the recent census of New York city:

"The recent census shows that in the last twenty-five years the population of the city has increased from 900,000 to 1,900,000. One million people, in large part formed of the poor and ignorant emigrants from Europe, have been added to our population. A certain acre near Essex and Stanton Streets, having 622 people on it, is the most crowded of any city in the world; but this maximum is nearly maintained for a whole square mile, including parts of wards, numbered 7, 10, 11, 13, 14, and 17. In this square mile there are gathered together 370,000 people, mostly aliens, while the enumeration of children under 5 years of age is 53,000. From the census returns giving the number of children of school age—that is, from 5 to 14 years inclusive—the estimated number in this square mile is 63,000. Fifty thousand should be in the primary schools, but there are in this whole square mile but 27,000 sittings in the primary schools, so that there are some 20,000 children more than can be received in the schools of this district."

Loss of the Eyes through Mourning.—According to the veteran missionary Dr. Martin, of India, it is not an uncommon thing to see Hindoo women, one or both of whose eyes have been lost through the manifestations of grief. On inquiring the cause of all this, the usual reply is that she has lost a child, and has cried till she may be said to have cried her eyes out. "That is," says he, "probably what has actually occurred in many cases. It is always a son, sometimes a husband. I never heard of a woman crying seriously for the loss of a daughter. In one case, both eyes had been lost by way of variety, for a buffalo. Buffaloes are prized above cows for their milk, as they give more milk, and of a richer quality, though with something of a tallowy taste. The female acquaintance of this woman waited upon her and advised her to weep, and offered to join with her in her efforts." They came, both young and old, some with one eye, and some with the remains of two, and some with strabismus and scarrings, and baring their heads, proceeded to form a circle with their hostess in the center. Then all, with one accord continued to shriek piteously for the space of two hours, while they beat their thighs and temples alternately with both hands. This is the customary mode of public mourning, though usually practiced only on the death of a husband or son.

Cook County Hospital for the Insane.—The Commissioners of Cook County, Illinois, have adopted the following order:

WHEREAS, It is the purpose of the County Commissioners of Cook County to secure in the management of the County Hospital for the Insane efficient service in all departments thereof, and to provide that in the treatment of patients therein, the highest and most approved means shall be used; and

WHEREAS, It is deemed expedient, in order to obtain the highest degree of service in the management of said institution that the counsel and advice be had of a board of physicians eminent in their profession, who are not county

employes, and who have no pecuniary interest in the management of said institution. Therefore, be it

Resolved, 1. That an advisory medical board, composed of three physicians eminent in the medical profession, be, and the same is hereby established, said board to be known and designated as the "Supervising Medical Staff of the Cook County Hospital for the Insane."

2. That the said supervising medical staff is hereby authorized to determine upon and formulate rules and regulations for the treatment and care of the patients in said hospital, and for the control and management of the resident physicians, nurses and attendants in charge of patients in said hospital, prescribing in said rules the duties and obligations of said physicians, nurses and attendants.

3. That the said rules, prepared as above, shall be submitted to the Board of County Commissioners, and upon the approval thereof by the said County Commissioners shall be and become of force and effect, and be binding upon all employes, physicians, nurses, and attendants at said hospital, and shall be in force by the superintendent of said hospital or asylum.

4. That the supervising medical staff is hereby authorized and empowered to inspect said hospital from time to time, and to examine into the condition, care, and treatment of the patients therein, and see that the rules and regulations thereof are enforced.

For the purpose of said inspection above provided the said supervising medical staff and the members thereof are hereby granted full freedom of said institution, and of each and every department thereof, at any time during the day or night. And the supervising medical staff is authorized to report to the President of the Board of County Commissioners at any time, when, in the judgment of its members, the good of the service requires it, any special or general matter relating to the condition, management, judgment, or rules of said hospital.

5. That until further ordered by the Board of County Commissioners there shall be employed at said hospital or asylum two physicians and two assistant physicians, who, subject to the supervision and direction of said medical staff, shall have charge of the medical treatment and care of the patients, as well as the direction of the nurses and attendants. It shall be the duty of said attending physicians to report in writing to the general superintendent any neglect, abuse, improper conduct, or infraction of the rules of any part of any nurse, attendant, or other employé. Said report shall be carefully pasted into a book and preserved for inspection. And it shall be the duty of the general superintendent to give notice in writing of every such complaint to the President of the Board of County Commissioners and to the chairman of the committee on Dunning institutions on the same day he receives such complaint.

6. That the County Civil-Service Commission be and the same is hereby requested to have applicants for positions of physicians at said hospital for insane examined as to their qualifications by the members of said supervising medical staff so far as practicable.

7. That Dr. Richard Dewey, Dr. Sanger Brown and Dr. Archibald Church be and they are hereby selected as members of the said Supervising Medical Staff of the Cook County Hospital for the Insane, to act in said capacity from the first Monday in October, 1895, until the first Monday in October, 1896.

Louisville Notes.

KENTUCKY SCHOOL OF MEDICINE.—At the meeting of the faculty of this school on the 21st inst., Dr. W. H. Wathen, who has been dean of the faculty for the past fifteen years, resigned, and Dr. Sam. E. Woody was elected to succeed him. Dr. Wathen will continue as professor of abdominal surgery and gynecology, but stated in tendering his resignation as dean, that his private business interfered with the proper conduct of the school. Dr. Woody, the newly elected dean, is professor of chemistry and diseases of children, and will continue as such, assuming his new duties October 1.

Hospital Notes.

THE new Silver Cross Hospital at Joliet, Ill., will be dedicated October 6. This hospital cost \$50,000, and has been greatly needed owing to the large number of sick and wounded sent from the drainage canal.—The court at Norristown, Pa., has filed an opinion in the estate of John Boyer, deceased, allowing the Protestant Episcopal Hospital of Philadelphia \$6,017. The deceased was a banker, and left a will giving Mrs. Mary Simpson the interest of \$5,000 for life, and at her death the principal to be paid to the hospital. Mrs. Simpson died in 1892, and the auditor awarded

¹ Rev. Int. de Med. et Chir. Prat., 1895, No. 16.

the interest and accretions on the principal sum, to other devisees, but the hospital filed exceptions which the court sustained.—Work will be begun upon the new hospital at Moline, Ill., in the spring. The probable cost of the building will be \$15,000.—The new hospital at Visalia, Cal., has been completed, at a cost of \$6,000.—The ninth annual convention of the Superintendents of the State Hospitals of New York was held at Rochester on September 10, holding its sessions at the Rochester State Hospital. The State Lunacy Commission was represented by two delegates.

Society Notes.

The Hill County (Texas) Medical Society held a regular meeting September 12 at Hillsboro.—The Jackson County Medical Society held a meeting at Kansas City, Mo., September 12. Four papers were read.—A regular meeting of the Fremont County Medical Society was held at Sidney, Iowa, September 11.—The Butler County, Ohio, Medical Society at the last meeting, held at Hamilton, decided to hold semi-monthly meetings instead of monthly as heretofore.—The Tri-State Medical Society will hold a meeting at Des Moines, Iowa, October 1, 2 and 3. The last meeting of this Society was held in Jacksonville, Ill.—The Toledo, Ohio, Medical Association held a regular meeting September 20.—The Franklin County, Pa., Medical Society held a regular meeting in Chambersburg, Pa., September 17.—The eighty-second annual meeting of the Vermont State Medical Society will be held in Burlington, October 10 and 11. There are about twenty papers on the program, and the wide range of subjects gives promise of a beneficial meeting. The officers are: President, J. H. Linsley; Vice-President, F. F. Chaffee; Secretary, D. C. Hawley; Treasurer, D. G. Kemp.—The seventh annual meeting of the Tri-State Medical Society will be held in Chattanooga, Tenn., October 8, 9 and 10. The preliminary program shows that this meeting will be up to the standard maintained for several years past.

Washington Notes.

HEALTH OF THE DISTRICT.—The death rate took an upward turn during the past week. From 95 deaths reported to the Health Department in the week previous, the number went up to 122. The annual death rate followed in the same ratio from 17.93 to 23.02, which is the normal figure. The increase in mortality may be attributed to no particular cause, but seems to be all along the line. Dangerous contagious diseases still maintain a minimum degree and do not attract the attention of the medical faculty, there having been but one death reported from diphtheria. The increase in the number of deaths from typhoid fever has determined the Health Department to institute a prompt and scientific inspection as to the cause, with a view to removing it if possible. In other respects the health of the city is at the normal, both as to mortality among children under 5 years of age and those persons over 60 years of age.

TO INVESTIGATE TYPHOID FEVER.—The Commissioners have appointed Dr. George M. Kober, special medical inspector, to investigate typhoid fever, at the compensation of \$5 per day, payable from the emergency fund. A more competent man could not be found to perform the duty. His previous scientific work on the subject is well known to the profession and he will undoubtedly make a very valuable report.

REPORT OF THE COLUMBIA HOSPITAL FOR WOMEN AND LYING-IN ASYLUM.—The Commissioners have received the report of Columbia Hospital from Nathaniel Wilson, President of the Board of Directors. For the coming year an appropriation of \$25,000 for the maintenance of the hospital and training school, and \$10,000 for the estimated cost of essential repairs to the main building are required. Patients discharged or left during the year, 566; died, 15; remaining under treatment July 1, 1895, 37. Of 573 patients treated, 473 were residents of the District of Columbia; 311 were colored, 26 white, and 1 an Arab. Of the children in the institution, 200 were colored, 101 white, and 1 Arabian; 1,690 new patients have been admitted to the dispensary, and 1,852 were treated. The total receipts of this hospital, including Congressional appropriation, were \$32,348.98. Of this, \$32,317.86 was expended for maintenance and improvements, leaving a balance of \$31.12.

THE PUBLIC SERVICES.

NOTICE.—An Army Medical Board

Will be in session at Washington City, D. C., during October, 1895, for the examination of candidates for appointment to the Medical Corps of the United States Army, to fill existing vacancies.

Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before October 8, for the necessary invitation, giving the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from which they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal acquaintance, from at least two reputable persons, as to his citizenship, character, and habits. The candidate must be between 22 and 29 years of age, and a graduate from a Regular Medical College, as evidence of which, his Diploma must be submitted to the Board.

Further information regarding the examinations may be obtained by addressing the Surgeon-General, U. S. Army, Washington, D. C.

Geo. M. STERNBERG, Surgeon-General, U. S. Army.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from September 15, 1895, to September 21, 1895.

First Lieut. Paul F. Straub, Asst. Surgeon (San Carlos, Ariz.), is granted leave of absence for one month, to take effect on or about Oct. 6, 1895.

Capt. Louis A. La Garde, Asst. Surgeon, is granted leave of absence for one month, from the date of his relief from duty at Ft. Logan, Colo. Major Henry M. Cronkhite, Surgeon, will report in person to the President of the Army retiring board to convene at Chicago, Ill., on Oct. 8, 1895, at such time as he may designate, for examination for retirement.

The following named officers are detailed to represent the Medical Department of the Army as delegates at the annual meeting of the American Public Health Association, to be held at Denver, Colo., Oct. 1 to 4, 1895: Lieut.-Col. Alfred A. Woodhull, Deputy Surgeon-General; Major Calvin DeWitt, Surgeon; Major Henry S. Tarrill, Surgeon.

Major Clarence Ewen, Surgeon, now on sick leave of absence, is relieved from further duty at Ft. Walla Walla, Washington, and ordered to Ft. Bliss, Texas, for duty, relieving Major Blah D. Taylor, Surgeon. Major Taylor, on being thus relieved, is ordered to Ft. McPherson, Ga., for duty at that post.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending September 21, 1895.

Asst. Surgeon M. S. Gneet, detached from the "Minnesota," and ordered to the "Vermont."

Surgeon R. C. Persons, detached from the "Minnesota," ordered home and placed on waiting orders.

Asst. Surgeon C. M. DeValin, detached from the "Vermont," ordered home and granted six months' sick leave.

Asst. Surgeon C. P. Bagg, ordered to the "Vermont."

Surgeon D. N. Bertolette, ordered home and placed on waiting orders when the "Atlanta" goes out of commission.

P. A. Surgeon P. H. Bryant, detached from the "Baltimore," and ordered to duty on the "Petrel."

P. A. Surgeon W. F. Arnold, detached from the "Petrel," and ordered to special duty in investigating the plague in China and cholera in Japan.

Marine-Hospital Changes. Official list of changes of station, and duties of Medical Officers of the U. S. Marine-Hospital Service, for the fifteen days ended September 15, 1895.

P. A. Surgeon C. E. Banks, to proceed from Washington, D. C., to Vineyard Haven, Mass., for temporary duty, Sept. 11, 1895.

P. A. Surgeon A. H. Glennan, granted leave of absence for five days, Sept. 3, 1895.

P. A. Surgeon C. P. Wertenbaker, granted leave of absence for three days, Sept. 3, 1895.

P. A. Surgeon E. R. Houghton, granted leave of absence for twenty-three days, Sept. 12, 1895.

Asst. Surgeon L. E. COPER, granted leave of absence for seven days, Sept. 3, 1895.

ORIGINAL ARTICLES.

GUAIACOL IN THE TREATMENT OF TYPHOID FEVER IN CHILDREN.

Read in the Section on Diseases of Children at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY ADOLPH KÖENIG, M.D.

PITTSBURG, PA.

The comparative rarity of typhoid fever in children is probably entirely due to the fact of infrequent exposure, and not to any lessened degree of susceptibility, as compared with adults. I believe that it can now be accepted as proved, that typhoid fever is essentially a water-borne disease and that drinking water, rather than foul air or direct communication is the medium of infection. We thus have an explanation of the rare occurrence of the disease in very young infants and the increasing ratio of its occurrence in children as they gradually receive more solid food and drink more water.

The pathologic lesions of typhoid fever in children are necessarily identical with those in adults, except that in children who have passed their very earliest period of life, and in whom the constructive metabolism is at its height, the necrotic process, which in the adult often goes on to perforation of the wall of the intestines, is in them resisted more strongly, by reason of their greater reparative power. In very young infants this does not hold good, for in them the constructive forces are not yet established to their fullest power and statistics seem to prove that perforation of the intestine, in this class of patients is as frequent as in adults. The difficulty of making an absolute diagnosis of typhoid fever in sucklings is however, very great and it is not unlikely that typhoid fever in them is often mistaken for the common diarrheal diseases of infants.

Considering the ordinary innocuousness of typhoid fever in children, the question of treatment resolves itself more into a general hygienic and dietetic supervision, than into drug administration. When, however, we consider the etiology and pathologic lesions present in the intestinal canal, during the latter stage of this disease, certain forms of medication seem rational and demanded. According to the modern bacteriologic investigations, typhoid fever is a self-limited disease which reaches its climax at about the tenth or twelfth day, after the development of the first symptoms, and the activity of the bacillus typhosus apparently ends about the middle of the third week. The pathologic lesions, however, remain in the form of ulcers, of greater or less circumference and depth, in the intestinal canal, and the disease then practically resolves itself into a surgical one. The question which then arises is how to prevent the infection of the intestinal lesions with septic germs. The intestinal tract is the fertile habitat of germs

always ready to attack its tissues under conditions of reduced vitality, and to prevent the growth and multiplication of such germs, to render the intestinal canal as uninhabitable as possible for them, is to my mind a rational, and in my experience an efficacious, treatment of typhoid fever. To render the intestinal tract as aseptic as possible, it becomes necessary to do more than to administer antiseptics. The first treatment a case of typhoid fever should receive is to clear the intestinal canal as much as possible of all foreign matter, and next, the administration of food should be so regulated as to restrict to the greatest possible extent all fermentative processes during the height of the disease, at which time the digestive functions and the absorption of nutritive material are very seriously interfered with, if not entirely arrested.

The treatment of typhoid fever in children adopted by me can best be described under the following subdivisions:

Initiatory Treatment.—When a child is seen for the first time, though the symptoms present point strongly to typhoid fever, it is impossible to make a positive diagnosis, but it is nevertheless my custom to place them upon treatment appropriate for typhoid fever. The first object to be aimed at is to clear out the bowels, and this is done by the administration of calomel well triturated with sugar, in doses of 1-20 to 1-10 of a grain, according to the age of the child every two or three hours. All solid food is immediately withheld, water however, being given to the extent of the patient's desire.

Regular Treatment.—If after a few days the temperature assumes the typhoid fever curve, the patient is at once placed on the following treatment:

R	Guaiacolis	f ʒ i
	Glycerini	f ʒ i
	Alcoholis	f ʒ ii

M. Sig.: One to six drops in whisky and water every two hours, according to the age of the patient.

This treatment is continued throughout the course of the disease, the dose of the guaiacol being increased or decreased according to the severity of the symptoms. The whisky is given in small quantities. In that form I believe it to conserve the tissues of the patient, to stimulate his vital functions and to generally improve his well-being. The dose is allowed to range from one-fourth to one teaspoonful, according to age.

When no desire for food is manifested, or where a decided aversion for it exists, only meat broth and barley-water is given. Milk is allowed either pure or diluted one-half with barley-water, if the condition of the digestive functions seems to warrant it. As soon as the bowels have become thoroughly emptied the calomel is withheld, to be again resumed should the indications demand it. This is the case, as a rule, during the later stage of the disease.

Under this plan of treatment, intestinal antiseptics is furthered as is evidenced by the slight degree of tympanitis; absence of sordes on the teeth and especially by the character of the stools, which are much less frequent and are practically destitute of the very disagreeable odor that characterized the passages of patients before the introduction of treatment directed toward intestinal antiseptics.

High temperature is combated by cold sponging alone. No depressing antipyretics of any kind are used.

While I claim that the course of an attack is materially modified in ordinary cases, I do not claim guaiacol as a specific, for under its use during the last five years, (creasote being used part of the time, in place of guaiacol) I have lost two cases. Both of these died during the latter part of the third week, apparently of acute disorganization of the central nerve centers. The peculiar cause of death in connection with these two fatal cases remains to be explained. In each case a younger brother succumbed to the same disease, under different treatment, and under the care of other practitioners within a short period of time. The question naturally arises, was there not some peculiar absence of resisting power in the members of the families in which these cases occurred? The course of the disease in these fatal cases was not specially severe, but as already stated at some time during the latter part of the third week the nerve centers suddenly became involved and death resulted from asthenia.

No difficulty whatever has been experienced in the administration of the remedy, which is a feature of no little value in remedies for children.

ACUTE LACUNAR DIPHTHERIA OF THE TONSILS.

Read in the Section on Diseases of Children, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY HENRY KOPLIK, M.D.
NEW YORK.

The writer has been induced to appear before your distinguished body to enlarge upon a theme previously brought to the notice of the profession, because he was convinced that the possible gravity of the apparently simple angina or lacunar tonsillitis was not yet generally accepted.

In a recent discussion upon the antitoxin treatment of diphtheria in the New York Academy of Medicine, one of the prominent speakers referring to bacteriologic diagnoses of diphtheria and especially those diagnoses which reveal the diphtheria not accompanied by membrane or parts of membrane in the throat, said that where the bacteriologic diagnosis of diphtheria, in the absence of clinical evidences, quarantines the house or separates a family from relatives and friends it is a sin against man. A further statement goes on to characterize the treatment of these mild cases in a diphtheria ward as a crime, etc. Another speaker while admitting that he would not give such patients who had no clinical evidences of diphtheria in their throats (membrane or parts of membrane) a clean bill of health, said it was difficult to know what to do with such cases. The terms "clinical diphtheria," "clinical evidences of diphtheria," were freely used and insisted upon as a diagnostic element in all cases where effective isolation is contemplated,

at least so one would surmise from a perusal of the printed discussion.

The above is mentioned to show that there is still a wide gap between those who work purely clinical and those who combine the clinical with the findings of scientific research. In other words, we have not advanced a step since the time of the immortal Trousseau, in the diagnosis and prophylaxis of the dread disease, diphtheria, or we have no right to advance. No membrane, no diphtheria! This, to a certain number, is as true to-day as it was in the days of the great pupil of Bretonneau. The writer wishes here to point out the great danger which such a quasi-sentimental definition of diphtheria must needs carry with it. In 1891 the writer of this article, convinced that the gravity of a certain class of apparently simple anginas was not appreciated, undertook to investigate both from a clinical and bacteriologic standpoint all varieties of anginas in which there could scarcely be said to exist at the outset, at least, any clinical evidences *locally* of diphtheria. There was in these cases no form of typical membrane. No such systematic attempt had been undertaken, up to this time, to the writer's knowledge. The profession were told from time to time, that during epidemics of diphtheria, or even in the absence of epidemic influence, what seemed to be a simple lacunar tonsillitis might eventuate as a diphtheria. Trousseau in his lectures upon diphtheria cites forms of lacunar amygdalitis followed by paralyses. These paralyses were similar to those which followed in cases of membranous diphtheria. Trousseau hesitated to call these anginas "diphtheria," even though followed by paralyses. There was no membrane, and he preferred to think rather that paralysis could follow in rare instances a simple tonsillitis. His inability to supply the connecting link between the membranous and the non-membranous cases of diphtheria was the only thing which deterred this clinician from grouping the two classes of cases under one heading. We are certain that had the link been at hand at that time, his views would have been more distinctly radical than they were. He simply said that certain simple anginas might rarely be followed by paralyses.

In 1886 we find this question still a mooted one. Jacobi, of New York, and Fraenkel, of Berlin, both clinical leaders in their respective cities, differed widely in their views upon these cases, Fraenkel insisting that the ground taken by his clinical opponent, that diphtheria may run its course as a lacunar amygdalitis, was too sweeping. At this time also, no proof additional to that submitted by former writers was brought forward to prove the theses of which we are speaking. Every one argued from clinical deduction purely, and clinical deductions seemed to differ when grouped by different observers. After all had been said and done, every one hung to the doctrine of Friedreich, that lacunar amygdalitis was an infectious disease, but would go no further.

Henoch (edition 1893) in his classical hand-book upon diseases of children says in the article upon diphtheria: "I do not recognize the existence of a pharyngeal diphtheria in the form of a simple angina."

Escherich (1890, Henoch's *Festschrift*) while denying the existence of Löffler bacilli in the lacunar tonsillitis of young children, admits their existence in cases of catarrhal anginas of older children, in cases in which at no time has there been membrane or

clinical evidences of diphtheria. Escherich, in this article, is guarded in his conclusions and reserves a decided classification for the opportunity given by a larger material than he had at his disposal.

Gerhardt was at this time also very decided in his view that danger lurked in the atypical diphtheria. He pointed out their capability of causing diphtheria in others.

In my first article (1891, *New York Medical Journal*) upon atypical cases of diphtheria, the first series of cases which were studied bacteriologically were similar to those seen and described clinically by Trousseau, Gerhardt and Escherich, in which we find at the outset no typical membrane. Indeed, during the whole course of the disease, no membrane appeared to the naked eye. The cases were those of a child 4 years of age, having the symptoms and local manifestations of a simple catarrhal angina, but in whose throat large numbers of virulent Löffler bacilli were found. This case was associated in the same family with another severe non-membranous angina, in a sister aged 5 years, to whom I presumed the first had communicated the illness, and in this second case we had the same bacteriologic result as in the first case. During the whole illness, neither of these cases manifested any membrane. Fully a week after the first case had been taken ill, a baby 2½ years old in the same family became afflicted with fatal diphtheria, in which membrane and portions of membrane appeared in the throat, and which also involved the larynx. It will be thus seen that here was an almost faultless group of cases observed daily, in which two had the typical "diphtheria *sine membrana*," followed by a third case in the same family of true clinical diphtheria. It will naturally be asked, Was diphtheria suspected in the catarrhal cases? Working upon diphtheria at the time, scrapings were obtained from these throats, as shown in my paper, and fortunately several times, and tested upon animals; the results justified our early suspicions. The symptoms in these cases in which absolutely no membrane or points of membranous deposit appears in the throat, I must say are equivocal. I have examined the throats of children who gave a set of clinical symptoms almost identical to the first class of cases and, as my work shows, I failed with equal precautions to find diphtheria bacilli. Thus the croupy coughs, the red throats, fever, enlarged glands and, I may say, even prostration upon which the stress was formerly laid, are not characteristic. The only way, it seems to the writer, to positively differentiate these cases is the bacteriologic method.

Another class of cases in which we must always be put upon our guard, are those in which a minute speck of membrane appears on the tonsil or uvula, looking like a drop of fibrinous secretion combined with a typical lacunar tonsillitis. These cases may be truly diphtheritic. Again, a third set of cases, showing pultaceous deposits of a stringy fibrinous character may prove to be non-diphtheritic or *vice versa*. A fourth set of cases are those in which the tonsil is the seat of a necrotic ulcerative process, with no distinct membranous formation. In only one part of the tonsil do we find an excavation, the base of which is covered with specks of exudate. Henoch has described such cases, and many still speak of these cases as ulcerative sore throat. I have proved many of these cases to be distinctly true diphtheria. In some, the children are scarcely ill enough in the

eyes of the parents to require treatment. It will be seen that there are forms of angina which are diphtheritic in their etiology, in which at no time are there manifestations of membrane, or such exudate as does appear is atypical.

Feer has confirmed the writer's work in the first set of cases, and it must now be admitted as firmly established that diphtheria "*sine membrana*" exists, though it introduces an unfortunate complexity into the problem of clinical diphtheria.

The most important class of atypical cases of diphtheria and perhaps the most common are those in which the appearances in the throat resemble in every detail the simple lacunar tonsillitis.

In 1894 I published a second paper, in which a series of consecutive cases, all giving the typical clinical picture of lacunar tonsillitis, were examined with special reference as to their diphtheritic or non-diphtheritic character. This paper adhered closely to this set of cases because in the first paper the material had spread over such a diverse field that it was not possible to judge the actual frequency of any particular set of the cases cited. In this series of lacunar tonsillitis, fully one-third of thirty-nine cases were shown to be true diphtheria. It was possible here, also, to divide the cases into groups as far as the severity and clinical symptoms were concerned.

The first group of cases are exceedingly mild; the patients show but little constitutional disturbance and complained but slightly of throat symptoms. Examination shows general hyperemia of the fauces, enlarged tonsils with open lacunæ. Some of the lacunæ showed an accumulation of yellow secretion at the surface opening. The lymph nodes at the angle of the jaw may or may not be enlarged.

The second group of lacunar diphtherias are those in which the local and constitutional symptoms are more pronounced. The patients show more prostration, the fever is quite high and there are other symptoms as pains in the limbs, furred tongue, etc. The tonsils are much enlarged and there exudes from the lacunæ a soft fibrinous exudate. There is no form of membrane anywhere on the tonsil and the lymph nodes are much enlarged. The plugs of these as also those of the first group contain Löffler bacilli.

The third group of cases are those which show distinctly malignant features from the outset. They do not remain purely lacunar after the first few days, and in this respect would resemble much, cases described by Heubner of membranous diphtheria, which early in their course resemble lacunar tonsillitis; and subsequently show coagulated exudate on the surface of the tonsil. The cases described by the writer belonging to this group, are truly septic in character, and beginning with a picture of lacunar tonsillitis, the infants the first day, even before the membrane is seen, have pallor and prostration which is quite characteristic and may at once put us on our guard. These are the cases which subsequently draw the nasal fossæ into the clinical picture. They are also the fatal cases. They begin as a lacunar tonsillitis and within forty-eight hours membrane and shreds of membrane are voided from behind the immensely swollen tonsils which completely occlude the fauces. It is not the intention of the writer to rehearse here the details of the bacteriologic examination of these cases of lacunar diphtheria of the tonsils, but there are some points which must be of vast and far-reaching importance, and which have been estab-

lished by the writer and since confirmed by Flexner, Booker (Johns Hopkins Bulletin, March, 1895), and others. The Löffler bacilli of diphtheria, in the cases of lacunar diphtheria are found, not so much on the surface of the tonsil, but in the depths of the lacunæ, in the fibrinous plugs, which occlude the lumina of the lacunæ. The bacilli are of equal virulence, whether obtained from the first group of mild cases or the third group of fatal septic lacunar diphtherias. The bacilli retain their virulence for weeks in the depths of the lacunæ, the patient being in apparent full convalescence, or the tonsils having returned to almost the normal size and appearance. In one case virulent bacilli were obtained from a lacunar plug of the tonsil in the third week of convalescence. A lacunar plug in one case, in which virulent bacilli had been isolated early in the disease showed non-virulent bacilli fully three weeks after the outset of the disease. In other words, virulent bacilli were replaced by the non-virulent variety in this particular lacunar amygdallitis.

Enough has been cited above, of the bacteriology of these cases, to show the importance of this class of cases of diphtheria. Too much weight can not be attached to these facts. We must not be turned aside by any fallacious arguments which continue to harp upon the desirability of a membrane in order to entitle a case to the dignity of the term, *clinical diphtheria*. This term, I believe, was first introduced into medicine by Trousseau. It is a landmark in the history of modern medicine, but it is time to protest against its use as a weapon with which to cast contempt on the class of cases concerned in this paper.

If prophylaxis is the ideal of modern hygiene, then the class of cases treated of in this paper, take a rank first in importance. Innocent in appearance, they are the means of disseminating a dread affection. Serious and unremitting isolation is the only method by which we can show our appreciation of their serious nature. Their importance crops out in the operating room constantly. At the last meeting of the American Pediatric Society, the writer of this paper insisted that those cases of tonsillotomy upon enlarged tonsils which were followed by membranous diphtheria, or even croup, were undoubtedly of the nature of the cases described in this paper. It has been shown by the writer that in these large tonsils, virulent diphtheria bacilli exist long into convalescence. As long as they are left to the natural fluids in the lacunæ no harm results to the patient, and we have even reason to believe, as pointed out in my second paper, that they gradually lose their original virulence. Cut this tonsil, however, and you expose to the propagation of the bacilli in the lacunæ the most favored of growing media, a freshly cut surface bathed in lymph, and a membrane results, in some cases spreading to the fauces and larynx. One case of this kind is enough to convince the most skeptical, and yet there are many such, doubtless, who are waiting for the case to occur to them.

Diagnosis.—How can we approach the diagnosis of these cases? The old methods, such as proposed by Henoeh, only apply to cases which finally develop membrane or portions of membrane. If we wish, however, to pick out the pure lacunar diphtherias in which membrane never forms, we will find that our safest method is the bacteriologic test. To test the urine to wait for specks of membrane to appear, only delays matters and does not aid us, for we have not

only albuminuria in the streptococcus tonsillitis, but also glandular swellings and prostration with low and high curves of temperature. The opponents of bacteriologic diagnosis say that the Löffler bacillus has been found on the normal mucous membrane. Would you call such a case diphtheria and isolate it? The answer to this fallacious argument is plain. The well authenticated cases in which investigators of acknowledged rank (Löffler, Roux) have found virulent bacilli on the normal mucous membrane, are exceedingly rare and exceptional. They are found in throats perhaps exposed to a diphtheria atmosphere. Since the inauguration of the simple crude methods of diagnosing a case of diphtheria by growing a culture and staining a few covers has come more and more into vogue, the bacilli in the normal throats have multiplied in frequency. We would ask that methods showing such evident flaws be not taken too seriously. They are necessary in rapid hygienic work, but must not be brought forward as an argument.

Given an angina in which Löffler bacilli have been demonstrated to exist in large numbers, such a throat is diphtheritic and must be grouped with diphtheria, membranous or otherwise. It should be unmercifully isolated, whether it isolates the patient from friends and family or sends the patient into a contagious ward where severe cases of diphtheria are treated. It has been maintained that the placing of such cases among severer cases is an injustice to the patient. Those who have studied diphtheria since the discovery of Löffler must subscribe to the views brought forward by Escherich. These mild cases of diphtheria must be explained on the ground of immunity. They do not develop membrane and can not develop severe diphtheria, because in these particular individuals there is a natural or acquired immunity which protects them against the severer manifestations of the disease. If you place them, therefore, in a ward in which there are very severe cases of diphtheria, no more injustice is done to the mild case of diphtheria than would be done to a correspondingly mild case of measles placed in a ward with very severe and complicated measles.

On the other hand, these mild cases of diphtheria or lacunar diphtheria or diphtheria "sine membrana," are capable of communicating fatal or severe diphtheria to others. If we grant the above, which is the result of years of work at the bedside and in the laboratory, the principal arguments of the alarmists fall to the ground.

CLINICAL EXPERIENCE WITH ANTITOXIN IN PRIVATE AND HOSPITAL PRACTICE IN THE TREATMENT OF DIPHTHE- RIA—(ALL FORMS).

Read in the Section on Diseases of Children at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY LOUIS FISCHER, M.D.

Instructor in Diseases of Children at the New York Post-graduate Medical School and Hospital; Physician in Charge of the Messiah Home; Physician to the Children's Department of the German Polyklinik.

NEW YORK.

My first successful case with antitoxin was published in the *New York Medical Record*, Oct. 6, 1894, in which a child 11 years old was attended by Dr. Gerlach. In this case I injected 5 ccm. of Aronson's antitoxin between the shoulder blades. The child was discharged, cured, on the fourth day. This pa-

tient was presented before the New York Post-Graduate Clinical Society at its first meeting in the Hospital Building in October.

Since then I have published a series of papers, embodying various clinical experiences; notably, however, papers that appeared on Nov. 17, 1894, in the *New York Medical Record*. A series of thirty-six cases, which were attended by me, was published in the January number of the *American Journal of Medical Sciences*, wherein I reported a very successful list of cases.

My percentage of deaths was but 5.8 per cent. The antitoxin used was brought over by me from Berlin last summer. Some of my patients were attended in the Municipal Hospital, Philadelphia, through the extreme courtesy of Dr. Welch, the supervising physician in charge, and also through Dr. Edward Davis, the editor of the *American Journal of Medical Sciences*. It is only necessary for me, however, to refer to the paper read by me before the German Medical Society of New York on March 4, 1895, in which I reported a series of 223 cases. These were largely made up of cases attended in hospitals and private practice, but most of them were those seen in consultation. The paper has since then appeared *in extenso* in the *New York Medical Record*, April 6, 1895. The mortality among the 223 cases was 15.11 per cent. This was by me in January, and can be accounted for in various more than twice as much as the first mortality, reported ways: 1, a great many cases were seen in consultation and were cases which were moribund, in other words, hopeless cases, and cases in which antitoxin was used as a last resort; 2, a great many deaths were also in children that had been suffering from mixed infections, cases of scarlet fever and diphtheria, cases of chickenpox and diphtheria, cases of measles and diphtheria. It is here that we can not look for any benefit from the antitoxin, because in some cases, especially in those which were fatal, I found that I was rather called upon to treat cases of septicemia and not cases of toxism, caused only by one infection, the Klebs-Löffler bacillus but rather the combined septic influences of the Klebs-Löffler bacillus and the streptococcus in scarlet fever and other microorganisms with which we are not so familiar.
